INTRODUCTION

ANTIBIOTIC is a young word in terms of the history of our language. It stems from antibiosis, a term coined in 1889 by Vuillemin (1) to describe a broad philosophic concept of a biologic relationship often observed but not previously specifically named. The term existed in the scientific vocabulary only a little more than 50 years before it was applied in the health professions in its present very restricted sense, and less than a decade later became a household word known to most well-informed laymen.

Rational application of the phenomenon of antibiosis for treatment of diseases according to scientific principles is a development of the last 20 years, but crude antibiotic therapy was practiced empirically at least 2,500 years ago and there was a prolonged flurry of laboratory experiments and less well-controlled clinical experimentation which started more than 80 years ago with the work of Pasteur and his students on anthrax (2) and was pursued enthusiastically, if not always carefully, by others in a wide array of infectious diseases for nearly 40 years. An antibiotic product, pyocyanase, derived from *Pseudomonas pyocyanea* (*aeruginosa*) was marketed in Europe before World War I. These early historical developments have been reviewed (3, 4).

The current era of antibiotic therapy began in 1929 with the now celebrated observation of Fleming and his coining the term "*penicillin*" to designate the then unidentified antibacterial metabolic product of the mold (5). This was followed by a lag period of a little more than a decade before the logarithmic period in which we now are emerged.

The antibiotics discussed below have been selected from those discovered or first marketed since 1955. Thus, the subjects reviewed represent some of the developments of approximately the most recent quarter of the active period of the current era of antibiotic therapy.

The discussion of specific antibiotics is preceded by some general comments on topics of current interest and import in antibiotic therapy. In general, these are topics the significance of which has been widely recognized only since 1955, although a few voices in the wilderness were warning about some of them prior to that time.

GENERAL CONSIDERATIONS

Blood Levels.—It is convenient and it has become conventional to compare different antibiotics or different formulations of a given antibiotic in terms of the concentration of the drug demonstrable in the serum at different times after a single oral dose or during a course of multiple doses. Unfortunately, there is a natural tendency to assume that such comparisons afford a valid basis for predicting therapeutic efficacy of the products, and much of the advertising of antibiotic products has taken advantage of this tendency. While comparison of blood levels produced may lead to valid conclusions regarding the relative therapeutic efficacy of different formulations of the same antibiotic, it is obvious that it is not equally justifiable to use such figures in the same way for evaluating different antibiotics. The data may provide useful physiologic and pharmacologic information about the drugs, e.g., absorption, resorption, excretion, metabolic degradation, etc., but they do not necessarily indicate anything about relative therapeutic efficacy.

First, there is the matter of bacterial sensitivity. A low concentration of a drug to which the infecting pathogen is very sensitive may be expected to be more effective than a considerably higher concentration of one to which it is only moderately sensitive.

Second, bacteria are more common in other tissues than in blood. Therefore, since the important point for therapeutics is the activity of the drug against the specific organism and the concentration of the drug at the site of infection where the organisms are, the blood level *per se* has little real significance in evaluation of therapeutic potential unless the gradient between the blood and the different tissues is known so that the concentration of the drug at the actual sites of infection can be calculated. Indeed, a study of "distribution volumes" of several antibiotics, including penicillins G and V; the tetracyclines; the macrolides, erythromycin and oleandomycin; streptomycin; and novobiocin, indicated that "high blood levels result in a low distribution volume, and vice versa" (6).

Probably more useful than serum concentration for evaluating potential therapeutic value of an antibiotic is the serum dilution factor, i.e., the extent to which the serum can be diluted and still remain bactericidal or bacteriostatic. Although this factor does not indicate anything about the concentration of the drug at the site of infection, it does at least take cognizance of the sensitivity of the organism to the specific antibiotic under investigation.

Enhancement of Blood and/or Lymph Levels.—Following the general line of fallacious reasoning referred to above, there has been considerable emphasis on preparations

formulated with agents reputed to provide higher blood levels of the antibiotic than can normally be achieved with equivalent doses of similar preparations lacking the adjuvant. The emphasis has been greatest in the tetracycline field where, it has been stated, "economic competition among pharmaceutical manufacturers for markets and over-zealous advertising agencies have led to some extravagant claims regarding enhancement of blood levels attainable with various formulations of tetracyclines" (7).

Careful experimentation and objectively critical appraisal of published results indicate that many of the claims of enhanced blood levels achieved with tetracyclines formulated with glucosamine, sodium hexametaphosphate, and other "potentiating" agents cannot be statistically supported and that for all practical purposes the various formulations are comparable in clinical efficacy whether or not they contain the alleged blood-level-enhancing factors. Indeed, most of the work reported prior to October 1957 on enhancement can be ignored as erroneous and irrelevant because results produced with the new formulations were compared to those produced with the then regularly available commercial formulations which contained calcium and/or magnesium salts that chelate tetracyclines, thus reducing their availability for absorption. Therefore, most of the results before late 1957 showing improved blood levels with the new formulations were due more to the depressing action of additives in the control products than to enhancing agents in the experimental ones. Moreover, many reports were based on studies employing single oral doses given to fasting, normal, healthy volunteers, an experimental situation bearing little resemblance to actual clinical practice with patients who receive multiple doses at different times without regard to time elapsed since the last meal. Subsequent work has failed to reveal significant, if any, advantages of the "enhanced" products under practical clinical conditions. For further discussion of the controversy over blood levels of tetracyclines and other antibiotic preparations, see reference 7 (pp. 62 and 214) and references 8–15.

Related to the blood-level *vs.* tissue-level controversy and the emphasis on agents to enhance blood levels is the matter of antibiotic concentrations in the lymph. The importance of the lymphatic system in bacterial invasion suggests the desirability of supporting this protective mechanism by providing significant concentrations of appropriate antibiotics in the lymph during bacterial attack. Macromolecular salts of various antibiotic bases with appropriate polysaccharides or certain polycarboxyl acids are stated to have increased affinity for the lymph system (16). The products have been designated antibiolymphins. In comparison with the corresponding streptomycin and neomycin sulfates, streptolymphin and neolymphin produce lower but more sustained blood levels and much higher and more prolonged lymph levels. Acute toxicity (mouse) is said to be less for "lymphins" than for the corresponding sulfates. The products have been prepared and tested in Czechoslovakia and are not available commercially in the United States.

Antibiotic Prophylaxis.—Apart from the now well-substantiated prophylactic use of benzathine penicillin in cases of known or suspected past history of rheumatic fever, there are few, if any, well-documented indications for antibiotic prophylaxis. Indeed, there is a mounting body of evidence that useless prophylaxis may not only contribute to gradual diminution of the therapeutic efficacy of antibiotics by sensitizing the patient and engendering emergence of resistant strains of bacteria, but may actually delay recovery (17, 18), predispose the patient to virus infections (17, 19), and encourage implantation in the respiratory and urinary tracts of organisms ordinarily uncommon in those regions except as transients or parasites (20).

The high incidence of respiratory disease and resultant loss of time from work or other regular activities has been a major factor in the (unfortunately) common practice of using antibiotics (mainly penicillin and tetracyclines) prophylactically in treating upper respiratory infections. The earliest study of mass prophylaxis (with penicillin) involving 1,486 subjects in the experimental group and 1,451 control subjects for a total of 9,264 patient-months disclosed no significant difference in incidence of respiratory or of nonrespiratory illness in the two groups (21). The argument that antibiotics are given in treating the common cold in pediatric patients to prevent secondary complications has been completely demolished with the demonstration in a series of 217 children that the incidence of secondary complications is the same (about 15%) whether or not antibiotics are given, that complications in untreated patients generally are of bacterial etiology and can be treated effectively with antibiotics if and when they arise while complications in subjects treated prophylactically often are viral and are not amenable to antibiotics, and that the average recovery time for uncom-

plicated cases was 5.8 days for the controls, 7.2 days for the penicillin group, and 8 days for patients treated with one of the tetracyclines (17). Specific treatment of complications at their inception is preferable to prophylaxis at the beginning of fever. Pure cultures of colon bacilli have been found in the throats of children given penicillin prophylactically for the common cold (22). Instances of routine antibiotic prophylaxis appearing to increase rather than decrease infection are numerous (17–26). A sharp increase in death rate (from 29 per 1,000 in 1954 to 144 per 1,000 in 1958) among infants born after premature rupture of fetal membranes has been correlated with prophylactic use of antibiotics (27). The subject of prophylaxis in its various ramifications, including indications and contraindications in various aspects of surgery (26, 28–31) where it was concluded in a survey of many top-ranking hospitals by the Medical Audit Program (32) that in a series of 1,536 patients there was a 74% needless misuse of antibiotics in inguinal herniorrhaphies, has been reviewed (ref. 7, p. 13).

Mixed Therapy.—*Combinations of Antibiotics.*—There are very few clearly substantiated indications for mixed therapy, despite the prevalence of this form of treatment. Outstanding examples that have been well established empirically are concurrent administration of penicillin and streptomycin in some cases of subacute bacterial endocarditis, and joint use of streptomycin and PAS and isoniazid in tuberculosis. In brucellosis, streptomycin or tetracycline given with an appropriate sulfonamide usually produces better clinical results than any one of the agents alone. But apart from these few instances, it is extremely difficult to find objectively critical reports to support administration of many of the antibiotic combinations that have been proposed for general use in other infections. Jones and Finland (33–40) in neither their own laboratory and clinical observations nor in thorough review of the literature could find experimentally demonstrable evidence to support mixed therapy as a general practice. As pointed out in the "New Drugs Development" volume of the 1960 edition of the U.S.D., "their conclusions lend support to the editorial view (41) that 'most often the only justification for including one or another of the components is the fact that it is being produced by a particular manufacturer or that pressure is brought to bear on the management by the sales force to provide some combination to meet effective competition.' "

Except in the three disease entities mentioned above, administration, in adequate dosage, of the more active member of any combination usually produces therapeutic results equal or superior to those produced by the combination. Carefully controlled studies have failed to confirm the subjective claim, vigorously promoted in some advertising, that simultaneous use of two or more antibiotics suppresses emergence of resistant strains of organisms from initially sensitive ones. While it is possible that in some instances emergence of such strains may be slightly delayed, careful studies have shown that it is not completely suppressed and that after repeated exposure to the mixtures, organisms become resistant to both components just as if they had been exposed to the single entities (36, 38, 42). For a possible exception to the general rule about joint use of two antibiotics, see the discussion of novobiocin (below).

Antibiotic-Corticosteroid Mixtures.—Simultaneous use of antibiotics and of corticosteroids, whether for treatment of a single disease entity or of different involvements, is a highly controversial matter. Only a few years ago, a general dictum was that when antibiotics are being employed, corticosteroid hormones are contraindicated. However, successful use of cortisone, to provide subjective improvement, during chloramphenicol treatment of typhoid and typhus fevers was demonstrated in 1954, although the numerous pitfalls, including the false sense of security that the dramatic subjective improvement of the patient may give the physician, were pointed out (43). In general, systemic use of antibiotic-steroid combinations or of the separate entities simultaneously is seldom warranted, and it should usually be looked upon with disfavor. A critical appraisal of the rationale and physiologic complications and of the rare indications and numerous contraindications for such use has been published (44).

While recognizing the inherent danger of systemic antibiotic-corticoid therapy, a number of investigators have recommended such mixtures for local use. Representative proposals are use of antibiotic-steroid mixtures in nebulized sprays for treatment of laryngeal conditions (45), and in ointments for cutaneous infections (46, 47), especially when pyogenic (48). Although the corticosteroids may alleviate irritation and inflammation and may thereby produce a subjective feeling of improvement on the part of the patient and, it is sometimes contended, accelerate healing processes, their use in any infection is potentially hazardous. The inflammatory process is an important first line of defense to localize infection. If this natural process is eliminated or

minimized before the antibiotic takes effect, the possibility of rapid spread of the infection, which may become systemic, is increased. Moreover, there is the possibility that some of the steroid may be absorbed and induce systemic effects of its own, and care must be exercised in selection of the appropriate compound. It has been reported that hydrocortisone decreases resistance to infection and depresses immune responses, while corticosterone, in the same dosage, does not (49).

Antibiotics and Gamma Globulin.—In another category of mixed therapy, joint use of gamma globulin and antibiotics, particularly chloramphenicol, has been reported to produce better response than antibiotics alone (50, 51).

The pros and cons of mixed antibiotic therapy have been reviewed and editorialized extensively (52–59).

Antibiotics as Growth Stimulants.—Certain antibiotics were shown as early as 1946 to have a pronounced growth-promoting effect on the young of some animals (60), and today fortification of feeds, especially for poultry and swine, is routine in animal husbandry and poultry raising. The subject of antibiotics in animal nutrition has been reviewed thoroughly (61).

Following demonstration of the beneficial effect of antibiotic-supplemented feeds on growth of young animals, it was natural that similar studies should be conducted with humans. Chlortetracycline, used in small amounts as a diet-supplement, has been reported to stimulate growth of grossly undernourished children (62), and tetracycline used similarly has been reported to produce marked improvement in growth of dystrophic infants (63).

ANTIFUNGAL ANTIBIOTICS

Amphotericin B

Trade Name: Fungizone (Squibb).
Biologic Origin: Streptomyces sp. (M-4575 in Squibb culture collection) isolated from soil collected in Orinoco River region of Venezuela.
First Reported: 1956 (64).
Clinical Use: antifungal in systemic and superficial mycoses; also to reduce or prevent yeast or monilial overgrowth during tetracycline therapy.
Usual Dose; Intravenous Infusion: 1 mg./Kg./day, the daily dose being dissolved in 1 L. of 5% glucose and infused over a minimum time of 6 hours. This route is more reliable than the oral route. *Oral:* 2 Gm./day for adults has been effective for coccidioidomycosis and other disseminated fungus diseases. Doses up to 5 Gm./day have been used. Daily dose is divided when drug is given orally.
Toxicity: Appears to be low, but nausea, diarrhea, anorexia, and mild reversible azotemia have been reported.

Chemistry.—Amphotericin consists of two closely related compounds, amphotericins A and B. The complete molecular structures are unknown, but the empirical formula, $C_{46}H_{73}NO_{20}$, has been determined for the B fraction. The chemical literature has been reviewed (65, 66).

Amphotericin B, which is several times more active than the A fraction against fungi *in vivo* (67) and is the form that is regularly available, is a lactone-containing polyene structure (68), a type of configuration that has particular interest because of its presence in a number of antibiotics that exhibit antimycotic activity. The aminodesoxyhexose, mycosamine, which occurs among the degradation products of nystatin, is also an important moiety of amphotericin B. Chemical evidence suggests varying degrees of relationship between amphotericin and nystatin and some of the less well-known antifungal antibiotics, e.g., candicidin, filipin, fungichromin, pimaricin, rimocidin, and trichomycin.

The amphotericins are soluble in lower alcohols and in water-saturated butanol, but are less soluble in anhydrous butanol and in water (69). Both amphotericins are stable at moderate temperatures when dry and protected from light and air. In solution, stability is closely related to temperature and pH, maximum stability being in the neutral range.

The biologic activity of amphotericins is markedly affected by pH. The MIC of amphotericin B against several test organisms decreases from about 2.5 mcg./ml. at pH 4.5 to about 0.02 mcg./ml. at pH 8.0 (70), but there is a plateau of more or less uniform activity between pH 6.0 and 7.5. Therefore, assays are generally performed in media adjusted to a value within that range. Various methods for assaying amphotericins biologically, using *Saccharomyces cerevisiae* and *Candida albicans* as test organisms, have been developed (64, 70–72), including techniques for specifically determining amphotericin B activity in serum (70) and other body fluids (72) and in mixtures of the A and B fractions (72).

Absorption and Excretion.—Although amphotericin is poorly absorbed from the gastrointestinal tract, concentrations several times those required to inhibit several species of pathogenic fungi *in vitro* can be achieved in the blood following oral administration (71). The drug disappears from the blood slowly, and concentrations from 30 to 80% of the maximum achieved may still be present 12 or more hours after the last dose. However, continued dosage does not lead to significantly increased concentration. Once a daily dose of 2 Gm. has been reached, very little

increase in blood level is achieved by increasing the daily intake.

Higher blood levels are produced by intravenous infusion than by oral administration, and even 20 hours after infusion blood levels above the maximum achieved by oral administration may be expected. Significant amounts of the drug are absorbed from the plasma by the red cells (73) and small amounts appear in the spinal fluid after infusion of 0.37 to 1.0 Gm. daily.

Absorption of intramuscular doses is insignificant (70).

Total 24-hour urinary output of amphotericin B usually ranges from about 100 to 300 mcg. when patients are given a 5-Gm. oral dose daily; slightly larger amounts being eliminated if a mixture of the A and B components is given. On an intravenous infusion regimen, about 5% of the total daily dose appears in the total 24-hour urine. However, excretion continues for several days after the last dose is administered, and as much as 40% of the total dose may ultimately be recovered. Blood levels up to 20% of the maximum achieved during therapy may still be present a week after treatment is discontinued.

Clinical Uses.—The most significant use of amphotericin is in treatment of the systemic mycoses, prognosis of which, until the advent of this drug, was usually poor and always entailed, at best, a long period of illness and of convalescence. Among such infections successfully treated with amphotericin are cryptococcosis (74–76), histoplasmosis (76, 78, 79), blastomycosis (76, 77), coccidioidomycosis (76, 80–84), *Candida albicans* peritonitis (85), and American leishmaniasis (86). See also the proceedings of the New York Academy of Science's "Second Conference on Medical Mycology" (86a).

The duration of infection before amphotericin was started has ranged in a number of cases from 1 month to 10 years (74, 80). Among six cases of cryptococcal meningitis clinically rated "poor," "critical," "paraplegic," or "moribund" at the start of treatment with 50 to 100 mg., intravenously infused in 1 L. of 5% glucose over a period of 6 hours daily for total doses of 1.4 to 3.7 Gm., 5 survived (74) and, of these, 3 were considered "normal" on the basis of clinical criteria and spinal fluid findings, 1 was considered improved, and the paraplegic case was rated "improved" in terms of spinal fluid findings, although "unchanged" in clinical status. Other investigators have administered oral doses (4 to 5 Gm./day) in treating cryptococcosis, histoplasmosis, blastomycosis, and coccidioidomycosis. A number of patients who failed to respond satisfactorily to oral therapy have been rated "apparent recovery" or "objectively improved" after intravenous therapy, and, in general the intravenous route is preferred because of its greater reliability.

In all cases, treatment is a prolonged affair, ranging in the instances cited from about 1 to 14 months. Unequivocal evaluation of antimycotic agents for systemic infections is a slow process because of the long follow-up periods necessary to establish cure indisputably rather than mere arrest. Results of studies of experimental infections in animals have suggested that in nontoxic doses amphotericin is fungistatic rather than fungicidal (87, 88). However, there is much interspecies variation in sensitivity to drugs and, pending more information, it cannot justifiably be assumed that the same conclusion applies to treatment of human infections.

Amphotericin B, formulated in an ointment, has been considered curative in infants with cutaneous candidiasis in the diaper area and in guinea pigs experimentally infected with *Trichophyton mentagrophytes* (67).

Given orally, the antiobiotic has been reported effective in checking and depressing tetracycline-induced overgrowth by *Candida albicans* in the gastrointestinal tract (89–94). A tetracycline-amphotericin ratio of 5:1 has been recommended (92). Mysteclin F (Squibb) is a preparation incorporating the two antibiotics in a single preparation in this ratio. Despite the reduction induced in the fecal load of *Candida*, amphotericin seems to have little or no effect on the number of *Candida* organisms recoverable from throat swabs and sputum (90).

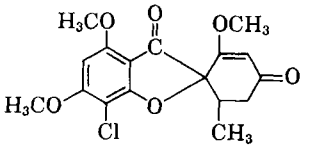
Unessential use of any antibiotic is undesirable for many reasons, several of which were mentioned above in the discussion of prophylaxis and of mixed therapy. Therefore, since not all patients receiving tetracycline develop candidial or monilial overgrowth, prophylactic use of amphotericin during tetracycline thrapy should be limited to classes of patients experience has shown to be particularly prone to such side effects, i.e., the elderly, the debilitated and/or undernourished, the pregnant, and the menstruating.

A mixture of amphotericin B (50 mg.) and neomycin (1 Gm.), given on an appropriate schedule, has been rated "one of the better drugs for preoperative preparation of the colon" in elective surgery (95).

Amphotericin may become an important adjunct in tissue culture for virus propagation.

At a concentration of 20 mcg./ml., it suppresses growth of species of *Candida, Rhodotorula, and Aspergillus* as effectively as 100 mcg. of nystatin (96).

Resistance.—No evidence of increased resistance of initially sensitive fungi ascribable to exposure to amphotericin in clinical practice has been reported. However, varying degrees of resistance can be induced *in vivo*, depending on the species and strain of fungus studied, the culture medium employed, the frequency of transfer, and other experimental variables (97–99). *In vitro*, there is cross resistance between amphotericin and nystatin (97). This is not surprising in view of the chemical relationship of the two drugs.



Toxicity.—Incidence of untoward side effects, either acute or residual, during clinical use of oral amphotericin appears to be low. However, experience with the drug is still relatively limited, in comparison with older antibacterial antibiotics. A dose of 2 Gm. daily given orally for 14 months has been used "with no subjective or objective side effects" and "no evidence of hepatic, renal, or hematopoietic reactions" (100). However, in a few instances "mild and reversible" azotemia, nausea, diarrhea, anorexia (76), and "transitory impairment of renal function, ... suggestive of nephrotoxicity" (101) have been reported. In general, the early impression of low clinical toxicity has been supported by more recent studies (86a) and is consistent with the results of pharmacologic and toxicologic studies on animals (102). Incidence of untoward effects may be considerably higher via the intravenous route.

Griseofulvin

Trade Name: Fulvicin (Schering), Grifulvin (McNeil). Also available as Griseofulvin (Ayerst).
Biologic Origin: Penicillium griseofulvin, P. janczewskii, P. nigricans.
First Reported: 1939 (98).
First Clinical Use: 1958 (116).
Clinical Use: Systemic treatment of superficial dermatomycoses. Nocardiosis, sporotrichosis, chromoblastomycosis, and deep infections with *Actinomyces bovis* have been reported to respond occasionally to griseofulvin, but generally it is not considered effective in systemic or deep mycoses.
Usual Dose; Adult: 250 mg. 4 times daily by mouth. In severe infections, 2 Gm. daily, in four divided doses, until clinical response is evident, then reduced to 1 Gm./day. *Children:* If over 50 lb., 250 mg. 3 times daily. *Infants* (Under 2 years): 125 mg. twice daily or, alternatively, 10 mg./lb. of body weight/day.
Toxicity: Apparently low, but gastrointestinal upset, diarrhea, headache, and occasional confusion, exhiliration, and insomnia have been reported. Decreased systolic blood pressure and lymphocytosis also have been reported. Side effects generally have not been severe enough to warrant discontinuance of the drug.

Historical Comment.—Griseofulvin, an antifungal compound originally discovered in 1939 among the metabolic products of *Penicillium griseofulvin* (103) and subsequently of other species of *Penicillium* (104, 105) was studied intensively by phytopathologists for nearly 20 years, as a potentially useful agent for systemic control of fungi pathogenic on plants, before it was investigated for possible usefulness in treatment of mycotic infections of animals. The antibiotic, also known as the "curling factor" because of the characteristic morphologic aberrations it causes in the germ tubes of sensitive fungi (106), is stated to affect only those species that have chitinous cell walls and to be ineffective against species that have cell walls of cellulose or of other nonchitinous material (107), but this view has been questioned. The uses of griseofulvin in plant pathology have been reviewed (108).

Chemistry.—The empirical formula, $C_{17}H_{17}ClO_6$, originally proposed (103) has been confirmed (109, 110), and the following structure has been developed (111).

Griseofulvin

Griseofulvin is only slightly soluble in water (0.001% at pH 7.0). It is soluble to the extent of 0.1% in methanol and ethanol (107). It is thermostable over the pH range 3.0 to 8.8 at 25° for at least 4 weeks and at pH 7.0 withstands autoclaving at 250° F. for 30 minutes. When dry, it is stable at 100° F. for at least 20 months (112).

Absorption and Excretion.—Orally administered griseofulvin is absorbed rapidly and excreted slowly. In experiments with dogs and guinea pigs, little or no antibiotic was found in urine collected within 24 hours after first administration of doses ranging from 0.1 to 2.0 Gm./Kg./day, and there was no significant cumulative excretion (113). During the third week of a continuous feeding experiment, there was little difference in total daily excretion of drug whether animals were dosed at 0.1, 0.2, or 0.5 Gm./Kg.

In another experiment, excretion continued for 1 week after the last of 3 days of dosing with 1 Gm./Kg. About 0.5% of a single oral dose of 50 mg./Kg. given to guinea pigs was recovered from feces collected during the first 24 hours, but

none was found in feces excreted during the next 24 hours. The doses used for these studies were well above those (15 mg./Kg./day for 5 to 15 days) that were curative for *Trichophyton mentagrophytes* infections in guinea pigs.

Data similarly indicating that only a small fraction of griseofulvin ingested by human beings is excreted in the urine have been reported (114), although others have reported recovery from urine of 50% or more of an orally administered dose (115).

Clinical Use.—Clinical interest in griseofulvin and its use in medicine stemmed from the demonstration in 1958, nearly 20 years after discovery of the drug, that, administered orally in adequate dosage, it provided effective and safe systemic protection for guinea pigs experimentally infected with ringworm (*Microsporum canis*) or with *Trichophyton mentagrophytes* and that it was curative even when the onset of treatment was delayed until the infection was well established (116). After a few days of treatment of ringworm, the fungus can be found only in the upper portions of the hair shaft; the lower portion, formed after initiation of treatment, grows out free of infection, presumably because of the presence of griseofulvin in the hair. That the antibiotic is actually present in hair after oral administration can be demonstrated by extraction with hot methanol (117). The drug proved to be effective in curing spontaneous *Trichophyton verrucosum* infections in calves (118), *Microsporum canis* infections in cats (119), and *M. canis* and *T. mentagrophytes* infections in dogs (120), and this led to the first trials in human medication.

The efficacy of griseofulvin as a systemic antidermatophyte in humans has been well established (114, 115, 120 136a). The following dermatophytes that commonly infect hair, nails, and skin are susceptible to it: *Trichophyton interdigitale*, *T. mentagrophytes*, *T. rubrum*, *T. schoenleini*, *T. sulfureum*, *T. tonsurans*, *Microsporum audouini*, *M. canis*, *M. gypseum*, and *Epidermophyton floccosum* (112), and it has been stated that the antibiotic " is active in low concentration against all the common dermatophytes" (116).

Infections caused by any of the above fungi in adults generally yield to an oral dosage of 250 mg. every 6 hours. In children, the total daily dose (but not the number of doses per day) may be reduced. (See capsule summary above.) Improvement and incipient clearing may occur soon after initiation of treatment, but cure may require several weeks or even months of continued dosage.

The rapidity of response to griseofulvin depends on the site and duration of infection. Tinea capitis may be "clinically cured" in 3 to 7 weeks, but if there is follicular involvement response generally is slower, and 3 to 4 months of daily dosage may be required (129). Infections of the glabrous skin may be cleared in 2 to 4 weeks, infections of the soles and palms in 2 to 8 weeks, when fingernails are involved 10 or more weeks may be needed to effect "clinical cure," and when toenails are infected an even longer time (123). Evidence of improvement in onychomycosis usually is seen within 2 weeks in fingernails and in 3 to 4 weeks in toenails, although complete cure may require several months, due to the relatively slow growth of nails, estimated at about 1 mm./wk. for fingernails and about 0.5 mm./wk. for toenails (112).

Topical application of griseofulvin may effect some improvement in dermatophytic infections, but generally the results are not as satisfactory as when the drug is given orally (137–139). This may be because griseofulvin probably does not eradicate the dermatophyte from infected hair, skin, or nails but rather, by its presence in the new tissue as it forms, renders the new tissue resistant to invasion. When the drug is applied topically, little, if any, occurs in the tissues. However, one group reported erratic response of tinea pedis to oral griseofulvin but good response to topical application (140). This is contrary to the majority of reports.

Although markedly effective against the superficial mycoses affecting skin, hair, and nails, griseofulvin generally is ineffective in deep mycoses in humans, when given orally in doses of 0.5 to 2.0 Gm. daily (138), a conclusion which is supported by the results found in experimental blastomycosis, histoplasmosis, cryptococcosis, and coccidioidomycosis (141). However, others have claimed "some therapeutic effect" in nocardiosis and sporotrichosis (142, 142a), in chromoblastomycosis (143), and perhaps in actinomycosis (128).

Resistance.—There are natural variations in susceptibility of fungus species to griseofulvin, even among the genera of dermatophytes that are most sensitive. However, although resistance can be induced *in vitro*, there is no evidence to date of emergence of strains with increased resistance from initially sensitive strains as a result of clinical use of the antibiotic. Occasionally, *C. albicans* has seemed to become dominant and to cause intertriginous dermatitis of groins and/or toe webs as the original griseofulvin-sensitive dermatophyte has been inhibited (129).

Toxicity.—Experiments on animals and clinical observation on humans indicate that toxicity of griseofulvin is low, both in incidence and severity. Mice survive oral doses of 50 mg./Kg. (112), but massive intraperitoneal doses (2 Gm./Kg.) cause severe damage to the seminal epithelium in rats, and intravenous doses of 100 to 200 mg./Kg. (about 10 times the therapeutic dose) cause arrest of mitosis at metaphase (144).

The comment "the incidence of toxicity and side reactions (with therapeutic doses in humans) is extremely low" (130) is typical of the majority of clinical reports. In most patients on whom laboratory studies have been performed, there has been no change in urinalysis, hemoglobin levels, differential counts, hepatic function, and no constant trend in variability of sperm counts. Occasionally, a transient decrease in total leukocyte count has been noted but frequently this has returned to normal despite continued medication.

However, in some instances, about 30% according to one author (145), a relative lymphocytosis has appeared and in some there has been mild albuminuria, although kidney function tests revealed no abnormality. Other side effects occasionally reported have been elevation of icteric index without visible evidence of jaundice, diarrhea, fatigue, vague feelings of gastrointestinal uneasiness after the first 3 to 7 days of treatment, a feeling of "fullness" in the head, confusion, exhiliration, and insomia. Incidence of these effects has been less than 2% and generally they have disappeared even though medication was continued. It has been suggested that some of the effects may have been psychogenic. Imbibing of alcohol while under griseofulvin treatment has been reported to lead to "tachycardia and a flush" (112), and morbilliform eruptions with temperature elevation have been noted (145).

An effect which probably is not of psychogenic origin is the reported 10 to 15% decrease in systolic blood pressure without any subjective symptoms. In the only report on this effect, it was observed in 26 of 52 patients studied (112).

There is no question of the tremendous value of griseofulvin in treating dermatomycoses. It fills a long-standing desire of dermatologists for a relatively safe drug for systemic treatment of such infections from within outwards to replace, or at least complement, the older and sometimes disappointing attack from the outside via topical medication. However, as the drug becomes more widely used, side effects and details not yet recognized may be revealed. The reported decrease in systolic pressure would be an interesting facet to pursue.

Nicetin

Nicetin is the Parke, Davis & Company trade name for the antifungal substance formerly designated CMA-37. This intensely bitter, light yellowish crystalline compound, which is soluble in water or in physiologic saline only to the extent of 0.125%, is closely related to chloramphenicol in chemical structure, but differs markedly from it in antibiotic activity.

Chemically, Nicetin differs from chloramphenicol only in having a ketone group substituted for the secondary alcohol group of the latter. But, in contrast to chloramphenicol, which is a potent antibacterial and antirickettsial drug with no significant action against fungi, Nicetin is effective in moniliasis and in some infections of skin and nails, but has little activity against bacteria.

In the first clinical trial, a case of bronchopulmonary moniliasis which had failed to respond to all other treatments and in which the patient was failing rapidly was given 1 Gm. of Nicetin on the first day and then 250 to 500 mg. 3 times daily. Favorable response occurred almost at once, and after 6 weeks of treatment the patient was free of cough and other symptoms and had gained weight (146). A 2% ointment of Nicetin and a 2% solution of the drug in propylene glycol were found far superior to ammoniated mercury and other common agents in treating 75 cases of various fungus infections of the skin, scalp, and nails (147). Desirable features of the drug are that it is fungicidal, not merely fungistatic, and that it is keratolytic, which facilitates its penetration in the deeper layers of infected skin.

Since Nicetin is so closely related chemically to chloramphenicol which has been alleged although not proved to induce aplastic anemia and other blood dyscrasias, systemic use, except in extreme situations unresponsive to other treatment, would be ill advised. Urinary frequency, dysuria, and hematuria have been observed when doses of 250 to 500 mg. of Nicetin have been given thrice daily. These effects have been ascribed to a chemically-induced hemorrhagic cystitis (147).

Two of 75 patients treated topically with 2% Nicetin (in ointment or in solution in propylene glycol) developed allergic reactions consisting of "intense edema" and marked erythema of the treated limb within 4 to 8 hours (147). The symptoms were controlled with antihistamines or with prednisone. It was not determined whether the reaction was a direct allergic response

to the drug or resulted from the sudden release of large amounts of allergenic lysis products from the invading fungus. Nonetheless, it was recommended that topical treatment not be continued for more than 10 days.

Note: Nicetin is not currently available commercially.

ANTIBACTERIAL ANTIBIOTICS

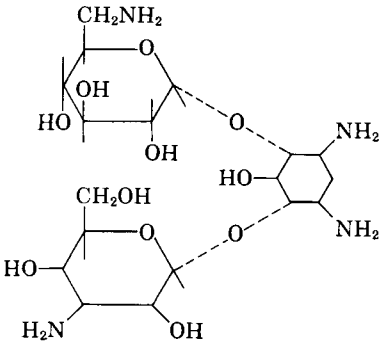
It is not difficult to find microorganisms that produce compounds antagonistic to bacteria. Despite the literally hundreds of antibacterial antibiotics that have been isolated and described, it still is not too difficult to discover a new one. But to find one that is clinically useful enough to warrant industrial production is becoming extremely difficult. To warrant production in the face of competition from the established agents, such as penicillin, the tetracyclines, chloramphenicol, etc., a new antibiotic must have some special characteristic that the others lack. One such characteristic is the ability to inhibit organisms, especially so-called "hospital" staphylococci, that have become resistant to the older antibiotics that have been prescribed with such abandon for a decade or more.

Kanamycin, novobiocin, ristocetin, and vancomycin all came into production during the period covered in this survey and were developed for marketing primarily because of their activity against penicillin- and tetracycline-resistant staphylococci. Frequently these antibiotics are no more active than the older ones against the common strains of *Staphylococcus*, and in some instances they are less active. It is to be hoped that restraint and responsibility will be exercised in prescribing these newer drugs, limiting their use to situations individually demonstrated to be unresponsive to the older agents, so that their effectiveness can be preserved. Many hospitals, through their own self-policing, have restricted use of novobiocin, ristocetin, vancomycin, and others to such situations.

Colistin attracts attention primarily because of its activity against recalcitrant Gram-negative bacteria and paromomycin, discovered in 1959, has been developed to the production stage primarily because of its special value in amebiasis, shigellosis, and salmonellosis.

Finally, several modifications of other antibiotics, e.g., semisynthetic penicillins and various derivatives of tetracyclines, have been developed during the past five years.

Colistin



Trade Name: Coly-Mycin (Warner-Chilcott).
Biologic Source: *Bacillus (Aerobacillus) colistinus*, isolated from soil collected in Fukuchima prefecture, Japan.
First Reported: 1950 (147a).
Clinical Use: Urinary tract infections due to Gram-negative organisms, including especially species of *Pseudomonas* but, in general, excluding species of *Proteus*. Also useful in respiratory, surgical, wound, burn, or other infections caused by sensitive organisms.
Usual Dose: 2.5 mg./Kg./day (1.1 mg./lb./day) in 2 to 4 divided intramuscular doses. In severe infections, a large total daily dose may be needed but the total daily dose should not exceed 5 mg./Kg. (2.3 mg./lb.).
Note: Orally administered colistin is poorly absorbed. Therefore, for systemic treatment, intramuscular injection is indicated.
Toxicity: No major toxic effects have been reported in patients receiving normal therapeutic doses. Occasional mild nausea, dermatitis, drug fever, and circumoral paresthesia have been noted but have subsided spontaneously upon withdrawal or reduction of the dosage. Mild pain at the injection site also has been reported.
Comment: Colistin, originally discovered in Japan in 1950, had been extensively studied and used clinically in Japan, Italy, and France before being introduced in the United States in 1959. Extensive references in the Japanese and European clinical literature are cited (147b). Colistin is similar to (and may be identical with) polymyxin E (147c, 147d).

Kanamycin

Trade Name: Kantrex (Bristol).
Biologic Origin: *Streptomyces kanamyceticus*, isolated from soil collected in Nagano prefecture, Japan.
First Reported: 1957 (148, 149).
Clinical Uses: Staphylococcal infections resistant to commonly used antibiotics. Refractory urinary tract infections, especially those due to staphylococci, *E. coli*, or gonococci. May be beneficial in *Proteus* infections but not indicated when *Pseudomonas* or enterococci are the etiologic agents. Tuberculosis may respond in favorable cases, but the drug is not impressive in advanced cases, especially those that have failed to respond to other drugs. *p*-Aminosalicylic acid should be used jointly with kanamycin.
Usual Dose: In acute or chronic infections, 1 to 2 Gm. daily, injected in 2 to 4 equally divided doses, or a dose of 15 mg./Kg./day may be used in divided doses. Total dose in any one course of treatment should, if possible, not exceed 40 Gm. For extended use in chronic illness, dose should not exceed 6 Gm./wk. In tuberculosis, a schedule of 1 Gm. twice a day, 2 days a week with PAS, 10 Gm. daily, has been recommended.
Note: For systemic medication, kanamycin must be given by injection, since it is not absorbed well from the gastrointestinal tract. Pain or irritation at the injection site is fairly frequent.
Toxicity: Acute toxicity is low in short-term therapy. Nephrotoxicity is the major untoward effect. Symptoms usually are mild and subside spontaneously when the therapy is terminated. However, upon continued use, as in chronic illness, eighth cranial nerve damage, involving auditory or vestibular function or both may occur.

Comment: Kanamycin was discovered in the laboratories of the Japanese National Institute of Health (Tokyo) in 1957 and was marketed in the United States in 1958. Results of some of the microbiologic and chemical research that preceded release of the drug have been recorded in a single symposium publication (150).

Chemistry.—Kanamycin, related chemically to neomycin and streptomycin, shares some of their antibacterial and pharmacologic characteristics. The molecule contains 2 amino sugars linked glycosidally to 2-desoxystreptamine. The latter is also a moiety of neamine (Neomycin A)

Kanamycin

The chemical research leading to characterization of the compound and elucidation of the above structure has been reviewed (66). A second antibiotic, kanamycin B, occurs in crude preparations (151–153) but is present only in minor amounts, if at all, in medicinal kanamycin.

Kanamycin is stable and water-soluble. It is resistant to acid and alkaline hydrolysis and is thermostable in the pH range of 2.0 to 11.0. At pH 6.0 to 8.0, it withstands boiling for 30 minutes. Detailed data on stability, solubility, and other pharmaceutically important properties have been published (154).

Absorption and Excretion.—Kanamycin is poorly absorbed following oral administration, and this route is not suitable for systemic medication. The drug is well absorbed following intramuscular or subcutaneous (155) or intraperitoneal injection (156).

In humans, kanamycin appears in the blood about 15 minutes after intramuscular injection, and peak levels are attained in about 1 hour on either a single- or multiple-dose schedule. The concentrations fall rapidly after the peak is achieved (157), and blood taken 24 hours after a single injection of 1 Gm. or less generally does not contain assayable amounts of the antibiotic.

In infants and children, intramuscular injection of 5 mg./Kg. produces blood levels roughly comparable to those obtained with 250 mg. in adults, but the concentration tends to fall more rapidly (158).

A progressive build-up of concentration is not seen on a multiple-injection schedule, and after successive doses of 0.25, 0.5, or 1.0 Gm. the blood levels are seldom more than a fraction of the levels achieved 1 hour after the initial injection.

Primary excretion of kanamycin is renal, although some also appears in the bile. The renal elimination appears to be simple glomerular filtration (155, 159). Total 24-hour urinary recovery from human subjects with normal kidney function has been reported as 40% of the total dose for bed patients (160), ranging up to 100% for healthy volunteers (161). These differences may not be as great as appears on the surface (157).

Normally, in patients with good kidney function, there is no build-up of concentration. But on a multiple-dosage schedule, the plasma level may increase abruptly when there is renal impairment, and with the elevated levels toxic manifestations, especially ototoxicity, may be anticipated. Since the drug is also nephrotoxic, it should be used only with extreme caution in subjects with functional renal problems (162). The serum half-life of kanamycin in normal subjects has been estimated to be about 4 hours, but in uremic patients the drug was detectable in the blood for 4 to 5 days after a single dose of 1 Gm. (162). Severe hepatic disease may also cause accumulation of kanamycin, even when the drug is administered orally, despite poor absorption from the gastrointestinal tract (162, 163).

Clinical Uses.—The *in vitro* antibiotic spectrum of kanamycin embraces several Gram-negative and some Gram-positive species of bacteria and various acid-fast organisms, including *Mycobacterium tuberculosis* H 37 Rv. In general, the clinically useful spectrum is similar, provided the drug is administered in adequate dosage for an adequate length of time.

Staphylococcal Infections.—Kanamycin in divided intramuscular doses of 10 to 100 mg./Kg./day was rated "good" in treating mild and moderately severe cases and as "effective" in about 50% of children severely ill with hospital-acquired straphylococcal infections during the 1958 epidemic outbreak in a maternity service in Houston, Texas (165). Most of the strains were resistant to penicillin, streptomycin, and the tetracyclines, but all were inhibited *in vitro* by less than 6.25 mcg. kanamycin/ml. The infections had existed for from 6 hours up to 40 days before initiation of kanamycin, and about two-thirds of the patients had already failed to respond to at

least one, and most of them to two or three, other antibiotics. Other studies, both *in vitro* and clinical, have confirmed the sensitivity of the majority of clinically isolated staphylococci to kanamycin (166–168).

From purely microbiologic considerations, such as sensitivity of organisms, static *vs.* cidal concentrations of drug, etc., neomycin is a more effective antistaphylococcal agent than kanamycin (166, 169), but kanamycin probably is not as toxic as neomycin and, therefore, is preferable to it for systemic medication (170, 171). Kanamycin, ristocetin, and vancomycin can be considered as essentially in the same category for treatment of staphylococcal infections recalcitrant to safer antibiotics.

Urinary Tract.—The rapid appearance of kanamycin, and the relatively high concentrations it reaches, in the urine make it a useful drug for treating susceptible infections of the urinary tract. Good results generally can be achieved when infections are due to *Staphylococcus, Escherichia coli,* or *Gonococcus* (172). *Proteus* infections respond moderately (172) and infections due to *Aerobacter* or to *Klebsiella* can be treated satisfactorily, if the dosage is adequate (173). Others have confirmed these conclusions (174–176). Tuberculous infections of the urinary tract also may respond, if sufficient dosage is provided for an adequate time and PAS is used jointly with kanamycin (172).

Pulmonary Tuberculosis.—Reports from Japan have rated kanamycin "almost equivalent to the streptomycin-PAS combination" and "an excellent antituberculosis drug" (177), but investigators in the United States have not been so enthusiastic (178–180) because of the "toxic potentialities for the eighth cranial nerve and the kidneys, and hypersensitivity reactions," and because of the rapid development of resistance by the tubercle bacilli to the drug.

Other Infections.—Reports are conflicting regarding the effectiveness of kanamycin in *Salmonella* and *Shigella* infections (181–184). Certainly it is not as effective as chloramphenicol in typhoid fever, although it may have some effect in reducing the typhoid-carrier state (183). Administered orally in adequate dosage, it is useful as a preoperative intestinal "antiseptic," giving adequate control of streptococci, coliforms, and *Clostridia* (185–187).

Kanamycin has been reported to be effective in reducing the "cerebral manifestations" resulting from absorption of bacterially formed protein metabolites in patients with cirrhosis of the liver (188), but others have found that the beneficial "blood ammonia changes may not be sustained or reproducible with repeated courses" of treatment (189).

In ointments or creams (0.5%) the antibiotic has been effective in the treatment of cutaneous bacterial infections and has not appeared to be irritant or allergenic (190). However, such use probably should be discouraged as long as effective agents not suitable for systemic administration are available.

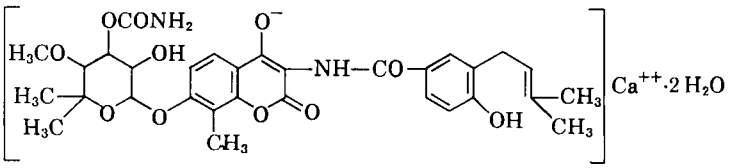
Resistance.—There is little or no cross resistance between kanamycin and most of the antibiotics commonly used systemically. However, there is almost complete cross resistance between kanamycin and neomycin and, among strains of *Staphylococcus aureus* and of *Enterobacteriaceae,* there may be complete cross resistance among kanamycin, neomycin, and paromomycin (168) and moderate cross resistance to streptomycin (168). Some cross resistance between kanamycin and streptomycin also appears in *Salmonella typhimurium* (191). Upon repeated exposure, other organisms, including *Mycobacterium tuberculosis,* also develop resistance to kanamycin (192–195).

Views are conflicting regarding emergence of resistant strains under clinical conditions (172, 183, 185, 196–198). The consensus seems to be that microorganisms, other than tubercle bacilli, do not readily develop resistance to kanamycin under clinical circumstances as long as the drug is used cautiously. However, highly resistant staphylococci have been isolated from clinical material (199).

Toxicity.—Results of acute and chronic toxicity studies in animals suggest that kanamycin is somewhat less toxic than streptomycin (155, 200).

Opinions differ concerning chronic toxicity upon extended use in humans, although there is agreement that the drug is potentially nephrotoxic and ototoxic. Donomae (201) considered auditory loss through eighth nerve damage "extremely improbable if the dosage is maintained below 6 Gm. per week," and he stated "there is no other side effect of considerable significance." However, others consider the drug "essentially nontoxic" in doses of 1.5 to 2.0 Gm. daily for less than a total amount of 40 Gm., but caution that when the total exceeds 40 Gm. "there is a clear chance" of permanent eighth nerve damage and deafness (161) and that even with lower total doses signs of renal impairment may be expected during or after treatment (202). Others also have commented on the need for vigilance to detect renal and auditory damage before irreparable

impairment occurs (171, 178, 198, 203, 204). It is clear that toxic effects will occur sooner and be more extensive in patients who have impaired renal function before therapy is started (205, 206) and that eighth nerve damage may continue to progress even after treatment with kanamycin has been discontinued (207).



The monopantothenate of kanamycin has been reported less acutely toxic than the sulfate in animals (208), but no studies were made of possible delayed effects.

Irritation, stinging, and pain at the injection site are common (161,198), the incidence possibly being as high as 50 to 60% (198).

Novobiocin

Trade Names: Albamycin (Upjohn); Cardelmycin (Pfizer); Cathomycin (Merck).
Biologic Origin: Streptomyces niveus (*S. spheroides*) isolated from soil collected in Queens Village, N. Y.
First Reported: 1956 (209, 210).
Clinical Use: Staphylococcal infections resistant to the antibiotics in common use. Limited applications in other infections (see text).
Dose; Adult: average 250 mg. orally every 6 hours or 500 mg. every 12 hours; in severe infections, 500 mg. every 6 hours or 1 Gm. every 12 hours. *Children:* 15 mg./Kg. daily in 4 divided doses or, in severe infections, 30 to 45 mg./Kg. daily in 4 divided doses. Prolonged treatment with high doses may lead to skin rashes and other complications.
Note 1: There is considerable variation from patient to patient in serum binding of the drug. Therefore, dosage should be determined on an individual basis.
Note 2: Because of dermatologic side effects induced if the drug is used in too large a dose or for too long a time, the minimal dose capable of coping with the infection should be employed. To be weighed against allergenic potential of the drug is its potential for inducing emergence of resistant strains of bacteria if used in sub-bactericidal amounts. Five hundred milligrams every 12 hours has been recommended as a safe middle course for adults.
Toxicity: Principal manifestations are skin rash, urticaria, and drug fever. Leucopenia also has been reported. Very high doses may induce liver damage. When properly used, the incidence of skin eruptions is relatively low, but precautions are necessary. (See Note above and also text which follows.)

Chemistry.—Novobiocin forms both acid and neutral salts. The calcium salt has the following structure

Calcium Novobiocin

The extensive literature on the chemistry of novobiocin has been reviewed (66).

Absorption and Excretion.—Novobiocin is not readily absorbed via the oral route (211), but the calcium and sodium salts are, as is dihydronovobiocin. The drug is absorbed following intramuscular injection also, but frequently causes appreciable reaction in muscle or subcutaneous tissue when so administered. In the discussion that follows novobiocin refers to the sodium or calcium salt.

Maximum serum levels are achieved within 2 to 4 hours after oral administration. According to Finland and Nichols (212) higher blood levels are achievable with novobiocin than with any other antibiotic given in comparable dosage. However, there is much patient to patient variability, and after a single dose of 250 mg., maximum serum levels may range from less than 3 to about 20 mcg./ml.

On a multiple-dosage schedule, there is some accumulation during the period of the first few doses, but the serum levels soon stabilize and only minor fluctuations occur when 500 mg. of the sodium salt are given at 6 to 8-hour intervals. Peak concentrations are higher and are reached earlier when the drug is given on an empty stomach. Following absoprtion, it quickly appears in almost all body tissues and fluids except the cerebrospinal fluid.

Novobiocin is excreted in the bile, urine, and feces. Major excretion is via the feces. Much of the fecal novobiocin probably arrives there via the bile, following hepatic concentration and elimination, but some probably represents unabsorbed drug. The sustained high blood levels novobiocin reaches may be brought about by reabsorption from the intestine of drug which, having been previously absorbed, has passed through the liver and again into the intestine via the bile.

Urinary excretion accounts for about 3% of the total administered dose (213). Concentrations are usually higher in the urine than in the serum, but the range of concentrations is not so great.

Clinical Uses.—Generally, the monobasic sodium salt is prescribed for adults; the neutral

calcium salt, suspended in syrup, often is preferred in pediatric practice.

Novobiocin is active principally against staphylococci and other Gram-positive organisms, although it has limited activity against some strains of selected Gram-negative species. Certainly, its major usefulness is in treating staphylococcal pyodermas insensitive to other antibiotics (214–218), and some investigators believe use of the drug should be restricted to such situations (215).

Novobiocin has been reported effective also in pneumococcic pneumonia (219), undulant fever (220), and in genitourinary infections due to *Bacillus proteus*, *Micrococcus aureus*, or *Streptococcus faecalis* (221). However, others have not been impressed with its performance in nonvenereal urinary infections by a variety of organisms (222, 223), and it has been declared ineffective in acute gonorrhea (224) and in primary and secondary syphilis (225).

In ophthalmology, novobiocin in a concentration of 1% is not irritating and does not inhibit corneal regeneration (226), and it is useful in treating ocular infections caused by susceptible organisms, especially staphylococci (227, 228).

Resistance.—There is a "definite tendency" for bacterial strains of "increased resistance" to appear, when novobiocin is used alone in clinical practice (229, 232). Laboratory data indicate that a one-step increase of ten-to thirtyfold may occur (230) but that a "synergistic" action and marked retardation of emergence of resistant bacterial strains occur when neomycin or bacitracin (230) or chloramphenicol, chlortetracycline, oxytetracycline, streptomycin, or penicillin (209), and novobiocin are used concomitantly. Synergism between novobiocin and tetracycline and novobiocin and nystatin in treating amebiasis also has been noted (231). These observations have led to the recommendation that another antibiotic to which the etiologic agent is initially sensitive should always be used jointly with novobiocin, especially when a prolonged period of treatment is anticipated, e.g., suppurating lesions or staphylococcal abscesses.

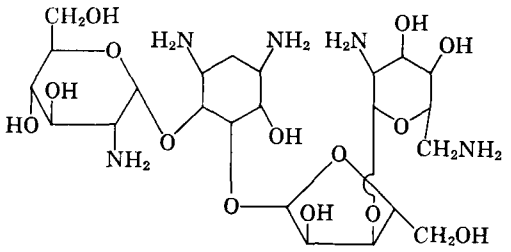
It should be cautioned that in selecting drugs for combined use, attention must be given to a third component, namely, the organism, in the complex system. Two antibiotics which act synergistically against one species or strain of microorganism might be indifferent, or even act antagonistically, against a different species with different metabolic requirements and pathways. Moreover, experience with other mixtures indicates that although emergence of resistant forms may be retarded, it is seldom eliminated and there is, therefore, always the possibility of producing organisms resistant to both drugs instead of just one.

Toxicity.—Novobiocin probably has a low order of toxicity when properly used, although the incidence of untoward complications has been reported to be as high as 12.7% in one study (232) and 18.7% in another (233). High doses were used in both series of patients. The most common side effect is transient skin rash or other dermatologic manifestation which disappears when the drug is withdrawn or therapy is terminated. A more serious effect is leucopenia, the incidence of which is said to be about 1% (234). An elevated icteric index also may arise, although it is not clear whether this is due to bile or to a yellow pigment metabolite of the drug (235). But in any event, the pigment may interfere with determination of serum bilirubin. Thrombocytopenia also has been reported (236).

That these are not constant features of novobiocin therapy is indicated by the report of a patient who received 250 mg. daily for 6 months after a priming dose of 250 mg. four times daily for 3 days and whose icteric index and blood cell count remained normal throughout the treatment (237). Despite a history of allergy to other drugs, the patient showed no evidence of allergy to novobiocin.

Animal experiments have demonstrated severe degenerative changes in liver and kidneys when high doses (300 mg./Kg./day) have been given.

While some authors have reported "remarkable freedom from side effects" (238), others have commented that eruptions were of "such alarming proportions to the patient and . . . physician . . . that the resultant effect was to curtail the number of patients available for study" (239).



In a comprehensive survey, involving 10 groups of clinicians and aimed at resolving the differences of opinion regarding toxicity of novobiocin, the overall incidence of skin rash was found to be 8.9%, and it was concluded that eruption is likely to occur only when the drug is given in a dose of 2 Gm. or more/day for 6 days or more (240). It was recommended that, in view of the therapeutic effectiveness of the drug in low concentrations against susceptible organisms and the ease with which high blood levels are obtained, 0.5 Gm. of novobiocin given orally twice daily should be an adequate dosage. It was estimated that on such a regimen the incidence of skin rash should be less than 1%.

Paromomycin

Trade Name: Humatin (Parke, Davis).
Biologic Origin: Streptomyces rimosus forma *paro-*

momycinus, isolated from soil collected in Colombia.
First Reported: 1959 (241).
Clinical Uses: Amebiasis, salmonellosis, and shigellosis. Also useful in management of hepatic coma and possibly clearing of typhoid and shigella carriers.
Usual Dose; Amebiasis: Adults 0.75 to 1.0 Gm. (or children 22 mg./Kg.) orally in divided doses for 5 days. Larger doses have been used for both children and adults with no ill effects. *Hepatic Coma:* 4 Gm. or more daily, in divided doses for 5 to 6 days. *Bacillary Dysentery and Nonspecific Diarrhea in Children:* Doses of 50 mg./Kg./day, in divided doses for 5 to 7 days.
Note: Paromomycin is not absorbed significantly from the gastrointestinal tract. Hence, in the conditions cited, the full effect of oral doses is exerted on organisms in that system.
Toxicity: Toxicity is low. In normal subjects and in patients free of diarrhea or dysentery, loose stools generally develop if the daily oral dose exceeds 2 Gm. for more than 3 days. On a dose of 4 to 10 Gm. daily, moderately severe diarrhea occurs, but other untoward effects have not been noted.

Chemistry.—Paromomycin is a stable, amorphous, white substance that is very soluble in water, moderately soluble in methanol, and sparingly soluble in absolute ethanol. It is optically acitve (242). Chemical studies (243, 244) leading to formulation of the following structure have been published.

Paromomycin

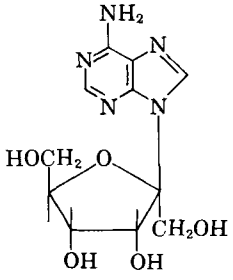
Paromomycin is basic and readily forms salts with acids, especially mineral acids. For clinical use, it is prepared as the sulfate.

Absorption and Excretion.—The drug is poorly absorbed following oral administration. In monkeys 1 to 3.5% of an oral dose can be recovered from the 24-hour urine, but up to 17% of an intravenous dose can be recovered in the same period (241). Rapid and efficient absorption follows subcutaneous administration in hamsters, and the drug persists in the plasma for about 4 hours (243). In humans, it is used only via the oral route.

Clinical Uses.—Paromomycin is active *in vitro* against a wide array of Gram-positive, Gram-negative, and acid-fast bacteria, including human type tubercle bacilli (241, 245). It is amebicidal also, either in the presence or absence of bacteria. By use of drug-resistant bacteria in the same culture with amebae, it has been shown that the drug is a direct-acting amebicide (243).

Since paromomycin is not absorbed from the intestinal tract, it is useful via the oral route for treatment of diseases that are caused by susceptible organisms and require vigorous antimicrobial action in the gut. It has been successful in amebiasis (246–252) and in bacillary and nonspecific diarrhea in children. It has proved effective, in a 5-day course of treatment (40 mg./lb.), not only in curing the primary infection in shigellosis and salmonellosis, but also in clearing carriers of the organisms (253). Typhoid carriers, previously treated with chloramphenicol, have been cleared by use of paromomycin (253).

A dose of 500 mg. given 4 times daily for 4 days is effective in the preoperative preparation of the colon for elective surgery.



Paromomycin is effective also in management of hepatic coma, unless some liver failure or massive uncontrolled gastrointestinal bleeding is underlying (254), and it may be possible to restore protein safely to the diet sooner when this drug is used than under the conventional treatments (255, 256).

Toxicity.—Toxicity is low. See capsule sketch at the beginning of this section and, for details, reference 241.

Psicofuranine

Psicofuranine, discovered in 1959 in culture filtrates of *Streptomyces hygroscopicus* var. *decoyicus* in the Upjohn Laboratories (257–259), is unusual in three respects: (*a*) it is a nucleoside antibiotic, (*b*) it has both antibacterial and antitumor activity, and (*c*) it has a low order of antibacterial activity *in vitro*, as tested in common laboratory media, but is highly effective in protecting experimentally infected animals. It is not commercially available at present.

The compound is very soluble in dimethylformamide, dimethylsulfoxide, and hot water. At room temperature, water solubility and methanol solubility are about 8 mg./ml. (257). It has been identified as 6-amino-9-D-psicofuranosylpurine (257) having the following structure

Psicofuranine

which is the same as that proposed for angustimycin (260), discovered in Japan. Psicofuranine is least stable in acid (half-life 18 hours at pH 2.0 and temperature 30°) and most stable at a neutral pH (261). Studies of the kinetics of degradation and of the products formed (261–263) have yielded information of potential value for estimating stability of the compound in aqueous media and for determining conditions suitable for bioassay (264, 265). The lack of activity of psicofuranine when conventional *in vitro* bioassays are attempted has been circumvented by development of special procedures which permit determination of concentrations down to 10 mcg./ml. in water or 3 mcg./ml. in blood or serum by a plate technique or as low as 0.5 mcg./ml. turbidimetrically (264). A physical method, involving paper chromatography and ultraviolet absorption characteristics (266), and a chemical method (267) also have been published, the latter being usefully applied in studies of absorption and excretion of the antibiotic (263, 268).

Dogs excrete a fraction of orally or parenterally administered psicofuranine in the urine (263), indicating absorption. There is evidence of irreversible binding of the drug, and a tendency for it to concentrate in the kidney (269), a factor that would need to be considered in patients with renal impairment. Determination of urine levels might be a useful criterion of absorption when low doses, following which it is difficult to determine blood levels, have been administered (269).

Despite the low order of *in vitro* activity, psicofuranine "compares favorably with commercially available antibiotics" in chemotherapeutic effectiveness in animals experimentally infected with *Staphylococcus aureus* (including strains resistant to other antibiotics), *Streptococcus hemolyticus*, and *Escherichia coli* (270). There appears to be no cross resistance between psicofuranine and antibiotics in common use (270).

Oral or intraperitoneal doses of 100 mg./Kg./day effectively increase the number of survivors and tumor regressions in rats with several types of tumors (271).

Acute LD_{50} values in the mouse and rat and subacute toxicity studies in the rat and the dog indicate that psicofuranine has a relatively low order of activity for these species (271). In the latter study, there was a tendency toward leucopenia at high doses, 300 or more mg./Kg./day. At very high dosage, there may be some liver damage and loss of weight.

Ristocetin

Trade Name: Spontin (Abbott).
Biologic Origin: *Nocardia lurida*, isolated from soil collected at the Garden of the Gods, Colo.
First Reported: 1957 (272, 273).
Clinical Uses: Staphylococcal or other Gram-positive infections resistant to other antibiotics.
Dose; Adult: 2 Gm./day, in 2 or 3 divided doses, intravenously in 5% dextrose containing 250 mg. of ristocetin per 125 ml. For severe or relatively insensitive infections, doses as high as 50 mg./Kg./day (4 Gm. for 165 to 175 pound adult) or higher may be used, but maximum dose should not exceed 6 Gm./day. *Children:* Doses should be proportionately less, according to weight.
Note 1: Administration of a single normal dose by the intravenous drip should be completed in 35 to 40 minutes. If rate is slower, adequate blood and tissue levels may not be achieved; if more rapid, irritation and other undesirable effects may occur.
Note 2: Concentration of ristocetin in dextrose solution infused should not exceed 1.25%, and when use of such a concentration is necessary rate of administration should not exceed 2 ml./min.
Toxicity: Hematologic complications (anemia, neutropenia, leucopenia), rash, fever, and diarrhea have been noted. Irritation and chemical thrombophlebitis may occur if too high a concentration of drug is used.

Chemistry.—Ristocetin, as available for medicinal use, consists of a mixture of two related amphoteric compounds, ristocetins A and B. Both contain amino and phenolic groups and sugars. The molecular weights of ristocetins A and B are probably about 4,000 (273). The compounds have been isolated as free bases and crystallized as sulfates. They are soluble in acidic aqueous media, but are only slightly soluble at neutrality. They are insoluble in most organic solvents.

Ristocetin is stable in acidic aqueous solutions but is rapidly inactivated above pH 7.0. Sterile solutions at an appropriate pH can be stored in a refrigerator for at least 1 month without significant loss of potency (273).

A plate assay techique, employing an appropriate strain of *Bacillus subtilis*, and a tube-dilution assay, using a saprophytic strain of *Corynebacterium* have been developed (272). Pure ristocetin A is used as the reference standard. This fraction, which is about one-fourth to one-third as antibacterially active as ristocetin B, has been assigned an arbitrary unit value of 1,000 units/mg.

Absorption and Excretion.—No ristocetin can be detected in either the blood or the urine after oral administration, but it is absorbed after intramuscular injection and can be detected in the blood (rabbit experiments) up to 8 hours after administration of 15 mg./Kg. or for about 3 hours after an intravenous dose. Similar values have been recorded in pediatric practice (274). Currently, only the intravenous route is

employed in medicine. About 30% of an intravenous dose (in dogs) can be recovered from urine passed in the first 4 hours and an additional 15% during the next 4 hours. Glomerular filtration appears to be the principal excretion mechanism. This may be followed by some tubular reabsorption (275).

Clinical Uses.—In general, ristocetin is not as active as penicillin and some other common antibiotics against the common cocci. Therefore, and also because it must be given intravenously, it is not suitable for treatment of routine infections. However, it is of value against infections caused by some strains of *Staphylococcus* and other cocci (streptococci, enterococci, pneumococci, etc.) that are insensitive to the conventional antibiotics (276–285), although failures also have been recorded (285, 286).

Ristocetin is active against the tuberculosis organism *in vitro*, but mouse protection studies and a few clinical trials in human patients have been disappointing.

Resistance.—Initially sensitive strains of staphylococci exposed to sublethal concentrations of ristocetin *in vitro* give rise to resistant variants in a slow, stepwise pattern (272, 287), but no cases of resistance arising during clinical use have been reported. Cross resistance with other commonly used antibiotics does not seem to occur.

Toxicity.—Untoward side effects are not uncommon in patients receiving ristocetin, although if the daily dose does not exceed 25 mg./Kg. and is given in two or three equally spaced and divided doses, complications generally are minimal. Much of the effect probably depends on the concentration of the solution used and the rate at which it is infused.

The most serious effects are hematologic. Eight in a series of 10 consecutive patients given from 750 mg. in 5 days to 57 Gm. in 11 days displayed such reactions (288) including neutropenia, acute anemia and platelet depression, and leucopenia. Studies with larger numbers of patients, numbering several hundred in the aggregate, indicate neutropenia in about 4 to 7.5% of patients recieving the drug (278, 280, 289).

Ototoxicity and nephrotoxicity also have been reported to occur occasionally (285), as well as rash, and local myositis (290) and, when doses are high, diarrhea.

Thrombophlebitis and irritation are induced at the injection site if too high a concentration is used. Care must be exercised to prevent spillage into adjacent extravascular tissue to avoid irritation and, generally, intramuscular injection should be avoided. It has been reported that the inflammatory response can be decreased by addition of 5 mg. of cortisone to intramuscular doses of 25 mg./Kg. (274). This seems to be a dubious procedure, in view of the possible complications produced by steroids in infection. It seems preferable to control (or minimize incidence of) such reactions by limiting the concentration of ristocetin solution that is employed. Usually a 0.2% solution in 5% dextrose is reasonably safe if it is infused at the appropriate rate (see capsule sketch at beginning of this section). In no instance should the concentration exceed 1.25%.

Vancomycin

Trade Name: Vancocin (Lilly).
Biologic Origin: *Streptomyces orientalis* isolated from soil samples collected in Indonesia and India.
First Reported: 1956 (291, 292).
Clinical Uses: Infections due to strains of staphylococci and other Gram-positive organisms resistant to the common antibiotics.
Usual Dose; Adults: 1 to 2 Gm. daily, administered intravenously in four equally spaced and divided injections, the drug being dissolved in 5% glucose.
Children: 20 mg./lb./day, administered as above.
Toxicity: Toxicity is relatively low. Most common untoward effect is phlebitis, following repeated injections. A rash sometimes occurs and, in prolonged treatment with high doses, ototoxicity and nephrotoxicity may appear.

Chemistry.—Elemental analysis of vancomycin base indicates at least 7% nitrogen, 16 to 17% carbohydrate, and 4.37% organic chlorine. Ultraviolet and infrared analyses indicate the presence of substituted phenolic groups and hydroxyl or amino, amide, and aromatic groups. Glucose and aspartic acid moieties also are known to be present, but the complete structure has not been determined. Estimates of molecular weight have ranged from 785 to 3,500, suggesting the possibility of macromolecular aggregation. Titration data indicate a value between 3,200 to 3,500 ± 200.

The free amphoteric base is insoluble in water, but is soluble (up to about 25%) in several polar, water-miscible solvents, e.g., dimethyl sulfoxide and dimethyl acetamide. The hydrochloride and the sulfate are water soluble, the solubility of the former being in excess of 100 mg./ml. The hydrochloride is moderately soluble in aqueous methanol also. It is precipitated from aqueous solutions by heavy metals and from acidic solutions by ammonium sulfate and sodium chloride (291, 293). It is the hydrochloride which is distributed for medicinal use under the name Vancocin (Lilly).

Stability decreases abruptly below pH 3.0

and above pH 7.0 at 37°. Within that range, loss of activity is about 10% in 6 days at 37°.

At 5°, there is about 10% loss in 6 months at pH values between 1 and 9 but about the same loss in 9 days at pH 10.0.

Absorption and Excretion.—For systemic action, vancomycin must be administered parenterally. The intravenous route is preferred because of mild to moderate pain commonly accompanying intramuscular injection.

The drug permeates most body fluids quickly, following injection, but only small amounts appear in the bile and, in the absence of meningeal damage, none in the spinal fluid. After a single dose of 500 mg., in healthy adults, antibacterial concentrations of vancomycin are soon present in the blood, and assayable amounts still remain after 24 hours (294). There is some accumulation of vancomycin following multiple repeated doses, and concentrations two to three times those required to kill most strains of micrococci *in vitro* generally are achieved.

Excretion is primarily renal, and high concentrations of vancomycin occur in the urine, even after a single dose of 500 mg. Values as high as 2,400 mcg./ml. have been found 1 hour after such a dose. The average concentration after 6 hours is about 300 mcg./ml., and after 24 hours is about 100 mcg./ml. (294).

After oral administration, very little vancomycin appears in the urine and, normally, none can be found in the blood of healthy subjects but large amounts, ranging from 400 to 24,000 mcg./Gm., depending on time elapsed since administration, are found in the stools. From none to about 110 mcg./Gm. may appear in the stools after intravenous doses.

It has been concluded from experiments with animals and observations on humans that "vancomycin is not metabolized to a great extent in the body" (295).

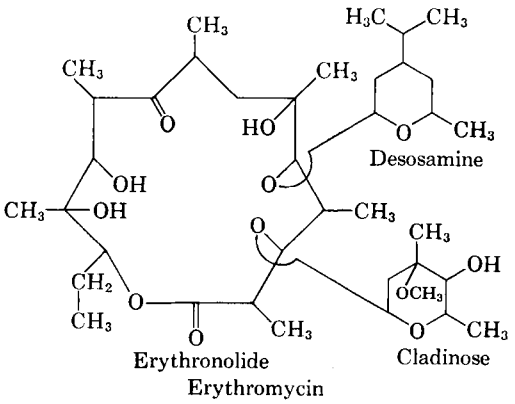
Clinical Uses.—Vancomycin is particularly active against Gram-positive cocci, especially staphylococci (291, 296–300). Indications for its use are pneumococcal bronchopneumonia, pharyngitis, erysipelas (301), acute micrococcal endocarditis (302), and, in general, infections due to staphylococci resistant to other antibiotics (300, 303–305). Vancomycin has been called the drug of choice for oral administration in micrococcal ileocolitis ". . . because of its bactericidal effect and because of the large quantities that are excreted in the stool . . ." (306).

Impaired renal function probably is a valid contraindication for use of vancomycin systemically.

In a study of eight antistaphylococcal antibiotics, including erythromycin and novobiocin, vancomycin was rated best with respect to bactericidal action and low resistance-inducing potential (307), and in another study of 1,350 organisms, more than one-third of which were strains of *Staphylococcus aureus* resistant to penicillin, all were found to be sensitive to vancomycin (296). Others have considered vancomycin, ristocetin, and kanamycin all about equally effective clinically (285).

Resistance.—In laboratory exposure, cultures of vancomycin-sensitive bacteria may lose some sensitivity to the drug, but usually only slowly and to a small extent (294, 297, 301). Clinical experience with the drug has been excellent with respect to its low resistance-inducing potential (301, 308, 309). However, strains rendered resistant to novobiocin or to ristocetin often are resistant to vancomycin also, indicating a high degree of cross resistance among the three drugs (285).

Toxicity.—Mild to severe phlebitis may occur in 10 to 25% of patients receiving several intravenous injections of vancomycin, and a skin rash has been noted in about 4 to 5%. These are the most common side reactions. However, when high doses and/or prolonged treatment are employed (or even with normal doses if there is uremia or kidney malfunction) high blood levels may occur and under these circumstances ototoxicity has been noted (285, 302, 303, 305). But, if proper precautions are used to guard against building up too high a serum level of vancomycin, even the patient with poor renal function need not be denied this antibiotic (310).



Evidence of eighth nerve damage, exhibited by auditory deficiency, generally has not been observed when serum levels have been within the limits usually provided by a total daily dose of 2 Gm. (range 7.6 to 20 mcg./ml. and average about 13 mcg./ml.) if there is no renal impairment. However, when prolonged treatment with vancomycin is indicated, serum levels of the antibiotic and renal function should be determined and audiometric tests should be made periodically in order to guard against possible deafness and nephrotoxicity.

The Erythromycin-Oleandomycin Controversy

Erythromycin, marketed by Abbott as Erythrocin and by Lilly as Ilotycin and, in the form of the propionyl ester, as Ilosone, was discovered in 1952 in culture filtrates of *Streptomyces erythreus* which had been isolated from soil collected near Iloilio City on the island of Panay in the Philippine Archipelago (311). Oleandomycin

(Matromycin, Pfizer) a metabolic product of *Streptomyces antibioticus* (312), is also available as triacetyloleandomycin (Cyclamycin, Pfizer) and as triacetyloleandomycin combined with glucosamine (Cyclamen, Wyeth; and Tao, Roerig). A 1:2 mixture of oleandomycin and tetracycline is marketed as Signemycin (Pfizer) and, phosphate-buffered, as Signemycin V (Pfizer).

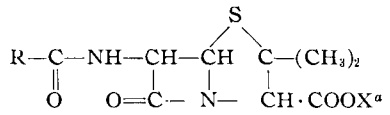
Erythromycin and oleandomycin are macrolide antibiotics. Among the dozen or so other members of the macrolide group of antibiotics thus far recognized are carbomycin, griseomycin, marbomycin, methymycin, picromycin, and spiramycin. The macrolides are characterized by a highly substituted many-membered lactone system to which is attached, glycosidally, an amino sugar. Other sugar and nonsugar moieties also may be present. The chemistry of these and other antibiotics with complex ring structures, notably peptide lactones and polyene macrolides, has been reviewed (65, 66, 313). The structure of erythromycin has been determined (314), but the complete structure of oleandomycin is still unknown.

Erythromycin

Although they are active against a number of Gram-positive organisms and against selected Gram-negative species, both antibiotics are valuable primarily because of their antistaphylococcal activity, especially against strains resistant to penicillin and the tetracyclines. Both drugs are readily absorbed from the intestinal tract and are administered orally for systemic action Certain derivatives, such as the propionyl ester of erythromycin and the triacetyl-derivative of oleandomycin, are more rapidly and uniformly absorbed than the respective parent compounds and produce higher serum levels. Neither drug is significantly toxic when properly used (see reviews in the "United States Dispensatory," 25th ed., 1955 and the 1960 Supplement thereto), although rare instances of jaundiec have been attributed to prolonged use of propionyl erythromycin ester lauryl sulfate but not of other forms of erythromycin. At the clinical level, erythromycin and oleandomycin preparations may be considered strictly competitive items.

The value of erythromycin in controlling and preventing spread of epidemic penicillin-resistant staphylococcal infection in hospital nurseries has been demonstrated (315, 316), and it has been considered a satisfactory substitute for penicillin prophylaxis of group A β-hemolytic streptococcal disease (317). A study of more than 12,000 newborn infants demonstrated that erythromycin ointment (5 mg./Gm.) is equally as satisfactory as silver nitrate as a prophylactic against ophthalmia neonatorum and is much less irritating (318). Numerous reports dealing with substantial numbers of patients comment favorably also on the clinical value of oleandomycin in treating infections caused by Gram-positive organisms (319–323). There is no question that both are useful drugs. However, they cannot be considered equivalent.

Many claims for the superiority of triacetyloleandomycin have been made on the basis of the relatively high blood levels it produces, reportedly from 80 to 140% higher than oleandomycin (324) and greatly in excess of those produced by erythromycin. However, evaluations made in terms of antibacterial activity of serum rather than actual content of antibiotic reveal "no significant difference (between triacetyloleandomycin and erythromycin) . . . in the ability to inhibit bacterial growth" (325) and that the "somewhat greater (four- to fivefold) blood levels of oleandomycin did not compensate for the marked difference in antibacterial activity" (326). Erythromycin is from 4 to 10 times more active than oleandomycin against strains of pneumococci, streptococci, and staphylococci sensitive to both (326), a view supported by others (34, 42, 327). It has been pointed out that the propionyl ester of erythromycin is absorbed more consistently than the base, and that the serum levels achieved with the ester compare favorably with those attained with triacetyloleandomycin and that "in terms of antibacterial activity of the subjects' serum . . . . propionyl erythromycin gave effective serum levels that were more than 10 times as high" (326). Objective studies have led to the conclusion that "oleandomycin and spiramycin are sufficiently inferior to erythromycin to indicate that their adoption for general use in the treatment of infections is unwarranted and should be discouraged" (36, 37). Entirely apart from the question of efficacy is the matter



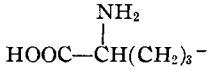
of resistance. Since cross resistance occurs between oleandomycin and erythromycin, one is faced with the situation that extensive "use of an inferior drug (oleandomycin) can deprive a better one of its usefulness" (328).

Many claims of synergism between oleandomycin and other antibiotics have been made, the most enthusiastic claims being made for a 2:1 mixture of tetracycline and oleandomycin (Signemycin, Pfizer). The view has been expressed editorially that the combination is essentially a "nostrum" foisted on an unsuspecting medical public to create a market for an "inferior agent," oleandomycin, by using it to dilute or contaminate "an established antibiotic, tetracycline," and that much of the advertising copy "exaggerates the truth and all too often only distorts it and renders it meaningless when inferior wares are being peddled" (329). When the claim for synergistic action of the mixture was shown to be misleading, advertising emphasis shifted to the claim that use of the mixture tended to retard emergence of resistant bacterial strains from initially sensitive ones. However, carefully controlled studies have failed to substantiate this claim and have shown that, after exposure to the mixture, organisms, often are resistant not only to oleandomycin but to tetracycline also, just as if they had been exposed to it alone (36, 37, 42).

Modified Penicillins

Any procedure which violates the integrity of the β-lactam or thiazolidine rings of the accompanying structure destroys the antibacterial activity of the molecule. Therefore, since the molecule is unstable under the conditions of many chemical procedures, efforts to produce biologically active new types of penicillin were seriously hampered and, until recently, the only successful attempts were those in which various precursors were added to the culture substrate with the hope that the mold would incorporate the compound or a moiety of it into the R group and produce a new form of penicillin. More than three dozen "unnatural" penicillins were biosynthesized in this way, and the structures and antibacterial activity of many of them have been summarized (4).

Synnematin B.—Synnematin, a product isolated in 1951 from *Cephalosporium salmosynnematin* (330, 331), is a mixture of two compounds (332), one of which, synnematin B, was later shown to be identical with cephalosporin N and to be a previously unknown biosynthetic penicillin, namely, D-4-amino-4-carboxy-*n*-butyl penicillin (333). Another source of synnematin B is



Type of Penicillin	R
Benzyl (penicillin G)	$-CH_2-C_6H_5$
D-4-Amino-4-carboxy-*n*-butyl (synnematin B, cephalosporin N)	$HOOC-CH(NH_2)(CH_2)_3-$
Phenoxymethyl (penicillin V)	$-OCH_2-C_6H_5$
Phenoxyethyl (phenethicillin)	$-O(CH_2)_2-C_6H_5$
2,6-Dimethoxyphenyl (methicillin, BRL-1241)	$-C_6H_3(OCH_3)_2$
Phenylmercaptomethyl	$-S-CH_2-C_6H_5$

[a] Depending on the type of penicillin, X in the commercially available products may be H, K, Na, or procaine.

Emericellopsis terricola var. *glabra*, a member of the *Aspergillaceae* (334, 335).

Synnematin B is unique among other known penicillins because of its effectiveness against the *Salmonella* and *Proteus* groups of organisms (336–343), including typhoid and paratyphoid A infections in man (343). This activity against important Gram-negative pathogens, the low degree of toxicity (comparable to conventional penicillins), and other pharmacologically favorable characteristics (344) should engender considerable interest in this antibiotic. In a single trial, it was found curative in primary syphilis (345).

Chemical studies (330, 346, 347) and assay techniques (334, 344) have been recorded. The fact that such a pronounced change in antibacterial spectrum is produced when the

group found in synnematin B is substituted for the

group of penicillin G suggests interesting leads for further study, now that techniques for producing semisynthetic penicillins have been developed.

Semisynthetic Penicillins.—In 1957, after many years of unsuccessful attempts, Sheehan

succeeded in total synthesis of an antibacterially active penicillin (348). The product was phenoxymethyl penicillin, a compound which had been produced experimentally in the United States about ten years before by the biosynthetic technique of adding precursors to the culture substrate of the mold but had been passed over as an item for industrial production until investigators in Europe demonstrated that its acid-stability made it particularly useful for oral administration (349–353). Phenoxymethyl penicillin, better known as penicillin V, is distributed as Pen-Vee-Oral (Wyeth) and V-Cillin (Lilly).

Sheehan's work was a chemical triumph and stands as a monument to man's pertinacity in his attempts to understand and duplicate the products of nature and then to improve on them. The methods developed permitted synthesis of penicillins not previously known, but the techniques were complicated, the yields were low, and none of the compounds produced proved sufficiently superior to biosynthetic penicillins to warrant industrial production. However, it was recognized that if one of the intermediates, 6-aminopenicillanic acid, could be obtained in sufficient quantity, synthesis from that point on should not be prohibitively expensive and that the possibilities for synthesis of new compounds should be almost limitless.

British workers observed that 6-aminopenicillanic acid occurs in crude penicillin fermentation media, presumably the mold also uses this as a building block in biosynthesizing penicillin, and they found a means of stopping the fermentation at that point and removing the moiety in reasonable yield by ion exchange (354). Synthetic methods can be employed to attach various acidic and other side chains to the naturally produced 6-aminopenicillanic acid, and more than 500 such semisynthetic penicillins have now been produced (355). The first of these to be exploited commercially was the potassium salt of a mixture of the D and the L isomers of 6-(α-phenoxypropionamido)penicillinate, commonly known as phenoxyethyl penicillin and assigned the generic name phenethicillin. Others that are being studied are sodium 6-(2,6-dimethoxybenzamido)penicillinate monohydrate and phenylmercaptomethyl penicillin.

Phenethicillin is available as Alpen (Schering), Broxil (Beecham), Chemipen (Squibb), Darcil (Wyeth), Dramcillin S (White), Maxipen (Roerig), and Syncillin (Bristol). It has appeared in the literature also as PA 228, BRL 152, P 152 DL, and as penicillin 152. The dimethoxybenzamido derivative is available as Celbenin (Beecham) and Staphcillin (Bristol) and has appeared in the literature also as BRL-1241 and, more recently, as methicillin.

Synthesis and physical comparison of the diastereoisomers of phenethicillin have been reported (356). The diastereoisometric mixture is more active than the individual components against sensitive organisms and has an antibacterial spectrum similar to that of penicillin V (357). Pharmacologically (358) and in clinical practice (359, 360), the two analogs of phenethicillin appear similar. Presence of food in the upper gastrointestinal tract when phenethicillin is administered orally markedly interferes with absorption—may reduce subsequent serum levels 30 to 60%—and to ensure maximum absorption the drug should be given on a fasting stomach or at least 1 hour before meals (360), although there is some evidence that, despite the lower serum levels achieved when the drug is given after a meal, the levels that are achieved are better sustained (361).

A major advertising claim made for phenethicillin is that, when given orally, it produces much higher blood levels than penicillin V given by the same route and than penicillin G given intramuscularly. It is also claimed that phenethicillin is excreted into the urine in greater amounts than penicillin V. The advertisements fail to point out that the "greater amounts found in the urine . . . produce appreciably less antibacterial activity when assayed against the same standard," that the "higher serum levels are also less active against hemolytic streptococcus and pneumococcus and no more active against *Staph. aureus* than those produced by orally administered penicillin V" (361). Nor is it pointed out that, although the peak concentration attained with oral phenethicillin is greater than that produced by intramuscular penicillin G when assayed in terms of drug given, "the peak is much lower when compared against the same standard and expressed in terms of units of penicillin G" or that the high serum levels attained with the new product are very brief while intramuscular penicillin G produces much more sustained levels and substantially greater urinary recovery (361). It has been pointed out that "thus, although the claim of better absorption and excretion and higher serum level of phenethicillin may be partly correct, . . . this is true in a very restricted sense and is therapeutically meaningless" and actually "misleading since it clearly implies greater antibacterial and presumably curative activity, which, in fact, the drug does not possess, at least in any broad sense of the various

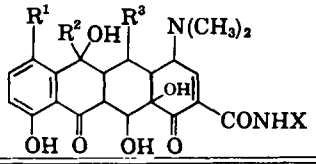
uses to which penicillin is put" (361). In the same study it was shown that phenylmercaptomethyl penicillin, which produces lower serum levels and is excreted in a smaller proportion in the urine provides "substantially and significantly greater antibacterial activity from equivalent doses given by mouth, fasting or after a meal, by any of the standards of comparison that were used" (361). In comparison with phenethicillin and penicillin V, phenylmercaptomethyl penicillin, whether given before or after a meal, produced the highest levels of antibacterial activity despite the fact that the concentrations in the serum were lower and a smaller proportion was recovered from the urine. As pointed out earlier in this paper, the concentration of an antibiotic in the serum is not alone a significant statistic for evaluation of its clinical value. Of equal importance is the activity of the drug against the specific pathogen to be controlled and, unless some uniform standards are applied, comparisons based on serum level, amount recovered in the urine, etc., are quite meaningless in any practical or therapeutic sense.

Others, in a comparative study of penicillins G, V, phenethicillin, and 6-(2,6-dimethoxybenzamido)penicillinate monohydrate (henceforth designated methicillin), also have drawn attention to "the quite large differences in the range of their antibacterial activity" and to the fact that "it is . . . no longer possible to treat all penicillins as though they were equivalent" (362). This situation is going to become more complicated and more confusing as the number of semisynthetic penicillins on the market multiplies unless some uniform standards of reference are adopted.

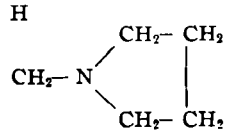
Methicillin attracts special interest because of its uniformly (to date) good performance against staphylococci resistant to penicillin G and the other penicillins currently available (362–370). It is "both stable and active in the presence of staphylococcal penicillinase" (368), although it may act as a penicillinase inducer and after 24 to 48 hours of growth of the organisms suffer some loss of activity (365). However, attempts to induce strains of *Staphylococcus aureus* to become resistant to methicillin have failed and *Staph.* strains reisolated from patients receiving the drug showed no change in the minimum inhibitory concentration (365). A novel proposal for controlling staphylococcal cross infection in hospitals is the spraying of methicillin into the air to produce droplets which circulate much as the staphylococci do. It has been reported that such a procedure prevented the usual acquisition of pyogenic staphylococci by newborn infants (371).

Methicillin is unstable in acid media; therefore, the oral route is not suitable for systemic medication. Given slowly by deep intramuscular injection, it is no more painful than penicillin G and no local reactions at the injection site have been noted. A dose of 1 Gm. of the sodium salt at 4- to 6-hour intervals has been recommended for adults (368).

A good comparative appraisal of the newer penicillins has been published by Dowling (371a).



Modified Tetracyclines



Despite the similarity of structure of members of the tetracycline family listed in the accompanying generalized formula, they are not quantitatively identical antimicrobially or pharmacologically. For example, frequently CTC is more active against staphylococci and pneumococci, OTC against *Pseudomonas pyocyanea*, and TC against *Proteus* (372, 373). The differences may be slight or relatively large, depending on the species and strain of organism involved. However, there is complete cross resistance among the three compounds, whether the organisms are resistant when isolated from clinical material (344) or are induced by exposure to any one of them in the laboratory (375).

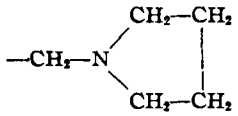
Pharmacologic differences are somewhat greater, especially with respect to absorption and excretion and to gastrointestinal side effects. TC generally produces higher and more prolonged antibiotic activity than OTC and CTC in the blood (376), and it is less likely to induce severe gastrointestinal disturbance, especially the acute, and sometimes fatal, staphylococcal enterocolitis which may follow treatment with CTC or especially OTC (377–380). Principally because of its supposed pharmacologic advantages, TC has largely replaced CTC and OTC in clinical practice.

Demethylchlortetracycline (Declomycin, Lederle).—The demethylchlortetracyclines, originally produced in 1957 by chemical manipulation of TC (381–383), constitute a group of derivatives with greater acid- and alkali-stability than the corresponding methylated compounds. Subsequently, 6-demethyltetracycline and 7-chloro-6-demethyltetracycline (DMCT) were found among the metabolic products of a mutant strain of *Streptomyces auriofaciens*, the organism from which CTC was obtained.

One of these, DMCT (available as Declomycin, Lederle), was found to be, on the average, about twice as active as TC against many pathogens and rarely less active, to be readily absorbed following oral administration, and to be excreted

Drug	Symbol	R^1	R^2	R^3	X	Year Discovered
Chlortetracycline	CTC	Cl	CH_3	H	H	1948
Oxytetracycline	OTC	H	CH_3	OH	H	1950
Tetracycline	TC	H	CH_3	H	H	1953
Demethylchlortetracycline	DMCT	Cl	H	H	H	1957
N-(Pyrrolidinomethyl)tetracycline	PMT	H	CH_3	H		1958

about half as rapidly as TC. A thorough and authoritative review of the bacteriologic, clinical, and pharmacologic position of DMCT has been published (384).



Against some strains of streptococci, DMCT may be almost 5 times as active as TC, although the average figure is about 2.3 (385). Against some resistant staphylococci, it may show somewhat lesser relative activity (386).

Presumably because of the lower rate of excretion of DMCT, therapeutic serum levels are maintained for a longer time after administration of this antibiotic than after an equivalent dose of TC. Therefore, satisfactory therapy can be achieved with DMCT given in smaller, or in less frequent, doses. DMCT, like its analogs, is concentrated in the liver and excreted into the bile, where the concentration may be up to 30 times that occurring in the serum at the same time (387).

Toxicity of DMCT appears to be no greater than that of its earlier analogs. In moderate doses, its tendency to cause diarrhea is minimal, and in therapeutically equivalent doses DMCT probably tends to produce slightly less, certainly not more, gastrointestinal side effect than TC.

A curious phototoxicity not observed in patients receiving other TC analogs has occurred in some subjects exposed to bright sunlight while under treatment with DMCT. The reaction manifests itself as an exaggerated sunburn with high fever, eosinophilia, and increased blood platelets. The effect occurs only on skin exposed to rays in the 2,700 to 3,200 Å. range, which is filtered out by ordinary window glass, and appears to be a true phototoxicity, not merely a hypersensitivity phenomenon (384, 388-390). The incidence is not definitely established. One observer noted 4 cases among 27 ambulatory patients (389) while another reported 40 instances among 2,682 patients (390).

Pyrrolidinomethyltetracycline (Syntetrin, Bristol). — N - Pyrrolidinomethyltetracycline (PMT) is prepared, by partial synthesis, from TC by replacing one hydrogen of the NH_2 group of the latter with

The dry compound is reasonably stable—loss of potency 15% in 4 months at 56°, 18% in 1 year at 37°, and 7% in 18 months at 25° (391). In solution, it may retain full potency for 1 or 2 days at room temperature. The compound is soluble in water, and concentrations of 1 Gm./ml. can be prepared over the pH range 1.5 to 8.5. Its chemical and physical properties have been reviewed (392) and abstracted (393).

Qualitatively and quantitatively, PMT is similar to TC in antibiotic spectrum. The principal advantage claimed for the derivative over the parent compound is greater solubility in the physiologic pH range (394). For systemic use it is given parenterally, and it may be a useful addition to the armamentarium for the patient who needs tetracycline therapy but cannot (or will not) accept oral medication. It is claimed to provide higher blood levels than TC and to cause less pain and irritation at the injection site (391), and to provide better therapeutic effects and fewer side effects, especially gastrointestinal, than oral TC (395–397). It is interesting that, despite the claim of less pain at the injection site, in preparing an intramuscular dosage form of PMT a local anesthetic (lidocaine, 40 mg./350 mg. PMT) has been added. Both the intramuscular and the intravenous dosage forms contain ascorbic acid.

One intravenous injection of 275 mg. per day for 4 to 7 days is normally adequate for average

infections due to sensitive organisms. Severe infections or those caused by less sensitive strains may require 2 to 4 injections daily. In children, 5 to 25 mg./Kg. is the normal dose range.

Intramuscular doses are given by deep injection into the upper outer quadrant of the gluteal muscle. Injection into dermal or subcutaneous tissue must be avoided. Injection in such tissues may cause unnecessary pain and tissue reaction. In intravenous administration, extravenous spillage must be avoided for the same reason.

Synthesis and Pharmacological Studies of Some Aliphatic Hemicholinium Analogs

By MARVIN F. POWERS, STEFAN KRUGER, and FRED W. SCHUELER

The aromatic nucleus of hemicholinium-3 was replaced with an aliphatic hexamethylene chain without loss of the characteristic pharmacological activity. The toxic dose was elevated in mice about tenfold by the change. Choline chloride was a very effective antidote to intoxication from the aliphatic hemicholinium. Another compound synthesized, a pyridine analog, had marked anticholinesterase activity, but caused a flaccid paralysis in avian musculature. A third compound, a trimethylamine analog, elicited neuromuscular blockade typical of decamethonium.

HEMICHOLINIUM-3, hereafter called HC-3, was synthesized in 1954 during an investigation of a series of bis-quaternary ammonium compounds (1). The general pharmacology of HC-3 has recently been reviewed by Schueler (2). Marshall and Long (3) synthesized and investigated pharmacologically some hemicholinium analogs and found none to be more potent than HC-3. The analogs studied by these workers contained structural changes at the cationic heads and in the biphenyl nucleus. It appears that the crucial moiety is at the cationic head rather than at the biphenyl grouping, since the introduction of an ether or a methylene linkage between the two phenyls elicited only a slight decrease in potency, whereas certain relatively minor changes at the cationic heads either markedly reduced or abolished HC-3-like activity (3). Considering the alterations already studied, one may question whether the aromatic nucleus is an essential feature in the HC-3 molecule. The introduction of a methylene chain would not only incorporate an aliphatic moiety, but would also provide an approach for a systematic study of the effect on pharmacologic activity

of alteration of the distance between the cationic heads, provided an aliphatic chain can successfully replace the biphenyl nucleus, with retention of characteristic hemicholinium-like action.

The aliphatic moiety least likely to alter extended molecular length would seem to be a hexamethylene chain, since in its extended configuration this chain approximates very closely the length of the biphenyl nucleus. The aromatic nucleus is rigid and permits no variation of distance between cationic heads, whereas the methylene chain allows a great deal of folding. However, the presence of two positively charged atoms in this molecule would necessarily entail coulombic repulsion between the like charges and thus tend to cause the molecule to be in a fully extended configuration. This paper reports the pharmacological studies of some aliphatic HC-3 analogs containing a hexamethylene chain.

MATERIALS AND METHODS

Suberic acid (0.1 mole) was reacted with 0.3 mole of thionyl chloride at 50° for 4 hours in a flask fitted with a reflux condenser (4). The excess thionyl chloride was then evaporated under reduced pressure. The acid halide was added dropwise to an ethereal solution of diazomethane at 0°. The diazomethane was prepared from Diazald[1] and dried over potassium hydroxide for 30 minutes. The reaction mixture was allowed to stand at room temperature overnight. The precipitated bis-diazoketone was then dissolved in chloroform, and anhydrous hydrochloric acid was bubbled through the solution for 20 minutes. Evaporation of the solvent left the crude compound 1,6-bis(chloroacetyl)-*n*-hexane as a brown mass.

After four recrystallizations from aqueous methanol, the product was obtained in the form of white plates melting at 85°, as stated in the literature (4), with a 60% yield.

One gram of the 1,6-bis(chloroacetyl)-*n*-hexane was dissolved in 15 ml. of cold dioxane, mixed with an excess (2 ml.) of β-dimethylamino ethanol, and heated on a water bath for 30 minutes. The gummy material which formed was dissolved in absolute alcohol. Upon addition of ether a white solid separated out. Three recrystallizations gave a product melting at 212°, with decomposition. This product, 1,10-bis(dimethyl-β-hydroxyethylammonium)-*n*-decan-2,9-dione dichloride was designated P-16-A.

The pyridine compound, P-16-B, was prepared in a similar manner, using pyridine as the amine. This product melted at 216°, with decomposition.

P-16-C was prepared by reacting trimethylamine with the 1,6-bis(chloroacetyl)-*n*-hexane in a pressure bottle for 2 hours at 100°. The product melted at 225°, with decomposition.

The melting points in all cases involving decomposition were determined by placing the compound on a hot Fisher-Johns melting block heated to within a few degrees of the expected melting point. Analyses of these compounds are detailed in Table I. Figure 1 shows the molecular configurations of these compounds and also that of HC-3.

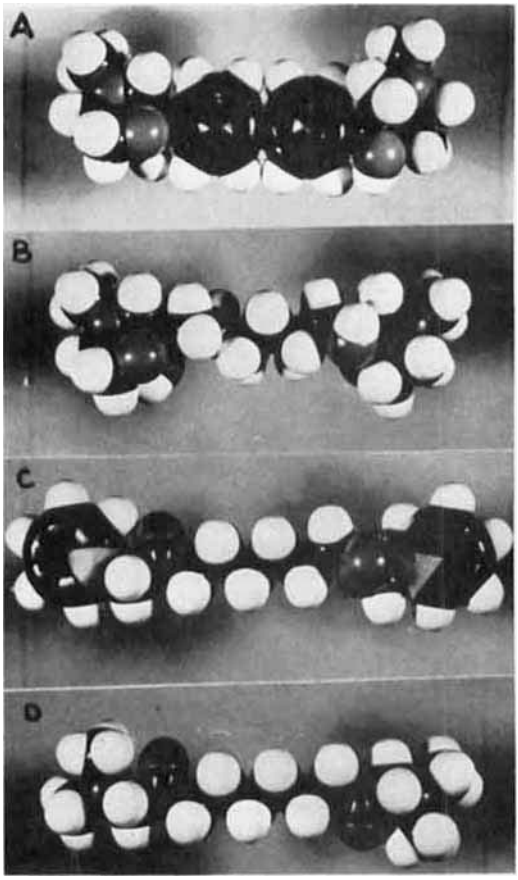

Fig. 1.—It can be seen that internitrogen distances are similar when the molecules are maximally extended. A is HC-3, B is P-16-A, C is P-16-B, and D is P-16-C.

Animal Studies.—Toxicity studies were done on white Swiss mice weighing about 25 Gm. In each case the compound was dissolved in 0.9% sodium chloride and injected intraperitoneally. Each dose level was administered to a group of 10 mice. Toxicity data were calculated by the method of Litchfield and Wilcoxon (5). Drug antagonism studies were carried out by administering various drugs in conjunction with each of the compounds being investigated, as specified in Table II.

Studies on blood pressure, sciatic-gastrocnemius activity, and respiratory function were done on nine mongrel dogs anesthetized with sodium pentobarbital 35 mg./Kg. intravenously. The trachea was cannulated and a water manometer was attached for recording respiration on smoked kymograph paper. The left common carotid artery was cannulated and blood pressure recorded by using a mercury manometer. Five milliliters of 2% mepesulfate (Roche) was introduced into the carotid cannula to avoid clotting of blood. The right vagus nerve was isolated and sectioned, and periodically the periph-

eral stump was electrically stimulated. The right sciatic nerve was isolated, ligated tightly, and arranged for supramaximal peripheral stimulation with a Grass model S4C stimulator at specified frequencies by shielded silver electrodes. The gastrocnemius was also isolated, sectioned distally, and connected to a lever for kymographic recording. Test doses of histamine, epinephrine, and acetylcholine were administered several times to obtain a standard response. The vagus was stimulated, and the intact right carotid artery was temporarily occluded for additional standard responses. This testing operation was conducted periodically after administration of P-16-A, P-16-B, and P-16-C to screen for autonomic-cardiovascular effects.

Bilateral sciatic-gastrocnemius preparations were done on 12 adult albino rabbits anesthetized with 200 mg./Kg. of phenobarbital sodium administered intravenously 1 hour prior to the experiment. Both sciatic nerves were tightly ligated and individually arranged for supramaximal peripheral stimulation by a Grass stimulator at various frequencies, using shielded silver electrodes. The gastrocnemius muscles were attached to kymographic levers for recording contraction height.

Seven chicks, four weeks old, were injected intramuscularly with 1 or 2 mg. of compound and observed for evidence of flaccid or spastic paralysis.

Twelve adult white leghorn hens were anesthetized with 25 mg./Kg. of sodium pentobarbital and prepared for kymographic recording by isolating the sciatic nerve, ligating it, and arranging it for peripheral stimulation supramaximally at specified frequencies at 5 msec. duration. The gastrocnemius muscle was attached to a kymograph lever. The cannulated trachea was insufflated with oxygen.

Enzyme Studies.—Enzyme inhibition studies were carried out manometrically, using "true" acetylcholinesterase, a commercial purified preparation of bovine erythrocyte acetylcholinesterase.[2] For the competitive studies, "pseudo" cholinesterase was used; the source was fresh dog plasma diluted 1:5 with 0.9% sodium chloride. Flasks contained a total volume of 2.0 ml. for each experiment. The standard procedure of Ammon was used as modified by Augustinsson (6).

Acetylcholine was used as the substrate, and a bicarbonate buffer served as the medium. All appropriate flask readings were corrected for nonenzymatic hydrolysis and for atmospheric pressure variations. Readings were taken every 10 minutes for a period of 1 hour in the experiments using "true" esterase, and every 5 minutes for a 40-minute period in the "pseudo" esterase experiments. Results were expressed as μl. of carbon dioxide evolved per interval of time. Determinations were always carried out using duplicate flasks.

RESULTS AND DISCUSSION

The toxicity of the aliphatic hemicholinium, P-16-A, is not as great as that of HC-3, the former being about one-tenth as potent in mice. See Table I. This decrease might be explained if one assumes that not all the molecules are maximally extended and that complete extension is essential for optimal activity. Similarly, the toxicities of the pyridine and trimethylamine analogs were decreased by about the same degree.

Figure 2 shows a typical result of P-16-A on a

[2] Winthrop Laboratories.

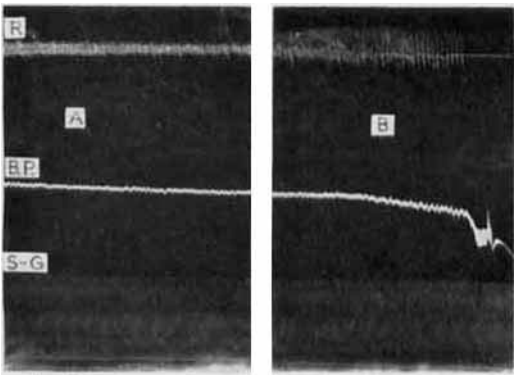

Fig. 2.—A recording of dog respiration (R), blood pressure (B.P.), and sciatic-gastrocnemius (S-G) effects when P-16-A, 1 mg./Kg. is administered at A. Respiratory function failed at B, 105 minutes after A, whereas the S-G activity continued.

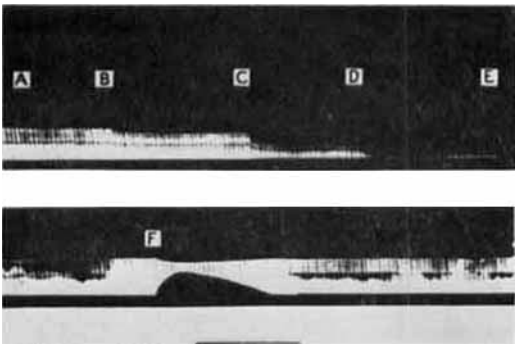

Fig. 3.—Adult hen sciatic-gastrocnemius preparation and the effects of P-16-B (top record) given in graded doses. A = 0.5 mg./Kg.; B = 1.0 mg./Kg.; C = 1.25 mg./Kg.; D = 1.5 mg./Kg.; E = 2.00 mg./Kg. No contracture is evident even though P-16-B is a cholinesterase inhibitor in mammals. Bottom record is P-16-C 80 mcg./Kg. given at F.

dog. The neuromuscular responses continue unaltered when stimulation is one per 10 seconds. However, the respiration fails about 100 minutes after administration. This latent action is very typical of HC-3 poisoning. Blood pressure falls only after respiratory embarrassment and failure have occurred. If oxygen is insufflated intratracheally throughout respiratory paralysis, the blood pressure remains stable, and eventually the respiratory function is restored. Administration of choline chloride intravenously, 20 mg./Kg., antagonizes the respiratory paralysis.

In a rabbit sciatic-gastrocnemius preparation P-16-A mimics HC-3. Frequency of stimulation is an important factor, since a frequency rate of one per 10 seconds is never accompanied by failure or by depression of function in the dosage used. In contrast, the rate of one per second is accompanied by functional failure. It is indeed true that an increase of frequency of stimulation can lower the effective dose of a neuromuscular blocking agent such as curare and decamethonium (7). However, with the latter two, it was observed that onset was rapid.

The trimethylamine analog (P-16-C) did not produce an HC-3-like response. The onset of paralysis was rapid and was not antidoted by choline chloride, as was P-16-A. See Table II. The functional response of the nerve-muscle preparation was actually further depressed by choline chloride. The hen sciatic-gastrocnemius preparation exhibited a mixed response with depolarization of end-plates, as reflected by contracture, and a slight flaccid paralysis, as represented by the decrease in contraction height. See Fig. 3.

The pyridine analog, P-16-B, exhibited effects which were very interesting. When 1 mg./Kg. was administered to dogs, a transient fall in blood pressure was noted; when a test dose of acetylcholine was given, the recovery of blood pressure was delayed. Increasing the dose of P-16-B to 5 mg./Kg. caused neuromuscular paralysis. Both doses caused copious salivation, micturition, and defecation. These latter effects are also observed in the intact, unanesthetized rabbit. Even though the electrical stimulus was predetermined to have been supramaximal, a transient increase in contraction height was observed.

A similar effect is observed with well-known cholinesterase inhibitors such as eserine. When the present compounds were studied in the presence of cholinesterase, it was found that P-16-B was the most potent *in vitro* inhibitor of the three compounds synthesized (see Table III). Assuming that cholinesterase inhibition was the primary action of P-16-B, it would be expected that the compound would produce depolarization and spastic paralysis in the chicken. The actual effect observed is, however, a flaccid paralysis (see Fig. 4). That P-16-B does not produce even transient spasticity is demonstrated in Fig. 4. When one starts with a very small dose P-16-B (1 mcg./Kg.) and gradually increases the dosage in a hen sciatic-gastrocnemius preparation, there is no apparent effect until a dose of 1 mg./Kg. is given. This latter dose causes a decrease in contraction height with no evidence of contracture. Table III illustrates the type of enzyme inhibition that P-16-B seems to produce. It was found that inhibition is apparently competitive in nature. Plotting the reciprocal of activity at several concentrations of the inhibitor (P-16-B) against the reciprocal of substrate concentration yields "curves" which share the same origin on the ordinate, thereby

All compounds caused rapid paralysis within 5 minutes except HC-3 (D) and P-16-A (G) which produced paralysis after a latent period of 20 to 30 minutes.

resembling the Lineweaver-Burk plot of a competitive inhibitor.

The fact that P-16-B, a potent anticholinesterase agent, effects a flaccid rather than a spastic type of paralysis in avian muscle is particularly interesting. A possible explanation may follow from the concepts of Ariëns, Van Rossum, and Simonis (8). P-16-B may represent a product with very high affinity but low intrinsic or specific activity with respect to postsynaptic acetylcholine receptors at the neuromuscular junction. Thus, while P-16-B is a potent anticholinesterase drug, its high affinity (in the manner of curare) causes it to block the actions of excess acetylcholine at this junction. For muscarinic receptors P-16-B apparently does not exhibit such a high affinity and therefore the effects of excessive acetylcholine due to its anticholinesterase effects are observed.

SUMMARY

Three new substances related to hemicholinium were synthesized: 1,10-bis(dimethyl-β-hydroxyethyl ammonium)-*n*-decane-2,9-dione dichloride, 1,10-bis(pyridinium)-*n*-decane-2,9-dione dichloride, and 1,10-bis(trimethylammonium)-*n*-decane-2,9-dione dichloride.

Pharmacological studies indicated that the biphenyl nucleus of HC-3 can be replaced with an aliphatic chain without serious loss of HC-3-type activity as observed by the actions which P-16-A produced. Possible reasons for the decrease in toxicity of the compounds have been discussed.

One of the compounds, P-16-B, was an anticholinesterase agent nearly as potent as eserine. Paradoxically, this compound prevented endplate depolarization. A possible explanation concerning the flaccid paralysis is discussed.

P-16-C appeared to exert a mixed action by causing contracture paralysis (spasticity), accompanied by a slight decrease in contraction height in a chicken sciatic-gastrocnemius preparation.

Substituted Sulfonyl Piperazines

By WINTHROP E. LANGE, ROBERT N. LAZARUS, and MERLE E. AMUNDSON†

In view of reports in the literature on the anticonvulsant action of various sulfonyl piperazines and of certain substituted 1-sulfonyl-4-β-aminoethylpiperazines as antishock agents, a series of mono- and disulfonyl β-aminoethylpiperazines have been prepared. The compounds were obtained, in most cases, by a modified Schotten-Bauman reaction. The carbobenzyloxy blocking group was employed in the preparation of the monosubstituted compounds and was removed by catalytic hydrogenation without cleavage of the sulfonyl group.

A LARGE NUMBER of 1,4-unsymmetrically substituted sulfonyl piperazines has been prepared for various purposes. Among them are 1-ethylsulfonyl-4-ethylpiperazine (1), a compound active in the treatment of hemorrhagic or heat shock, and 1-diethylsulfonyl-4-(2′-thiazoyl)piperazine (2), active as an anticonvulsant. Jacob and Suau (3) later found that 1-substituted sulfonyl-4-β-aminoethylpiperazines were useful in the treatment of hemorrhagic and traumatic shock. The presence of a β-aminoethyl group in other piperazine compounds has, in general, provided compounds with pharmacological activity, varying from adrenergic (4) to curarimimetic (5). This agrees with many of the known antihistamines, antispasmodics, and local anesthetics in which the ethylene group between oxygen and nitrogen or nitrogen and nitrogen provides the most active compounds. This suggested that the activity of sulfonyl piperazines could possibly be enhanced by inserting a β-aminoethyl group between the sulfonyl group and the piperazine nucleus. It also appeared desirable to prepare 1-β-aminoethylpiperazines containing two sulfonyl groups. The present investigation is intended to make available for testing various arylsulfonyl compounds.

DISCUSSION

The methods which have been employed in the preparation of the disubstituted arylsulfonyl compounds have generally involved the treatment of 1-β-aminoethylpiperazine with two equivalents of an arylsulfonyl chloride in aqueous media with an inorganic base to neutralize the liberated hydrogen chloride, or in alcoholic media with pyridine as the hydrogen chloride acceptor. The second procedure was more time-consuming and did not give good yields. The products, which are described in Table I, were obtained in a good state of purity either as the free base or as the sodium salt. They also gave correct carbon-hydrogen analyses after one recrystallization. It was noted that the carbon-hydrogen analyses for 1-benzenesulfonyl-4-β-benzenesulfonamidoethylpiperazine also would be the same for the monosulfonated compound and differentiation was not possible by treating the compound with dilute acid. However, the calculated nitrogen content of the two compounds was different. The product obtained gave a correct nitrogen analysis which proved that it was disubstituted.

It was also decided to prepare the monosulfonated β-aminoethylpiperazines, i.e., 1-arylsulfonyl-4-β-aminoethylpiperazine. It is necessary, therefore, to have a blocking group present on one of the nitrogens of the piperazine ring, prior to the introduction of the β-aminoethyl group, which can be removed by a nonhydrolytic procedure.

The blocking group selected for investigation was carbobenzyloxy, since it may be cleaved from the piperazine nitrogen by catalytic hydrogenation. 1-Carbobenzyloxypiperazine was prepared by a method based on that of Goldman (6), which in turn was modified by Foye and Fedor (7). The amino group of β-aminoethyl chloride, in turn, was protected with a benzoyl group prior to its reaction with 1-carbobenzyloxypiperazine. 1-Carbobenzyloxy - 4 - β - benzamidoethylpiperazine was readily prepared and the blocking group was removed by catalytic hydrogenation in a manner similar to the one reported by Goldman and Williams (8). The hydrogenation was successfully carried out using hydrogen and 10% palladium-on-charcoal in refluxing alcohol.

The desired 1-arylsulfonyl-4-β-benzamidoethylpiperazine was obtained by shaking the 1-β-benzamidoethylpiperazine with the appropriate arylsulfonyl chloride in water with sodium hydroxide or sodium carbonate to neutralize the liberated hydrogen chloride. Hydrolysis of the benzoyl blocking group with acid also cleaved the arylsulfonyl group. The compounds obtained in this manner are shown in Table I. The equation illustrates the synthesis of 1-benzenesulfonyl-4-β-benzamidoethylpiperazine.

For comparative purposes, several new arylsulfonylpiperazine compounds were prepared. When a basic aqueous-alcoholic solution of 1-carbobenzyloxypiperazine was treated with various arylsulfonyl chlorides at room temperature a good yield, in most cases, of 1-carbobenzyloxy-4-arylsulfonylpiperazines resulted. Hydrogenation by the previously described procedure gave the 1-arylsulfonylpiperazines shown in Table II. When the catalytic hydrogenation procedure was employed for the removal of the carbobenzyloxy group from 1-

carbobenzyloxy - 4 - *p* - nitrobenzenesulfonylpiperazine it was found, as expected, that the nitro group was also reduced to an amino group. In one case the arylsulfonylpiperazine was further treated with α-chlorotoluene to give the 1-arylsulfonyl-4-benzylpiperazine.

Antishock and anticonvulsant tests have not been completed with these compounds. However, two of the compounds, 1-β-benzenesulfonamidoethyl-4-benzenesulfonylpiperazine, and 1-β-(*p*-aminobenzenesulfonamidoethyl)- 4- *p* - aminobenzenesulfonylpiperazine were inactive in a general pharmacodynamic screen and central nervous system test carried out at the Schering Research Laboratories.

EXPERIMENTAL

Melting points were taken on a Fisher-Johns block and are uncorrected. Analyses were obtained from the Weiler and Strauss Microanalytical Laboratory, Oxford, England, and from Geller Laboratories, Bardonia, N. Y.

N-Benzoyl-β-chloroethylamine.—This compound was prepared by the procedure of Brintzinger, Pfannstiel, and Daddebusch (9). An 85% yield of white needles was obtained which melted at 105–106° as previously reported (9).

1-Carbobenzyloxypiperazine.—This compound was prepared by the procedure of Goldman and

Williams (6). A 45% yield of colorless product was obtained which boiled at 160–165° (2 mm.). The reported boiling point (6) is 158–161° (1.4 mm.).

1 - Carbobenzyloxy - 4 - β - benzamidoethylpiperazine.—A mixture of N-benzoyl-β-chloroethylamine (5.5 Gm., 0.03 mole), sodium carbonate (12 Gm.), and 1-carbobenzyloxypiperazine (6.6 Gm., 0.03 mole) in xylene (100 ml.) was refluxed for 6 hours or until carbon dioxide no longer was evolved from the reaction mixture. The excess sodium carbonate and the sodium chloride formed during the reaction were removed by filtration, and the xylene was removed by vacuum distillation. The residue was recrystallized from isopropyl alcohol to yield 9.8 Gm. (89%) of 1-carbobenzyloxy-4-β-benzamidoethylpiperazine; m.p. 104–105°.

1 - Benzenesulfonyl - 4 - β - benzamidoethylpiperazine.—In a 300-ml. three-neck flask equipped with a hydrogen inlet tube, a mechanical stirrer, and a reflux condenser was placed 3.7 Gm. (0.01 mole) of 1 - carbobenzyloxy - 4 - β - benzamidoethylpiperazine and 1 Gm. of 10% palladium-on-charcoal in 100 ml. of ethanol. The mixture was stirred and heated by an oil bath at 85° while hydrogen was bubbled in continuously. After 6 hours, when the evolution of carbon dioxide had ceased, the catalyst was removed by filtration and the solvent was evaporated under reduced pressure. A chilled aqueous solution of the residue was treated with 1.8 Gm. (0.01 mole) of benzenesulfonyl chloride and 4.0 ml. of 4 *N* sodium hydroxide. After stirring for 3 hours at room temperature, the mixture was cooled and filtered, yielding 2.1 Gm. (57%) of white crystals. The product was first recrystallized from water and then from ethanol to give white needles melting at 235–239°.

1 - *p* - Nitrobenzenesulfonyl - 4 - β - benzamidoethylpiperazine.—The hydrogenation procedure was identical with the one described for the previous preparation. A chilled aqueous solution of the residue was treated with 2.2 Gm. (0.01 mole) of *p*-nitrobenzenesulfonyl chloride and 4.0 ml. of 4 *N* sodium hydroxide. After stirring for 6 hours at room temperature, the mixture was cooled and concentrated under reduced pressure. The product was recrystallized from an alcohol-water mixture to yield 1.8 Gm. (64%) of pale yellow crystals; m.p. 210–212°.

1 - *p* - Toluenesulfonyl - 4 - carbobenzyloxypiperazine.—To a solution of 10.24 Gm. (0.04 mole) of 1-carbobenzyloxypiperazine and 7.7 Gm. (0.04 mole) of *p*-toluenesulfonyl chloride in 100 ml. of an ethanol-water mixture was added a few pellets of sodium hydroxide. The mixture was shaken for 3 hours, allowed to stand overnight, and the white precipitate was collected. Recrystallization from ethanol yielded 5.1 Gm. (34%) of 1-*p*-toluenesulfonyl - 4 - carbobenzyloxypiperazine; m.p. 145–147°.

1-*p*-Toluenesulfonylpiperazine.—A solution containing 3.74 Gm. (0.01 mole) of 1-*p*-toluenesulfonyl-4-carbobenzyloxypiperazine in ethanol was hydrogenated in an analogous manner to that previously described. The product obtained after evaporation of the alcohol was recrystallized from a methanol-water mixture. A yield of 1.3 Gm. (54%) of 1-*p*-toluenesulfonylpiperazine was obtained; m.p. 103–105°.

1 - *p* - Toluenesulfonyl - 4 - benzylpiperazine.—A mixture of 1-*p*-toluenesulfonylpiperazine (1.2 Gm., 0.005 mole), sodium carbonate (1 Gm.), and α-chlorotoluene (0.63 Gm., 0.005 mole) in xylene (50 ml.) was refluxed for 6 hours. The excess sodium carbonate and the sodium chloride were removed by filtration, and the xylene evaporated under reduced pressure. Recrystallization from methanol yielded 1.2 Gm. (75%) of pale brown platelets melting at 121–123°.

1 - *p* - Nitrobenzenesulfonyl - 4 - carbobenzyloxypiperazine.—To a solution of 10.24 Gm. (0.04 mole) of 1-carbobenzyloxypiperazine and 8.86 Gm. (0.04 mole) of *p*-nitrobenzenesulfonyl chloride in 100 ml. of ethanol was added a few pellets of sodium hydroxide. A small amount of heat was applied to the mixture to initiate the reaction. The mixture was shaken for 2 hours, and after refrigeration overnight, the white precipitate was collected. Recrystallization from ethanol yielded 14.3 Gm. (96%) of 1 - *p* - nitrobenzenesulfonyl - 4 - carbobenzyloxypiperazine; m.p. 155–156°.

1-*p*-Aminobenzenesulfonylpiperazine.—A solution containing 6 Gm. (0.015 mole) of 1-*p*-nitrobenzenesulfonyl-4-carbobenzyloxypiperazine in ethanol was hydrogenated in an analogous manner to that already described. The product obtained after evaporation of the solvent was recrystallized from ethanol. A yield of 3 Gm. (75%) of product was obtained which melted at 210–213°.

1 - β - (*p* - Nitrobenzenesulfonamidoethyl) - 4 - *p*-nitrobenzenesulfonylpiperazine.—To 6.43 Gm. (0.05 mole) of 1-β-aminoethylpiperazine[1] and 22.2 Gm (0.1 mole) of *p*-nitrobenzenesulfonyl chloride in 100 ml. of water was added sufficient sodium hydroxide to maintain an alkaline pH. The mixture was stirred for 8 hours, acidified with dilute hydrochloric acid, and the precipitate collected. Recrystallization from an ethanol-acetone mixture yielded 13 Gm. (52%) of pale yellow needles which melted at 207–209° (decompn.).

1 - β - (*p* - Aminobenzenesulfonamidoethyl) - 4-*p*-aminobenzenesulfonylpiperazine.—To a solution of 10 Gm. of stannous chloride dihydrate in 10 ml. of concentrated hydrochloric acid was slowly added 2.5 Gm. (0.005 mole) of 1-β-(*p*-nitrobenzenesulfonamidoethyl) - 4 - *p* - nitrobenzenesulfonylpiperazine. The reaction temperature was kept at 25–30° by cooling with water. After the addition was complete, and the reaction mixture had been stirred for 2 hours at room temperature, it was poured into a cold solution of 4 *N* sodium hydroxide. The resulting white precipitate was collected on a filter and recrystallized from an ethanol-water mixture. A yield of 1.8 Gm. (82%) of crystalline solid was obtained which melted at 206–207°.

1 - β - (*p* - Toluenesulfonamidoethyl) - 4 - *p*-toluenesulfonylpiperazine.—A solution of 5 Gm. (0.04 mole) of β-aminoethylpiperazine, 19 Gm. (0.1 mole) of *p*-toluenesulfonyl chloride, 100 ml. of an ethanol-water mixture, and 4 Gm. of sodium hydroxide was shaken for 3 hours at room temperature. The mixture was allowed to stand overnight at room temperature, and after cooling it was acidified with dilute hydrochloric acid. The resulting white solid was collected, dried, and recrystallized from ethanol, yielding 7.3 Gm. (43%) of product; m.p. 160–162°.

[1] Aldrich Chemical Co.

The monohydrated sodium salt of 1-β-(*p*-toluenesulfonamidoethyl) - 4 - *p* - toluenesulfonylpiperazine was obtained by filtration of the precipitate which appeared in the reaction mixture before acidification; m.p. 213-215°.

Anal.—Calcd. for $C_{20}H_{23}N_4NaO_5S_2 \cdot H_2O$: C, 50.20; H, 5.90. Found: C, 49.5; H, 5.9.

1 - β - Benzenesulfonamidoethyl - 4 - benzenesulfonylpiperazine.—This compound was prepared in a manner similar to that described in the previous procedure. A yield of 89% of colorless needles was obtained which melted at 144–146°.

Prediction of Stability in Pharmaceutical Preparations VIII

Oil-in-Water Emulsion Stability and the Analytical Ultracentrifuge

By EDWARD R. GARRETT†

An oil-in-water emulsion clears in a centrifugal field to form a packed, semirigid "cream." Subsequently, a true oil or continuous phase is spun-out of the "cream." It is shown that rates of emulsion clearing can be stated as a function of the ultracentrifugal r.p.m. and that the rate of clearing under simple gravity can be predicted for the oil-water emulsion as initially constituted. "Bad" emulsion can be differentiated from "good" emulsion by the ready formation of a separate oil phase in the former. In the latter case, an induction period exists before a continuous oil phase is spun out at an accelerating rate, which rate is a function of the centrifugal force.

THE PREDICTION of stability in pharmaceutical preparations has largely dealt with chemical transformations (1, 2). The basic philosophy has been the application of stress or energy to promote decomposition and the following of degradation or of some property of the degradation as a function of time. This function has been linearized and the slopes of such linear plots have been used as estimates of specific rates (k). The reproducibility of such functions at varying degrees of stress would validate their use in prediction of rates under marketing or storage conditions. There are classical relations that describe the variation of such rate parameters with the degree of stress. In the cases previously discussed, a rate at a given temperature is linearized on the basis of it being first, second, etc., order and the apparent rate constant (k) or property proportional to rate constant is correlated with the absolute temperature by means of the Arrhenius expression, which in its logarithmic form is

$$\log k = -(\Delta H_a/2.303\ R)(1/T) + \log P \qquad \text{(Eq. 1)}$$

Thus the accelerated reactions can be used to evaluate the parameters of Eq. 1, i.e., ΔH_a and the resultant quantitative expression may be used to predict specific rates or functions thereof at lower temperatures.

Since the nature of the function is known from the reproducibility among the various accelerated studies, the predicted rate constants may be used in such a function to predict thermal stability at lower temperatures.

The same philosophy may be used in predicting physicochemical stability of pharmaceutical formulations where preservation of the pharmaceutical elegance is of primary interest rather than the integrity of the drug.

A case in point is a colloidal suspension or emulsion. An admirable example of an oil-water emulsion[1] (3, 4) is available commercially. It is a

Prediction of Stability in Pharmaceutical Preparations VIII

Oil-in-Water Emulsion Stability and the Analytical Ultracentrifuge

By EDWARD R. GARRETT†

An oil-in-water emulsion clears in a centrifugal field to form a packed, semirigid "cream." Subsequently, a true oil or continuous phase is spun-out of the "cream." It is shown that rates of emulsion clearing can be stated as a function of the ultracentrifugal r.p.m. and that the rate of clearing under simple gravity can be predicted for the oil-water emulsion as initially constituted. "Bad" emulsion can be differentiated from "good" emulsion by the ready formation of a separate oil phase in the former. In the latter case, an induction period exists before a continuous oil phase is spun out at an accelerating rate, which rate is a function of the centrifugal force.

THE PREDICTION of stability in pharmaceutical preparations has largely dealt with chemical transformations (1, 2). The basic philosophy has been the application of stress or energy to promote decomposition and the following of degradation or of some property of the degradation as a function of time. This function has been linearized and the slopes of such linear plots have been used as estimates of specific rates (k). The reproducibility of such functions at varying degrees of stress would validate their use in prediction of rates under marketing or storage conditions. There are classical relations that describe the variation of such rate parameters with the degree of stress. In the cases previously discussed, a rate at a given temperature is linearized on the basis of it being first, second, etc., order and the apparent rate constant (k) or property proportional to rate constant is correlated with the absolute temperature by means of the Arrhenius expression, which in its logarithmic form is

$$\log k = -(\Delta H_a/2.303\ R)(1/T) + \log P \qquad \text{(Eq. 1)}$$

Thus the accelerated reactions can be used to evaluate the parameters of Eq. 1, i.e., ΔH_a and the resultant quantitative expression may be used to predict specific rates or functions thereof at lower temperatures.

Since the nature of the function is known from the reproducibility among the various accelerated studies, the predicted rate constants may be used in such a function to predict thermal stability at lower temperatures.

The same philosophy may be used in predicting physicochemical stability of pharmaceutical formulations where preservation of the pharmaceutical elegance is of primary interest rather than the integrity of the drug.

A case in point is a colloidal suspension or emulsion. An admirable example of an oil-water emulsion[1] (3, 4) is available commercially. It is a

[1] Marketed as Lipomul I.V. by Upjohn.

clinically useful fat emulsion in an aqueous continuous phase which is well tolerated on intravenous administration and has therapeutic utility (4) since it is a high caloric material for intravenous alimentation.

The primary criteria for the stability of the preparation is the preservation of the emulsion or the retention of the complete dispersion of fat in water. A classical evaluation of such stability is vigorous shaking for 72 hours at 5° with essentially no change in particle size. Particle size may be estimated from hemocytometer particle counts. It has been shown that well over 90% of the fat is present in particles which were submicroscopic with not over 0.02% of the visible particles larger than 1.5 μ in diameter (3).

The importance of the maintenance of stability of such a preparation is obvious. Not only would nondispersed oil be conducive to embolism, but unstable oil particles would resist metabolism where the particulate nature of the fat is considered mandatory. Solvolytic degradation would tend to decrease emulsion stability. Phosphatide hydrolysis would diminish dispersing agent and increase solvolysis rates. Such a model of degradation would be autocatalytic in nature.

There are two aspects of the stability prediction of colloidal suspensions or emulsions. The one relates to the shelf life of the emulsion when gravitational influences alone are to be considered, i.e., oil flotation of the emulsion.[1] The other is the stability prediction of emulsion when chemical degradation produces an inherent emulsion instability or tendency for oil coalescence. This paper primarily reports on studies of the former or physical instability, but also considers the implications of the latter.

EXPERIMENTAL

Analytical Ultracentrifuge.—The data presented in this paper were obtained from quantitative measurement of photographs of sector cells filled with the oil-water emulsion.[1] The sector cell was counterbalanced in the rotor of the Spinco analytical ultracentrifuge, model E (5) which may be operated at speeds up to 60,000 r.p.m. The optics are a Schlieren optical system (5, 6) but may also be used to measure light transmittance in different levels of the cell. The operating temperature was maintained within 2° of the initial temperature of 29° for the duration of a run.

The oil-water emulsion[1] was prepared as specified in the literature (3, 4). It was opaque and initially the photographic film was sensitized only by light which passed through (*a*) transparent air above the emulsion, i.e., toward the center of the rotor, and (*b*) a reference hole in the counterbalance. This latter is manifested in the photographic negative by a dark reference bar from which the distance to the center of the rotor is 7.30 cm. (see Figs. 1b and 5b).

The clearing of the oil-water emulsion on ultracentrifugation was demonstrated by an increasing transparency in the bottom of the cell, i.e., away from the center of the rotor. The recording of this phenomenon on the photographic negative which magnifies the actual cell 2.21 times radially (or along the vertical length in the figures) was by an increasing band of darkness. The difference between the distance, x in cm. corrected for magnification, of the leading edge of this band to the near edge of the reference bar and 7.30 cm. is the distance of the slowest floating oil particles from the center of the rotor (Fig. 5b). The measurements of the x distance were performed in two ways: (*a*) by magnification in a photo enlarger and projection on a system of coordinates with a selection of scale such that 10 times the magnification of the original cell geometry resulted, and (*b*) by use of the Spinco Analytrol to determine the optical absorbance of the photographic film as a function of the distance across the film (Fig. 6b). This latter technique gave a good sharp line at the water-emulsion or water-cream interphase. Both methods gave data in good agreement.

Specific Emulsions.—Freshly prepared emulsion,[1] maintained at 5°, preparation A, and a similar material, preparation B, maintained for one-half year at 37°, were ultracentrifuged at speeds ranging from 12,590 to 52,640 r.p.m. and the clearing of the emulsions was measured (see Figs. 1–6). The log $(7.30 - x)$ cm. values (Fig. 5b) were plotted against time for each r.p.m. and the constant slopes, k, were determined. These values are listed in Table I.

The preparation B was considered as an example of unsatisfactory emulsion in that its acidity had increased; it gave grossly observable oil and significant changes in particle size when subjected to vigorous shaking for 72 hours at 5°.

The flotation rates of oil particles were extreme at the higher r.p.m. values. Thus, most of the maximum possible clearing of the emulsion had occurred in the time necessary to bring the ultracentrifuge up to the desired r.p.m. setting. Since the valid flotation rate for a given r.p.m. could only be estimated from measurements made at constant r.p.m., the largest error of estimate of k is at the larger r.p.m. values.

ABSORBANCE
FIG. 6b

Figs. 1a–6b.—Clearing of oil-water emulsion at 24,630 r.p.m. The ultracentrifugal pictures were taken at 2.21 magnification of the i.v. emulsion at 32°. The rotor reached full speed at 158 seconds. The times in seconds of ultracentrifugation are given below the appropriate figures. Figs. 1b and 5b interpret the photographs as to the clearing of the emulsion to the flotation of oil particles as a "cream," Fig. 6b shows a plot of the absorbance of the film.

Inspection of the material in the sector cell after ultracentrifugation showed a clear liquid at the bottom and a resilient white creamy froth or "cream" at the top of the cell with semisolid or plastic attributes which readily redispersed in the aqueous phase on agitation to give the same k constant as before (see Table I).

The formation of an oil phase occurred at higher r.p.m. values (see Figs. 7–16). Runs were conducted on both preparations A and B from 39,460 to 59,780

Figs. 7–11.—Flotation of oil in a "poor" oil-water emulsion at 52,640 r.p.m. from the "cream" of adhered oil particles. The times in seconds of ultracentrifugation are given below the appropriate figures. Figs. 10 and 11 are labeled for identification of the layers. The geometry of cell with respect to the center of the rotor is given in Fig. 11. The rotor reached full speed in 6 minutes.

r.p.m., and the depth of the oil phase was correlated with the time of ultracentrifugation (see Fig. 11 for $y - y_0$). The nature of the oil phase was demonstrated by its immiscibility with water and miscibility with oil.

Thermal instability was checked by subjection of emulsion[1] A to 75° and removal of aliquots on the third and subsequent days. These samples were toxic and on gross observations showed poor dispersivity and high acid titer. On ultracentrifugation at 52,640 r.p.m. no band on the photographic negative appeared that could be assigned to formation of an oil layer (see Figs. 10 and 11). However, inspection of the cell after centrifugation did show that the oil had separated but was now opaque.

CALCULATIONS AND RESULTS

Sedimentation of particles heavier than the suspending medium and flotation of particles lighter than the suspending medium follow the same laws on ultracentrifugation except for sign. The former sediment away from the axis of rotation; the latter float toward the axis of rotation. The theory of convection-free sedimentation in centrifugal fields as developed by Svedberg (5–7) applies to a sector-shaped cell whose side walls are in the direction of the centrifugal force so as to provide an unobstructed path to the floating particles.

The classical expression relating the distance, x, of a particle from the axis of rotation with the time, t, of centrifugation and the r.p.m. of the rotation is

$$\log x_2/x_1 = \frac{V(\rho - \rho')\ (\text{r.p.m.}2\pi)^2\ (t_2 - t_1)}{k\eta} \qquad \text{(Eq. 2)}$$

where x_2 and x_1 are positions of the particle at t_2 and t_1, respectively, V is the volume of the particle, ρ and ρ' are the densities of the particle and medium, respectively, k is a shape constant for the particle size, and η is the coefficient of viscosity of the fluid.

For a given material at a given temperature, the equation reduces to

$$\log x_2 = kt + \log x_1 = S(\text{r.p.m.})^2 t + \log x_1 \qquad \text{(Eq. 3)}$$

where t is the time from the start of the centrifugation and S is defined as the sedimentation (or flotation) constant.

It is apparent that a plot of the logarithm of the position of a floating particle from the axis of rotation against the time of ultracentrifugation should be a straight line. Typical photographs of emulsion clearing as characterized by the appearance of a nonopaque vehicle are given as Figs. 1 through 6. The value 7.30-x cm. represents the position of the slowest floating particle from the axis of rotation. The plots of the logarithm of this value for a given r.p.m. against time are straight lines as shown by the examples in Fig. 17. These plots confirm the validity of Eqs. 2 and 3.

It also follows that plots of the slope $k = S(\text{r.p.m.})^2$ against the square of the r.p.m. should be linear and

FIG. 16b

Figs. 12a–16b.—Flotation of oil in a "good" oil-water emulsion, i.v. emulsion, at 52,640 r.p.m. from the "cream" of adhered oil particles. The times in seconds of ultracentrifugation are given below the appropriate *a* figures. The *b* figures are diagrammatic representations of the coalescence of particles in the "cream." The rotor reached full speed in 6 minutes.

pass through the origin as do the examples given in Fig. 18. The resultant sedimentation coefficient is $S = 12.14 \times 10^{-14}$ for rate of rotation in min.$^{-1}$ and rate of particle displacement in the cell in sec.$^{-1}$ as calculated from the slope of the line in Fig. 18.

The data plotted in Fig. 18 are given in Table I and are typical of the data obtained from both "good" and "bad" emulsions, defined as such by the stability tests previously described. Maintenance of emulsion[1] at 40° for one-half year produces a "bad" emulsion.

The observed clearing of the emulsion by ultracentrifugation does not vary with the degree of "goodness" of the emulsion. This is not wholly unexpected since an oil-in-water emulsion should posses a spectrum of oil particle sizes and, the smaller the particle, the greater its resistance to flotation by Brownian motion and charge repulsion, i.e., higher charge/mass ratio.

In general, flotation, creaming, and coalescence are not necessarily correlated with emulsion clearing as manifested by the appearance of a clear solution. It follows that a "bad" emulsion may have a sufficient population of small oil particles which impart turbidity to the solution for as long a time as "good" emulsion under the same conditions of ultracentrifugation. It also follows that the measurement of the emulsion clearing rate and the sedimentation constant measures only the flotation of that population of particles which is the smallest size possible and says nothing about the population of larger particles.

The clearing of "good" emulsion[1] proceeded until a narrow band of opaque material remained at the "top" of the cell, adjacent to the air-liquid boundary, i.e., closest to the axis of rotation (see Figs. 5a and 5b). A clear liquid slowly appeared adjacent to the air-liquid boundary and in both "bad" (Figs. 7–11) and "good" (Figs. 12a–16b) emulsions replaced a portion of the area of opacity. The initial rate of clearing of the opaque band for "good" emulsion[1] accelerated with time, as can be observed by the plots of Fig. 19, curves b, c, and d.

Inspection of the sector cell after ultracentrifugation disclosed a clear aqueous solution below a semisolid froth-like band or "cream" which lay below a transparent oil. Agitation of the cell redispersed the "cream" which had the same flotation parameter for emulsion clearing as did new or fresh emulsion.

Emulsion which was characterized as "bad" on the premises of poor dispersivity, high acid titer, and toxicity did not show the long inductive period of "good" emulsion in spinning out oil from the "cream" (see Fig. 19a). Whereas the "good" emul-

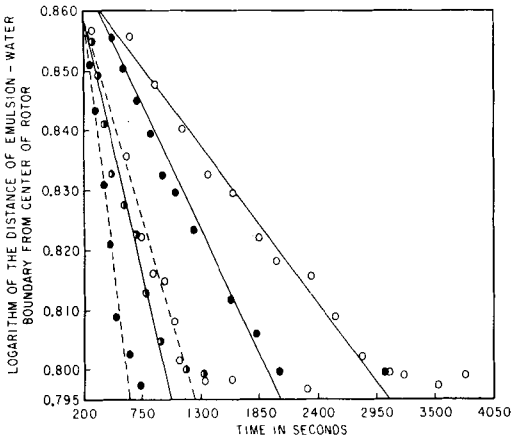

Fig. 17.—Examples of clearing of oil-water emulsion from i.v. emulsion at various centrifugal speeds. Plots of the logarithm of the distance of the emulsion-water boundary from the center of the rotor against the time of ultracentrifugation in seconds at 30°. The symbols and corresponding r.p.m. are: —⊙—, 12,590; —●—, 15,220; - -O- -, 20,410; —◑—, 24,630; - -●- -, 35,600.

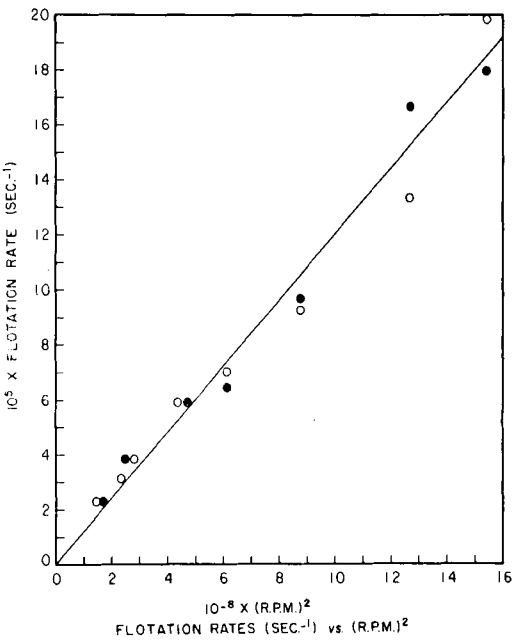

Fig. 18.—Flotation rates for the clearing of oil-water emulsion at 30° against the square of the r.p.m. The open circles are for a stable or "good" emulsion. The closed circles are for an unstable or "poor" emulsion. The flotation rates are the slopes of the plots of the logarithm of the distance of the emulsion-water boundary from the rotor center against time for each r.p.m. The apparent flotation constant from the slope of this figure is 12.14×10^{-14}.

sion manifested an induction period and then an acceleration of rate in spinning out oil, where such factors are an apparent function of r.p.m. or centrifugal field intensity (see Figs. 19b, c, and d), "bad" emulsion produced oil almost instantly with a first-order decay in amount of oil formed. Subsequent to this initial spin-out by "bad" emulsion the inductive and accelerated process of further oil spin-out characteristic of "good" emulsion was noted (see Fig. 19a).

The readily spun-out oil of "bad" emulsion had an apparent half-life in this particular sector cell of 1,200 seconds and was relatively independent of the r.p.m. values studied. However, all the emulsion was well cleared by that time for the same r.p.m. For as low as 35,600 r.p.m. the emulsion was cleared in 620 seconds. When the determined S value is used in Eq. 3, it can be calculated that the emulsion would be cleared in less than 200 seconds at 59,600 r.p.m.

It is thus apparent that the rate of coalescence to produce an oil layer, even with "bad" emulsion, was significantly slower than the rate of clearing of the oil emulsion of the smallest oil particle.

DISCUSSION

The coincidence of the apparent flotation rates of "good" and "bad" oil-in-water emulsions indicated that a population of the smallest oil particles was present in both preparations and lagged behind on ultracentrifugation. An alternative explanation is that the solutions were so concentrated that the larger oil particles "swept out" the emulsion, that is, aggregates were formed during the process of emulsion clearing that had similar clearing rates in both "good" and "bad" emulsions. This latter explanation implies that there would be no gradation in size of oil particles from bottom to top of the clearing emulsion and thus in the ultimate "cream." It also suggests that Eq. 2 would not hold, that there would be a nonlinearity early in the plots of Fig. 17 as

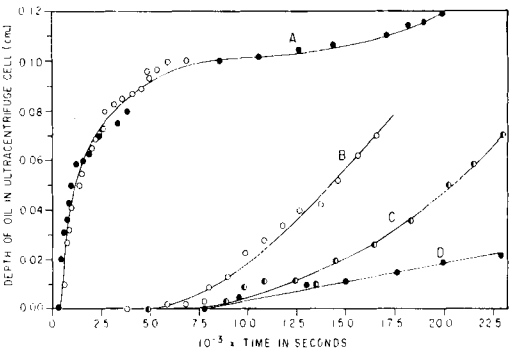

Fig. 19.—Increase of oil coalescence as a function of time for "bad", curve A, and "good", curves B, C, and D, oil-water emulsions. The symbols and ultracentrifugal r.p.m. at 30° are: ⊙, 59,780; ◐, 52,640; ●, 47,660.

aggreates were formed by "sweep-out." However, no deviation from linearity was observed in such plots until the emulsion clearing approached the meniscus or the phase boundary of the "cream."

Also, the slower the ultracentrifugal speeds, the greater would be the opportunity for particle "slippage" and thus gradation according to size. If aggregation on ultracentrifugation (before "cream" formation) was a distinct factor, the flotation rates

would not be expected to be as linear with the (r.p.m.)^2 as they were in Fig. 18.

It may also be predicted that clearing rates would be expected to change with the dilution of the oil-in-water emulsion by the continuous (water) phase if it is the aggregates rather than the smallest particles that determine emulsion clearing rates since particle stratification would be more favored under dilute conditions. Investigations are planned to evaluate these possible models.

The flotation of oil particles to the top of the cell continued until a "cream" of oil particles was formed, i.e., an adhered mass of particulate oil where the "skin" of each particle is highly resistant to the applied gravitational forces.

A model can be proposed that is consistent with the facts to explain the coalescence of the "cream."

In general, the larger oil particles should be on top of the small (see Fig. 12b). The higher the oil concentration, the less probable should be a truly systematic gradation of particle size. On subjection to gravitational force the larger particles are more readily deformed than the smaller in the same manner that large balls of mercury on a table top are more deformed than small ones (8). The larger particles are thus more subject to unequal forces and the skin may be more readily ruptured so that coalescence of two larger particles may occur to form even larger ones (see Figs. 13b–16b). The strength of the "skin" would be a function of the dispersing agent concentration and the retention of maximum conditions in the vehicle for its function and stability.

In the case of "bad" emulsion, the production of higher acidity most probably by hydrolysis indicated a variation in conditions which decreased the skin-strength of the more readily deformed larger particles. The coalescence, which undoubtedly proceeded to a minor degree in the nonstressed "poor" emulsion, was thus accelerated in the "cream" where maximum close contact of oil particles was effected. Sufficient numbers of unstable large particles exist in "bad" emulsion so that after a definite amount of distortion (since the rate of coalescence is very much less than the rate of creaming) coalescence readily occurred as a function of the numbers of large unstable particles.

Subsequent to this spin-out of oil by a first-order process under gravitational stress, the phenomenon encountered in "good" emulsion becomes predominant. In this case, the skins of the larger particles had greater strength than those in "bad" emulsion. Nevertheless, they coalesced to form larger particles but a certain population had to exist before a continuous phase of oil appeared. Simultaneously, the populations of smaller particles were coalescing although at lower rates. However, since the greatest portion of the oil is distributed among the populations of small particles and since these need more time to coalesce, an acceleration in the formation of a continuous oil phase was noted only after a large induction period.

Since the force of deformation is a function of r.p.m. (see Appendix), it is to be expected that the rate of this acceleration of continuous oil phase formation would also be a function of the r.p.m.

After the ready coalescence of the relatively large, unstable, deformed particles in "bad" emulsion, only a fraction of the total oil available had been spun out. The residual small oil particles followed the same coalescing pattern of the "good" emulsion.

This model is consistent with the prediction that the stability of a rigid sphere approaching an unbounded plane is inversely proportional to the radius of the sphere, provided that electrical double layer interaction, electroviscuous effects and London-van der Waals forces of attraction are negligible (9). Rigid behavior was reported to occur with high interfacial tensions, small bubble diameters (<0.1 cm.), and in the presence of surfactants, conditions which certainly exist in our oil-in-water emulsions (9, 10). In an oil/water system containing surfactants, Cockbain and McRoberts (10) have shown that the stability of oil droplets increased rapidly with decreasing diameter below 0.1 cm.

These studies and the conclusions drawn therefrom provide the necessary background for the prediction of stability of emulsions and dispersions by use of the analytical ultracentrifuge.

Knowledge of flotation parameters under the stress of a centrifugal field permits the prediction of flotation (or sedimentation) under the influence of simple gravity. The Appendix provides a detailed procedure which when applied to the emulsion[1] predicts that less than 1 cm. depth of the oil-water emulsion as initially constituted would be cleared in a year's time. It can also be safely stated that no significant coalescence of the oil particles in the initially constituted emulsion to form a continuous phase would occur during the pharmaceutical lifetime of the product.

The specific qualification considered is that the preparation is as initially constituted. Obviously, when chemical changes occur with time and result in "bad" emulsion, this is not so.

However, the effect of chemical deterioration on emulsion stability can be studied in such a manner as to expedite prediction. Ultracentrifugal characterization of thermally stressed preparations would permit evaluation of rate constants of continuous oil phase appearance as functions of gravitational stress. Measurements of sedimentation and coalescent rates as functions of enhanced temperature and time of subjection to enhanced temperature should permit prediction of emulsion stability by combining the lessons learned from accelerated thermal and ultracentrifugal stability studies.

SUMMARY

1. It is shown that the analytical ultracentrifuge is an excellent tool for the evaluation of emulsion stability.

2. The slopes of the plots of the position of the emulsion-water boundary from the center of the ultracentrifugal rotor against time are shown to be functions of the square of the r.p.m.

3. The discontinuous oil phase is cleared from the continuous phase by ultracentrifigation to form a cream, a packed particulate mass of adhered oil globules. The rate of clearing under simple gravity has been predicted for the emulsion as initially constituted. Less than 1 cm. depth

of the oil-water emulsion would be cleared in a year's time on the shelf provided that no change in chemical constitution occurred in that interval.

4. Emulsion clearing rates essentially may measure the flotation of the population of smallest particles, which exist in both "good" and "bad" emulsions, and may not permit differentiation between two such preparations.

5. Highly unstable particles that are readily spun out of the "cream" on ultracentrifugation exist in "bad" emulsion but not in "good" emulsion. This initial spin-out of a continuous oil phase for "bad" emulsion decays with time and only accounts for a fraction of the total. The residual follows the same pattern as the spin-out of continuous oil phase in "good" emulsion.

6. "Good" emulsion demonstrates an induction period at high r.p.m. values before a continuous oil phase can be observed and may indicate a "yield" value. Subsequently, the rate of coalescence accelerates and the acceleration rate is a function of the r.p.m. and may be considered a measure of the toughness of particle "skin."

7. A consistent model for these phenomena is the more ready flotation of large oil particles so that the "cream" is a grading of large to small oil particles from top to bottom. Unstable large particles immediately coalesce as a function of their number. Stable particles coalesce to form larger ones. The larger they are, the more readily are they deformed under centrifugal stress. However, a critical number of such large ones is necessary before coalescence and the spin-out of oil in "good" emulsion.

APPENDIX

The force, F, on a particle in a gravitational field is

$$F = V(\rho - \rho')a \qquad \text{(Eq. 1)}$$

where V = volume of particle, ρ and ρ' are the densities of the particle and medium, respectively, and a is the acceleration due to the field (7). When steady state conditions are reached, there is a constant particle velocity, v, and the gravitational force equals that applied to the particle by Stokes law so that

$$V(\rho - \rho')a = k\eta v \qquad \text{(Eq. 2)}$$

where k is a shape constant and η is the coefficient of viscosity of the fluid medium (7).

Equation 2 may be solved for velocity, v, and in a centrifuge of a given r.p.m. where $2\pi x$ is the distance traveled by a particle in one rotation at a distance, x, from the axis of rotation where the acceleration is $a = u^2/x$ and u = r.p.m. $2\pi x$ is the velocity of the particle, then

$$v = dx/dt = V(\rho - \rho')\,4\pi^2\,(\text{r.p.m.})^2\,x/k\eta \qquad \text{(Eq. 3a)}$$

$$= K4\pi^2(\text{r.p.m.})^2x \qquad \text{(Eq. 3b)}$$

$$= S(\text{r.p.m.})^2x \qquad \text{(Eq. 3c)}$$

where t is in minutes.

If the initial distance of the particle is x_1 from the axis of rotation at $t_1 = 0$, and the distance at time $t_2 = t_c$ is x_2, then Eq. 3a, 3b, and 3c may be integrated between these limits and

$$\ln x_2/x_1 = S(\text{r.p.m.})^2t_c \qquad \text{(Eq. 4a)}$$

$$= K4\pi^2(\text{r.p.m.})^2t_c \qquad \text{(Eq. 4b)}$$

Under gravity, $a = g$ in Eq. 2 and

$$v = dx/dt = V(\rho - \rho')g/k\eta \qquad \text{(Eq. 5a)}$$

$$= Kg \qquad \text{(Eq. 5b)}$$

which integrates between the limits $t_1 = 0$ and $t_2 = t_g$ for x_1 and x_2 to

$$x_2 - x_1 = Kgt_g \qquad \text{(Eq. 6)}$$

The ratio of the time necessary for the particle to fall a distance $l = x_2 - x_1$ under true gravity to the time under ultracentrifugation where d is the original distance of the particle from the axis of rotation of the ultracentrifuge can be derived from Eqs. 4 and 6 and is

$$t_g/t_c = 4\pi^2\,(\text{r.p.m.})^2/g\,\ln\,(l/d + 1) \qquad \text{(Eq. 7)}$$

Since g = 980 cm./sec.^{2} = 3.53 × 10^6 cm./min.^{2}, Eq. 7 may be converted to an expression in logarithms to the base ten

$$t_g/t_c = 4.856 \times 10^{-6}l(\text{r.p.m.})^2/\log(l/d + 1) \qquad \text{(Eq. 8)}$$

This relation is derived for sedimentation; for flotation the sign is reversed.

For the set of flotation studies plotted in Fig. 17 the time interval, t_c, between the ordinate values of 0.8500 (log 7.08 cm.) and 0.8000 (log 6.31 cm.) corresponds to the flotation of a particle of l = 0.77 cm. with a d = 7.08 cm. initial distance from the axis of rotation of the ultracentrifuge. Based on r.p.m. values ranging from 12,590 to 35,600 and the respective t_c values the time, t_g, for the emulsion clearing of 0.77 cm. of emulsion[1] on the shelf under gravity alone as calculated from Eq. 8 averages 311 days. The range of calculation of t_g was 271 to 376 days.

Spectrophotometric Study of Aqueous Solutions of Warfarin Sodium

By C. F. HISKEY, E. BULLOCK, and G. WHITMAN

The pKa of the enolic form of warfarin has been determined by a spectrophotometric technique and found to be 5.05 ± 0.1. It was found that if its solutions were prepared with an alkaline buffer they could be kept stable and free of precipitation for several weeks when stored at refrigerator temperatures.

SINCE the discovery by Link (1) of the hypoprothrombinemic properties of warfarin sodium,[1] the use of this agent both in a parenteral as well as in the oral form, has become widespread. The oral method of administration is the preferred one, but there are occasions when this route is contraindicated. This occurs, for example, in instances where the patient with a thromboembolic episode cannot swallow because of vomiting or of being comatose. In such cases it is necessary to administer the drug intravenously or intramuscularly. There is usually an initial larger dose of 25 to 50 mg., which is subsequently followed by 5 or 10-mg. daily maintenance doses.

The warfarin sodium used in the parenteral preparation is supplied in the form of a lyophilized powder, containing with it sufficient sodium chloride. When an appropriate amount of sterile water is introduced into the vial a clear isotonic solution containing about 25 mg. of the drug per ml. is obtained. It became of interest to determine whether the lyophilized warfarin powder could be reconstituted to give stable solutions, which on the succeeding days following the start of therapy, could be used for the maintenance doses.

While investigating this problem some difficulties were experienced with such solutions. Precipitates were occasionally found and, consequently, it was decided to make a systematic study of the absorption spectra of warfarin sodium solutions in order to determine the acid ionization constant of the enol form. Because of the very low solubility of the enol form, the more common potentiometric method could not be applied. The data obtained were useful in setting up the conditions for producing stable parenteral solutions and, being of general interest, are therefore presented here.

EXPERIMENTAL

Effect of pH on the Absorption Spectra of Warfarin Solutions

Warfarin powder corresponding in its properties to those described in U.S.P. XVI was used in all of these studies. Two solutions were prepared at a concentration of 6.06×10^{-5} M with respect to warfarin. One was made 0.01 N with hydrochloric acid and the other was made 0.01 N with sodium hydroxide. The absorption spectra of these two solutions were determined using a DK-2 recording spectrophotometer with 1-cm. silica cells and using water as the reference solvent.

The spectra so obtained are presented in Fig. 1 where A represents that of the enolic form and B that of the enolate form. It will be observed that the enolic form has absorption peaks at 274, 282, and 305 mμ. In addition, a peak in the vicinity of 319 mμ emerges as a shoulder on the 305 mμ peak. The enolate spectrum shows a main peak at 308 mμ with a shoulder in the vicinity of 293 mμ. There is, as would be expected, a general shifting of this spectrum toward the visible. Isosbestic points are observed at 289 and 251 mμ. A summary of the molar absorptivities is given in Table I.

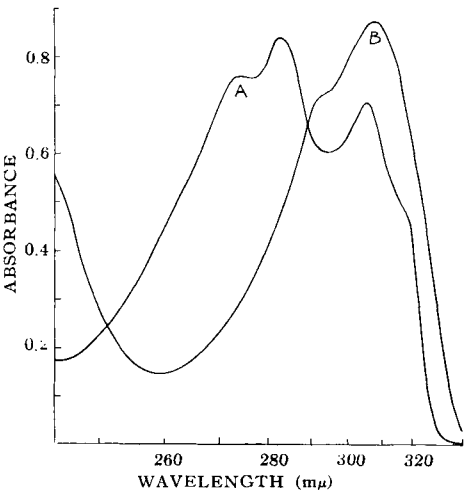

Figure 1

Received January 26, 1961, from Endo Laboratories Inc., Richmond Hill 18, N. Y.
Accepted for publication March 1, 1961.
Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.
The authors would like to acknowledge the assistance of Dr. Nathan Weiner who suggested that this study be performed.

[1] Warfarin is the coined generic name for the synthetic hypoprothrombinemia-inducing agent 3-(alpha-acetonyl benzyl)-4-hydroxycoumarin. Coumadin sodium is the registered trademark of Endo Laboratories for this chemical.

TABLE I.—SUMMARY OF MOLAR ABSORPTIVITIES

Form	mμ	Molar Absorptivity
Enol	274	12,500
	282	13,900
	305	11,600
Enolate	308	14,400
	293	11,900

In order to determine the acid ionization constant of this compound, a group of solutions was prepared with identical molar concentrations of the anticoagulant, i.e., 5.5×10^{-5} *M*, but with a pH varying between 2 and 10. These were prepared by adding disodium hydrogen phosphate in an amount sufficient to give a 0.1 *M* solution. The pH was adjusted in a preliminary way to the desired value by adding either hydrochloric acid or sodium hydroxide, after which the solutions were brought to volume. The spectrum was then recorded for each solution, after which a final pH measurement was made. Some of the spectral curves that were obtained are shown in Fig. 2.

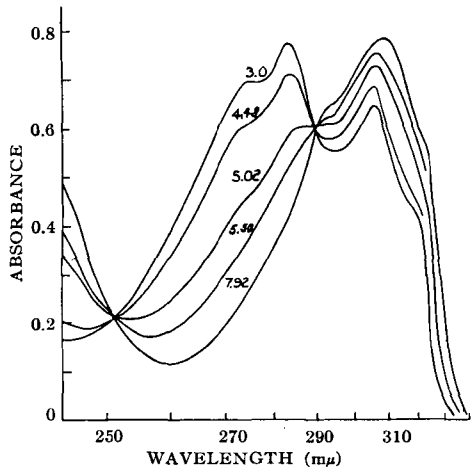

Figure 2

The data were solved for the pKa by assuming an enol-enolate equilibrium given by the simple proton transfer reaction shown in Eq. 1. From the Nernst relation we may write Eq. 2

$$\text{Enol} + H_2O \rightleftharpoons \text{Enolate}^- + H_3O^+ \quad \text{(Eq. 1)}$$

$$\text{pH} = \text{pKa} + \log \frac{(\text{Enolate})}{(\text{Enol})} \quad \text{(Eq. 2)}$$

where the terms in the brackets represent the concentration of the acid and base forms. Inasmuch as the spectrophotometric method involves a concentration determination rather than an activity determination, the expression in Eq. 2 is only approximate.

By examining the curves obtained in Fig. 2, it will be observed that the largest spectral change occurs in the 274 mμ region. This was the region chosen for our calculations since it would give us the greatest change per pH unit. The concentrations of the enolate and enol forms were found by fitting the data into an equation of the form shown in Eq. 3

$$A = a_1bc \frac{h}{h + \text{Ka}} + a_2bc \frac{\text{Ka}}{h + \text{Ka}} \quad \text{(Eq. 3)}$$

where A, is the absorbance of the solution at 274 mμ, a_1 and a_2 are the absorptivities of the enol and enolate species, respectively, b is the path length of the absorption cell, c is the concentration of the anticoagulant in the solution, and h is the activity of the hydrogen ion in these solutions. Having determined these concentration values it can be seen that substituting them into Eq. 2, a linear plot of the data should be obtained with a slope of unity. In Fig. 3 this has been done and reasonable agreement with Eq. 2 is observed. The pKa determined graphically is 5.05 ± 0.1. Thus, it is seen that the enol is an acid nearly as strong as acetic acid. At a pH of 8 or higher the warfarin will be completely in the enolate form. Consequently, clear stable solutions may be anticipated at that pH.

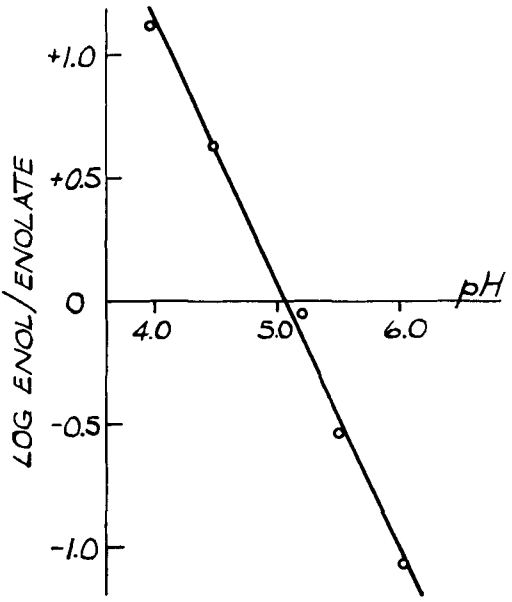

Figure 3

This study was performed in order to determine whether reconstituted vials of lyophilized warfarin sodium injection are stable enough to be used over a period of time as a multidose vial. Samples from three lots of 50-mg. vials and three lots of 75-mg. vials were reconstituted with 2 and 3 ml., respectively, of sterile water. In another study similar vials were reconstituted with similar amounts of disodium hydrogen phosphate buffer at a concentration of 10 Gm. per L. Daily withdrawals were made which were assayed for the warfarin sodium content. The vials were examined each day for the appearance of crystals and for discoloration of the solution. The reconstitution and withdrawals were made under simulated clinical conditions and the vials were stored in a refrigerator between withdrawals.

Before reconstitution, the metal caps were removed and the vials were weighed with the rubber caps and seals in place. The sterile water and disodium hydrogen phosphate solution were injected into each vial with a 5-ml. syringe and the vials were weighed to determine the precise amount of solution that had been added. The buffer solution had pre-

viously been placed in 10-ml. bottles, sealed with rubber caps and metal seals, and autoclaved at 248° F. and 15 p.s.i. for 15 minutes.

The anticipated concentration could be computed by using the original assay value for each lot. A 1-ml. tuberculin syringe was used to remove a 0.2-ml. portion of solution immediately after reconstitution, and daily thereafter. The amount of solution withdrawn was determined by injecting the solution into small, tared, stoppered test tubes which were weighed and transferred quantitatively to a suitable volumetric flask. Dilutions were made with freshly prepared 0.01 *N* sodium hydroxide to give a concentration of warfarin sodium equal to 1 mg./100 ml.

The absorbance was determined on the Beckman DU spectrophotometer at 308 mμ, using 0.01 *N* sodium hydroxide in the reference cell. Computation of concentration was as follows:

$$\text{mg./ml.} = \frac{11.62 \times A_{308} \times W_2}{\text{ml. solution} \times W_1}$$

where W_1 = weight of sample, W_2 = total weight of container contents after addition of phosphate solution, W_1/W_2 is the fraction of the total contents of the vial taken for assay, and ml. solution refers to the volume of phosphate solution added to the vial.

Daily withdrawals of 0.3 and 0.4 ml. from other vials of these lots were made employing similar methods. Sterile conditions were maintained. All syringes were thoroughly washed, wrapped in brown paper, autoclaved at 248° F. and 15 p.s.i. for 15 minutes, and dried in an oven at 105° C. Before

each entry into a vial, the caps were rubbed with alcohol.

The results obtained with the phosphate buffer are presented in Table II. With sterile water, similar results were obtained but it was noticed after a few days that about half of the vials showed precipitation of the enol form. When precipitates were observed the vials were discarded. Since this would be unsatisfactory from a manufacturers as well as a clinical viewpoint, use of sterile water for reconstitution and multiwithdrawals is not recommended.

The data in Table II indicate that a vial of reconstituted warfarin sodium solution with disodium hydrogen phosphate buffer is quite stable over a reasonable period of time and can be used as a multidose vial.

Oral *versus* Subcutaneous Potency of Codeine, Morphine, Levorphan, and Anileridine as Measured by Rabbit Toothpulp Changes

By FLOYD E. LEADERS and H. H. KEASLING†

The ratio of oral *vs.* subcutaneous potency of codeine, morphine, levorphan, and anileridine has been obtained using rabbit toothpulp threshold changes. Values for codeine, morphine, and levorphan were approximately equal. The value for anileridine was approximately one-half that of the other agents.

MORPHINE is generally recognized to be inactive when administered orally (1). Likewise, oral codeine in doses up to 60 mg. is ineffective as an analgesic agent (2, 3). Levorphan (4) and anileridine (6), however, have been reported to have approximately equivalent analgesic potency by either oral or subcutaneous routes of administration. The differences in reported efficacy of these compounds by these routes prompted this study. The change in toothpulp thresholds in the rabbit was chosen to compare the oral *vs.* subcutaneous potency of codeine, morphine, levorphan, and anileridine.

METHODS

Toothpulp threshold changes were measured as reported by Yim, *et al.* (5), using 0.7 to 1.5 Kg. rabbits. Fresh drug solutions were prepared daily in 0.9% saline and administered to the rabbit subcutaneously or orally by stomach tube.

The drugs utilized in this study were codeine phosphate, morphine sulfate, levorphan tartrate, and anileridine dihydrochloride. All doses were given in terms of μm./Kg. of the base.

The values for total area under the time-response curve were approximated as described by Winter and Flataker (7). These figures were obtained from the percentage changes of each individual rabbit. The peak percentage change during the first 90 minutes post drug was utilized in the analysis of peak responses.

A two by two parallel line bioassay was performed on all data except that of levorphan. A two by three parallel line bioassay was used in this instance. Both peak effect and total area under the curve responses were statistically analyzed by the method of Finney (8), using log response and log dose as effect and dose metameters, respectively.

RESULTS

The results of the bioassay of oral *vs.* subcutaneous doses of codeine phosphate, morphine sulfate, levorphan tartrate, and anileridine dihydrochloride are presented in Figs. 1 and 2. Log dose was plotted against both the log of the total area under the response curve and the log of the peak response. The relative potencies with fiducial limits are summarized in Table I.

Table II illustrates the results of the analysis of variance for each of these groups.

DISCUSSION

Our data demonstrate that codeine, levorphan, and morphine have subcutaneous-oral relative potency values of approximately equivalent magnitudes as measured by elevation of toothpulp thresholds in rabbits. This would be expected since they are close chemical congeners. Absolute potency, however, did vary from drug to drug. These data would thus be in agreement with the literature which

reports codeine, morphine, and levorphan to be less active orally than parenterally in man. Anileridine has a relative potency value of approximately one-half that of the other compounds tested, although this figure does fall within the confidence limits for levorphan. This relative potency of anileridine is

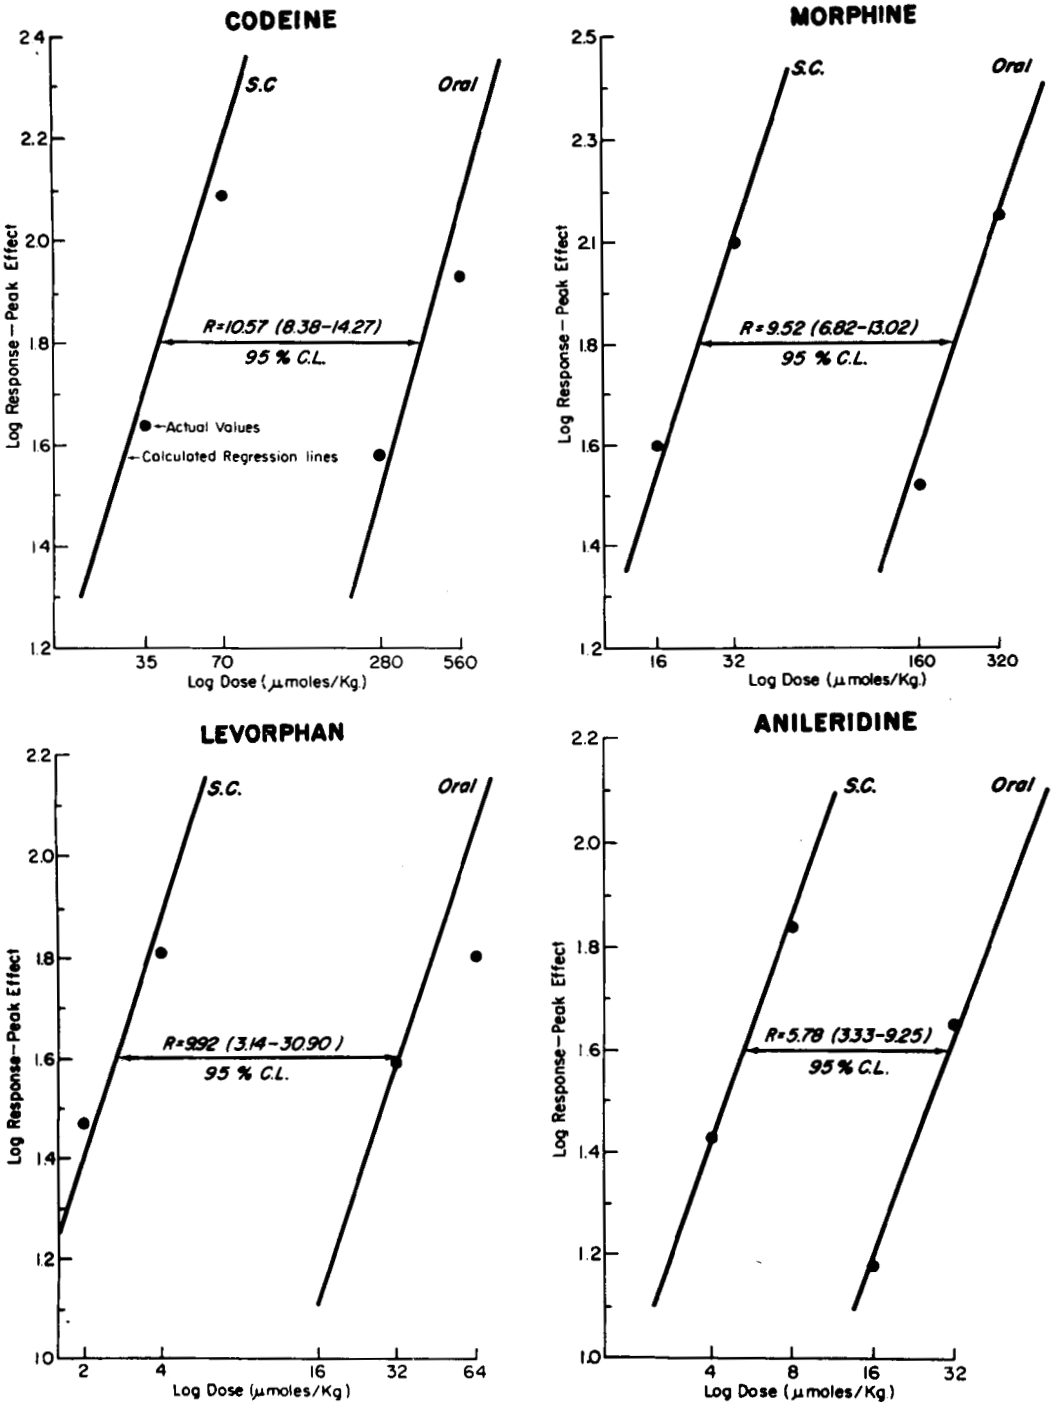

Fig. 2.—Results of bioassay of oral vs. subcutaneous codeine, morphine, levorphan, and anileridine. Response = peak effect.

similar to findings reported previously in rats (6), and would possibly be expected to differ from the values of the other agents since it is not closely related to them chemically.

Greater variations were found for peak response than for total area. Our results demonstrate that the relative potency values are greater when calculated from the peak effect figures than when calculated from the total area response data. This difference reflects the relatively lower peak effects following oral administration.

In the absence of clinical bioassay data it is

difficult to assess the predictive value of this procedure. It is to be hoped that the pertinent human data will be available in the near future.

SUMMARY

Changes in toothpulp threshold in rabbits have been measured following oral and subcutaneous codeine, morphine, levorphan, and anileridine. Codeine, morphine, and levorphan had approximately equal relative potency values. The relative potency value for anileridine, a structurally dissimilar compound, was approximately one-half that of the other agents. These data would thus agree with clinical reports that codeine, morphine, and levorphan are less active orally than when given parenterally. Relative potency values were greater when calculated from peak effect data than when calculated from the total area under the curves.

Solubilization of Benzoic Acid Derivatives by Polyoxyethylene Stearates

By FRANK W. GOODHART† and ALFRED N. MARTIN

A series of five hydrophilic surfactants, all polyoxyethylene stearates,[1] was used in aqueous solution to solubilize a group of solid benzoic acid derivatives. The concentration of solubilizate rendered soluble was a linear function of surfactant concentration which is characteristic of solubilization of semipolar compounds. The critical micelle concentration of Myrj 59 was determined by two methods, and these data support the theory of micellar solubilization by nonionic surfactants. With a few exceptions, solubility was greater in the least hydrophilic surfactant solutions.

In recent years it has become quite common to employ nonionic surfactants as solubilizing agents for certain drugs. Although basic understanding regarding these phenomena is lacking, several reports have appeared regarding this type of solubilization. A nonalcoholic phenobarbital elixir has been prepared by using 2 to 5 per cent Tween 80 (1), and a parenteral solution of reserpine was stabilized using the same solubilizing agent (2). Numerous sources have pointed out the usefulness of nonionic surfactants for solubilizing vitamin A palmitate, vitamin A alcohol, vitamin D (3, 4), and volatile oils such as peppermint (5).

Correlation between the hydrophilicity of the nonionic surfactants and the chemical structure of solubilizates has not been investigated to any great extent. Cohen, using polyoxyethylene ethers of alkyl alcohols (6) as illustrated

$$C_nH_{(2n+1)}O(CH_2CH_2O)_{n'}H$$

found that if n was held constant, polar solubilizates dissolved better as n' increased (7). For a fixed n', the solubility of hydrophobic substances increased as n increased (8, 9).

Moore and Bell (10) solubilized various perfumery compounds in a series of surfactants containing 10–60 units of ethylene oxide. They found the optimum amount of ethylene oxide content for maximum solubilization differed for the various solubilizates such as benzyl alcohol, phenylethyl alcohol, benzaldehyde, and others.

It can be seen from these studies that an optimum hydrophilic-lipophilic balance exists for solubilized compounds just as it does for emulsifiable oils. Therefore, this investigation was undertaken to relate the degree of solubilization of closely related solid solubilizates to the hydrophile-lipophile character of the surfactant. A group of five polyoxyethylene stearates was chosen as the solubilizing agents. Since these surfactants were all of one chemical type differing only in ethylene oxide content, they served as an excellent series for comparing solubilization of related compounds as a function of hydrophile-lipophile balance.

EXPERIMENTAL

Materials and Reagents.—A series of five polyoxyethylene stearates (Myrj surfactants) listed in Table I; deionized-distilled water; hydrochloric acid, reagent grade; recrystallized benzoic, salicylic, *p*-aminobenzoic, and *p*-hydroxybenzoic acids; and recrystallized ethyl *p*-aminobenzoate, butyl *p*-aminobenzoate, methyl *p*-hydroxybenzoate, propyl *p*-hydroxybenzoate, and butyl *p*-hydroxybenzoate.

Myrj 52[a]	16.9
Myrj 53	17.9
Myrj 59	18.8

[a] Official in U. S. P. XVI as polyoxyl 40 stearate.

Instruments.—Beckman D U spectrophotometer, Cenco-du Nouy tensiometer, and a constant temperature shaking apparatus.

Solubilization Studies.—Since the presence of salts decreases the critical micelle concentration (cmc) (11) and, therefore, affects solubilization, the ionization of all solubilizates was suppressed by using hydrochloric acid solution, 0.005 *N*. This concentration of hydrochloric acid was found by experimentation over a range of concentration to be adequate. This acidic solution was used to prepare stock solutions of the Myrj surfactants and as a diluting agent for all spectrophotometric determinations.

The equilibration containers were one-half ounce screw-cap bottles. About 200 mg. of benzoic acid derivative was added to each of a series of bottles so as to provide an excess of solubilizate in all samples. Various concentrations of Myrj stock solution and hydrochloric acid solution were pipetted into each bottle so that a range of surfactant concentrations was obtained. A blank containing

[1] Myrj surfactants were supplied through the courtesy of Atlas Powder Co., Wilmington, Del.

only the solubilizate and the hydrochloric acid solution was also prepared for each run. The samples were capped and sealed around the necks with a strip of water-resistant plastic tape. The samples were equilibrated in a shaking apparatus at a temperature of 25.0 ± 0.1° for a period of forty-six to fifty hours. This time was shown by preliminary experiments to be sufficient for equilibration. After equilibrium had been reached, aliquots were taken by means of a pipet fitted with a cotton filter. Sufficient dilutions were made so that the solutions could be read spectrophotometrically at the wavelength of maximum absorption for each solubilizate. In all instances, the dilutions were large enough so that no absorption resulted from the presence of the Myrj compounds.

Determination of the cmc of Myrj 59.—Above a concentration of surface-active agent known as the critical micelle concentration (cmc), surfactant molecules form colloidal aggregates known as micelles. Two methods were employed to determine the cmc of Myrj 59 solutions. A solubility study was carried out in dilute Myrj 59 solutions. The method employed was the same as the solubility study previously discussed. A break in the solubility curve is indicative of micelle formation (12).

In order to corroborate the cmc determined by solubility equilibria, surface tensions of dilute Myrj 59 solutions were measured. The Cenco-du Nouy tensiometer was calibrated according to the conventional method (13), and the correction factor of Harkins and Jordan (14) was used to correct the observed readings. The cmc for Myrj 59 was found more precisely by saturating the surfactant solutions with benzoic acid. The sharp break occurring in the surface tension-concentration curve is again indicative of the cmc (12).

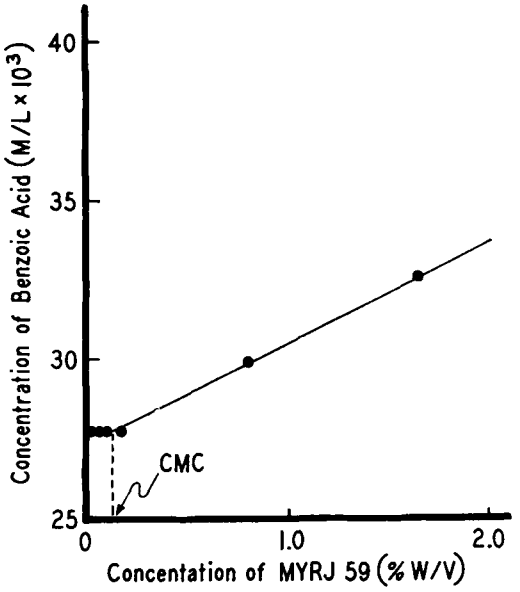

Fig. 1.—Solubility of benzoic acid at 25° illustrating one method of obtaining the critical micelle concentration (cmc).

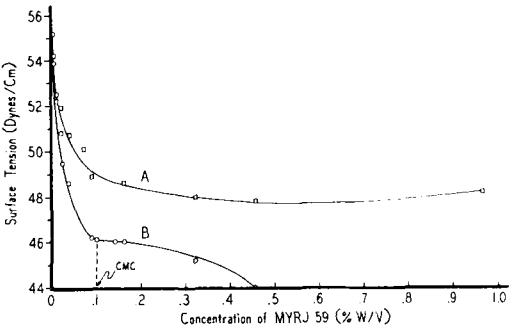

Fig. 2.—Surface tensions of Myrj 59 solutions at 23° illustrating cmc. A, In 0.005 *N* hydrochloric acid; *B*, in 0.005 *N* hydrochloric acid saturated with benzoic acid.

RESULTS AND DISCUSSION

Critical Micelle Concentration.—Figure 1 illustrates the solubility of benzoic acid in dilute Myrj 59 solutions. Up to a Myrj 59 concentration of about 0.1%, the solubility of benzoic acid is not increased. Above this concentration, benzoic acid is solubilized, presumably by the micellar aggregates of surfactant which form.

The surface tensions of Myrj 59 solutions are illustrated in Fig. 2*A*. The reduction in surface tension indicates the surfactant molecules are aggregating and forming micelles (12) until a practically constant limiting value is obtained. No cmc can be deduced from this curve. The curve representing the surface tensions of Myrj 59 saturated with benzoic acid (Fig. 2*B*), however, shows a sharp break at a surfactant concentration of 0.1%. The significance of this break is that the cmc has been reached and the solutions acquire new physical properties making them capable of solubilizing insoluble compounds (12). The agreement of a cmc of about 0.1% for Myrj 59 by both the solubility and surface tension measurements supports this fact.

Solubilization and Complexation.—It is a well established fact that carboxylic acids and phenols undergo complexation with surfactants of the polyether class (15, 16). Moreover, the present study indicates that micellar solubilization of benzoic acid occurs in solutions of polyoxyethylene stearates above the cmc.

The colloid chemist has attributed increased solubility above the cmc to true or micellar solubilization. While Myrj surfactants do contain some free polyglycol (17), results obtained from measuring cmc indicate the principal mechanism of solubilization in this study is micellar solubilization. However, Patel and Kostenbauder (18) in their studies on the interaction of *p*-hydroxybenzoic acid esters with Tween 80 showed that a positive intercept on a Langmuir-type plot may be used to differentiate between complex formation and micellar solubilization.

Since complexation should be evident below the cmc where micellar solubilization is not a factor, and since no interaction was observed in this investigation by the solubilization method used, it is reasonable to conclude that complexation is insignificant in this study below the cmc. Whether

[a] Percentages of ethylene oxide per surfactant molecules calculated from formula of Griffin (21). The percentages are: Myrj 49, 75.0% w/w; Myrj 51, 80.0% w/w; Myrj 52, 84.5% w/w; Myrj 53, 89.5% w/w; and Myrj 59, 94.0% w/w. Concentrations were corrected for water content.

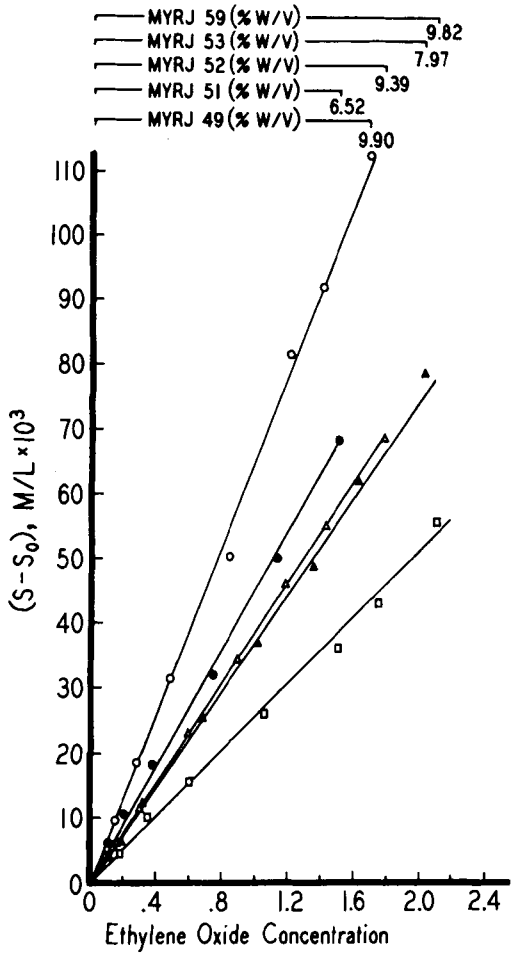

Fig. 3.—Solubilities of benzoic acid in Myrj solutions at 25°. ○, Myrj 49; ●, Myrj 51; △, Myrj 52; ▲, Myrj 53; □ Myrj 59.

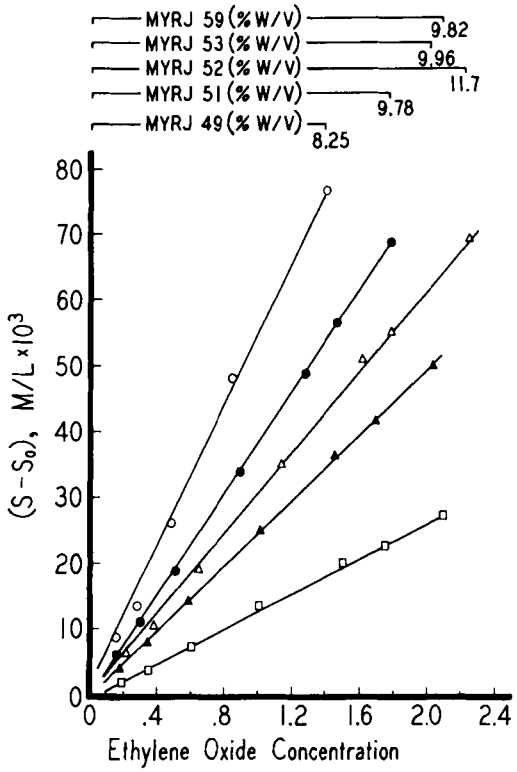

Fig. 4.—Solubilities of butyl *p*-aminobenzoate in Myrj solutions at 25°. ○, Myrj 49; ●, Myrj 51; △, Myrj 52; ▲, Myrj 53; □, Myrj 59.

or not the two effects occur together above the cmc cannot be decided by the present experimental method.

Degree of Solubilization.—The quantity of solubilizate brought into solution by the surfactant was calculated by subtracting the solubility in the acidified water solution, S_0, from the solubility, S, in the Myrj solutions. This quantity ($S - S_0$) was plotted against the surfactant concentration in equivalents of ethylene oxide per L. on rectangular coordinate graph paper. Figures 3, 4, and 5 show the solubilization of benzoic acid, butyl *p*-aminobenzoate,[2] and propylparaben by the five surfactants studied. The results are typical of the solubilization curves obtained with all solubilizates. The linear relationships obtained with each of the five Myrj compounds correspond to results obtained by other workers using nonionic surfactants to solubilize semipolar molecules (18–20).

The moles of solubilizate per equivalent of ethylene oxide in the surfactant were obtained by calculating the slopes of the solubilization isotherms and are listed in Table II. From these data the

[2] Butesin is the trade name of Abbott Laboratories, North Chicago, Ill., for butyl *p* aminobenzoate.

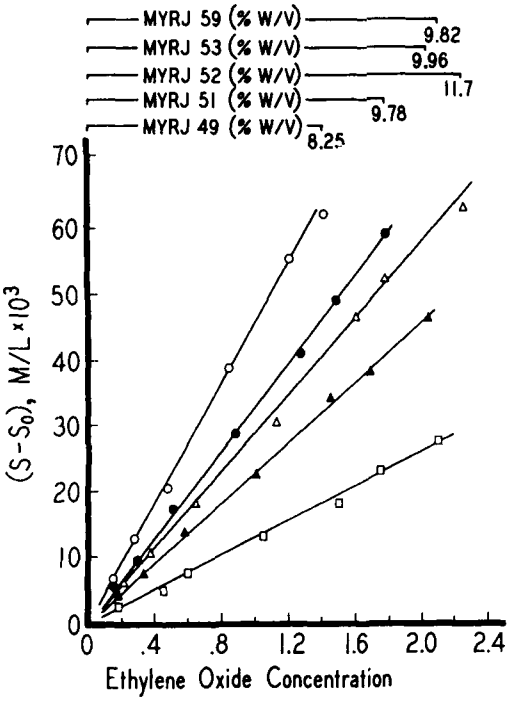

Fig. 5. —Solubilities of propylparaben in Myrj solutions at 25°. O, Myrj 49; ●, Myrj 51; △, Myrj 52; ▲, Myrj 53; □, Myrj 59.

quantity of solubilizate brought into solution by a specific concentration of Myrj 49, 51, 52, 53, or 59 can be calculated. Since the solubility in the acidified water has been subtracted, the intercepts of these curves are zero.

If the moles of solubilizate could be plotted against the moles per L. of surface-active agent, the slopes would be greatest for the most hydrophilic surfactant, i.e., the surfactant containing the longest polyoxyethylene chain. However, when molar solubilization is plotted against equivalents of ethylene oxide, the moles of solubilizate taken into the micelle per individual ethylene oxide unit is measured. The slope of such a plot shows that the efficiency of solubilization in these terms decreases with increasing length of the polyoxyethylene chain, i.e., with increasing hydrophilicity or molecular weight.

Solubilization and Chemical Structure of the Solubilizate.—The differences in the degree of solubilization for the various solubilizates can be compared on the basis of molar ratios. As shown in Table II, the molar ratios for benzoic, salicylic, and *p*-aminobenzoic acids were quite similar in all five surfactant solutions. However, *p*-hydroxybenzoic acid was solubilized to a significantly greater degree than these three acids. In general, the alkyl esters of *p*-hydroxybenzoic and *p*-aminobenzoic acids show a marked decrease in molar ratio when compared to the free acids. As a rule, all solubilizates have maximum solubilities in the least hydrophilic surfactant solutions and minimum solubilities in the most hydrophilic surfactant solutions when molar ethylene oxide concentrations are used as a criterion.

Solubilization Type.—Above the cmc, a solubilized compound is contained within the hydrocarbon layers of the surfactant or is adsorbed between the hydrophilic portions of the micelle known as the palisade layer (22). The solubilizate may also be adsorbed on the surface of the micelle (23). Nonpolar compounds are solubilized in the hydrocarbon interior of the micelle as evidenced by an increase in long X-ray spacings, while polar solubilizates are solubilized in the palisade layers of the micelle and show no change or a decrease in X-ray spacings (24). Above the cmc, the molar ratio of a nonpolar solubilizate to surfactant varies with the concentration of the solubilizing agent, while the molar ratio of a polar solubilizate is constant (22, 23). Since the solubilizates employed in this work were partially polar and since constant molar ratios were obtained (Figs. 3, 4, and 5), it is reasonable to believe the principal interaction causing increased solubility is associated with the polyoxyethylene portion of the surfactant. A possible explanation is that of Beckett, *et al.* (16), which proposes some displacement of water molecules from the oxygen atoms in the glycol chain and the resultant attraction of phenol type compounds to the oxygen atoms.

Degree of Binding of *p*-Hydroxybenzoic Acid and Its Esters in Myrj Solutions.—Figure 6 illustrates the ratio of total to free methylparaben as a function of concentration of the five Myrj compounds studied. It has been pointed out that a plot of this type can be deduced from solubility data as well as dialysis studies (18). The inhibition of anti-

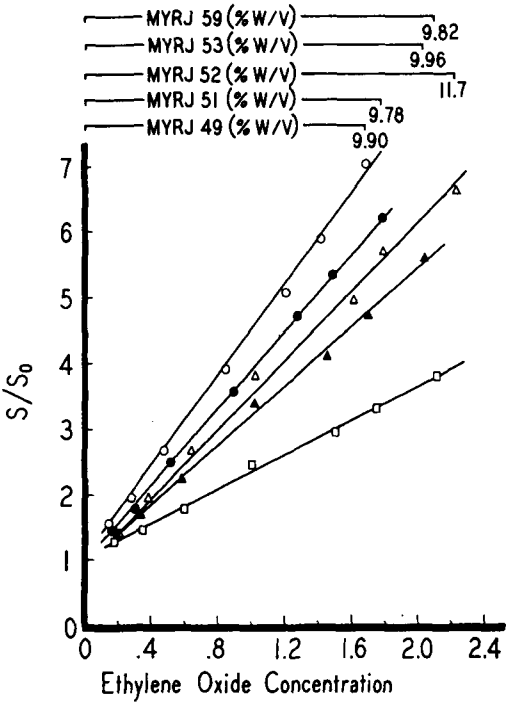

Fig. 6.—Binding of methylparaben in various Myrj solutions at 25° illustrating the ratio of bound to free paraben as a function of Myrj concentration. O, Myrj 49; ●, Myrj 51; △, Myrj 52; ▲, Myrj 53; □, Myrj 59.

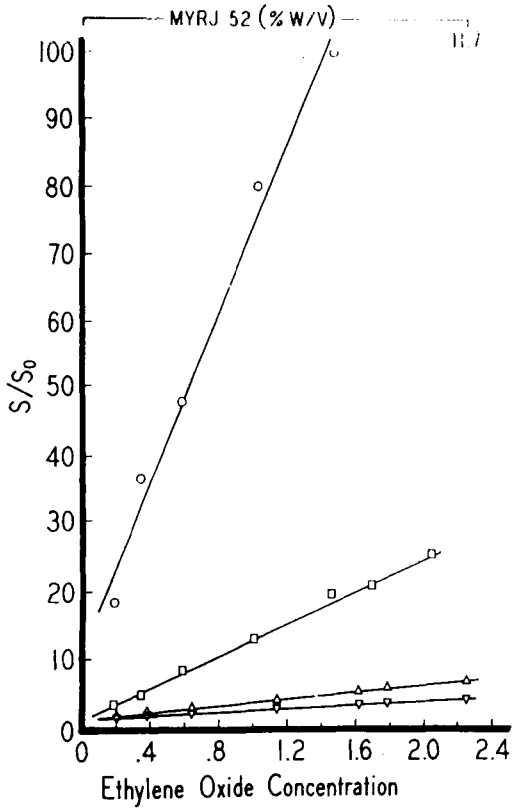

Fig. 7.—Binding of *p*-hydroxybenzoic acid and three of its alkyl esters in Myrj 52 solution at 25° illustrating the ratio of bound to free solubilizate as a function of Myrj 52 concentration. O, Butylparaben; □, propylparaben; △, methylparaben; ▽, *p*-hydroxybenzoic acid.

bacterial action by esters of *p*-hydroxybenzoic acid in the presence of nonionic surfactants has been well recognized by the pharmaceutical chemist (16). From graphs such as Fig. 6, the percentage of bound to free preservative can be calculated, thus giving the effective concentration of preservative employed (18, 25).

Figure 7 compares the binding of *p*-hydroxybenzoic acid and its butyl, propyl, and methyl esters in Myrj 52 solutions. It can be observed in Fig. 7 that an increase in the ester alkyl chain length enhances binding to Myrj 52. The binding is particularly pronounced for butylparaben which is 99% bound in a 7% Myrj 52 solution. Butylparaben, however, forms a milky white turbid solution in high concentrations of Myrj 52. This phenomenon is not at all uncommon to solubilization by nonionic surfactants, but was not observed in any other system employed in this study.

SUMMARY

1. The relationship between the hydrophilicity of five polyoxyethylene stearates on the solubilization of a group of solid benzoic acid derivatives has been studied.

2. In general, the solubilities of the compounds studied were greatest in the least hydrophilic surfactant.

3. The linear solubility isotherms and the value of critical micelle concentration are characteristic of solubilization of semipolar compounds by nonionic surface-active agents.

Effect of Certain Drugs on Perfused Human Placenta I

Narcotic Analgesics, Serotonin, and Relaxin

By RONALD F. GAUTIERI and HENRY P. CIUCHTA†

Perfusion studies conducted on full term human placentas yielded results indicating that morphine sulfate exhibited a direct vasoconstrictor action on placental vessels. This effect was also observed with meperidine hydrochloride and codeine sulfate, although the action of the latter agent was comparatively weak. Nalorphine hydrochloride antagonized the constrictor effect of morphine sulfate and codeine sulfate, but not that produced by meperidine hydrochloride. In addition, serotonin and relaxin both elicited powerful transient vasoconstriction.

IT IS GENERALLY concluded that the primary circulatory action of morphine is vasodilation, which is due to relaxation of blood vessels (1). Hypotension in cats and dogs (2), and cutaneous vasodilation of the flush area in man and animals (3) caused by morphine, support this concept. The mode of action for this effect is probably mediated centrally and peripherally and not directly upon the blood vessels involved, for vascular relaxation is not in accord with the principal action of morphine on smooth muscle elsewhere in the body which usually is stimulated to contract.

Many investigators, including von Euler (4), and Eliasson and Aström (5), have reported the effects of a number of drugs on perfused placental vessels, but there is no available information in the literature concerning the action of morphine on these vessels. Since morphine has been shown to have paradoxical actions on different smooth muscle, it becomes imperative to discern the effect that it may have on placental vasculature.

Narcotic analgesics, such as morphine (6), meperidine (7), and methadon (8), are well known to cross the placental barrier without much difficulty. Since this occurs with therapeutic dosage, the risk of neonatal respiratory depression is very high. With the advent of N-allylnormorphine (9), fortunately, respiratory depression, if present in the newborn, can be alleviated readily (6). Although the respiratory depression is undoubtedly due to the effect of the narcotic on the fetal respiratory center, the possibility arises that part of the depression may be due to decreased oxygenation of fetal blood brought about by a decreased blood flow through placental vessels which have been constricted by a direct acting drug.

The human placenta has been shown to be devoid of nervous tissue by Schmitt (10) and Spivack (11). Thus, it may be used as a nerve-free preparation in which direct effects of drugs acting on the smooth muscle of the linings of its blood vessels may be clearly elucidated. Therefore, it is the main purpose of this investigation to observe the effects brought about on the placental vasculature by not only morphine but also other narcotic agents, and in the event that there are direct effects, attempt to antagonize them.

MATERIALS AND METHODS

Full term placentas were obtained from the hospital within 5–15 minutes after normal delivery. Each was transported to the laboratory in a container of preheated (38°) Tyrode's solution which was modified by the addition of 0.525% polyvinylpyrrolidone (Plasdone C).

The preparation subsequently was flushed free of blood by injecting 10% sodium citrate solution into one of the arteries. Cannulae were inserted into the vein and one artery of the umbilical cord 5–10 cm. from the placenta. The remaining umbilical artery was ligated. The whole preparation was then placed into a perfusion chamber containing the modified Tyrode's solution which was maintained at a constant 37° by means of a Bronwill thermoregulator. The arterial cannula was connected with rubber tubing to a hydrostatic reservoir which was adjusted to yield pressures ranging between 50–60 mm. Hg. The solution in the reservoir, which had a pH range of 7.2–7.4, was maintained at 37° and aerated. The venous outflow, ranging between 10–60 ml./min., was measured directly and not reperfused.

A total of six placentas were discarded for quantitative reasons, i.e., the outflow per minute was either negligible or so far below the average preparation that it was considered impractical to measure.

Received April 28, 1961, from Temple University, School of Pharmacy, Philadelphia 40, Pa.
Accepted for publication May 19, 1961.
Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.
† Teaching Fellow, Smith Kline and French Foundation.
The authors wish to express sincere thanks to the members of the obstetrical staff of Temple University Hospital for the generous supply of placentas; to Drs. D. E. Mann, Jr., and E. J. Larson for their valuable suggestions and discussions, and to Messrs. J. C. Tatnall and P. DeLuca for their technical assistance.

In 30 successful perfusion experiments the average duration of each preparation was between 2 and 3 hours.

The following drugs were injected into the rubber tubing adjacent to the arterial cannula in a volume of distilled water not exceeding 1 ml.: morphine sulfate, meperidine hydrochloride, codeine sulfate, nalorphine hydrochloride, 5-hydroxytryptamine creatinine sulfate (serotonin), relaxin, and alcoholic amyl nitrite.

RESULTS

Morphine.—Morphine sulfate in doses of 0.2–0.4 mg. (in eight preparations) had a pronounced constrictor action on the placental vessels. This effect (Fig. 1) was sustained and characterized by a slowly progressive decrease in the volume flow rate. The reduction in the flow rate ranged between 35–92% (Table I). Upon subsequent administration of 5 mg. of nalorphine, the morphine-induced vasoconstriction was antagonized, with the flow rate returning to near normal (Fig. 2, Table II).

TABLE I.—COMPOSITE RESULTS

Drug	No. of Experiments	% Reduction in Flow Rate (Range)
Morphine	8	35–92
Meperidine	3	39–42
Codeine	3	6–11
Serotonin	5	19–61
Relaxin	3	59–84

TABLE II.—NALORPHINE ANTAGONISM OF NARCOTIC-INDUCED VASOCONSTRICTION

Drug	No. of Experiments	Av. % Return to Preinjection Flow Rate
Morphine-nalorphine	3	90
Codeine-nalorphine	3	91
Meperidine-nalorphine	2	0

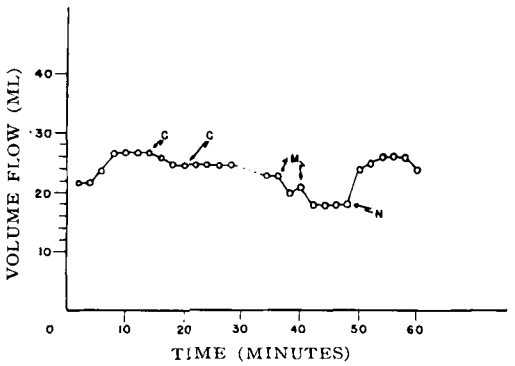

Fig. 2.—Effect of codeine sulfate and morphine sulfate on volume flow rate in vessels of the perfused human placenta and nalorphine antagonism. C, Codeine, 1.0 mg.; M, Morphine, 0.2 mg.; N, Nalorphine, 5.0 mg.

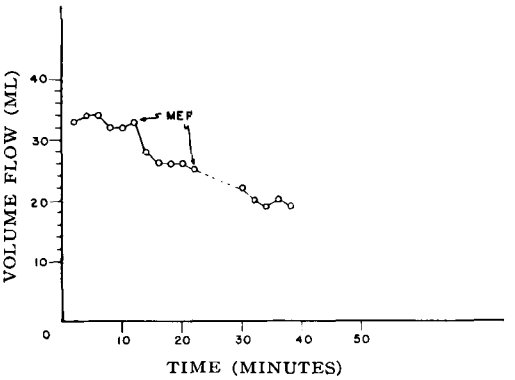

Fig. 3.—Effect of meperidine hydrochloride on volume flow rate in vessels of the perfused human placenta. MEP, Meperidine, 1.0 mg.

Meperidine.—In three experiments, meperidine hydrochloride in doses of 1–2 mg. produced a reduction in flow rate, as noted in Fig. 3, qualitatively similar to that which was observed with morphine. The per cent reduction in flow rate, which ranged between 39–42% (Table I), though not as great as that obtained with morphine, was also sustained.

Although meperidine produced a response akin to that of morphine, nalorphine was unable to antagonize it (Table II). However, the administration of 1 ml. of alcoholic amyl nitrite (1.8% v/v amyl nitrite) following nalorphine was successful in bringing about a marked increase in the flow rate.

Codeine.—Codeine sulfate in doses of 1–2 mg. (Fig. 2) produced a slight vasoconstriction in three preparations, resulting in a decrease in the flow rate of 6–11% (Table I). The administration of nalorphine antagonized this effect (Table II).

Nalorphine.—Nalorphine hydrochloride, 5–10 mg., used alone in a fresh preparation, was unable to exert any discernible effect on placental circulation. When it was administered prior to an injection of 0.2–0.4 mg. of morphine it was observed to block completely any vasoconstrictor action that this agent normally had on the placental vessels.

Serotonin.—In five experiments employing serotonin creatinine sulfate, a powerful vasoconstrictor of

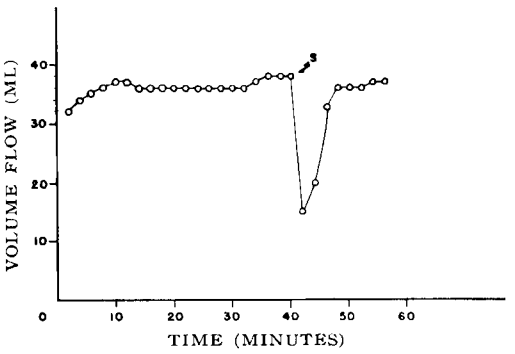

Fig. 4.—Effect of serotonin on volume flow rate in vessels of the perfused human placenta. S, Serotonin, 0.05 mg.

placental vessels, the results compared favorably to those of Astrom and Samelius (12) but the degree of constriction was not as marked. The dose of serotonin used was 50 mcg. in 0.5 ml. distilled water.

As seen in Fig. 4, after obtaining a consistent flow rate, the injection of serotonin caused an immediate decrease in this rate with almost a complete recovery to the preinjection level in approximately 6–8 minutes. The per cent reduction in the flow rate, as noted in Table I, ranged between 19–61 %.

Relaxin.—A dose of 1 ml. of relaxin[1] produced an immediate vasoconstriction in three preparations. The reduction in the flow rate produced by relaxin varied between 59–84% (Table I) during the succeeding 2 minutes. Most of this effect, although very pronounced, wore off in about 10 minutes.

DISCUSSION

The results of these experiments indicate that morphine exerts a direct constricting effect on the smooth muscle found in the linings of placental vessels. These findings are in contrast to the effects of morphine on other vascular beds where usually vasodilation is observed (2, 3). However, the constriction which occurred was analogous to that which morphine produces on gastrointestinal smooth muscle in that it was progressive and sustained.

Dornhorst, *et al.* (13), have shown that epinephrine and norepinephrine, in effective dosage, cause fetal asphyxia and cyanosis of the placenta in the rabbit and guinea pig. Because these conditions occur in response to drugs which act directly on placental vessels to constrict them, it may be concluded that any other agent which acts directly on these vessels causing vasoconstriction may also cause fetal asphyxia and placental cyanosis. Therefore, it is obvious that since morphine has been shown in this investigation to be capable of producing direct vasoconstriction in placental vessels, it may contribute partly to the fetal asphyxia sometimes caused by morphine. Of course the results reported here with morphine were those occurring *in vitro*, but it seems rather likely that similar effects would also be manifested *in vivo*.

Nalorphine was observed (Table II) to antagonize readily morphine-induced vasoconstriction in placental vessels, and it is probable that this would also occur *in vivo*. Consequently, its use *in vivo* would not only prevent central respiratory depression in the newborn but also any decreased oxygenation of fetal blood which may occur in response to the direct constricting action of morphine on these vessels.

The vasoconstrictor effect brought about by codeine in three preparations was very mild and susceptible to antagonism by nalorphine (Table II). Therefore, it would appear that fetal asphyxia due to codeine would be less marked than that produced by morphine and would be mainly due to just central respiratory depression.

Meperidine appeared to exert an effect on placental vessels that was similar to that produced by morphine. However, in the dosage employed, nalorphine was not able to antagonize the vasoconstriction caused by meperidine (Table II). Possibly if larger doses of meperidine were used, nalorphine may have exerted some antagonistic action, for it is well known that in order for nalorphine to cause withdrawal symptoms in the addict, at least 2,000 mg. must be ingested per day (14). Therefore, on this basis it seems likely that some antagonism of the constricting action of meperidine might have occurred if very large doses had been employed.

Serotonin was used in all preparations that were utilized as controls in this experiment. Five such preparations were set up and allowed to run for varying time intervals to discern any changes in the normal flow rate/min. through the placental vessels. In each case there was a period of 5–15 minutes where the flow rate increased slowly and then leveled off to a point where it would not change by more than 6% in one hour. In order to obtain effects similar to Astrom and Samelius (12), 50 mcg. of serotonin had to be administered. In each case a very profound vasoconstriction was observed which was greatest during the first 2 minutes immediately following the injection. This effect was transient, for within 4–5 minutes, the preinjection flow rate/min. was approximated. Succeeding doses of serotonin brought about a similar reduction in the flow rate as long as a sufficient time interval was allowed between injections. In a few instances, where serotonin administrations were made before the original flow rate was obtained, there occurred a diminished response to the usual vasoconstrictor effect which may be considered to be a tachyphylactic phenomenon.

Three placentas were treated with relaxin in order to observe whether this hormone of late pregnancy would cause any direct effect on placental vessels. In all cases a very pronounced constrictor action was observed. This action was transient, but the original volume flow rate/min. was never attained. This leads one to hypothesize that the constrictor effect of relaxin may be due to a contaminant in the tissue extract or even the relaxin itself. Should relaxin cause a constrictor effect *in vivo*, it may play an important role in fetal asphyxia.

The vasodilation which occurred with alcoholic amyl nitrite was probably due to the ethyl alcohol and amyl nitrite which are both known to exert a direct relaxing effect on smooth muscle. Nitrates (5) have been reported to cause a similar result on placental vessels, so these findings were anticipated.

Comparison of the Gastrointestinal Absorption of Aluminum Acetylsalicylate and Acetylsalicylic Acid in Man

By GERHARD LEVY and BERNICE A. SAHLI

The gastrointestinal absorption rate and biological availability of aluminum acetylsalicylate have been studied in human subjects by the urinary excretion method. Acetylsalicylic acid absorption from orally administered aluminum acetylsalicylate was found to be less rapid than from aspirin, probably due to the very slow dissolution of the aluminum salt in gastrointestinal fluids. In the form used in this study, aluminum acetylsalicylate was incompletely absorbed after oral administration. Dosage forms containing this drug must be carefully evaluated with respect to absorption rate and biological availability.

THE ALUMINUM salt of acetylsalicylic acid has been admitted recently to the National Formulary (1) and is used currently in a number of proprietary pharmaceuticals. According to the background information which accompanied the proposed monograph on aluminum acetylsalicylate (Al.ASA) at the time it was considered for admission to the National Formulary (2), the drug has several significant advantages over acetylsalicylic acid (ASA). These are greater palatability, stability, and absence of astringent taste or acetic odor which is often found with ASA. As a result of its relative inertness, Al. ASA is said to be compatible with many more drugs than is ASA.

Neither the official monograph, nor the introductory statement which accompanied it at the time of submission, made reference to any possible difference in the rate or extent of gastrointestinal absorption of Al.ASA as compared with ASA. Al.ASA is a constituent of certain proprietary pharmaceuticals which are intended, among others, for the relief of acute pain and fever. Since Al.ASA is practically insoluble in water (1, 3), the possibility suggests itself that the absorption rate of the drug from the gastrointestinal tract of man may be considerably less than the absorption rate of ASA. If this is the case, there is the further possibility that Al.ASA is absorbed only partially, and that a portion of the undissolved drug is excreted in the feces. Accordingly, the gastrointestinal absorption rate and biological availability of Al.ASA have been investigated and compared with those of ASA. The present communication reports the results of this investigation and also presents certain physical-chemical data pertinent to the interpretation of the biological observations.

Received April 24, 1961, from the Biopharmaceutics Laboratory of the University of Buffalo, School of Pharmacy, Buffalo 14, N. Y.
Accepted for publication May 19, 1961.
Presented to the Scientific Section, A. PH. A., Chicago meeting, April 1961.
The authors wish to acknowledge gratefully the cooperation of the volunteers who served as test subjects for this investigation.

EXPERIMENTAL

Materials.—Acetylsalicylic acid U.S.P., aluminum acetylsalicylate N.F. With each drug, only the fraction passing through a 100-mesh sieve was used in the investigation. Both compounds were assayed colorimetrically (4) after alkaline hydrolysis and were found to contain 100 ± 0.5% of the theoretical amount of salicylate.

Absorption Tests.—Healthy male adults served as test subjects. Their weights and ages are listed in Tables I and II. In the initial absorption test utilizing nine subjects, the drugs were administered

In the form used in this study, aluminum acetylsalicylate was incompletely absorbed after oral administration. Dosage forms containing this drug must be carefully evaluated with respect to absorption rate and biological availability.

THE ALUMINUM salt of acetylsalicylic acid has been admitted recently to the National Formulary (1) and is used currently in a number of proprietary pharmaceuticals. According to the background information which accompanied the proposed monograph on aluminum acetylsalicylate (Al.ASA) at the time it was considered for admission to the National Formulary (2), the drug has several significant advantages over acetylsalicylic acid (ASA). These are greater palatability, stability, and absence of astringent taste or acetic odor which is often found with ASA. As a result of its relative inertness, Al. ASA is said to be compatible with many more drugs than is ASA.

Neither the official monograph, nor the introductory statement which accompanied it at the time of submission, made reference to any possible difference in the rate or extent of gastrointestinal absorption of Al.ASA as compared with ASA. Al.ASA is a constituent of certain proprietary pharmaceuticals which are intended, among others, for the relief of acute pain and fever. Since Al.ASA is practically insoluble in water (1, 3), the possibility suggests itself that the absorption rate of the drug from the gastrointestinal tract of man may be considerably less than the absorption rate of ASA. If this is the case, there is the further possibility that Al.ASA is absorbed only partially, and that a portion of the undissolved drug is excreted in the feces. Accordingly, the gastrointestinal absorption rate and biological availability of Al.ASA have been investigated and compared with those of ASA. The present communication reports the results of this investigation and also presents certain physical-chemical data pertinent to the interpretation of the biological observations.

Received April 24, 1961, from the Biopharmaceutics Laboratory of the University of Buffalo, School of Pharmacy, Buffalo 14, N. Y.
Accepted for publication May 19, 1961.
Presented to the Scientific Section, A. PH. A., Chicago meeting, April 1961.
The authors wish to acknowledge gratefully the cooperation of the volunteers who served as test subjects for this investigation.

EXPERIMENTAL

Materials.—Acetylsalicylic acid U.S.P., aluminum acetylsalicylate N.F. With each drug, only the fraction passing through a 100-mesh sieve was used in the investigation. Both compounds were assayed colorimetrically (4) after alkaline hydrolysis and were found to contain 100 ± 0.5% of the theoretical amount of salicylate.

Absorption Tests.—Healthy male adults served as test subjects. Their weights and ages are listed in Tables I and II. In the initial absorption test utilizing nine subjects, the drugs were administered

[a] Expressed as mg. of salicylic acid. [b] 1.00 Gm. of aspirin, or 1.12 Gm. of aluminum acetylsalicylate.

in crossover fashion 30 to 60 minutes after the noon meal with exactly 100 ml. of water. A small amount of urine was collected just prior to drug administration and served as a blank. Urine samples were then collected exactly 1 and 2 hours after drug administration. The crossover test was carried out after one week. The test subjects were instructed to eat essentially the same type and quantity of food, and at the same time, as in the previous week.

The second absorption test involved five subjects, and was initiated in the morning on empty stomachs. The test subjects were instructed to empty their bladder of overnight urine and to drink one glass of water. One hour later, the urine blank was collected and the drug was administered with 100 ml. of water. Exactly 1 hour later, the first urine sample was collected. From then on, urine samples were obtained at intervals of approximately 3 hours (except for the greater night-time interval) for about 36 hours. The time of urine collection and the volume were carefully noted.

In the case of "sustained" ASA administration, the drug was given in divided doses at 0, 3, 6, and 9 hours. The participants of the second study were cautioned not to eat until the first-hour urine sample had been collected. The interval between successive tests was 3 days or more. The drugs were administered in random order.

Analytical Method.—Salicylate in the urine was determined colorimetrically with ferric nitrate reagent (4, 5), using a Bausch and Lomb Spectronic 20 colorimeter. All readings were corrected for blank values. For first and second-hour urine samples, the zero hour blank values were used. For all other urine samples, average blank values were obtained from 24-hour urine collections of each subject.

For the determination of dissolution rates, the drug contained in aliquots of the dissolution medium was subjected to alkaline hydrolysis. The solution was then acidified, appropriately diluted with 0.1 *N* hydrochloric acid, and assayed spectrophotometrically with a Beckman model DU spectrophotometer in terms of salicylic acid.

Excretion Rates.—Individual cumulative plots of the amount of apparent salicylate excreted *vs.* time were constructed. Excretion rates were determined graphically at 1, 3, 6, 9, 12, and 15 hours over the 2-hour period having the cited time as the midpoint. The individual excretion rates were then averaged and used to construct the excretion rate *vs.* time plot.

In the case of Al.ASA, the 4-hour average excretion rate was also calculated in order to characterize the excretion rate *vs.* time curve more adequately.

Determination of Dissolution Rates.[1]—Flat-faced, one-half inch diameter tablets of the pure drugs were prepared by means of a specially modified Carver model B hydraulic press. The compression pressure was 10,000 lb. (approximately 50,000 lb. per square inch). These tablets were mounted on Plexiglas holders with the aid of paraffin wax in such a manner that only one surface of the tablet was exposed (Fig. 1). The holder with the tablet was attached to a metal shaft which, in turn, was connected to an electronically controlled precision stirring motor.[2]

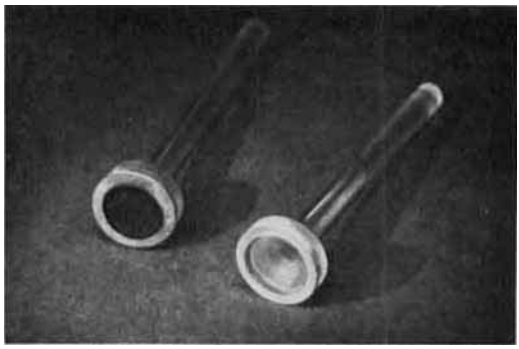

Fig. 1.—Plexiglas tablet holder for dissolution rate determinations. Empty holder (right) and holder on which a tablet has been mounted (left). The tablet shown in the picture was colored with charcoal to improve visualization.

A 200-ml. quantity of the dissolution medium was placed in a 500-ml. three-neck round-bottom flask which was immersed in a constant temperature bath adjusted to 37 ± 0.1°. After temperature equilibration was attained, the tablet attached to the Plexiglas holder was immersed in the dissolution medium to a depth of 1 inch. Under these conditions, the metal shaft did not come into contact with the solution. Just prior to immersion of the tablet, the stirrer was turned on at 555 r.p.m. The speed of rotation could be monitored by means of a continuous reading tachometer attached to a second shaft which reflected stirring speed at a fixed ratio.

Aliquots of 5 or 10 ml. were removed from the flask at appropriate intervals of time for analysis. A similar volume of dissolution medium was added each time to maintain constant volume. The tablet in its holder was weighed before and after the dissolution run as a check on the assay. The conditions of the dissolution experiment were such that the concentration of drug in the dissolution medium was a small fraction of its total solubility in order to maintain the quantity $(C_s - C)$ in the Noyes-Whitney dissolution rate expression almost constant (6, 7).

[1] The procedure is based in principle on a method developed and suggested to us by Dr. Eino Nelson, University of California, School of Pharmacy, San Francisco.

[a] Expressed as mg. of salicylic acid. [b] Equivalent to 1.00 Gm. of aspirin. [c] ASA = 1 Gm. given in one dose. "Sustained" ASA = 0.5 Gm. initial dose, then 0.167 Gm. every 3 hours for three doses. Al.ASA = 1.12 Gm. given in one dose.

RESULTS AND DISCUSSION

The results of the initial comparative study of Al.ASA and ASA absorption are shown in Table I. In this study, the drugs were administered after the noon meal rather than on empty stomachs so that the results may reflect absorption under conditions of normal use. The doses given were 1.00 Gm. of ASA powder and the equivalent (1.12 Gm.) of Al.ASA, respectively. The apparent salicylate excretion 1 hour after ASA administration was about three times greater than that from the aluminum salt. After 2 hours, the difference in mean amounts of salicylate excreted cumulatively was still two and one-half fold. In both instances, the differences were statistically significant ($P < 0.005$). These observations indicate that Al.ASA is absorbed much more slowly than the acid form of the drug, and that it cannot be expected to be as efficacious as ASA in the treatment of acute conditions where a reasonably rapid onset of drug action is desirable.

There is always the possibility of incomplete biological availability when a drug is absorbed from the gastrointestinal tract at an unusually slow rate since part of the drug may not be absorbed during the time in which it is in contact with the absorption sites and hence be excreted in the feces. On the other hand, poorly soluble compounds frequently afford a type of sustained action which may be desirable under certain circumstances. Accordingly, the second experiment was designed to determine salicylate excretion rate as a function of time, as well as the total amount of salicylate excreted. The rationale for using urinary excretion rates to reflect absorption rates and drug plasma levels is indicated by the following relationship (8)

$$dA/dt = K \cdot f \cdot V \cdot C \qquad \text{(Eq. 1)}$$

where A is the amount of drug excreted, K is a constant, f is the fraction of absorbed drug which is excreted eventually in the urine, V is the apparent volume of distribution, and C the drug concentration in the plasma at time t. In the case of the drugs used in this study, the values for K, f, and V are identical. Therefore, differences in excretion rate are a direct indication of differences in C, the concentration of drug in the plasma.[3] The described relationship is limited to cases where the urinary excretion rate is proportional to plasma concentration.

[3] Good comparative correlation between plasma salicylate levels and urinary excretion rates of salicylate has recently been demonstrated by Levy and co-workers (9).

In theory at least, there is the possibility that a comparative study of the urinary excretion of salicylate in the manner described may give results that are misleading. Equation 1 assumes that the ratio of the various metabolites of salicylic acid which are excreted in the urine is the same with both drugs. While this assumption appears reasonable as long as the drugs do not differ in their effect on urinary pH, it has been shown that when large doses of a drug are given, the endogenous mobilization rate of a conjugating compound may become the limiting factor in determining the rate of formation of a given metabolite (8). Thus there is a theoretical possibility that a greater fraction of the more rapidly absorbed ASA is excreted as the glucuronide of salicyclic acid than would be the case when the slowly absorbed Al.ASA is used. Since the analytical method serves to determine free salicylic acid and salicyluric acid, but not the glucuronide (10), and since the overall salicylate excretion rate is the sum of the excretion rates of each of the various metabolites and of the free drug, it is possible to obtain comparative data which do not reflect adequately the true relationship between the absorption rates or total excretion rates after administration of the two drugs.

The problem described above was overcome by the administration of ASA on a "sustained" dosage schedule. One-half gram of the drug was given at zero hour, and 0.167 Gm. was then administered every 3 hours for three doses. The dosage schedule was based on a 6-hour half-life of salicylate.[4] In this manner, any significant difference in the ratio of the excreted metabolites due to differences in absorption rate would become apparent by a comparison of the amount of salicylate (as free salicylate and salicyluric acid) excreted after single dose and "sustained" ASA administration, respectively.

The amounts excreted 1 hour after administration of ASA in single dose, of the same drug in divided doses, and of Al.ASA, as well as total amounts excreted, are listed in Table II. In this experiment, the drug was given on an empty stomach. As in the previous experiment, the first hour salicylate excretion as a result of ASA administration was about three times as high as that from Al.ASA. The difference was statistically significant ($p < 0.005$). The greater first hour absorption of both

[4] The maintenance doses, when determined by specific elimination rate constant × initial dose × hours between dosings, should actually be 0.173 Gm. A slightly lower dose (0.167 Gm.) was used as a matter of convenience in order to use an initial dose of 0.5 Gm. and provide a total of 1.00 Gm. in four doses.

drugs in the second experiment as compared with the first one is probably due to the fact that the drugs were given on empty stomachs and after the noon meal, respectively. With respect to total salicylate excretion, it is apparent that the effect of absorption rate on the ratio of the principal urinary metabolites of the drug (salicyluric acid and salicylic acid glucuronide) is negligible for the doses used in this study, since the average total apparent salicylate excretion after "single dose" and "sustained" ASA administration is essentially the same.

The total apparent salicylate excretion from Al.ASA is markedly less than that from ASA. Compared with the amount of drug excreted when ASA was given on the "sustained" dosage schedule, the biological availability of Al.ASA is only about 80% and this difference is statistically significant ($p < 0.02$). It must be concluded that Al.ASA in the form used in this study is incompletely absorbed. The degree of biological availability will of course vary depending on factors such as the particle size, the dosage form, and the experimental methods, inasmuch as the latter can affect gastrointestinal motility, pH, and gastric content. In the present study, Al.ASA was of a particle size smaller than 100 mesh, which is much more favorable than the larger particles or granules usually found in compressed tablets, as far as gastrointestinal absorption is concerned.

Figure 2 is a plot of urinary excretion rate of salicylate as a function of time. The biological half-life of salicylic acid as observed in the present study was about 6 hours. This is in excellent agreement with the 6.1-hour half-life reported by Brodie and Burns on the basis of plasma level studies (11), and is very similar to the 5 to 6-hour half-life determined by Chapman and co-workers (12), who used the urinary excretion method. The excretion rate curve obtained from "sustained" drug administration resulted in a period during which excretion rates were essentially constant. While the plateau is distinct, it is appropriate to point out that certain limitations inherent in the urinary excretion method can tend to idealize the data (13). The graphic determinations of excretion rates have been carried out with due consideration of these pitfalls and the linearity of the individual cumulative salicylate excretion curves is based, in each instance, on four experimental points. The excretion rate *vs.* time curve for Al.ASA is somewhat difficult to characterize after the 6th hour. As expected the area under the curve is smaller than that under the other two curves, reflecting the incomplete availability of the drug.

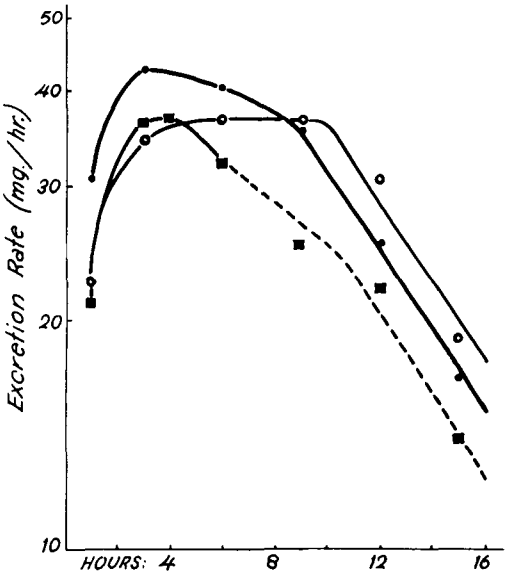

Fig. 2.—Average excretion rate of apparent salicylate as a function of time after administration of 1.00 Gm. aspirin or equivalent. ●, single dose of aspirin; ○, divided doses of aspirin; ■, single dose of aluminum acetylsalicylate.

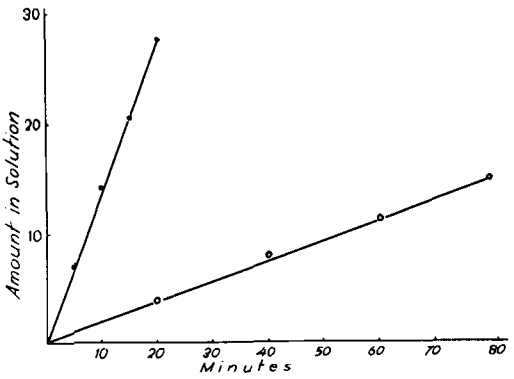

Fig. 3.—Dissolution of aspirin (●) and aluminum acetylsalicylate (○) in 0.1 *N* hydrochloric acid solution. The amount in solution is expressed as mg. salicylic acid.

Figure 3 shows the results of dissolution rate determinations using 0.1 *N* hydrochloric acid as the dissolution medium. Expressed in terms of salicylic acid, the dissolution rate of ASA is 65.1 mg./hr.-cm.^{2}, while that of Al.ASA is 8.88 mg./hr.-cm.^{2} under the conditions of the experiment. It is apparent that the dissolution rate of ASA is significantly greater than that of the aluminum salt. Similar differences were found when alkaline media were used. Since the absorption of salicylates is rate-limited by their dissolution rate in gastrointestinal fluids (5, 14), and since the dissolution rate of Al.ASA is considerably smaller than that of ASA, it is reasonable that the absorption and excretion rates of the former are also smaller than those of the latter. Dissolution of the Al.ASA used in this study in gastrointestinal fluids is evidently sufficiently slow to be incomplete, so that only part of the administered drug is eventually absorbed.

The ratio of the amounts of salicylate excreted 1 hour after administration of ASA and Al.ASA is not as unfavorable to Al.ASA as the *in vitro* dissolution data imply. This may be due to differences in the "functional" surface area of the two drugs. "Functional" surface area refers to the area actually in contact with gastrointestinal fluids and is related to particle size and shape, tendency of the particles to aggregate, and wettability of the drug solids, among others. Microscopic examination reveals that the average particle size of Al.ASA

Fig. 4.—Photomicrograph of aluminum acetylsalicylate (left) and aspirin (right) used in this study. (22 × magnification).

used in this investigation was considerably smaller than that of ASA (Fig. 4). Better quantitative correlation between dissolution and absorption rates could possibly be obtained by administering thin, highly compressed, nondisintegrating tablets of the pure drugs so that surface area would be the same in each case. The contact-irritation liability of salicylates (14,15) makes such an experiment unfeasible.

The results of this investigation indicate that Al.ASA is inherently absorbed less rapidly than ASA, and that this difference is probably due to the slow dissolution of Al.ASA as compared with ASA. Administration of Al.ASA in the form used in this study would not bring about a pharmacologic effect as rapidly as administration of ASA. The use of Al.ASA may be limited markedly by its absorption pattern and by the possibility of incomplete biological availability. While it must not be excluded that the use of certain additives could enhance sufficiently the dissolution rate of this drug to overcome the shortcomings outlined above, it is necessary to subject Al.ASA preparations to careful clinical evaluation to assure complete availability of the drug and to ascertain that it is absorbed at a rate consistent with the medicinal use of the particular product.

Paper Chromatographic Separation and Colorimetric Estimation of the Glycosides of *Digitalis ferruginea* Seeds

By AYHAN ULUBELEN

Digitoxin, gitoxin, digoxin, digilanide A, digilanide B, digilanide C, obtained from *Digitalis ferruginea*, were successfully separated by paper chromatographic techniques and estimated colorimetrically with alkaline 3,5-dinitrobenzoic acid.

A SURVEY of the literature to date would indicate that, the seeds of *Digitalis ferruginea* have not been investigated either qualitatively or quantitatively for their cardioactive glycoside content. Considerably less attention has been given to the phytochemical investigation of the seeds of the digitalis species than of their leaves. The phytochemical investigation of the seeds of digitalis species, therefore, has been initiated as part of a long range program. In these initial studies the air-dried seeds of *Digitalis ferruginea* that were collected from Uludag-Bursa, Turkey, on October 7, 1959, were used.

A number of authors have used different reagents for the colorimetric estimation of various cardiac glycosides. The most important methods are those based on the Baljet reaction (1–6), colors given by the xanthydrol reagent (7–10),

Received April 3, 1961, from the University of Minnesota, School of Pharmacy, Minneapolis 14.
Accepted for publication May 17, 1961.

Keller-Kiliani reaction (11, 12), color reaction with 2,4-dinitrophenylsulfone (13, 14), fluorimetric methods (15, 16), methods based on the Raymond reaction (17), and color reaction with 3,5-dinitrobenzoic acid (18, 19).

An attempt was made to adapt the Baljet reaction to the small amounts of all six glycosides which were found in an extract of the seeds of *Digitalis ferruginea*. Since the intensity of the colors was very weak and not equally uniform with all six glycosides, this method was not used. The Raymond reaction, although a little more promising, was not used for the same reasons.

Finally, the method based on the color reaction given by 3,5-dinitrobenzoic acid was applied to the small amounts of glycosides and good results were obtained.

This method was described as a modification of the Raymond process by Canbäck (20) and used by Kedde (21), Rowson (18), and Lemli (19), in the estimation of digitoxin or total glycoside content of *Digitalis purpurea*.

EXPERIMENTAL

Extraction.—Before extraction, the seeds were crushed with a ball mill using flint stones. A 50-Gm. quantity of the powder, which was an oily mass, was extracted with ether. The ether was removed and the oily content of the seeds was found to be 19.4%. The ether-extracted powder, when percolated with methanol, gave a reddish-brown extract that was concentrated in a vacuum. The solid residue thus obtained was extracted with chloroform-methanol mixture, 2:1 (by volume). This extract was shaken with a 2% aqueous solution of sodium hydroxide until the aqueous layer became colorless (3 × 10 ml. sodium hydroxide was used). The chloroformic solution then was made neutral by shaking with 1% acetic acid, dried with anhydrous sodium sulfate, and evaporated in a vacuum. The residue was dissolved in a chloroform-methanol mixture, 2:1, and diluted to exactly 5 ml.

Paper Chromatography

Whatman No. 1 paper, approximately 11.5 × 36 cm., was used in the descending technique.

System I.—Method of Gisvold (22), methyl isobutyl ketone - isopropyl ether - tetrahydrofuran-formamide, 40:10:15:15 (by volume). The stationary phase formamide was applied to the paper via a 30% solution in acetone, no equilibration being necessary. The atmosphere of the tank was kept saturated by the same solvent system which was placed in a glass dish on the bottom of the tank. Development time was 4 to 5 hours.

Results.—Six very small distinct spots corresponding to digilanide A, digilanide B, digilanide C, digoxin, gitoxin, and digitoxin, respectively, were obtained with a good separation (Fig. 1). The R_f values were: digilanide C, 0.073; digilanide B, 0.126; digilanide A, 0.210; digoxin, 0.300; gitoxin, 0.490; and digitoxin 0.710.

System II.—Method of Tulus and Ulubelen (23),

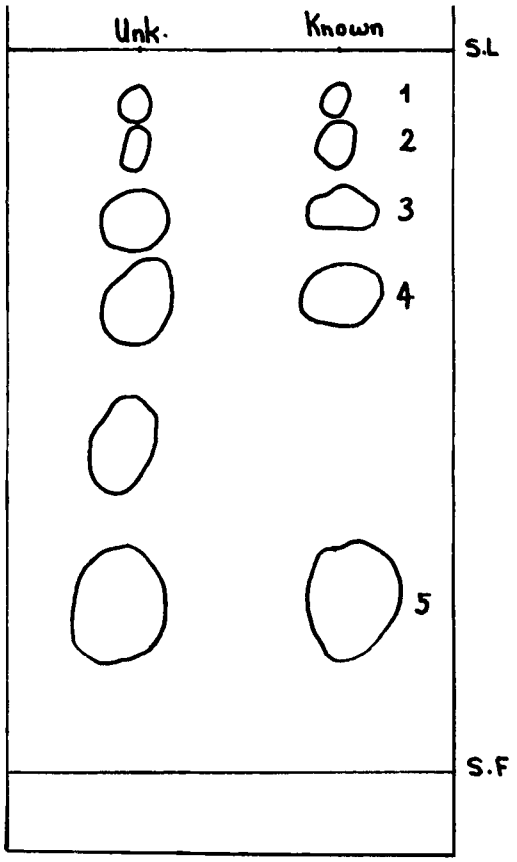

Fig. 1.—Solvent system 1. S.F, solvent front; S.L, starting line; 1, digilanide C; 2, digilanide B; 3, digilanide A; 4, digoxin; 5, digitoxin.

xylene-methyl ethyl ketone-methanol-formamide 10:10:4:0.4 (by volume). The paper was first impregnated with a 1% solution of lithium chloride and dried in the air, then the stationary phase formamide was applied to the paper by means of a 10% solution in acetone. The tank was saturated with the same solvent system; overnight equilibration was necessary. Development time was 1.5 hours.

In both systems the papers were dried 20 minutes at 110° and a sprayed Raymond's reagent was used to locate the glycosides.

Results.—The six glycosides separated very distinctly when solvent system II was used. The spots obtained by this system were somewhat larger than those obtained with solvent system I, and therefore the R_f values are different (Fig. 2). These values are as follows: digilanide C, 0.160; digilanide B, 0.210; digilanide A, 0.310; digoxin, 0.410; gitoxin, 0.610; and digitoxin, 0.780.

Preparation of the Standard Curves

A Coleman universal spectrophotometer was used in the colorimetric assays.

In order to determine the minimum time necessary for full color development and to test the stability of the color, a series of samples containing 50, 300, and 500 mcg. of digitoxin were added to 2 ml. of

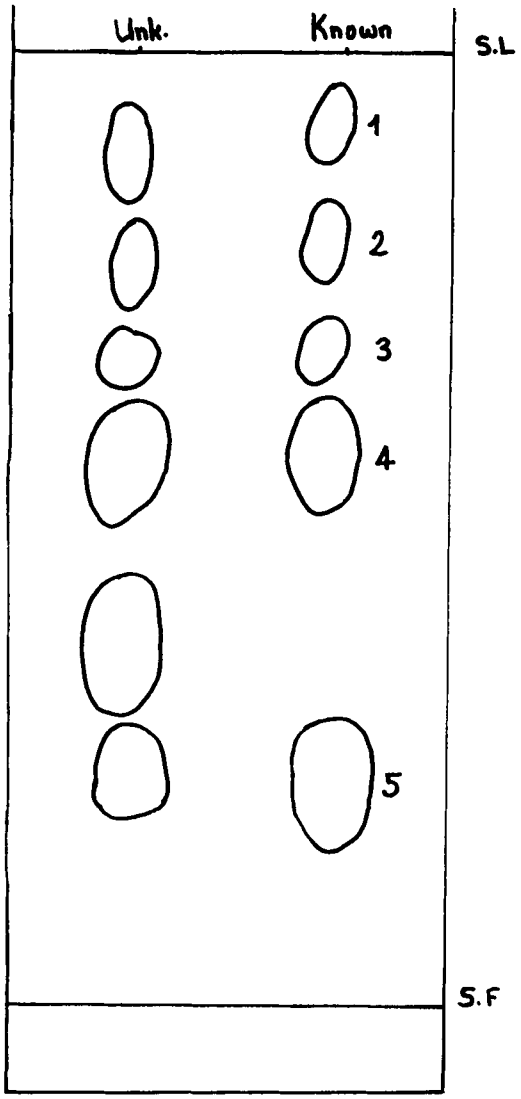

Fig. 2.—Solvent system II. S.F, solvent front; S.L, starting line; 1, digilanide C; 2, digilanide B; 3, digilanide A; 4, digoxin; 5, digitoxin.

2% 3,5-dinitrobenzoic acid (reagent I) and 1 ml. 1 *N* alcoholic solution of sodium hydroxide (reagent II), and diluted to 10 ml. with 50% alcohol. The intensities of the colors were measured at 1, 3, 5, 10, 15, 20, 30, and 40-minute intervals, and it was found that after 3 minutes the maximum color was reached. This color was stable for 30 minutes for all concentrations of digitoxin that were used. The value of color intensity for 50 mcg. was 0.08; for 300 mcg. was 0.300; and for 500 mcg. was 0.45.

The wavelength for maximum absorption was determined with 400 mcg. digitoxin and 535 mμ was found as the best wavelength (Fig. 3, Table I).

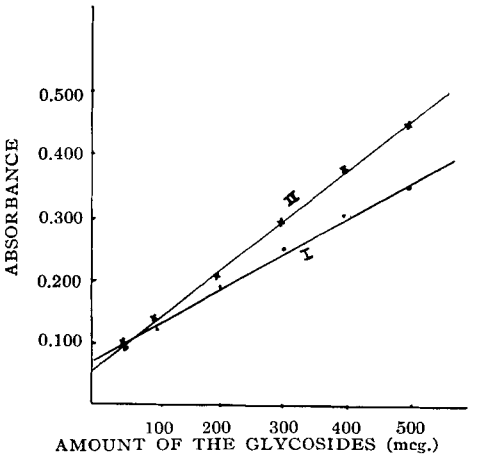

Fig. 4.—Relationship between the concentration of the glycosides and the intensity of the colors when the Kedde reaction was used. Curve I, digilanide A, digilanide B, digilanide C; curve II, digitoxin, digoxin.

TABLE II.—REPRODUCIBILITY OF THE INTENSITY OF COLOR

Sample	Absorbance 100 mcg.	Absorbance 500 mcg.
1	0.135	0.46
2	0.130	0.455
3	0.130	0.45
4	0.130	0.45

Reproducibility of the color was checked and the results are shown in Table II.

The amounts of the reagents I and II were varied, respectively, and it was found that 1.5 ml. of reagent I and 1 ml. of reagent II were sufficient for the development of maximum color when 500 mcg. of digitoxin was used in each case (Tables III and IV).

Standard curves were prepared by plotting various concentrations of digilanide A, digilanide B, digi-

lanide C, digitoxin, and digoxin *versus* the intensities of the colors over a range 50–500 mcg. The concentrations were found proportional to the absorptions within this range. Table V gives the results and Fig. 4 shows the curves.

Table V and Fig. 4 show that digilanide A, B, and C give the same curve (curve I) and digitoxin and digoxin give curve II. There is no reason why gitoxin should not also give the same curve.

Analysis of Glycosides of the Seeds

Known amounts of glycosides (150 mcg. each) were applied to the paper and after development according to the methods I and II, respectively, the areas on the paper containing glycosides were cut out and extracted by means of 10 × 2 ml. methanol. The solvent was evaporated and the color was developed as described previously. The amounts of the known glycosides were measured against a blank, which was prepared with the reagents. The amount that was applied to the paper was always recovered. Then exactly 60 μl. of the chloroformic solution of the crude drug, which was previously prepared, was applied to the paper. After development, the areas on the paper containing the glycosides were cut out and extracted by means of 10 × 2 ml. methanol and the colors were developed and measured as described above. Results are shown in Table VI.

Interactions of Xanthine Molecules with Bovine Serum Albumin

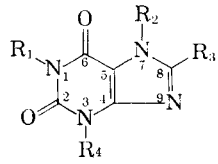
By M. L. EICHMAN†, D. E. GUTTMAN, Q. VAN WINKLE, and E. P. GUTH

The binding of a number of structurally related xanthine compounds by bovine serum albumin was investigated in an attempt to elucidate some of the structural specificities of the interaction. The study included caffeine, theophylline, 8-nitrotheophylline, 8-chlorotheophylline, theophylline-7-acetic acid, 8-methoxycaffeine, 8-ethoxycaffeine, 8-chlorocaffeine, 8-methylcaffeine, theobromine, 8-nitrotheobromine, uric acid, 1,3,7-trimethyluric acid, uracil, and 1,3-dimethyluracil. Under the conditions employed, interactions between the protein and uric acid, uracil, and dimethyluracil could not be detected. The remaining compounds were bound to varying degrees and evidence was obtained to indicate that a single site on the protein was responsible for the major portion of the binding. Anionic species were generally found to possess much stronger interactive tendencies than those which had no formal charge.

THE ABILITY of serum proteins, particularly albumin, to reversibly bind numerous small molecules has been recognized for many years (1). The majority of earlier investigations were of a qualitative nature. Only in recent years have attempts been made to quantitate the results and to explain the nature of the equilibria and forces involved in the interactions (2, 3). Concomitant with advances in the theoretical aspects of these interactions, there has been an increase in the study of the associations of drug molecules with proteins. Steroid hormones (4), barbiturates (5), sulfonamides (6, 7), penicillins (8), salicylates (9), and other therapeutic agents have been shown to interact with serum albumins.

Goldstein (1), and Brodie and Hogben (10) have discussed the significance of such behavior in the transport, deposition, and elimination of drugs in the body. In addition, it appears that the pharmacologic activity of many medicinal agents is intimately related to their abilities to combine with specialized functional proteins. Elucidation of the factors involved in such interactions may thus contribute to the understanding of drug action.

The interaction of xanthine compounds with components in blood serum had been noted in the early investigations of Pak (11) and Aiello (12). More recently, Schack and Waxler (13) demonstrated that theophylline can be bound by the plasma proteins of rabbits. In the present study, the bindings of caffeine and a number of structurally related compounds by bovine serum albumin (BSA) were quantitatively investigated in an attempt to determine the dependency of the interaction on structural and environmental variables. The compounds employed are listed in Table I. The results will show that the interaction of xanthine derivatives with BSA was dependent on the nature of substituents at the 1, 7, and 8 positions, the acid strength of the compound, and on the hydrogen-ion concentration of the system.



EXPERIMENTAL PROCEDURE

Materials.—Bovine serum albumin, fraction V (BSA), purchased from Armour Laboratories (lots T16812 and U17912), was used throughout this study. Electrophoretic analysis of lot T16812 indicated an albumin content of 97.5%. A molecular weight of 69,000 was assumed. Both lots of albumin were found to exhibit similar binding tendencies for caffeine. Reagent grade mono, di, and trisodium phosphate salts were employed to buffer the solutions and to obtain an equilibrium ionic strength of 0.16. The xanthine derivatives were either purchased or prepared by standard synthetic procedures. All xanthine and albumin solutions were prepared imediately prior to use.

Dialysis Studies.—Equilibrium dialysis experiments, essentially as described by Hughes and Klotz (14), were used to investigate the binding of xanthines by BSA. Ten-milliliter samples of albumin in phosphate buffer were accurately pipetted into bags prepared from Visking cellophane casing. The bags were placed into tubes, each containing a different concentration of the xanthine derivative. The range of concentrations employed was from 5×10^{-5} M to 2×10^{-2} M. A series of control tubes in which buffer solution was used in place of protein solution was similarly prepared. The bags prevented the passage of albumin into the external solutions, but were permeable with respect to the xanthine molecules. Binding of xanthines by the dialysis membrane was found to be insignificant. Equilibrium was established by gentle mechanical

8-Nitrotheobromine	H	CH_3	NO_2	CH_3	273	1.218
Uric acid	H	H	OH	H	291	1.136
Trimethyluric acid	CH_3	CH_3	OH	CH_3	295	1.636

shaking at 9 ± 1° for 30 hours. All xanthine compounds were studied at pH 6.85. In addition, the interactions of caffeine, theophylline, 8-nitrotheophylline, and 8-chlorotheophylline were also investigated over a wide pH range. At equilibrium, the external solutions were analyzed for the xanthine derivative and the exact pH determined from measurements on the albumin solution in each tube. Solutions of 0.4% albumin were employed in studies of the binding of 8-chlorotheophylline and 8-nitrotheophylline. Albumin solutions, 2%, were used in all other studies.

Analytical Methods.—The concentration of xanthine derivative in each solution was determined spectrophotometrically with a Beckman model DU spectrophotometer. For each compound, the wavelength of maximum absorption was employed. The experimentally determined molar absorptivities are listed in Table I. Appropriate dilutions were made where necessary so that all spectrophotometric readings were recorded below 0.8 absorbance units. Suitable blanks were employed to correct for spectral contributions of dialyzable components in the albumin and from soluble substances in the dialysis membrane. The albumin concentrations were determined spectrophotometrically at 278 mμ. The molar absorptivity of albumin was determined to be 4.603×10^4. This value was not corrected for nonalbumin impurities present in the protein. The pH values of the protein solutions were determined at 25° with a Beckman model G pH meter after each dialysis experiment.

THEORY AND RESULTS

A cursory examination of the data reveals marked differences in the tendencies of the compounds investigated to associate with BSA. This is illustrated in Table II, where the percentage of each xanthine bound by a 2% albumin solution is tabulated. The values are seen to range from 3% for the total amount of theobromine bound, to 98% for 8-nitrotheophylline and 8-chlorotheophylline. These figures were determined from dialyses of 10 ml. of 1×10^{-4} *M* solutions of each xanthine against 10 ml. of BSA solution.

TABLE II.—PERCENTAGE OF EACH XANTHINE DERIVATIVE BOUND BY 2% ALBUMIN SOLUTIONS

Compound	% Bound
Caffeine	17
Theophylline	20
Theobromine	3
8-Chlorocaffeine	58
8-Methoxycaffeine	67
8-Ethoxycaffeine	46
8-Methylcaffeine	40
8-Chlorotheophylline	98
8-Nitrotheophylline	98
Theophylline-7-acetic acid	44
8-Nitrotheobromine	3
Uric acid	6
1,3,7-Trimethyluric acid	83
Uracil	Negligible
1,3-Dimethyluracil	Negligible

In view of these results, it was considered desirable to characterize quantitatively each of the systems studied by one or more equilibrium constants and to determine the number of sites on the protein molecule participating in the interactions. In this way, a clearer understanding of the interactions may be achieved so that logical comparisons between compounds can be made. The mathematical analysis of binding data of the type presented here has been described and discussed by Klotz (2, 15) and Scatchard (16). If only one class of sites on the protein is responsible for the binding, the number of moles of small molecule bound per mole of protein can be related to the concentration of the free small molecule by

$$r = \frac{nk(\mathrm{A})}{1 + k(\mathrm{A})} \qquad \text{(Eq. 1)}$$

where r = moles of small molecule bound per mole of protein, n = number of binding sites available on each protein molecule, k = association constant for

the reaction, and (A) = concentration of unbound small molecule. The values of n and k can be graphically determined by plotting the data in accordance with a rearranged form of Eq. 1

$$r/(A) = nk - rk \qquad \text{(Eq. 2)}$$

A plot of $r/(A)$ *vs.* r will result in a straight line of slope $-k$ and ordinate and abscissa intercepts of nk and n, respectively.

When both the protein and the small molecule possess a formal charge, an electrostatic correction factor must be applied. In such cases, a modified formula, as suggested by Scatchard (16), can describe the system

$$[r/(A)]\ f = nk - rk \qquad \text{(Eq. 3)}$$

where $f = e^{2wZ_PZ_A}$, Z_P = the charge on the protein, Z_A = the charge on the small molecule, and w = an electrostatic parameter. Tanford, *et al.* (17), evaluated w to be equal to 0.026 at $\Gamma/2 = 0.16$. At pH 6.85, Z_P was taken as -7 and Z_A was -1 for the anionic xanthines and 0 for the neutral molecules. If the xanthine molecule is uncharged, f is unity, and Eq. 3 becomes identical to Eq. 2.

A general description of the system where two or more classes of binding sites on the macromolecule participate in the interaction is given by Eq. 4. In this case, each class of sites will possess a different affinity for the small molecule

$$r/(A) = \frac{n_1k_1}{1 + k_1(A)} + \frac{n_2k_2}{1 + k_2(A)} + \ldots + \frac{n_ik_i}{1 + k_i(A)} \qquad \text{(Eq. 4)}$$

Such behavior is indicated by curvature of the $r/(A)$ *vs.* r plot. It can be shown that the abscissa and ordinate intercepts in this case will be Σn and Σnk, respectively. In order to evaluate constants from nonlinear data of this type, a method described by Scatchard, *et al.* (18), and Karush (19) was employed, in which only two classes of sites on the protein were assumed to account for the binding. Our results indicated Σn to be equal to three. The data were therefore evaluated for several compounds with the assumption that the two classes of binding sites contain one and two groupings, respectively. The curves calculated on this basis agree well with those drawn through the experimental points. The values for k_1 and k_2 are listed in Table III. Where no values are given for k_2, secondary interactions have been found to be negligible and the bindings are therefore adequately represented by k_1. This was the case for caffeine and its 8-substituted derivatives. Their k values were obtained by linear extrapolation to the ordinate axis in the $r/(A)$ *vs.* r plots, as illustrated in Fig. 1. In contrast, secondary interactions were quite prominent in the case of 8-chlorotheophylline, theophylline-7-acetic acid, and trimethyluric acid. The values for both k_1 and k_2 were estimated for these compounds.

DISCUSSION

The ability of caffeine to form complexes with a large number of structurally different small molecules has been well documented (20, 21). On this basis, it was expected that several different groupings on the albumin macromolecule might serve as binding sites for caffeine. From the study illustrated in Fig. 2, it was apparent, however, that the principal interaction with BSA involved only one site on the protein. The low magnitude of k_2 indicated that secondary associations were of minor significance. Information pertaining to the nature of the primary site was adduced from the influence of pH on the interaction. This is illustrated in Fig. 3. The

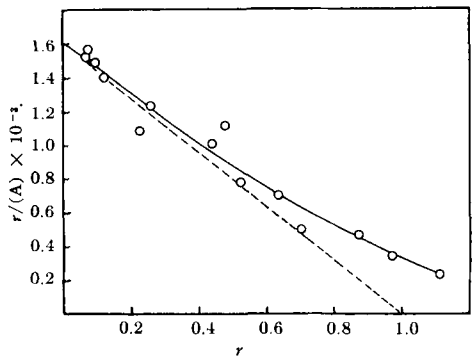

Fig. 2.—The interaction of caffeine with BSA at pH 4.80. – – –, primary interaction; ——, primary plus secondary interactions.

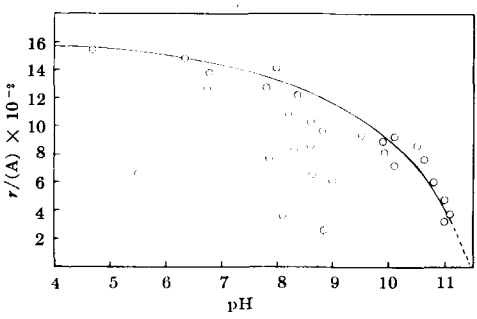

Fig. 3.—The effect of pH on the binding of caffeine.

gradual decrease in binding which occurred between the pH values of 4.8 and 8.5 may be the result of slight changes in the structure of the albumin. The marked decrease in association above pH 8.5 may be rationalized either by assuming that a specific interaction occurred between caffeine and a protonated site on the protein or by considering a binding site to be involved which was either blocked or abolished by a configurational change which resulted from the neutralization of a protonated group on the protein. Ionizable substituents on albumin include carboxyl, imidazole, amino, phenolic, guanidino, and sulfhydryl groups. Since the protonated • amino groups of lysine dissociate in the pH range where the major decrease in binding occurred, it is quite possible that neutralization of such a group is related to the marked decrease in the interaction.

The xanthine precursors, uracil and 1,3-dimethyluracil, as well as the dimethylxanthines, theophylline and theobromine, were investigated for binding activity in order to elucidate further the factors involved in the interaction. It was initially considered that the pyrimidinedione nucleus might be responsible for the binding. However, investigations with uracil and dimethyluracil revealed that neither compound was capable of interaction. The interactions of caffeine and theophylline as compared with that of theobromine emphasize the importance of N_1 substitution. The strengths of binding exhibited by the former compounds were considerably greater than that of the latter. It appears therefore, that not only are both rings required in order for significant binding to occur, but, in addition, substitution at the N_1 position is also a necessary prerequisite.

In contrast to caffeine, theophylline exhibited an increase in interaction as the pH was raised above 4.8, as shown in Fig. 4. From the association constants, k_1 and k_2, listed in Table III for several pH values, it is seen that this increase is the result of both greater primary and secondary interactions. The differences in the binding behaviors of caffeine and theophylline can be attributed to the ionization of theophylline (pKa 8.7). The fraction of theophylline in its anionic form becomes significant within the pH region where the rise in association occurred. It appears, therefore, that the negatively charged form of theophylline is more strongly bound than the uncharged molecule. At higher pH values the sharp decrease in the binding of theophylline parallels that observed with caffeine and is most probably related to the release of a proton from a specific acidic group on the protein.

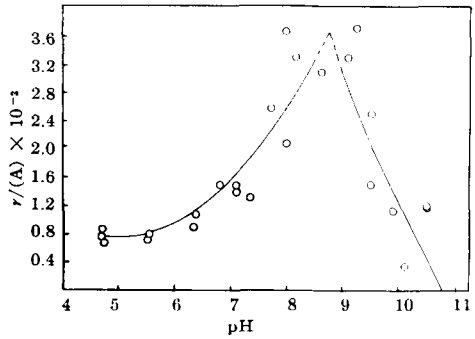

Fig. 4.—The effect of pH on the binding of theophylline.

The interactions of 8-substituted caffeines are graphically represented in Fig. 1. It is seen that in all cases association appears to involve one site on the protein. Marked differences in binding strength are, however, apparent. For example, the association constant for the 8-methoxycaffeine–BSA interaction is approximately ten times that found for the analogous caffeine system. Although it is difficult to interpret these results, the involvement of both steric and electronic factors are considered likely. Greater van der Waals attraction forces, resulting from the larger molecular size of the small molecule may account for the increased binding of the substituted derivatives. Another possible explanation lies in the ability of the small molecule to fit into a receptor site on the protein. Lumry and Eyring (22) have indicated that the molecule which would provide the best fit for the binding site would be expected to produce the strongest interaction. The 8-substituted caffeines, because of their larger sizes, may be more capable of filling the available space.

The interactive tendencies of 8-chloro and 8-nitrotheophylline at pH 6.85 were considerably greater than those of other compounds investigated. The binding curve for 8-chlorotheophylline is shown in Fig. 5 where a theophylline curve is also plotted for comparative purposes. A similar curve was obtained for the 8-nitrotheophylline–BSA system. The marked curvature is indicative of rather

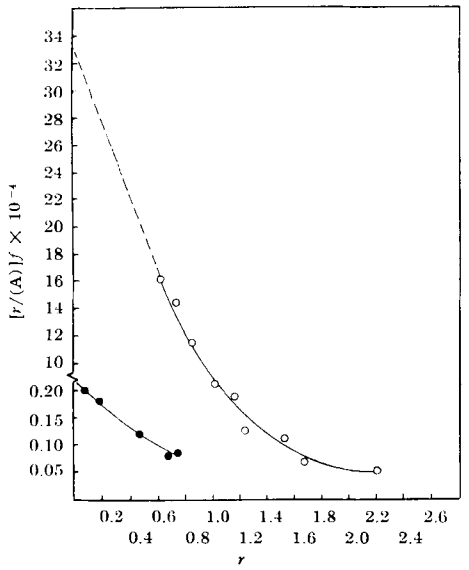

Fig. 5.—The bindings of 8-chlorotheophylline and theophylline by BSA at pH 6.85. O, 8-chlorotheophylline; ●, theophylline.

strong secondary interactions. It may be noted from Table III that the association constants for 8-chlorotheophylline and 8-nitrotheophylline at pH 6.85 are larger than those of other compounds investigated by magnitudes ranging from approximately ten to several hundred.

It is significant in this respect to compare the degrees of ionization at pH 6.85 of the various compounds investigated. It is found that 8-chlorotheophylline (pKa = 5.5) and 8-nitrotheophylline (pKa = 3.6) were completely ionized at this pH value. Furthermore, studies which are illustrated in Fig. 6 demonstrate a marked relationship between the degree of association with BSA and the ionization characteristics of the two compounds. 8-Nitrotheophylline, for example, was completely ionized throughout the pH range investigated and its interactive tendencies remained relatively constant between pH values of 4.8 and 8.5. In contrast, the fraction of 8-chlorotheophylline which existed in the

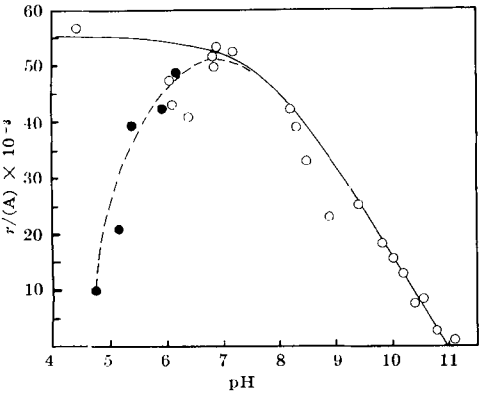

Fig. 6.—The effect of pH on the binding of 8-nitrotheophylline and 8-chlorotheophylline. O, 8-nitrotheophylline; ●, 8-chlorotheophylline.

ionized form increased in the pH range of 4.8 to 6.5 and was the predominant specie at pH values above this. Its association with BSA exhibited a similar pH dependency. Both compounds exhibited the diminution in binding at higher pH values which seems to be a characteristic of xanthine derivative-BSA interactions.

It can be concluded from the studies with theophylline and its 8-substituted derivatives that the anionic forms possess much greater binding tendencies than their nonionic counterparts. The basic nature of the association does, however, appear to be the same. The primary interactions of both types appear to involve one grouping on the protein and in both cases marked inhibition of binding occurred at pH values above approximately 8.5.

In view of these results, it was of interest to investigate the interactions of other anionic xanthine derivatives. Studies were therefore conducted with theophylline-7-acetic acid, trimethyluric acid, and uric acid. The binding of theophylline-7-acetic acid was observed to be greater than that of theophylline but significantly less than that of the 8-substituted theophyllines. This indicated that factors other than the mere presence of a negative charge determine the affinity with which the xanthine molecule is bound by the protein. This is substantiated by the results of studies with uric acid and trimethyluric acid. These compounds, too, are ionized at pH 6.85; their negative charge occurring at N_9. The interaction of uric acid was slight. On the other hand, trimethyluric acid was bound to a greater degree than the 8-substituted caffeine derivatives. Here too, however, its association constant was considerably smaller than those for the 8-substituted theophyllines.

On the basis of these results it can be stated that, although negatively charged species appeared to be more strongly bound to albumin than neutral molecules, the position of charge is of great significance. Theophylline and its 8-substituted derivatives ionize through removal of the proton from N_7. In view of the greater electronegativity of oxygen as compared to nitrogen, Cavalieri, *et al.* (23), have suggested that the negative charge probably resides on the oxygen on C_6. This shift in position of charge is facilitated by resonance in the molecule. It is consistent with the results to hypothesize that this oxygen participates directly in the binding reaction; perhaps through hydrogen bond formation with a protonated grouping on the protein. The strength of such a bond would be substantially increased if the oxygen were to possess a negative charge. In addition, it may be noted that a methyl substituent on the N_1 position will increase the electron density around the oxygen through an inductive effect.

Although the information which has been provided by this preliminary study is insufficient to characterize completely the interaction between BSA and xanthine derivatives, some interesting observations have been made. Of particular interest is the suggested involvement of only one grouping on the protein molecule. There is evidence to suggest that this grouping is an ϵ amino group of lysine. Since it has been reported that albumin contains 22 lysine residues, it can be speculated that the configuration of the macromolecule is such that only one of the lysine side chains is in an environment which will permit significant interaction with this family of

small molecules. Further studies are being undertaken to substantiate this hypothesis and to determine the nature of the forces which are responsible for the association.

The influence which slight structural modification of the small molecule has on the degree and strength of binding is also rather intriguing. The large differences which were found among the 8-substituted caffeines are particularly interesting. Variations in biological half-lives and in pharmacological activities might be partially explainable on this basis and studies are planned to test this possibility.

Effects of Tranquilizers on Bacterial Toxemias III

Chlorpromazine

By LEO GREENBERG and JAMES W. INGALLS

Previous papers from this laboratory have indicated the role of reserpine and meprobamate in overwhelming bacterial toxemias experimentally induced in laboratory animals. The present study was primarily concerned with chlorpromazine. In rats and mice, pretreatment with chlorpromazine was shown to prolong significantly the survival of animals inoculated with lethal doses of tetanus or botulinus toxins. Similar prolongations following chlorpromazine pretreatment were demonstrated with *E. coli, S. typhosa,* and *S. marcescens* endotoxins. At identical doses, neither hydroxyzine nor methaminodiazepoxide pretreatment consistently provoked similar responses to toxin challenges.

SINCE 1957, our laboratories have been primarily concerned with the role of tranquilizing drugs in experimental stress induced in laboratory animals through the use of cultures of virulent microorganisms and by various potent microbial products, both of exotoxic and endotoxic type. We have found that reserpine exerted a highly significant life-prolonging effect in tetanus and botulinus exotoxemias and pneumococcal septicemia of mice (1). Similar prolongation of survival time in exotoxemias was found with meprobamate treatment in rats of both sexes as well as mice, although no influence on pneumococcal septicemia was observed (2). Further, the life-prolonging properties of meprobamate were shown to extend to animals inoculated with lethal doses of purified lipopolysaccharide endotoxins of *Escherichia coli* and *Salmonella typhosa* (2). In all cases, the prolongation of survival time was associated with a specific set of experimental conditions, namely the administration of a relatively large dose of tranquilizer approximately 1 hour prior to challenge with an overwhelmingly lethal dose of the toxic agent.

The present study summarizes the results of our investigation of chlorpromazine within this framework of bacterial stress. In the case of chlorpromazine, unlike that previously found with reserpine and meprobamate, the literature is replete with references, both clinical and experimental, indicating an influence of the drug in disease processes. Unfortunately, the direction and magnitude of the influence reported has sometimes been contradictory. Thus, it has been noted that chlorpromazine shortened survival time from pneumococcal (3, 4) or *Salmonella*

Effects of Tranquilizers on Bacterial Toxemias III

Chlorpromazine

By LEO GREENBERG and JAMES W. INGALLS

Previous papers from this laboratory have indicated the role of reserpine and meprobamate in overwhelming bacterial toxemias experimentally induced in laboratory animals. The present study was primarily concerned with chlorpromazine. In rats and mice, pretreatment with chlorpromazine was shown to prolong significantly the survival of animals inoculated with lethal doses of tetanus or botulinus toxins. Similar prolongations following chlorpromazine pretreatment were demonstrated with *E. coli, S. typhosa,* and *S. marcescens* endotoxins. At identical doses, neither hydroxyzine nor methaminodiazepoxide pretreatment consistently provoked similar responses to toxin challenges.

SINCE 1957, our laboratories have been primarily concerned with the role of tranquilizing drugs in experimental stress induced in laboratory animals through the use of cultures of virulent microorganisms and by various potent microbial products, both of exotoxic and endotoxic type. We have found that reserpine exerted a highly significant life-prolonging effect in tetanus and botulinus exotoxemias and pneumococcal septicemia of mice (1). Similar prolongation of survival time in exotoxemias was found with meprobamate treatment in rats of both sexes as well as mice, although no influence on pneumococcal septicemia was observed (2). Further, the life-prolonging properties of meprobamate were shown to extend to animals inoculated with lethal doses of purified lipopolysaccharide endotoxins of *Escherichia coli* and *Salmonella typhosa* (2). In all cases, the prolongation of survival time was associated with a specific set of experimental conditions, namely the administration of a relatively large dose of tranquilizer approximately 1 hour prior to challenge with an overwhelmingly lethal dose of the toxic agent.

The present study summarizes the results of our investigation of chlorpromazine within this framework of bacterial stress. In the case of chlorpromazine, unlike that previously found with reserpine and meprobamate, the literature is replete with references, both clinical and experimental, indicating an influence of the drug in disease processes. Unfortunately, the direction and magnitude of the influence reported has sometimes been contradictory. Thus, it has been noted that chlorpromazine shortened survival time from pneumococcal (3, 4) or *Salmonella*

Presented to the Scientific Section, A. PH. A., Chicago meeting, April 1961.

enteritidis infection (2, 5), but did not influence *Salmonella typhimurium* infection (2). It shortened survival time from nasally inoculated streptococci but not from intraperitoneally inoculated streptococci (3). It either depressed (6,7) phagocytosis or enhanced (8) phagocytosis, depending upon the technique used. It had no apparent influence on *Plasmodium berghei, Trypanosoma Congolese,* or *Trypanosoma brucei* infections (3). In low doses, the drug shortened survival from *Trypanosoma cruzi* infections, but did not do so in moderate doses (9). In high doses, chlorpromazine treatment increased survival from *Trypanosoma evansi* infection (9).

In experimentally induced endotoxemias, chlorpromazine treatment is usually reported to exert a favorable influence on survival time (10–14) although no protection against *Aerobacter aerogenes* endotoxin was found (13). With *Salmonella typhosa* endotoxin, Noyes, *et al.* (13), have reported prolongation of survival time with chlorpromazine treatment in two experiments, and decreased survival time in one experiment. Little information exists concerning the role of the drug in exotoxemias. An increased mortality from *Clostridium perfringens* toxin but no influence on botulinus, tetanus, or *Pasteurella pestis* intoxication with chlorpromazine treatment has been noted (13).

Our investigation has been concerned primarily with the influence of chlorpromazine on exotoxemias and in stress induced by purified endotoxins. In almost all cases, hydroxyzine[1] and methamiondiazepoxide[2] were used as comparisons to chlorpromazine since, to the best of our knowledge, no previous study has investigated the possible role of these two potent tranquilizers in bacterial stress.

EXPERIMENTAL

Materials and Methods.—The animals used in this study were 200–300-Gm. male and female CFN rats and 20–25-Gm. CF_1 male mice (Carworth Farms), caged in small groups and kept in the thermostatically controlled animal house for several days prior to use. In all experiments, food was withheld after the toxic challenge but water was allowed *ad libitum.*

All drugs[3] were diluted with sterile, isotonic saline. In all experiments, matched groups of 10 animals were used. Tranquilizer injections were made intraperitoneally in a volume of 0.2 ml. 1 hour prior to the toxin challenge. Control animals received 0.2 ml. of sterile saline injection. The control and experimental animals in any given series were inoculated within a few minutes of one another.

Clostridium botulinum type A toxin[4] diluted with two parts of glycerol and having a mouse LD_{50} of approximately 5×10^6/ml. was used as a challenge, as was tetanus toxin[5] in 0.85% saline with 0.3 *M* glycine, an Lf. titer of 870/ml., and a mouse LD_{50} of 112 million. Toxins were stored in the refrigerator, the botulinus material at −20° to maintain potency.

Escherichia coli, Salmonella typhosa, and *Serratia marcescens* endotoxins were purchased as powdered lipopolysaccharides from Difco Laboratories. Powdered *Salmonella equi* endotoxin was graciously sent by Dr. Otto Westphal of the Dr. A. Wander Forschungsinstitut of Freiburg-Zahringen, Germany. All toxins were diluted with sterile saline and warmed to body temperature prior to intraperitoneal injection in a volume of 0.1 ml.

For the single diphtheria experiment, large male guinea pigs were purchased locally. Diphtheria toxin[5] partially purified from broth, with an LD_{50} of approximately 3×10^5/ml. was used as the challenge.

RESULTS AND DISCUSSION

The data comparing chlorpromazine with hydroxyzine and methaminodiazepoxide in various exotoxic and endotoxic conditions are summarized in Table I. From these data, a consistent pattern of response with chlorpromazine pretreatment is evident. In all cases, a moderate dose of the drug administered intraperitoneally 1 hour prior to challenge either by exotoxins or endotoxins resulted in a marked increase in survival time. This response is apparently unrelated to the general tranquilizing properties of chlorpromazine since neither of the other two tranquilizing drugs tested, hydroxyzine and methaminodiazepoxide, showed similar propensities.

Although the data are not included in Table I, preliminary studies showed that marked increases in survival time were not induced by relatively small doses of chlorpromazine (on the order of 2.5 mg./Kg.); and, as in our previous findings with reserpine (1) and meprobamate (2), no influence on survival was noted if the drug was administered after the toxin challenge.

It will be noted that of the three major exotoxins of bacterial origin, only tetanus and botulinus toxins were employed in this study. Mice and rats are notoriously refractory to diphtheria toxin, and the effects of various tranquilizers, including chlorpromazine, on survival from diphtheric intoxication in guinea pigs has been presented earlier (15). It may be of interest to mention that since this earlier study did not include data on methaminodiazepoxide, 11 guinea pigs were pretreated with 25 mg./Kg. of the drug prior to challenge with diphtheria toxin. Eleven untreated control animals showed a mean death time of 12.9 ± 0.5 hours while the treated animals died in 13.1 ± 0.5 hours, a difference of no statistical significance.

In speculating on the mode of action by which chlorpromazine manifests its antitoxic properties,

we noted with interest a suggestion by Boroff (16) that both chlorpromazine and reserpine release serotonin into the peripheral circulation and that both of these drugs should antagonize toxins since serotonin itself has been shown to exert a powerful antitoxic effect in laboratory animals (16, 17). If the underlying assumption concerning serotonin release is true, this is an attractive hypothesis, and our results with chlorpromazine would not be surprising. However, Berger, *et al.* (18), were not able to demonstrate any increase in serotonin metabolites after chlorpromazine administration, although the response was marked after reserpine administration.

Moreover, it has been reported recently (19) that a dose of reserpine known to release considerable serotonin into mouse circulation was ineffective in altering the lethality of an *Escherichia coli* endotoxin. We therefore undertook a large-scale experiment to clarify this point. Using 20 matched groups of animals, high and low doses of reserpine administered at different times prior to challenge with four different *E. coli* lipopolysaccharide preparations were evaluated. Death times were recorded hourly around the clock until the conclusion of the experiment. In no case did reserpine treatment have any significant effect, either for better or worse, on the lethality of the various endotoxins.

Until further information is available, we can only conclude that the relationships among chlorpromazine, reserpine, and serotonin in regard to their effects in endotoxemias are obscure, and we find no evidence for the suggestion that the antitoxic activity of chlorpromazine and reserpine can be explained by serotonin increase in the peripheral circulation of treated animals. In fact, after 4 years of intensive research with reserpine, meprobamate, and chlorpromazine in bacterial stress, we are unable to discern any evidence that the antitoxic properties of these three agents are manifested through a single mode of action.

SUMMARY AND CONCLUSIONS

1. Rats and mice were subjected to overwhelming bacterial stress, using purified exotoxins and various lipopolysaccharide endotoxins.

2. In all cases, a single, moderate dose of chlorpromazine administered 1 hour prior to toxin challenge resulted in a prolongation of survival time.

3. Neither hydroxyzine nor methaminodiazepoxide altered survival time significantly in toxin-challenged animals.

4. Doubt is cast on the probability that the antitoxic properties of chlorpromazine are simply a reflection of the release of serotonin into the circulation of treated animals.

Anticonvulsant Properties of Some N-Substituted Hydantoins

By HAROLD H. WOLF†, EWART A. SWINYARD, and LOUIS S. GOODMAN

The neurotoxic doses, anticonvulsant potencies, and protective indexes of three N-substituted hydantoins were compared with similar values concomitantly determined for phenantoin and diphenylhydantoin. The experimental agents induced overt evidence of neurotoxicity only after doses which were significantly higher than those required for phenantoin and diphenylhydantoin and exhibited anticonvulsant potencies which were generally less than those for the two clinical agents. Of the experimental compounds, 1-methyl-5,5-phenylethylhydantoin appeared most promising. Structure-activity studies indicated that mono-methyl substitution on a nitrogen of the hydantoin ring exerted a more favorable influence on anticonvulsant activity than either di-methyl or mono-ethyl substitution and that optimal activity was obtained when the methyl substitution is on the nitrogen in position 3 of the hydantoin ring.

THE AVAILABILITY of three N-substituted hydantoins offered the opportunity to explore further the structure-activity relation of some phenantoin congeners. Our interest in these compounds was also stimulated by a preliminary clinical report (1) which indicated that one of them is clinically effective in epilepsy. For this reason it seemed desirable to obtain precise experimental data on this agent in order to provide additional information on the correlation between the laboratory assay and clinical efficacy of anticonvulsant drugs.

METHODS

Male albino mice (Carworth Farms, CF No. 1 strain) were used as experimental animals. They were maintained on Rockland mouse diet and allowed free access to food and water except for the short time they were removed from their cages for testing. The following anticonvulsant agents were studied: 1-methyl-5,5-phenylethylhydantoin (No. 1),[1] 1,3-dimethyl-5,5-phenylethylhydantoin (No. 2),[1] 3-ethyl-5,5-phenylethylhydantoin (No. 3),[1] 3-methyl-5,5-phenylethylhydantoin (phenantoin),[2] and diphenylhydantoin.[3] All drugs were given orally as suspensions in 6% acacia solution, except for diphenylhydantoin which was given as the sodium salt in an aqueous solution. The concentration of the drug suspension or solution employed was such that the dose administered always represented 1 ml. per 100 Gm. body weight.

Anticonvulsant potencies (ED_{50}s) were determined by three tests (two electrical and one chemical). The tests based on electrically-induced convulsions measured the ability of a drug to prevent the hindleg tonic-extensor component of maximal electroshock seizures evoked by supramaximal current (MES test; 50 ma. alternating current, 0.2-second stimulus duration, corneal electrodes) and to elevate the threshold for low-frequency electroshock seizures (l.f. EST) induced in mice by unidirectional current delivered at an intensity twice threshold (0.2-millisecond duration, 3-second stimulus duration, six pulses per second). The test based on chemically-induced convulsions measured the ability of a drug to afford complete protection against seizures induced by the subcutaneous injection of pentylenetetrazol (Metrazol; 85 mg./Kg.; s.c. Met. test). A Grass stimulator (model S4B) was used for the l.f. EST test; otherwise the details of the various procedures, the end points employed in mice, and the characteristics of the electroshock apparatus have been described elsewhere (2–4). In addition, the mean neurotoxic dose (TD_{50}) was determined for each drug. The end point for minimal neurotoxicity was muscular incoordination, based on the inability of the animal to remain for 1 minute on a horizontal rod rotating at 6 r.p.m. Each drug was tested at the time of its peak activity as measured by the neurotoxicity test. For the determination of the ED_{50} or TD_{50}, groups of 8 to 12 mice were given various doses of drug until at least three points were established in the range between 0 and 100% seizure protection or minimal neurotoxicity. The results obtained were then plotted on logarithmic probability paper and a regression line was fitted to the plotted points by eye. From this plot of the data the respective ED_{50}, TD_{50}, 95% fiducial limits, and protective index (P.I. = TD_{50}/ED_{50}) were calculated by the method of Litchfield and Wilcoxon (5).

RESULTS

The time of peak effect, neurotoxicity, and anticonvulsant potency of the N-substituted compounds in mice, in comparison with phenantoin and diphenylhydantoin, are shown in Table I. The time of peak effect as measured by the test for minimal neurotoxicity varies from 1 hour for No. 3 to 3

hours for No. 1 and diphenylhydantoin. Phenantoin and No. 2 exhibit peak activity at $1^1/_2$ and $2^1/_2$ hours, respectively. The TD_{50}s range from 110 mg./Kg. for diphenylhydantoin to 442 mg./Kg. for No. 3. Phenantoin, No. 2, and No. 1 induce overt symptoms of neurotoxicity in 50% of the animals after doses of 200, 275, and 292 mg./Kg., respectively.

With regard to anticonvulsant potency, Table I shows that, except for No. 1 by the l.f. EST test and for diphenylhydantoin by the s.c. Met. test, the N-substituted hydantoins are considerably less potent than either phenantoin or diphenylhydantoin. This is clearly established by examining the potency ratios obtained by dividing the ED_{50} for phenantoin by the ED_{50} for No. 1. Thus, the potency ratio is 0.45 by the MES test and 0.53 by the s.c. Met. test. On the other hand, there is no significant difference between the potency of No. 1 and the two clinically established hydantoins by the l.f. EST test. Furthermore, No. 1 is effective by the s.c. Met. test in a dose of 75 mg./Kg., whereas diphenylhydantoin is ineffective by this test.

Table I also lists the protective indexes (P.I.) of the five compounds as derived from their TD_{50}s and ED_{50}s by the various tests. It may be seen from the table that No. 1 exhibits the highest P.I. of the experimental N-substituted compounds by all three tests and that these P.I.s are significantly higher than those for No. 3. However, the difference between the P.I.s for No. 1 and No. 2 is significant only in the case of the l.f. EST test. Except for No. 1 by the l.f. EST test, the P.I.s for the N-substituted compounds are all less than those for phenantoin. Thus, the P.I.s for No. 1 and phenantoin by the MES test are 2.86 and 4.35, respectively, and by the s.c. Met. test 3.89 and 5.00, respectively. Although the N-substituted compounds all have P.I.s less than diphenylhydantoin by the MES test, they all exhibit P.I.s greater than those for diphenylhydantoin by the l.f. EST and s.c. Met. tests. In addition, No. 1 has the highest P.I. of any of the five compounds examined when compared on the basis of the l.f. EST test; however, the difference between the P.I.s for No. 1 and phenantoin by this test is not significant.

DISCUSSION

The data presented indicate that, except for diphenylhydantoin as measured by the s.c. Met. test, the profiles of anticonvulsant activity of the N-substituted compounds are qualitatively similar to those of phenantoin and diphenylhydantoin. Thus, all drugs tested have the ability to abolish the hindleg tonic-extensor component of maximal electroshock seizures and to elevate the threshold for l.f. EST and s.c. Met. in nontoxic doses. The ineffectiveness of diphenylhydantoin by the s.c. Met. test is in agreement with other reports from our laboratories (3, 6, 7).

The sequence of neurotoxic manifestations which follow the oral administration of the experimental N-substituted hydantoins and phenantoin is very similar, but there is a threefold difference in the time for maximum neurotoxic effect (compare No. 1 and No. 3, Table I) and a somewhat more than twofold difference in the dosage required to produce minimal neurotoxicity (compare No. 3 and phenantoin, Table I). The ratios of the TD_{50}s (phenantoin or diphenylhydantoin/N-compounds) indicate that the N-substituted compounds are only 45 to 73% as toxic as phenantoin and 25 to 40% as toxic as diphenylhydantoin.

With regard to anticonvulsant activity, No. 1 is more effective in elevating the threshold for electrically- and chemically-induced seizures than in modifying the pattern of seizures induced by supramaximal electroshock. Conversely, diphenylhydantoin is more effective in modifying the pattern of maximal electroshock seizures than in elevating the threshold for electrically- and chemically-induced seizures. On the other hand, No. 2, No. 3, and phenantoin do not exhibit significant selectivity of action when compared for ability to modify pattern and to elevate seizure threshold.

The two methyl-substituted hydantoins (No. 1 and No. 2) are significantly more potent by all three tests and significantly more toxic than the ethyl-substituted hydantoin (No. 3). Except for No. 1 by the l.f. EST test, there is no significant difference in the anticonvulsant potency or the neurotoxicity of No. 1 and No. 2. A comparison of phenantoin and No. 2 reveals that mono-methyl substitution (phenantoin) has more influence on anticonvulsant potency than di-methyl substitution (No. 2). Comparison of the anticonvulsant potencies of the two mono-methyl compounds (No. 1 and phenantoin) indicates that methyl substitution in position 3 induces approximately a twofold increase in the anti-MES and anti-s.c. Met. activity, but has no significant effect on the l.f. EST. These observations suggest that N-methyl substitution increases anticonvulsant activity more than does N-

ethyl substitution, and that for optimal activity the N-methyl substitution on the hydantoin ring should be in position 3, as in phenantoin.

An evaluation of the P.I.s derived from the experimental data reveals that No. 1 has the highest value of the three experimental drugs tested. Comparison of the P.I.s of No. 1 and those of the two clinical compounds indicates that, except for diphenylhydantoin by the s.c. Met. test, all three agents exhibit satisfactory P.I.s by all three tests. The difference between the P.I.s for No. 1 and phenantoin by the l.f. EST and s.c. Met. tests is not significant.

A preliminary clinical report (1) and unpublished observations communicated to us by Dr. Leonard W. Jarcho, Division of Neurology, University of Utah, suggest that No. 1 is effective in some patients with grand mal epilepsy resistant to other anticonvulsant therapy and, in contrast to phenantoin and diphenylhydantoin, in some patients with petit mal. Observed side effects are said not to be serious and, to date, gum hypertrophy has not been reported. Should more extensive clinical studies unequivocally establish that No. 1 is effective in patients not responding to conventional antiepileptic therapy and does indeed possess a broader spectrum of activity and lower incidence of toxicity than do the related hydantoins, it would represent a significant addition to the drugs currently available for the treatment of epilepsy.

SUMMARY

The anticonvulsant potencies (ED_{50}s) of three experimental N-substituted hydantoins, 1-methyl-5,5-phenylethylhydantoin (No. 1), 1,3-dimethyl-5,5-phenylethylhydantoin (No. 2), and 3-ethyl-5,5-phenylethylhydantoin (No. 3), and of phenantoin and diphenylhydantoin were determined in mice by the following three tests: maximal electroshock seizure pattern (MES) test, low-frequency electroshock seizure threshold (l.f. EST) test, and pentylenetetrazol seizure threshold (s.c. Met.) test. In addition, the dose of each drug which produced minimal evidence of overt neurotoxicity in 50% of animals (TD_{50}) was determined and protective indexes (TD_{50}/ED_{50}) were calculated. On the basis of the results obtained the following conclusions appear justified:

1. The TD_{50}s for the three experimental drugs are significantly higher than those for phenantoin and diphenylhydantoin.

2. The N-substituted compounds exhibit activity by all three tests; but, except for diphenylhydantoin by the s.c. Met. test and No. 2 by the l.f. EST tests, they are less potent than the two clinically employed agents. Number 1 is more effective in elevating seizure threshold than in modifying maximal seizure pattern, whereas diphenylhydantoin is more effective in modifying maximal seizure pattern than in elevating seizure threshold. Number 2, No. 3, and phenantoin exhibit no striking selectivity of action.

3. On the basis of P.I.s, No. 1 appears to be the most promising of the three experimental drugs tested. The P.I. for No. 1 by the MES test is significantly lower than that for phenantoin or diphenylhydantoin, but by the l.f. EST and s.c. Met. tests its P.I.s are significantly higher than those for diphenylhydantoin and not significantly different from those for phenantoin.

4. Mono-methyl substitution (No. 1 and phenantoin) exerts a more favorable influence on anticonvulsant activity than does either dimethyl (No. 2) or mono-ethyl (No. 3) substitution. Except for activity as measured by the l.f. EST test, the drug with methyl substitution in the 3 position (phenantoin) is more neurotoxic and exhibits significantly more anticonvulsant activity than the compound with the methyl group in position 1 (No. 1).

5. No. 1 appears worthy of more definitive clinical trial.

Evaluative Procedures for Film-Forming Materials Used in Pharmaceutical Applications

By JOSEPH L. KANIG and HARRIS GOODMAN†

The current interest in films for use in many pharmaceutical applications has motivated a study in which meaningful testing procedures have been developed or adapted for evaluating such films. The testing procedures studied were found to be rapid, efficient, reproducible, and valid for the evaluation of the pertinent properties of several different series of film-forming materials. The studies were conducted on the free films which were cast from these materials. Data gathered on solubility, moisture absorption, water vapor transmission rates, and the effects of temperature, humidity, and light on the free films indicate that the testing methods may be used to predict the effects of these variables on the performance of the films when they are utilized in a dosage form.

THE POTENTIAL utilization of films as specialized coatings on medications, as vehicles for medicaments, or as packaging agents has prompted several studies within recent years which evaluated various film-forming materials for these applications.

A study of polyvinylpyrrolidone (1) as a film former established a simple and rapid method for coating tablets. Similar studies were made using polyethylene glycol (2), hydroxyethylcellulose and sodium carboxymethylcellulose (3), and zein (4) as the coating materials. Several patents have been issued on film-coating materials such as silicones (5), sodium carboxymethylcellulose (6), and cellulose acetate phthalate (7). Other investigations have utilized films as moisture-protective barriers on such medicaments as ascorbic acid (8) and sodium *p*-aminosalicylate (9). Films of various compositions have been studied as enteric coatings (10) and as vehicles for medicaments (11).

All of the reported studies indicated that when films were investigated for use as specialized coatings on dosage forms, the film-forming agents were evaluated after being applied to the dosage form. This procedure often gives rise to variables which are not introduced by the film itself and may lead to erroneous or misleading results which may serve to deter an investigator from further study. In addition, many important properties of the film itself are evaluated only with difficulty after it was been applied to a dosage form. The addition of special modifiers to the film or the combination of two or more film-forming materials in one formula often results in altering the properties of the film. It is therefore desirable to assess the effect of such modifications before applying the film to a dosage form. In this manner, the properties of the free film could be evaluated without being influenced by the nature of the dosage form or the coating technique.

It was the purpose of this study to utilize free films as a means of establishing rapid screening procedures which would evaluate the critical properties of films *per se*. The objectives were (*a*) the selection of simple methods for accurately producing uniform test films, and (*b*) the adaptation of methods for rapidly evaluating these films.

EXPERIMENTAL

The five major film characteristics which were selected as being most critical in pharmaceutical applications are: (*a*) solubility, (*b*) moisture absorption, (*c*) water vapor transmission, (*d*) reaction to temperature, and (*e*) reaction to light. Other characteristics which were not included in this study are adhesiveness, tensile strength, hardness, and oxygen transmission. These might be of importance in special cases.

Apparatus

For Film Casting.—The Gardner Ultra Applicator[1] was selected over other types of film-forming devices since it offered the advantages of simplicity of adjustment and operation in the casting of films. The Ultra Applicator (Fig. 1) is composed of two parts, a block and a blade. The stainless steel rails attached to the block are tapered at a gradient of 10 mils per 2-inch length. A thumb screw holding the blade to the underside of the block permits the

[1] Gardner Laboratory, Inc., Bethesda 14, Md.

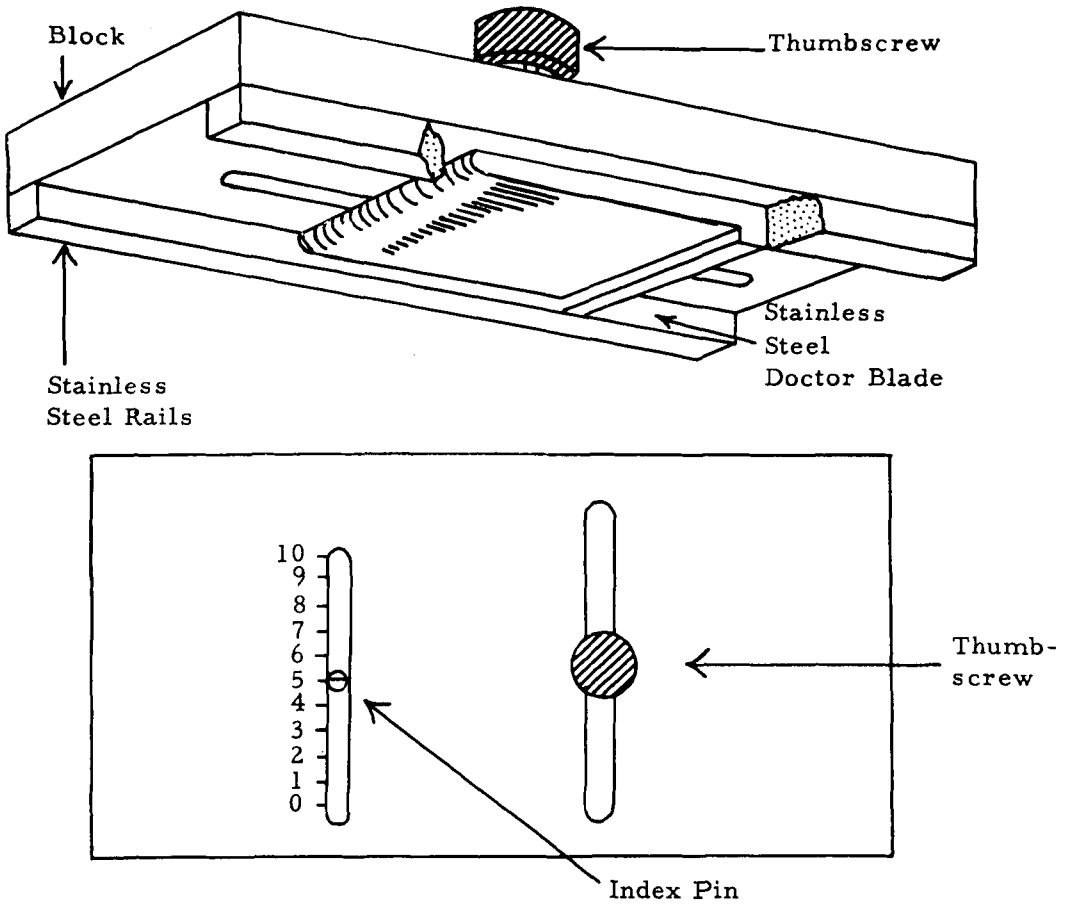

Fig. 1.—Gardner Ultra Applicator.

positioning of the blade along the gradient so that films of any desired wet film thickness may be drawn on a suitable surface. The critical dimensions of the applicator itself are held within 0.0001 inch tolerance which assures optimum accuracy of draw downs over its entire length. Models of the Ultra Applicator are available for producing wet films ranging from 0 to 20 mils in thickness, and from 0.75 to 6 inches in width.

When used, the blade position is adjusted for the desired wet film thickness and the block is placed over a small pool of the solution of the film former on a smooth surface. The entire applicator is then drawn downward over the pool to spread it evenly over the surface. The resulting wet films are then dried and removed for evaluation.

The surface onto which the films are cast also affects the production of uniform films. Highly polished chromium plated stainless steel plates, measuring 8 by 13 inches, were selected for this purpose since it has been shown that film-forming materials drawn over such a surface encounter less resistance in flowing over it than over ordinary steel surfaces (12).

For Film Evaluation.—The dry film thickness was measured by means of an Ames dial comparator, model 2w.[2] This dial comparator was fitted with an indicator capable of accurately recording 0.0001 inch thicknesses. Contact point area and contact pressure was designed to meet A.S.T.M. standards for thickness measurement of plastic film or similar materials. Contact pressure was controlled by use of a 19-oz. dead weight.

Water vapor transmission (W.V.T.) rates of free films were established by using the water vapor permeability cup, No. 305-7, Carson type, cast wax seal.[3] This type of vapor permeability cup meets the specifications of the A.S.T.M. test No. E96-53T, and is available with wax casting template and weighing cover.

Materials

In order to evaluate films which are indicative of a wide range of pharmaceutical applications, this investigation was conducted with the following film forming agents which represent four major groups of films based on solubility. The agents which were used were: (*a*) ethylcellulose, representing water-insoluble films; (*b*) methylcellulose, representing water-soluble films; (*c*) zein, representing varying solubility depending on pH; and (*d*) polyvinylpyrrolidone and ethylcellulose combination, representing slowly soluble films.

[2] B.C. Ames Co., Waltham 54, Mass.

[3] Thwing Albert Instrument Co., Philadelphia 44, Pa.

The combination of polyvinylpyrrolidone and ethylcellulose was chosen because it offered the possibility of evaluating a film which was composed of water-soluble and water-insoluble components, both of which are soluble in a common solvent such as ethanol, and could thus be cast as a single film.

Preliminary work was done to establish the optimum conditions for film casting and drying. Various solvent systems, concentrations of film forming materials, wet film thicknesses, and drying times and temperatures were tried for each of the materials studied.

Procedure

Once a particular formulation was found to be suitable, a bulk solution of sufficient volume was prepared from which all film samples could be produced for evaluation. The following solutions were used in this investigation:

Solution A	
Ethylcellulose, 50 cps.	10% w/v
Alcohol U.S.P.	20% v/v
Toluene	70% v/v

Films of various thicknesses were produced by drying the wet films at 94° for 8 minutes.

Solution B	
Methylcellulose, 400 cps.	5% w/v
Purified water	95% v/v

Films were prepared at a drying temperature of 80° at drying times of 8 to 14 minutes.

Solution C	
Zein	21.60% w/v
Oleic acid	15.90% v/v
Alcohol U.S.P.	56.25% v/v
Purified water	6.25% v/v

Films were produced from this solution after drying the wet films for 6 to 10 minutes at 51°.

Solution D	
Ethylcellulose, 50 cps.	10.2% w/v
Polyvinylpyrrolidone	3.2% w/v
Citroflex a-4	3.5% v/v
Alcohol U.S.P.	83.1% v/v

Films were developed and dried for 4 minutes at 44°.

Oleic acid in solution C, and Citroflex a-4 in solution D were added as plasticizers to eliminate brittleness of films as they dried.

Testing of Films

Solubility of Films.—Film samples were cut to uniform size by using a 1 × 3 inch glass microscope slide as a cutting template. A scalpel was used to cut strips of films of these dimensions and these strips were evaluated initially and again at stated intervals after being exposed to test conditions.

A sufficient number of strips of each different film of various thicknesses was stored in 4-ounce, wide-mouth glass containers with plastic screw caps and maintained at room temperature, 40°, and 60°. Samples of each were withdrawn at 1, 2, 4, 8, and 12-week intervals and were checked for any changes in solubility. In all cases, solubility tests were conducted in both artificial gastric and artificial intestinal fluids. The U.S.P. formulations for these solutions were employed.

The strips of film were immersed completely in 100 ml. of test fluid which was maintained at 37°. The test fluid was constantly kept in motion by means of a magnetic stirrer and the rate of movement was adjusted so as to create and maintain a small vortex. The solubility of the films in the testing solutions was rated visually; the end point being a complete solution of the film. Reproducibility of results was obtained within a very small range of time measured in seconds in several determinations of different samples of the same film. A similar evaluation procedure was used by Jarrell in a study involving the solubility of carboxymethylcellulose films (13).

Moisture Absorption by the Films.—A standardized method for determining water absorption by plastics has been approved by the A.S.T.M. and has been designated as A.S.T.M. test No. D570-59T. This test is designed for all shapes of plastics, including sheets, rods, and disks. A modification of this method was used for the testing of films in this study as follows: Films were prepared and cut into 1 × 3 inch strips. The strips were then conditioned by placing them in an oven at the temperatures and for the drying times which had been used originally in drying the wet films. This step was carried out to insure uniformity of the films within each group before testing. The conditioned sample strips were then suspended by means of fine wire in relative humidity chambers. The wire was made to pierce each strip in such a manner as to permit free access of the moist air to all surfaces of the films. Three chambers were set up to produce relative humidities of 10, 52, and 93%, respectively. The relative humidity in the chamber was controlled by the use of different saturated solutions containing excess solute. The conditioned film specimens were accurately weighed, placed in the relative humidity chambers, and then removed and weighed again at the end of 1, 2, 4, 8 and 12-week intervals. Increase or decrease in weight, changes in physical appearance or in solubility were then observed. Per cent moisture absorption was calculated by means of the following formula

$$\frac{\text{weight of exposed film} - \text{weight of conditioned film}}{\text{weight of conditioned film}} \times 100$$

The percentages calculated by means of this formula were plotted against time to establish the point of maximum absorption for each specimen film.

Moisture absorption data on films must include consideration of the following factors before the results may become applicable: (*a*) dimensions of the specimen, (*b*) conditioning time and temperature, (*c*) exposure procedure used, (*d*) time intervals of exposure and sampling, (*e*) percentage increase in weight, (*f*) observations as to changes in physical appearance of film specimens, and (*g*) effects on solubility.

Water Vapor Transmission.—The method employed to measure W.V.T. was a modification of the A.S.T.M. test No. E96-53T. Procedure E of this test for materials in sheet form was adapted for measurements of W.V.T. at an elevated temperature, with a low humidity on one side of the film and a high humidity on the other side.

The Carson type water vapor permeability dish was employed as the testing apparatus. These aluminum dishes are made with specially designed

flared edges upon which disks of film specimens may be placed and sealed in place with a wax seal. Drierite desiccant, No. 8 mesh, was placed within the dish to a height of within 3 mm. of the film sample being tested. In order to insure perfect sealing of the film disk to the edges of the dish and thus prevent leakage of water vapor around the film, a specially designed template was employed to define the test area and to help in forming the wax seal. The template was carefully placed over the film specimen, which was resting on the edges of the dish, and molten wax was poured into the space between the beveled edge of the template and the outer edge of the dish. When the wax solidified, the template was removed by gently twisting it until it came free. A mixture of 60% microcrystalline wax and 40% paraffin was found to be adequate for sealing the edge of the film to the edge of the dish.

Four specimens of each film were prepared in this manner. The entire assembly was accurately weighed and then placed in a constant humidity chamber at 37.8 ± 1.5° and 91% R.H. ±2%. A control blank apparatus was included in each batch for the purpose of establishing if any significant change could be attributed to the test apparatus itself. No significant change was noted at any time.

The W.V.T. of a sample was calculated in terms of grams per square inch per 24 hours as follows

$$\text{W.V.T.} = \frac{(g)\,(24)}{(t)\quad(a)}$$

where g = weight change in grams, t = time, in hours, during which weight change occurred, and a = area of exposed specimen film in square inches.

Light Stability Test.—Film samples were cut into 1 × 3 inch strips and placed in open Petri dishes. These were positioned in a light stability cabinet[4] recently described by Lachman and his coworkers (14). The cabinet is constructed so that samples may be placed at various distances from the light source so that light intensity to which samples are subjected may be regulated. By placing the samples at a distance of three feet from the light source, they were subjected to a twentyfold increase in intensity over ordinary light. Samples were studied visually for possible changes in appearance at the end of 4 and 6-week intervals.

RESULTS AND DISCUSSION

Effect of Storage on Solubility of Films.—The four groups of films tested offer a wide degree of solubility characteristics. As had been expected, films of methylcellulose were soluble in the artificial digestive test fluids. No solubility changes were observed in these films upon storage at elevated temperatures for 12 weeks. As had equally been anticipated, films of ethylcellulose were completely insoluble in both gastric and intestinal fluids, and the insolubility of the films was not altered after periods of storage at different relative humidities or temperatures. Different film thicknesses also had no effect on the solubility of these films. Specimen films were considered insoluble when they indicated no change after 24 hours immersion in the testing apparatus.

The results of the solubility studies on zein films substantiated the properties of this material as being insoluble in gastric fluids but rapidly soluble in intestinal fluids. The rate of solubility in artificial intestinal fluid was directly proportional to the thickness of the film, ranging from 1.5 seconds for test strips of 0.6 mil thickness to 9 seconds for test strips of 1.5 mil thickness. The solubility rates of the zein films were in no way altered by the storage conditions.

The combination of ethylcellulose and polyvinylpyrrolidone proved to be completely insoluble in both gastric and intestinal fluids. The original anticipation that this combination would yield a slowly soluble film due to contributory characteristics of each component did not materialize. The possibility exists that the ethylcellulose completely dominated the film characteristics by coating the polyvinylpyrrolidone molecules, and that different combinations of these materials might reverse this situation.

Storage Stability of Films.—The effects of elevated temperatures on the physical characteristics of the film other than its solubility should be noted. Films of ethylcellulose and methylcellulose were found to be completely stable under all temperature conditions. There were no physical changes in these films after 12 weeks. Definite physical changes in the zein films were observed. These changes involved a darkening in color and an increased brittleness. In the case of the thinnest film (0.6 mil) the change became apparent at the 40° temperature level at the end of 8 weeks. At the end of the same period, samples of all thicknesses at 60° had become brown in color and brittle. The cause of this discoloration and increased brittleness was traced to the oleic acid plasticizer used in this film. Oleic acid at 80° has been shown to absorb approximately four atoms of oxygen per molecule with a low yield of peroxide and a considerable evolution of water and carbon dioxide (15). It has also been noted that the oxidation reaction is accelerated by heat and light (16). The long term exposure of the film to the elevated temperature might have caused the acceleration of this oxidation of oleic acid producing a discoloration and a brittleness of the film. The use of other plasticizers such as ethyl lactate, propylene glycol, or sodium lactate might eliminate this problem. No reports could be found in the literature to indicate previous knowledge of such a problem with an oleic acid plasticized zein film.

Moisture Absorption by Films.—The method developed for evaluation of the effect of relative humidity on film properties produced results which were uniform and reproducible. In the case of methylcellulose, results indicated that these films absorbed relatively low amounts of moisture, and reached a point of equilibrium at the end of 3 weeks in relative humidities of 10 and 52%. These relative humidities did not produce any apparent physical changes in the films at the end of 12 weeks.

Moisture absorption in the 93% R.H. chamber, however, was so great that the films became soft and gummy within 4 weeks, the point at which maximum absorption was reached. Figure 2 indicates the percentage of moisture absorption for methylcellulose films of 0.5 mil thickness.

[4] The authors are indebted to Ciba Pharmaceutical Products Inc., Summit, N. J., for making available the light stability cabinet used in this study.

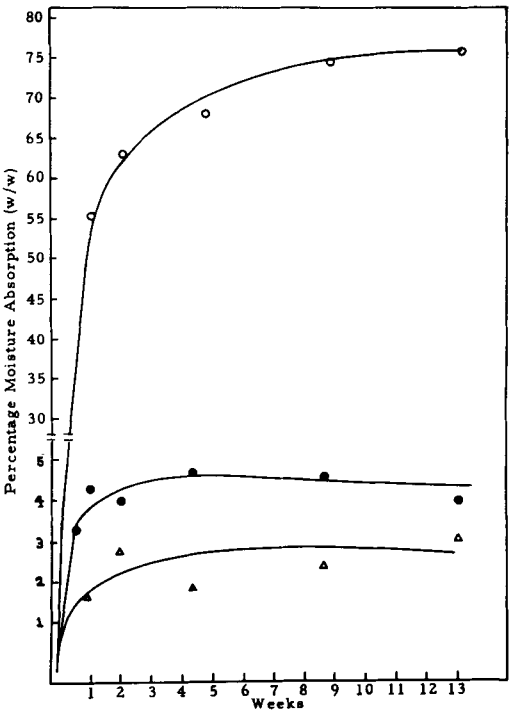

Fig. 2.—Moisture absorption of methylcellulose film of 0.5 mil thickness. O, 93% R.H.; ●, 52% R.H.; △, 10% R.H., all at 37.8°.

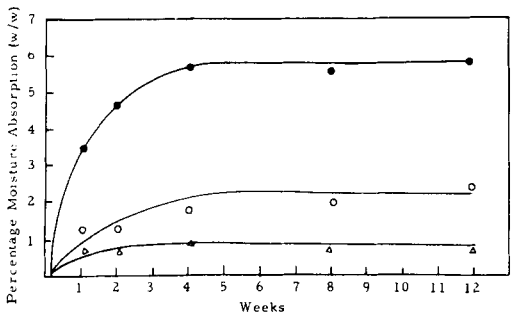

Fig. 3.—Moisture absorption of ethylcellulose film of 1 mil thickness. O, 93% R.H.; ●, 52% R.H.; △, 10% R.H., all at 37.8°.

The amount of moisture absorption by the ethylcellulose films reached equilibrium in 3 to 4 weeks (Fig. 3). It was discovered that the percentage of absorbed moisture was not directly proportional to relative humidity. Regardless of thickness, the films consistently absorbed a higher percentage of moisture at 52% R.H. than they did at 93% R.H. This odd phenomenon was not reported anywhere in the literature and no feasible explanation of this can be offered at this time. Relative humidities at the different levels had no visible effect on the physical properties of the ethylcellulose films.

The zein films showed moisture absorption patterns similar to those of methylcellulose. In relative humidities of 10 and 52%, the moisture absorption was 1.5% or less; equilibrium being established within 3 weeks. Films stored at 93% R.H. were softened considerably by the end of the first week and in some instances the test strips became completely deformed.

The value of studying films produced by a combination of film-forming agents was demonstrated effectively by the moisture absorption rates of the ethylcellulose-polyvinylpyrrolidone films. It has been shown that the moisture content of polyvinylpyrrolidone films is directly related to relative humidity; with the equilibrium percentage of moisture being about one-third of the relative humidity (17). Thus, it could be calculated that if a polyvinylpyrrolidone film was exposed to a relative humidity of 90%, the moisture content at equilibrium would approach 30%. Likewise, at relative humidities of 10 and 52%, the moisture absorption of a polyvinylpyrrolidone film would reach equilibrium at about 3 and 17%, respectively.

Figure 4 indicates that the film composed of a combination of ethylcellulose and polyvinylpyrrolidone absorbed only 0.6% at the 10% R.H. level, and between 3 and 5% moisture at the 52% level. It therefore appears that at the lower levels of relative humidity the ethylcellulose content of the film exercised a major role in the film properties achieved. However, in the 93% R.H. chamber, the same film continued to absorb moisture, and at the end of 12 weeks had absorbed as much as 12%. In this instance it is quite probable that the inherent hygroscopic properties of the polyvinylpyrrolidone overshadowed the effect of the ethylcellulose content. This phenomenon was not observed in ethylcellulose-polyvinylpyrrolidone films of 1.0 mil thickness, in which instance a maximum of 7% absorption of moisture in the 93% R.H. chamber was recorded and this level remained constant after 3 weeks.

Water Vapor Transmission.—Ethylcellulose films showed a W.V.T. rate which varied inversely with the thickness of the film. Figure 5 indicates that the W.V.T. decreased almost linearly with an increased thickness of film. Figure 6 demonstrates that methylcellulose films exhibited W.V.T. charac-

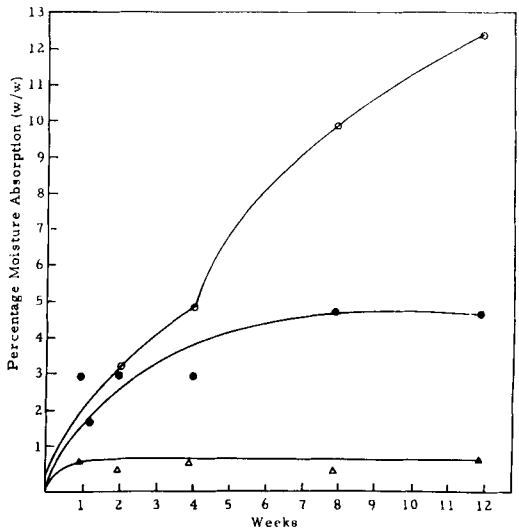

Fig. 4.—Moisture absorption of ethylcellulose-polyvinylpyrrolidone film of 1.5 mil thickness. O, 93% R.H.; ●, 52% R.H.; △, 10% R.H., all at 37.8°.

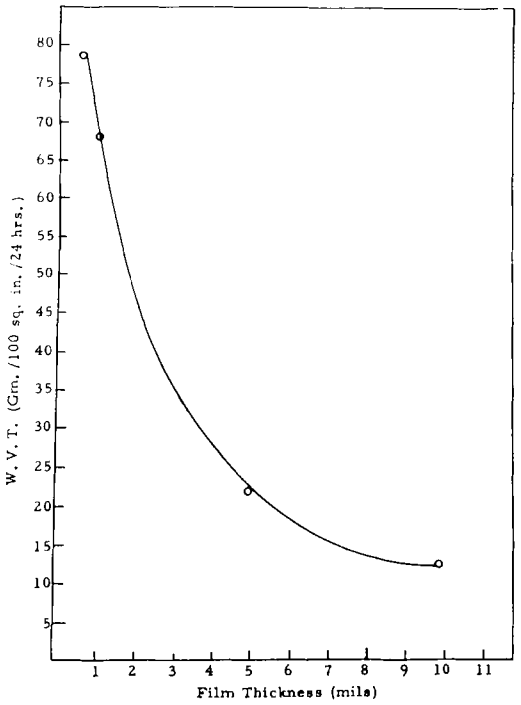

Fig. 5.—Water vapor transmission of ethylcellulose films, 91% R.H. at 37.8°.

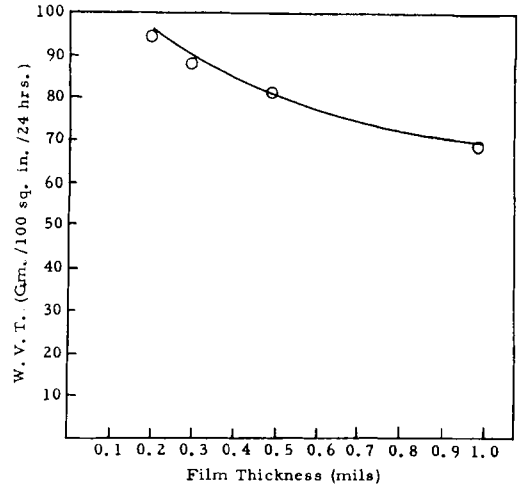

Fig. 6.—Water vapor transmission of methylcellulose films, 91% R.H. at 37.8°.

teristics which were very similar to those of ethylcellulose films, even though the former material is completely soluble in water while the latter is insoluble.

Zein films (Fig. 7) manifested the lowest W.V.T. rates of all the tested films. These films should, therefore, offer good protection qualities against moisture when applied to dosage forms. It has been shown that the major factors controlling the W.V.T. of a film are: chemical structure, polarity, symmetry, and the size of the polymers or molecules making up the film (13, 18). A recent study (19) has demonstrated that the films containing more polar groupings permit larger amounts of moisture vapor to pass through them. The low W.V.T. of the zein films, therefore, may be attributed to the large number of nonpolar side chains making up the polymer units.

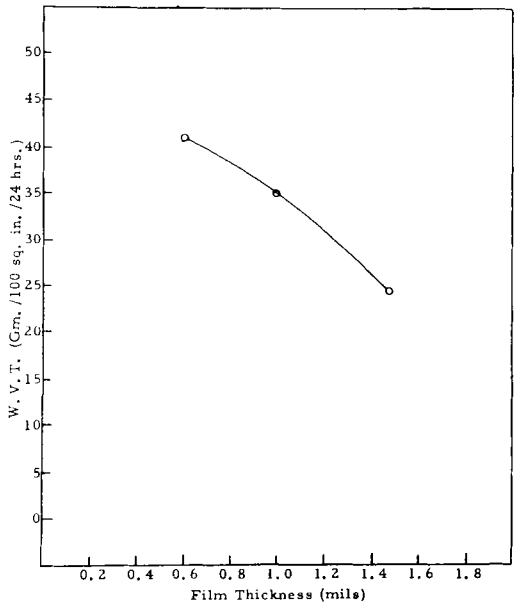

Fig. 7.—Water vapor transmission of zein films, 91% R.H. at 37.8°.

Light Stability of Films.—Samples of all films exposed for a period of 6 weeks in the light stability cabinet indicated complete physical stability with the exception of zein, which underwent a change from an initial light tan color to almost colorless in this period of time. The brittleness of the film was increased at the same time and may have been caused by the oxidation of the oleic acid plasticizer as previously noted in the effects of high temperatures on the same film. The discoloration of the film was probably due to a bleaching of the color constituents of zein. These observations suggest the necessity of the use of other plasticizers, and the addition of ultraviolet light-absorbing agents in those instances where bleaching of films is undesirable.

SUMMARY

1. Meaningful testing procedures have been developed or adapted for the rapid evaluation of film-forming agents for pharmaceutical use.

2. The testing procedures developed were used to evaluate several free films, and the results obtained either substantiated expected results or indicated properties which might not have been revealed in an applied film.

3. Data on the physical properties observed as a result of the evaluation of free films not only indicate the validity of the testing procedures but also point out the need for further study of free films in contrast to the current methods of evaluation of applied films.

Toxicity and Central Depressant Activity of D-1-Phenyl-2-ureidopropane

By ELVEN K. BAUMAN and ALBERT R. HASKELL†

D-1-Phenyl-2-ureidopropane was prepared by the method of Toritaku and alternatively, by reacting 1-phenyl-2-aminopropane directly with urea. The LD_{50} of this ureide was found to be 840 mg./Kg. The compound was found to act as a central nervous system (CNS) depressant rather than as a sustained action CNS stimulant, as suggested by Toritaku. Comparison of the structural formula of 1-phenyl-2-ureidopropane with that of the barbiturates and hydantoins supports the experimental evidence that this compound acts as a barbiturate-like central nervous system depressant.

THE PREPARATION of sustained release amphetamine compositions has depended principally upon three approaches: (*a*) the preparation of beads of active ingredient coated with shellac, wax, or other insoluble substance, (*b*) the formation of a complex between amphetamine and an ion exchange resin, and (*c*) the formation of insoluble salts of amphetamine, such as the tannate, which are then slowly converted to soluble amphetamine salts in the acid stomach.

Our attention has been directed toward the search for new amphetamine compounds which would hydrolyze to give sustained amphetamine action or which, in themselves, would provide prolonged stimulation of the central nervous system.

Toritaku (1) has indicated that the urea derivative of amphetamine hydrolyzes *in vivo* to give a sustained amphetamine action. Toritaku's patent described the preparation of the compound but reported no biological tests to demonstrate the amphetamine action. This study was therefore initiated to determine the toxicity and duration of action of D-1-phenyl-2-ureidopropane.

Received March 29, 1961, from the Midwest Research Institute, Kansas City, Mo.
Accepted for publication April 21, 1961.
† Marion Laboratories, Inc., Kansas City, Mo.

EXPERIMENTAL

Synthesis.—D-1-Phenyl-2-ureidopropane was prepared from D-1-phenyl-2-aminopropane sulfate and potassium cyanate as described by Toritaku (Fig. 1).

D-1-Phenyl-2-aminopropane sulfate, 60 Gm. and potassium cyanate, 30 Gm., were placed in 350 ml. distilled water and boiled for 30 minutes. After three recrystallizations from water, white needles were obtained which melted at 138.5 to 139°, which agrees with previously reported data (2, 3). The actual yield from the reaction was 55 Gm. or 90 % of the theoretical yield, 58 Gm.

D-1-Phenyl-2-ureidopropane was also prepared by the reaction of D-1-phenyl-2-aminopropane with urea (Fig. 2.). This method was abandoned because of low yield.

Biological Examination.—The intraperitoneal LD_{50} of this compound was determined by the method of Hagan (4). White rats, 200 Gm., both male and female, were used as experimental animals. Following determination of the intraperitoneal LD_{50}, the compound was administered orally to 200-Gm. rats, both sexes, at a dose of twice the intraperitoneal LD_{50}. The experimental animals were compared to the controls by visual examination.

Results.—The data from the intraperitoneal

Dose, mg./Kg.	Final Dosage Levels and Mortality Ratios[a] Time, hr.										
	1/2	1	1 1/2	2	2 1/2	3	3 1/2	4	4 1/2	5	24
700	0/6	0/6	0/6	0/6	0/6	0/6	0/6	0/6	0/6	0/6	0/6
800	0/6	0/6	0/6	1/6	1/6	1/6	1/6	1/6	2/6	2/6	2/6
900	0/6	0/6	1/6	2/6	3/6	4/6	4/6	4/6	4/6	4/6	4/6

[a] The figures in this table indicate the ratio between the number of animals which succumbed and the number of animals injected.

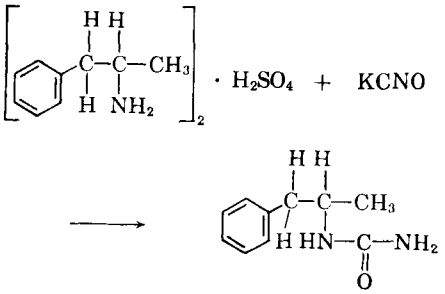

Fig. 1.—Preparation of 1-phenyl-2-ureidopropane from amphetamine sulfate and potassium cyanate.

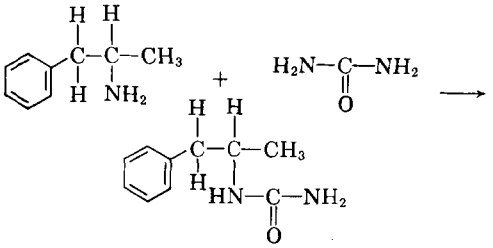

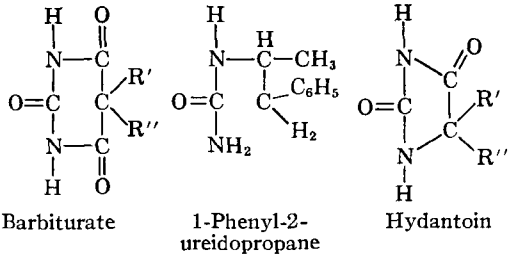

Fig. 2.—Preparation of 1-phenyl-2-ureidopropane from amphetamine and urea.

LD_{50} determination are shown in Table I. The intraperitoneal LD_{50} for 200-Gm. rats appears to be approximately 840 mg./Kg. During this procedure no convulsions or other symptoms of central nervous system stimulation were observed.

When 200-Gm. rats were subjected to an oral dose of this compound equal to two times the intraperitoneal LD_{50} dose the onset of drug activity occurred in approximately 60 minutes and was indicated by general lethargy, loss of irritability, and lack of coordination when walking. Two hours after the administration no voluntary movement of the test animals was observed. At this point shallow breathing was apparent and pulse rates were found to be about one-half of normal. Two of the 12 rats had lost the righting reflex but continued to respond to the tail dip test using water at 160°F. Recovery, indicated by the return of coordinated

Barbiturate 1-Phenyl-2-ureidopropane Hydantoin

Fig. 3.—The structure of 1-phenyl-2-ureidopropane and two typical CNS depressant nuclei.

movement and response to noise, occurred between 6 and 8 hours after administration. All animals survived. It was again observed that no convulsions occurred in the test animals but rather the signs and symptoms of central nervous system depression were apparent.

DISCUSSION

The striking feature of the animal experiment was the absence of any reaction similar to that in rats treated with 1-phenyl-2-aminopropane. In all cases the test animals gave the appearance of having been treated with a central nervous system depressant such as a barbiturate. For example, of 12 animals treated orally, 10 had a marked loss of coordination and the remaining 2 were under light anesthesia, having lost the righting reflex but still responding to pain.

An examination of the structural formula of the compound in question provides an explanation for the observed experimental facts. In Fig. 3 are shown the basic structural components of 1-phenyl-2-ureidopropane, of the barbiturate nucleus, and the hydantoin nucleus. Examination of Fig. 3 will show that the basic components of a central nervous system depressant are present in 1-phenyl-2-ureidopropane and therefore that central nervous system depression from this compound should not have been unexpected.

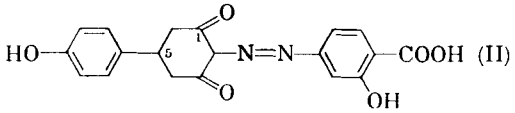
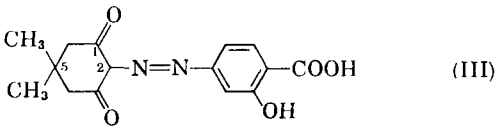
Coupling of Diazotized *p*-Aminosalicylic Acid (PAS) with 5-(*p*-Hydroxyphenyl)-cyclohexanedione-1,3 and Related Compounds

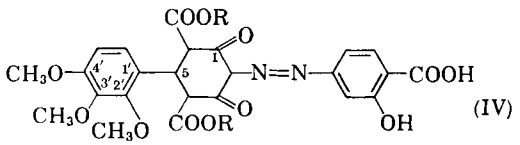


By PHILLIPOS E. PAPADAKIS and S. C. PIRRUCCELLO

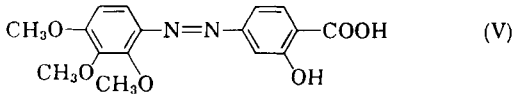
The syntheses of five derivatives of PAS are described. The compounds were prepared for study as agents having possible increased antimetabolite and/or antimicrobial properties.



IT IS KNOWN that many azo compounds are useful as dyes, diagnostic agents, indicators, staining agents for bacteria, etc. Some azo compounds depending on the radicals and functional groups involved in their structures have important physiological properties. The fact that PAS has been used with or without other drugs in the chemotherapy of tuberculosis prompted these authors to do this work, namely the synthesis of compounds (I) to (V). This report is an extension of previous work (1) and deals with the coupling of diazotized *p*-aminosalicylic acid with each of the following compounds: (*a*) 5-(*p*-hydroxyphenyl) 4,6-dicarbethoxycyclohexanedione-1,3; (*b*) 5-(*p*-hydroxyphenyl)-cyclohexanedione-1,3; (*c*) 5,5-dimethylcyclohexanedione-1,3; (*d*) 5-(2′, 3′, 4′-trimethoxyphenyl) 4,6-dicarbethoxycyclohexanedione-1,3; (*e*) trimethoxybenzene. The coupled products are represented by the formulas (I) to (V), respectively.

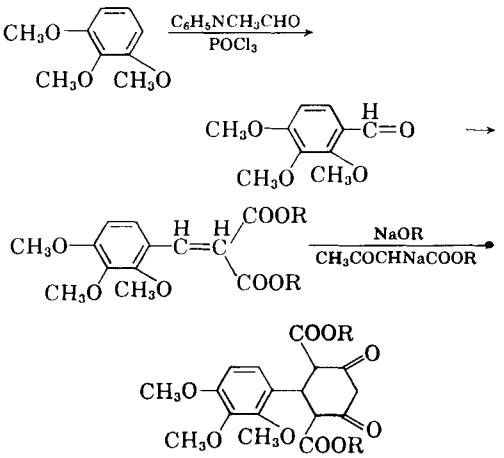


(I)



(II)

(III)



(IV)

(V)

The general methods of the preparation of compounds (*a*) and (*b*) have been previously described (2, 3). The sequence of synthesis for the preparation of compound (*d*) which is a new compound is as follows

The methods used for some of the above syntheses have been described (2, 4).

EXPERIMENTAL

In the diazotization process each of the reagents (*a*) to (*d*) was dissolved in dilute sodium hydroxide and the solution cooled to 0°. In another container an equivalent amount of the sodium salt of *p*-aminosalicylic acid was dissolved in distilled water and to this solution hydrochloric acid was added (calculated to react with: the sodium salt of PAS, the amino group of PAS, and the sodium nitrate). The calculated amount of sodium nitrite was added, a little at a time with stirring. The diazonium salt thus prepared was mixed with the sodium derivative of the respective cyclic dione. The mixture was stirred and then allowed to stand at 3° for 1 hour. Then the mixture was made acid to Congo red paper. A red-brown precipitate was formed which was filtered and washed with distilled water. Products (I) and (III) were recrystallized from 75% alcohol. Products (IV) and (V) were dissolved in ether and reprecipitated with petroleum ether. For the formation of (V) the trimethoxybenzene was dissolved in the minimum quantity of dioxane at 10° and added, with stirring, to the diazonium salt of PAS at 0°. Sodium hydroxide was added to take care of the hydrochloric acid. After stirring for 1 hour at 4° the mixture was made acid to Congo red paper, a black-red precipitate was formed which was filtered, dissolved in ether, and reprecipitated with petroleum ether. The analyses of the compounds following are given in Table I: I, N-2-[5-(*p*-hydroxyphenyl)-4,6-dicarbethoxy-cyclohexanedione-1,3]-azo-N-*p*-salicylic acid; II, N-2-[5-(*p*-hydroxyphenyl)-cyclohexanedione-1,3]-azo-N-(*p*-salicylic acid); III, N-2-[5,5-dimethyl-cyclohexanedione-1,3]-azo-N-(*p*-salicylic acid); IV, N-2-[5-(2′, 3′, 4′-trimethoxyphenyl)-4,6-dicarbethoxy-cyclohexanedione-1,3]-azo-N-(*p*-salicylic acid); V, N-1-(2,3,4-trimethoxybenzene)-azo-N-(*p*-salicylic acid).

New Alkaline-Stable Species for Selected Members of the Tetracycline Family

Sir:

We have recently observed a new modification of selected members of the tetracycline family which shows greatly enhanced stability under alkaline conditions. This derivative is a complex having the following general formula: (tetracycline - group - antibiotic) - $(aluminum)_a$-$(calcium)_b$-(gluconic acid)$_c$ where a, b, and c are the molar ratios of the respective constituents. Although the molar ratios a, b, and c can vary over a wide range in this derivative, greatly enhanced alkaline stability occurs only when the molar ratios of aluminum and calcium are three or greater. The molar ratio of gluconic acid does not appear to contribute significantly to the alkaline stability, but appears to play an important role in solubilizing the derivative.

In measuring the alkaline stability of derivatives in this series, extensive use has been made of half-life determinations, as reported by McCormick, *et al.* (1). Half-life values have been determined in 0.1 *N* sodium hydroxide at 90–100° by following the time change in (*a*) ultraviolet absorbance at 365 mμ and (*b*) the microbiological activity of the antibiotic.[1] Table I *demonstrates* the enhanced alkaline stability of selected members of the tetracycline family in this series of derivatives.

[1] Microbiological assays were performed under the direction of Dr. J. J. Corbett, Biological Assay Development Laboratory.

New Alkaline-Stable Species for Selected Members of the Tetracycline Family

Sir:

We have recently observed a new modification of selected members of the tetracycline family which shows greatly enhanced stability under alkaline conditions. This derivative is a complex having the following general formula: (tetracycline - group - antibiotic) - $(aluminum)_a$-$(calcium)_b$-(gluconic acid)$_c$ where a, b, and c are the molar ratios of the respective constituents. Although the molar ratios a, b, and c can vary over a wide range in this derivative, greatly enhanced alkaline stability occurs only when the molar ratios of aluminum and calcium are three or greater. The molar ratio of gluconic acid does not appear to contribute significantly to the alkaline stability, but appears to play an important role in solubilizing the derivative.

In measuring the alkaline stability of derivatives in this series, extensive use has been made of half-life determinations, as reported by McCormick, *et al.* (1). Half-life values have been determined in 0.1 *N* sodium hydroxide at 90–100° by following the time change in (*a*) ultraviolet absorbance at 365 mμ and (*b*) the microbiological activity of the antibiotic.[1] Table I *demonstrates* the enhanced alkaline stability of selected members of the tetracycline family in this series of derivatives.

[1] Microbiological assays were performed under the direction of Dr. J. J. Corbett, Biological Assay Development Laboratory.

[a] The trademarks of the American Cyanamid Co. for 6-demethylchlortetracycline, chlortetracycline, and tetracycline are Declomycin, Aureomycin, and Achromycin, respectively.
[b] No change observed after 4 to 6 hours in 0.1 *N* sodium hydroxide at 90–100°.

The various members of the tetracycline family in the table above demonstrate the effects of methylation, chlorination, and deoxygenation of the tetracycline ring system on the ability of complex formation to slow the rate of alkaline degradation. Chlortetracycline is unusual in that repeated alkaline stability studies with complexes described with this antibiotic have failed to demonstrate greatly enhanced alkaline stability.

The resistance of certain of these derivatives to attack by alkali enables them to be prepared as stable solutions when the solution is sufficiently alkaline to avoid C·4 epimerization occurring in the pH range of 2–6 (2) and anhydro formation occurring under very acidic conditions.

Those derivatives showing enhanced alkaline stability experience little or no change in their susceptibilities toward acid degradation and toward C·4 epimerization in comparison to the uncomplexed antibiotic. The lack of significant change toward acid degradation is of particular interest because both alkaline degradation and acid degradation involve chemical alteration of the C·6 hydroxyl, together with other changes in ring C in the antibiotic. The fact that complexing can produce great changes in the alkaline reactivity of the C·6 hydroxyl and little change in the acid reactivity of the C·6 hydroxyl is an important clue to the mechanism of alkaline stability enhancement via complex formation. When 6-deoxy-6-demethyltetracycline is used as the antibiotic in this derivative, greatly enhanced stability toward acid (3) and alkali is observed.

Additional observations on this series of derivatives with the tetracycline family will be presented at a later date.

Book Notices

Pharmacological Principles of Medical Practice. 5th ed. By JOHN C. KRANTZ, JR., and C. JELLEFF CARR. The Williams & Wilkins Co., 428 East Preston St., Baltimore 2, Md., 1961. xi + 1498 pp. 15 × 22.5 cm. Price $15.

The fifth edition of this excellent and widely used treatise and textbook has been extensively revised. The text material has been updated to include the very latest information available before printing. Although judicious pruning kept the book from being unwieldy, this edition contains 186 pages more than the fourth edition. Librarians will note that the first word in the title of the book has been changed from "Pharmacologic" to "Pharmacological." Students will be more concerned with the included nomenclature changes indicated for the psychotropic drug classifications; the beautiful color plate diagram of the normal menstrual cycle showing pituitary, ovarian, and endometrial activity; and many other additions in this edition. The index is exceptionally thorough and enhances the reference value of the book.

Microbial Cell Walls. By MILTON R. J. SALTON. John Wiley & Sons, Inc., 440 Park Ave., South, New York 16, N. Y., 1961. ix + 94 pp. 12.5 × 18.5 cm. Price $3.50.

Lectures on microbial cell walls, including the chemistry, enzymic degradation, and their biosynthesis are included in this booklet. A general index is appended.

Chemotherapy of Tuberculosis. By WILLIAM F. RUSSELL, JR. and GARDNER MIDDLEBROOK. Charles C Thomas, 301–327 East Lawrence Ave., Springfield, Ill., 1961. xiv + 130 pp. 15 × 23 cm. Price $6.50.

A concise monograph on tuberculosis with practical considerations on current chemotherapy. Part 1 covers measures for determining the appropriateness and the adequacy of chemotherapy; Part 2 considers parasite-drug-host relationships; and Part 3 considers combined drug treatment. An excellent review, with index.

Annual Review of Biochemistry. Vol. 30. Edited by J. MURRAY LUCK, FRANK W. ALLEN, and GORDON MACKINNEY. Annual Reviews, Inc., Palo Alto, Calif., 1961. vii + 758 pp. 15 × 22.5 cm. Price $7 in the U. S., $7.50 foreign.

Volume 30 in this excellent review series includes reports on: biological oxidation; chemistry of carbohydrates, lipids, and nucleotides; biochemistry of muscle, steroid hormones, polyamines, cultured mammalian cells, genetic factors, and the dividing cell; metabolism of lipids, nucleic acid (and biosynthesis), carbohydrates, and amino acids. Vitamins, proteins, and other subjects are covered in the total of 24 reports, with many references. Appended are author and subject indexes for volume 30 and a cumulative index of chapter titles for volumes 26–30.

The various members of the tetracycline family in the table above demonstrate the effects of methylation, chlorination, and deoxygenation of the tetracycline ring system on the ability of complex formation to slow the rate of alkaline degradation. Chlortetracycline is unusual in that repeated alkaline stability studies with complexes described with this antibiotic have failed to demonstrate greatly enhanced alkaline stability.

Volume 30 in this excellent review series includes reports on: biological oxidation; chemistry of carbohydrates, lipids, and nucleotides; biochemistry of muscle, steroid hormones, polyamines, cultured mammalian cells, genetic factors, and the dividing cell; metabolism of lipids, nucleic acid (and biosynthesis), carbohydrates, and amino acids. Vitamins, proteins, and other subjects are covered in the total of 24 reports, with many references. Appended are author and subject indexes for volume 30 and a cumulative index of chapter titles for volumes 26–30.

The Nature of Sleep. Edited by G. E. W. WOLSTENHOLME and MAEVE O'CONNOR. Little, Brown & Co., 34 Beacon St., Boston 6, Mass., 1961. xii + 416 pp. 14 × 20.5 cm. Price $10.

A compilation of the 18 reports and discussions at the Ciba Foundation Symposium, June 1960. Much of the research was related to applications of electroencephalogram data. Author and subject indexes are appended.

Composition of Gum Turpentines of Pines. By N. T. MIROV. Technical Bulletin No. 1239, Forest Service U. S. Dept. of Agriculture, 1961. For sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. 158 pp. 14.5 × 23 cm. Price $1.50.

This monograph on pine turpentines discusses their general physical, chemical, and analytical characteristics, and systematically presents their composition. References are given to 166 published reports; 30 of them by the author appeared in THIS JOURNAL during 1951–1958. An appendix tabulates the chemical compounds found in pine gum turpentines.

Canadian Cancer Conference. Vol. 4. Edited by R. W. BEGG, ARTHUR HAM, C. P. LEBLOND, R. L. NOBLE, and R. J. ROSSITER. Academic Press, 111 Fifth Ave., New York 3, N. Y., 1961. xii + 435 pp. 15 × 23 cm. Price $12.

Topics of current interest presented at the fourth Canadian Cancer Research Conference (1960) are compiled in this volume under the main headings: Perspectives in biochemistry in cancer research, Cell behavior, Viral carcinogenesis, and Chemotherapy. Twenty-three papers were presented. Author and subject indexes are appended.

Poliomyelitis. Compiled and edited for the International Poliomyelitis Congress. Medical Department, J. B. Lippincott Co., East Washington Square, Philadelphia 5, Pa., 1961. xxiv + 435 pp. 17.5 × 25.5 cm. Price $7.50

A compilation of papers and discussions presented at the Fifth International Poliomyelitis Conference at Copenhagen, July 1960. The Preface notes that the Conference was held in an atmosphere of scientific tension due to the controversial situation created by the state of experimentation with the Salk and Sabin vaccines. The first license to produce Sabin type I polio vaccine was issued by HEW August 17, 1961. License for type II was expected shortly thereafter, with an indefinite period before licensing of type III.

Heterocyclic Compounds. Vol. 7. Edited by ROBERT C. ELDERFIELD. John Wiley & Sons, Inc., 440 Park Ave., South, New York 16, N. Y., 1961. vii + 878 pp. Price $37.50.

The seventh volume of this authoritative treatise considers compounds containing two oxygen or two nitrogen atoms in different rings and the chemistry of five- and six-membered monocyclic compounds carrying three hetero atoms, together with the benzo derivatives of the latter in some instances. The general format of the series is maintained, and a thorough index is appended.

Pharmaceutical Analysis. Edited by EINAR BROCHMANN-HANSSEN and TAKERU HIGUCHI. Interscience Publishers, Inc., 250 Fifth Ave., New York 1, N. Y., 1961. ix + 854 pp. 15 × 23 cm. Price $28.50

Selected methods of analysis currently used in manufacturing control laboratories are given and explained in this book. Areas covered by contributing authors include: Hydroxybenzoic acids and derivatives, Carbohydrates and glycosides, Steroids, Sulfonamides and sulfones, Derivatives of carbamic acid and urea, Amino acids, Alkaloids and other basic nitrogenous compounds, Antipyretic analgesics, Antibiotics, Vitamins, Metal-containing organic compounds, and Acid-base titrations in glacial acetic acid. A useful working text and reference, this book is a valuable addition to the analytical library. An index is appended.

The Extra Pharmacopoeia, Martindale. Supplement 1961. Published by direction of the Council of the Pharmaceutical Society of Great Britain. The Pharmaceutical Press, 17 Bloomsbury Square, London, W.C.I., London. Obtainable in the U. S. from Rittenhouse Books, 1706 Rittenhouse Square, Philadelphia 3, Pa., 1961. xi + 315 pp. 12 × 18 cm. Price 32s. 6d.

This Supplement to volume I of the Extra Pharmacopoeia 1958 was published in lieu of a complete revision of volume II (1955). The new schedule is based upon the need for more rapid coverage of the type of information in volume I, e.g., composition, general properties, actions and uses, dosage, and toxic effects of drugs in current use. Since 1958, about 200 new drugs and 800 proprietary medicines have been introduced in Great Britain. Some of the information in volume II (1955) also has been updated; particularly, the entire section on 'Counter' Proprietaries is revised and included in this Supplement. The excellent style and format of the past is retained, and the Society group under Dr. K. R. Capper has done a very good job.

Developments in Industrial Microbiology. Vol. 2. Edited by SAUL RICH. Consultants Bureau Enterprises, Inc., 227 W. 17th St., New York 11, N. Y., 1961. xiv + 306 pp. 16.5 × 25 cm. Price $9 domestic, $10.50 foreign.

The proceedings of the 1960 meeting of the Society for Industrial Microbiology include 27 reports, covering petroleum microbiology, nonmedical aspects of antibiotics, deterioration and decay in products ranging from cosmetics to missiles, assay procedures in the fermentation industry, and various other subjects. A limited cumulative index for volumes 1 and 2 is appended.

Clinical Endocrinology. 3rd ed. By LAURENCE MARTIN. Medical Book Dept., Little, Brown & Co., 34 Beacon St., Boston 6, Mass., 1961. vii + 275 pp. 14 × 21.5 cm. Price $8.

The author presents a concise and practical review on endocrine disease with the emphasis on the general medical practitioner's view. Advances since the 1954 edition have been incorporated.

The Nature of Sleep. Edited by G. E. W. WOLSTENHOLME and MAEVE O'CONNOR. Little, Brown & Co., 34 Beacon St., Boston 6, Mass., 1961. xii + 416 pp. 14 × 20.5 cm. Price $10.

A compilation of the 18 reports and discussions at the Ciba Foundation Symposium, June 1960. Much of the research was related to applications of electroencephalogram data. Author and subject indexes are appended.

Composition of Gum Turpentines of Pines. By N. T. MIROV. Technical Bulletin No. 1239, Forest Service U. S. Dept. of Agriculture, 1961. For sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. 158 pp. 14.5 × 23 cm. Price $1.50.

This monograph on pine turpentines discusses their general physical, chemical, and analytical characteristics, and systematically presents their composition. References are given to 166 published reports; 30 of them by the author appeared in THIS JOURNAL during 1951–1958. An appendix tabulates the chemical compounds found in pine gum turpentines.

Canadian Cancer Conference. Vol. 4. Edited by R. W. BEGG, ARTHUR HAM, C. P. LEBLOND, R. L. NOBLE, and R. J. ROSSITER. Academic Press, 111 Fifth Ave., New York 3, N. Y., 1961. xii + 435 pp. 15 × 23 cm. Price $12.

Topics of current interest presented at the fourth Canadian Cancer Research Conference (1960) are compiled in this volume under the main headings: Perspectives in biochemistry in cancer research, Cell behavior, Viral carcinogenesis, and Chemotherapy. Twenty-three papers were presented. Author and subject indexes are appended.

Poliomyelitis. Compiled and edited for the International Poliomyelitis Congress. Medical Department, J. B. Lippincott Co., East Washington Square, Philadelphia 5, Pa., 1961. xxiv + 435 pp. 17.5 × 25.5 cm. Price $7.50

A compilation of papers and discussions presented at the Fifth International Poliomyelitis Conference at Copenhagen, July 1960. The Preface notes that the Conference was held in an atmosphere of scientific tension due to the controversial situation created by the state of experimentation with the Salk and Sabin vaccines. The first license to produce Sabin type I polio vaccine was issued by HEW August 17, 1961. References are given to 166 published reports; 30 of them by the author appeared in THIS JOURNAL during 1951–1958. An appendix tabulates the chemical compounds found in pine gum turpentines.

Canadian Cancer Conference. Vol. 4. Edited by R. W. BEGG, ARTHUR HAM, C. P. LEBLOND, R. L. NOBLE, and R. J. ROSSITER. Academic Press, 111 Fifth Ave., New York 3, N. Y., 1961. xii + 435 pp. 15 × 23 cm. Price $12.

Topics of current interest presented at the fourth Canadian Cancer Research Conference (1960) are compiled in this volume under the main headings: Perspectives in biochemistry in cancer research, Cell behavior, Viral carcinogenesis, and Chemotherapy. Twenty-three papers were presented. Author and subject indexes are appended.

Poliomyelitis. Compiled and edited for the International Poliomyelitis Congress. Medical Department, J. B. Lippincott Co., East Washington Square, Philadelphia 5, Pa., 1961. xxiv + 435 pp. 17.5 × 25.5 cm. Price $7.50

A compilation of papers and discussions presented at the Fifth International Poliomyelitis Conference at Copenhagen, July 1960. The Preface notes that the Conference was held in an atmosphere of scientific tension due to the controversial situation created by the state of experimentation with the Salk and Sabin vaccines. The first license to produce Sabin type I polio vaccine was issued by HEW August 17, 1961. License for type II was expected shortly thereafter, with an indefinite period before licensing of type III.

Heterocyclic Compounds. Vol. 7. Edited by ROBERT C. ELDERFIELD. John Wiley & Sons, Inc., 440 Park Ave., South, New York 16, N. Y., 1961. vii + 878 pp. Price $37.50.

The seventh volume of this authoritative treatise considers compounds containing two oxygen or two nitrogen atoms in different rings and the chemistry of five- and six-membered monocyclic compounds carrying three hetero atoms, together with the benzo derivatives of the latter in some instances. The general format of the series is maintained, and a thorough index is appended.

Pharmaceutical Analysis. Edited by EINAR BROCHMANN-HANSSEN and TAKERU HIGUCHI. Interscience Publishers, Inc., 250 Fifth Ave., New York 1, N. Y., 1961. ix + 854 pp. 15 × 23 cm. Price $28.50

Selected methods of analysis currently used in manufacturing control laboratories are given and explained in this book. Areas covered by contributing authors include: Hydroxybenzoic acids and derivatives, Carbohydrates and glycosides, Steroids, Sulfonamides and sulfones, Derivatives of carbamic acid and urea, Amino acids, Alkaloids and other basic nitrogenous compounds, Antipyretic analgesics, Antibiotics, Vitamins, Metal-containing organic compounds, and Acid-base titrations in glacial acetic acid. A useful working text and reference, this book is a valuable addition to the analytical library. An index is appended.

The Extra Pharmacopoeia, Martindale. Supplement 1961. Published by direction of the Council of the Pharmaceutical Society of Great Britain. The Pharmaceutical Press, 17 Bloomsbury Square, London, W.C.I., London. Obtainable in the U. S. from Rittenhouse Books, 1706 Rittenhouse Square, Philadelphia 3, Pa., 1961. xi + 315 pp. 12 × 18 cm. Price 32s. 6d.

This Supplement to volume I of the Extra Pharmacopoeia 1958 was published in lieu of a complete revision of volume II (1955). The new schedule is based upon the need for more rapid coverage of the type of information in volume I, e.g., composition, general properties, actions and uses, dosage, and toxic effects of drugs in current use. Since 1958, about 200 new drugs and 800 proprietary medicines have been introduced in Great Britain. Some of the information in volume II (1955) also has been updated; particularly, the entire section on 'Counter' Proprietaries is revised and included in this Supplement. The excellent style and format of the past is retained, and the Society group under Dr. K. R. Capper has done a very good job.

Developments in Industrial Microbiology. Vol. 2. Edited by SAUL RICH. Consultants Bureau Enterprises, Inc., 227 W. 17th St., New York 11, N. Y., 1961. xiv + 306 pp. 16.5 × 25 cm. Price $9 domestic, $10.50 foreign.

The proceedings of the 1960 meeting of the Society for Industrial Microbiology include 27 reports, covering petroleum microbiology, nonmedical aspects of antibiotics, deterioration and decay in products ranging from cosmetics to missiles, assay procedures in the fermentation industry, and various other subjects. A limited cumulative index for volumes 1 and 2 is appended.

Clinical Endocrinology. 3rd ed. By LAURENCE MARTIN. Medical Book Dept., Little, Brown & Co., 34 Beacon St., Boston 6, Mass., 1961. vii + 275 pp. 14 × 21.5 cm. Price $8.

The author presents a concise and practical review on endocrine disease with the emphasis on the general medical practitioner's view. Advances since the 1954 edition have been incorporated.

The Nature of Sleep. Edited by G. E. W. WOLSTENHOLME and MAEVE O'CONNOR. Little, Brown & Co., 34 Beacon St., Boston 6, Mass., 1961. xii + 416 pp. 14 × 20.5 cm. Price $10.

A compilation of the 18 reports and discussions at the Ciba Foundation Symposium, June 1960. Much of the research was related to applications of electroencephalogram data. Author and subject indexes are appended.

Composition of Gum Turpentines of Pines. By N. T. MIROV. Technical Bulletin No. 1239, Forest Service U. S. Dept. of Agriculture, 1961. For sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. 158 pp. 14.5 × 23 cm. Price $1.50.

This monograph on pine turpentines discusses their general physical, chemical, and analytical characteristics, and systematically presents their composition. References are given to 166 published reports; 30 of them by the author appeared in THIS JOURNAL during 1951–1958. An appendix tabulates the chemical compounds found in pine gum turpentines.

Canadian Cancer Conference. Vol. 4. Edited by R. W. BEGG, ARTHUR HAM, C. P. LEBLOND, R. L. NOBLE, and R. J. ROSSITER. Academic Press, 111 Fifth Ave., New York 3, N. Y., 1961. xii + 435 pp. 15 × 23 cm. Price $12.

Topics of current interest presented at the fourth Canadian Cancer Research Conference (1960) are compiled in this volume under the main headings: Perspectives in biochemistry in cancer research, Cell behavior, Viral carcinogenesis, and Chemotherapy. Twenty-three papers were presented. Author and subject indexes are appended.

Poliomyelitis. Compiled and edited for the International Poliomyelitis Congress. Medical Department, J. B. Lippincott Co., East Washington Square, Philadelphia 5, Pa., 1961. xxiv + 435 pp. 17.5 × 25.5 cm. Price $7.50

A compilation of papers and discussions presented at the Fifth International Poliomyelitis Conference at Copenhagen, July 1960. The Preface notes that the Conference was held in an atmosphere of scientific tension due to the controversial situation created by the state of experimentation with the Salk and Sabin vaccines. The first license to produce Sabin type I polio vaccine was issued by HEW August 17, 1961. License for type II was expected shortly thereafter, with an indefinite period before licensing of type III.

Heterocyclic Compounds. Vol. 7. Edited by ROBERT C. ELDERFIELD. John Wiley & Sons, Inc., 440 Park Ave., South, New York 16, N. Y., 1961. vii + 878 pp. Price $37.50.

The seventh volume of this authoritative treatise considers compounds containing two oxygen or two nitrogen atoms in different rings and the chemistry of five- and six-membered monocyclic compounds carrying three hetero atoms, together with the benzo derivatives of the latter in some instances. Review Article

Colorants for Pharmaceuticals

By CHARLES J. SWARTZ and JACK COOPER

THE USE of colorants to improve the appearance or other characteristics of pharmaceuticals has been reported in early documents. In many of these, color was closely associated with diseases and their treatment. Since then, the artificial coloring of foods and medicines for various purposes has increased slowly until, in the middle of the 19th century, the discovery of the first synthetic dyestuffs provided the spark which brought into being a rainbow of new colors. Today, as a result of the imaginative research efforts of color manufacturers, a wide range of synthetic organic coloring agents has been made available for numerous industrial uses.

Though a minor consumer of colorants compared to the food or cosmetic industries, pharmaceutical manufacturers have a considerable interest in the use of dyes as colorants. Artificial colors are included in various dosage forms of pharmaceuticals for several reasons. Naturally, one such application is for the purpose of producing an eye-appealing product. Quite apart from esthetic enhancement and consumer appeal, it is often stated that certain colors elicit specific associated effects in some persons. In view of such psychological factors, color is often employed to create related taste responses in a patient prior to the ingestion of a medication. In order to increase the acceptability of various products, an organoleptically compatible color is selected with due consideration for the population group for which the drug is primarily intended.

Received from the Research Department, Ciba Pharmaceutical Products, Inc., Summit, N. J.

Colorants have also been used in pharmaceuticals to conceal or modify undesirable visual impressions which are inherent to a particular preparation. In dosage forms containing active principles resulting from crude drug extraction techniques, differences in the color of the finished product occur as a result of the normal variation between crude drug lots. This point has been recently stressed by Tucker (1) who proposes the use of a color spray drying technique to minimize such differences. In certain tablet dosage forms, small variations in the method of manufacture or physical characteristics of ingredients will produce tablets with varying degrees of whiteness. Syrups and elixirs containing natural flavoring oils also exhibit batch variations in color. Therefore, the addition of artificial colorants provides the means by which a reproducible, uniform appearance of the finished product can be obtained.

Certain drug products contain added color to achieve a desirable cosmetic effect. Preparations for the treatment of skin conditions such as acne may, in addition to their therapeutic ingredients, also contain a skin-tone color to conceal the blemishes caused by the primary condition.

Knowledge gained in recent years has produced a tremendous increase in the use of drugs in veterinary medicine, both therapeutically and prophylactically. These drug products are often marketed by pharmaceutical manufacturers in the form of a "premix" which, prior to distribution to the ultimate consumers, will be mixed by the feed manufacturer with large quantities of animal or poultry feed. Some manufacturers

have colored these premixes artificially to give the feed manufacturer a visual aid in determining whether the medicated premix has been adequately dispersed throughout the finished feed.

One of the most important uses of dyes in drug specialties is for the purpose of identifying the drug in question. With the ever increasing number of drug preparations reaching the market it is readily understandable that any distinguishing feature which enables the physician, pharmacist, and nurse to identify a produce readily is essential medically and toxicologically. The importance of drug identification by color for these reasons has also been recognized by the Food and Drug Administration (2). The expense of special monograms and the limited variations in possible tablet shape also make the coloring of tablets an almost indispensable aid in the identification of drug products.

These several and varied uses of colors in medicinals emphasize the importance of dyes as used by pharmaceutical manufacturers. In the light of recent Food and Drug Administration rulings proposing to delist the great majority of dyes certified for drug use, it is quite clear that a thorough evaluation of the chemical and biological properties of such dyes is an urgent consideration.

CHEMISTRY OF COLORANTS

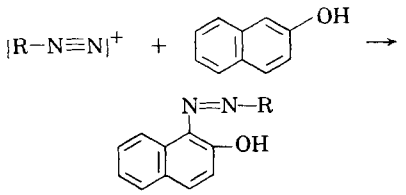
The current literature on the reactions of dyes in pharmaceutical dosage forms is rather limited as a result of the practice of discarding a dye if its characteristics in a particular system were not satisfactory. Formulators may soon find that they will no longer be able to replace dyes in dosage forms readily when they find that they are physically or chemically incompatible with some component of the composition. Instead, it will be necessary to determine the nature of the offending property and if possible, eliminate it.

Generally speaking, the colorants still available for use in pharmaceuticals can be divided into three major groups: synthetic dyes, lakes and pigments, and natural coloring principles. The basis for the distinction between dyes and pigments is a physical rather than a chemical property, with solubility usually employed as the criterion. Dyes are defined as colorants which are soluble in some commonly available liquid, such as water, alcohol, or oils (3). Those colorants which are essentially insoluble in such liquids or in any medium in which they are designed to be used are classified as pigments.

A specialized area of synthetic pigments of pharmaceutical interest is the class of lakes of the FD&C dyes. These insoluble materials are prepared from certified water-soluble dyes by combination with a basic aluminum or calcium radical and precipitation on a substrate of aluminum hydrate, thus forming an insoluble salt. In addition, there are numerous inorganic pigments such as titanium oxide, iron oxide, etc., which are completely insoluble in organic solvents and aqueous solutions. The constitution, properties, and biological significance of natural coloring principles have been the subject of an excellent review by Mayer (4), although such colors have been largely replaced by the certified synthetic colorants.

Synthetic Dyes.—As the list of certified synthetic colorants for pharmaceuticals threatens to become minimal, a consideration of the properties of those dyes remaining available should be undertaken. First, the properties of an ideal colorant for pharmaceuticals might be contemplated (5). These would include: (*a*) ability to withstand temperatures ranging from 10 to 110° or even higher, (*b*) must be stable within a pH range of 2–9, (*c*) must be stable to light over long intervals of exposure, (*d*) should be available in both an oil-soluble and water-soluble form, (*e*) should blend well with other colorants in various systems, (*f*) should resist oxidation and reduction, (*g*) color strength should be capable of standardization so that there is no batch to batch variation, and (*h*) the necessity of being without suspicion of carcinogenic activity.

Although there are currently no dyes that fulfill all of the above, many of these criteria can be met. Information concerning the chemical structures and physical properties of the certified dyes are available from numerous sources (5–13). In a paper prepared for the Perkin Centennial, Zuckerman (12) has discussed the structure and properties of present day certified colorants. From a chemical standpoint the certified FD&C colors fall into five classes: azo, triphenylmethane, indigoid, xanthene, and pyrazolone.



Azo dyes, however, comprise almost 90% of the total volume of certified colors used. A knowledge of their chemical structure can be employed to predict, to a fair degree, the physical properties of these colorants. The general formula for an azo dye is

$$R_1—N{=}N—R_2$$

R_1— is any aryl group

R_2— is a phenol, amine, or other group capable of coupling to a diazonium salt

The general coupling reaction involved in the formation of the finished dye would be (8)

Inskeep and Kretlow (14) have illustrated, in great detail, the general procedures for the preparation, purification, and blending of certified dyes of the azo type. The batch operation is carefully described in a flow sheet as well as through the use of structural formulas. It is pointed out that the presence of water solubilizing groups such as SO_3Na, COONa, and, to a lesser extent, the OH group, whether substituted on the diazonium component or the coupling component, increases the water solubility of the dye molecule. The absence of these groups gives molecular structures which exhibit true oil solubility. The manufacture of colorants of certified purity is a highly specialized branch of the dyestuff industry because extraordinary precautions and controls are necessary to eliminate objectionable side reaction products and metallic or other impurities. For example, the maximum amounts of lead and arsenic permissible are 10 and 1.4 p.p.m., respectively, in the FD&C colors and 20 and 2 p.p.m. for the D&C and Ext. D&C colors (15). The water, acids, alkalies, solvents, and intermediates used must all be the purest obtainable.

As noted by Zuckerman (12) the specific properties of a dye, such as fastness and chemical behavior, depend largely on the substituent groups. These groups are of two kinds: the chromophoric groups and the auxochromic or salt-forming groups such as the acidic or hydroxyl group. The chromophoric groups determine the chemical class to which the dye belongs and its oxidation or reduction potential. The auxochromic groups are largely responsible for the coloring properties and the action toward acids, alkalies, and light. An additional function of an auxochromic group is to stabilize the molecule so that the new molecular configuration has a greater resonance stabilization than the unsubstituted compound. This stabilization causes absorption in the longer wavelengths and results in a deepening of the color. Changes in dyes consisting either in complete or partial loss of color may occur for several reasons, which will be discussed under the heading of stability.

Since it is impossible to produce synthetic dyes commercially which consist of a single chemical entity, the importance of definitive analytical methods for the determination of these dyes is self-evident. The well established methods for the analysis of certified colors are given in "Official and Tentative Methods of Analysis of the Association of Official Agricultural Chemists" (16). However, incomplete and side reactions during synthesis normally produce substances other than the principle component. Also, certain extraneous materials may be introduced during the process of isolation of the pure dye. Research conducted in the color laboratories of the U. S. Food and Drug Administration as well as in the laboratories of dye manufacturers has established for the majority of FD&C colors: (*a*) their chemical structure, (*b*) the identity of the isomeric and homologous colors, and (*c*) the identity of colorless organic constituents.

As a result, rapid and accurate methods for the quantitative analysis of all organic constituents expected to be present in a dye are now available. This then permits interested regulatory agencies to describe each color accurately and to determine whether each batch submitted for certification is equivalent to the reference standard material previously approved.

Jones, *et al.* (17, 18), were able to separate and determine the pure dye content of samples of triphenylmethane colors by a stepwise synthesis and analysis of all components of all products of the reactions. They were further able to differentiate each of the isomers of all of the various dyes by a variable reference technique (19).

Several investigators (20–30) have isolated and identified intermediates produced in the preparation of FD&C dyestuffs. In particular, the work of Link (20) presents a general procedure by which dyestuffs can be examined for the presence of uncombined intermediates. The procedure involves a chromatographic separation followed by a spectrophotometric identification of the uncombined intermediates. A technique for the purification of FD&C Red No. 2 suitable for use as an analytical reference standard was also described by Link (21). Methods suitable for the detection of six subsidiary colors in FD&C Red No. 2 are also presented.

Jones, Harrow, and Heine (28) undertook a thorough investigation of the composition of FD&C Blue No. 2. This color is prepared commercially by sulfonating indigo. Each of the possible symmetrical sulfonated compounds was prepared in addition to various disulfonated products and a chromatographic method of

separating many of the products was developed. A spectrophotometric method which was developed was found to be a much more precise method than titration with standard titanium trichloride for determination of pure color in FD&C Blue No. 2.

Of the FD&C colorants, the one distinct chemical class remaining is found in FD&C Red No. 3, an iodofluorescein derivative. A thorough study of a closely related series, the bromofluoresceins, was conducted by Graichen and Molitor (29) in 1959. It can be expected, however, that the chemistry of the iodofluoresceins is practically identical with that of the bromofluoresceins. A total of at least 10 halogenated products theoretically could be expected under the conditions employed for the iodination of fluorescein.

Thus, information is now available on the chemistry of the certifiable color additives and their subsidiary products formed through secondary reactions. This information should be expected to contribute materially to the clarification of legislation designed to evaluate certifiable color additives of the FD&C series.

Pigments and Lakes.—Approval by the Food and Drug Administration in 1959 of certified lake pigments for pharmaceutical uses has considerably enlarged the utility of this class of colorants. Previously, only titanium dioxide, purified carbon black, and carmine were approved by the FDA for food, drug, and cosmetic use. This development results in a significant step forward for the pigment field. The general manufacturing details of pigment preparations, together with their properties, have been reviewed by Anstead (31). He also includes a summary of the requirements of colors for cosmetics including aspects of relevant legislation in Great Britain and the United States.

An excellent review of the chemistry and physics of organic pigments is provided by Pratt (34). Of particular note is a special chapter in which emphasis is placed on a new interpretation of the significance of physical structure of pigments as related to color. This factor is of fundamental importance in the use of nondissolved materials. With dyestuffs, consideration of the relationship between color and structure has been largely restricted to the basis of chemical or molecular structure. In pigment technology, in addition to chemical properties, a study and measurement of particle size and shape, aggregation, molecular space relationships, and surface conditions are essential for total understanding and utility of these materials. As there are many applications for these materials in the food, drug, and cosmetic fields, Powers (9) encouragingly states that inorganic pigments have excellent light fastness and complete insolubility in solvents and aqueous solutions. He notes that the most important pigments are the iron oxides, chrome oxide greens, ultramarine blues and pinks, and the carbon blacks. A summary of the properties of the above is supplied. Mattiello (11) has compiled a book describing the chemical compositions, manufacturing processes, properties, uses, and methods of identification of pigments. The various chapters have been written by recognized authorities in the field of protective coatings and pigments, with each section being prefaced by an excellent brief theoretical discussion.

Zuckerman (32) briefly describes the use of lake colors in and on food products and notes that application will surely be found in many areas in addition to their use in foods. Lake colors are odorless and tasteless and are resistant to migration due to their insolubility. Jablonski (10) has reviewed the use of pigments and lakes in food products. He notes that until recently only lakes prepared from animal or vegetable coloring matters achieved widespread usage. With the exception of the use of titanium dioxide in tablet coating, reports on the use of pigments in lakes in pharmaceutical products are sparse. Tucker and co-workers (33), however, have reported on tablet color coating with pigments.

With few exceptions the natural organic coloring matters find little use in the pharmaceutical field. A comprehensive review of the significant chemical and physical properties of the natural colorants is supplied by Mayer (4). Various authors (6, 9) have commented briefly on their use in the drug field and summarized their application properties.

STABILITY OF COLORANTS IN PHARMACEUTICAL SYSTEMS

Although the use of synthetic dyes for imparting color to medicinals is obviously widespread in the pharmaceutical industry, investigations into the stability and stabilization of colors in these products have, until recently, received little attention by pharmaceutical researchers. With a few notable exceptions, the literature on the use of colorants for pharmaceuticals is so scattered and incomplete as to offer little assistance to a worker in the field of color stability as far as industrial application is concerned. The photosensitivity of these dyes, when incorporated into various formulations, represents a formidable

problem. Though this is a generally recognized difficulty, a conspicuous lack of information still exists in the pharmaceutical literature concerning the influence of light and heat on color fastness. This lack of data can be ascribed to several factors, among which are: (*a*) the unavailability of a suitable exaggerated light stability cabinet, (*b*) the unavailability of appropriate analytical techniques for measurement of color changes under the various circumstances, (*c*) the common practice of discontinuing the use of a specific color when found unsuitable in a given formulation without determining the nature of the objectionable characteristics, and (*d*) the treatment of such data as confidential within a particular company.

Aspects of Photostability.—Approaches to predicting the stability of colorants have been based on both chemical and physical measurements. Since the principle mode of reduction of color intensity results from photochemical reactions, interested individuals have attempted to utilize various exaggerated light testing techniques in an effort to predict the degree of photosensitivity of dyes contained in their products. However, although it is known that tests of this nature have become more prevalent, few reports exist in the pharmaceutical literature concerning their use. This may be attributed to the fact that the methods employed were not completely satisfactory or were highly specific (35). Experiments performed by Arny, *et al.* (36, 37), disclosed the effects of sunlight and diffused light on various pharmaceutical ingredients when stored in several types of glass containers. Of all the commercially available glasses studied, the authors found that amber glass afforded the greatest protection.

Although there is some lack of information concerning the photostability of pharmaceuticals, there appears to be an abundance of data available on the influence of light on textiles, dyes, and pigments (38–47). The necessity of having a standard light source is well recognized in these fields.

The most readily available source of radiant energy is sunlight, but Hadfield (47) has thoroughly delineated the unsuitability of sunlight or daylight as a source of light in testing color stability. He points out that the radiation received from the sun is subject to wide variation both in total intensity and in distribution of energy. Because of this, exposure tests to sunlight result in marked differences in relative effect for samples exposed to this light source. It has been reported by Appel and Smith (43) that by limiting the exposure of samples to between 9 a. m. and 3 p. m. on clear days, the low intensity radiation and high atmospheric humidity occurring at intervals during continuous exposure is avoided. This, they indicate, yields data that have been shown to be generally reproducible at different times of the year and in different parts of the United States. Despite the above efforts at standardization of sunlight exposure, the findings of other investigators appears to be at variance with the findings of Appel and Smith.

Attempts to measure the energy of the sun's rays and to make exposures for a definite number of energy units were inadequate in that the following factors were not taken in consideration: (*a*) variation of sun intensity from season to season and area to area, (*b*) daily cycles of change in temperature and humidity, (*c*) variations in spectral character of radiation during time of exposure, and (*d*) the presence of atmospheric impurities (48). In an endeavor to concentrate the sun's rays and thereby decrease the time required for fading exposure, lenses were utilized, though unsuccessfully, because of the excessive heat developed (49). In order to control, diminish, or eliminate the effect of these variables, various artificial light sources have been developed with a spectral energy distribution intended to simulate that of direct sunlight. Sources such as carbon arcs (50, 51), mercury vapor lamps (52), fadeometers (39, 41, 44), and tungsten filament lamps (42, 45) have been used to determine the light stability of colored textiles, dyes, and pharmaceuticals susceptible to photochemical reaction.

Since most pharmaceutical preparations are usually stored in retail pharmacies, storage areas of a warehouse, homes, hospitals, and doctors' offices, the amount of light in the ultraviolet spectrum of sunlight that penetrates through the glass store front or window panes is substantially decreased because of absorption by the glass. Husa (58) indicated that ordinary glass absorbed the shorter ultraviolet light as well as the longer infrared found in sunlight. This would suggest that the decomposition caused by sunlight passing through glass would be due to visible light and/or the ultraviolet and infrared rays which are nearest in wavelength to visible light.

In a report by Esselen and Barnby (59), light intensities outside and inside retail stores were measured and compared. The data obtained indicate that the outdoor readings were over 400 times the average reading taken on typical store shelves exposed to light of normal intensity.

Pharmaceutical products are very seldom exposed to direct sunlight and when they are, it is for a relatively short period of time. As a result, it was felt that a high intensity light source which would closely simulate ordinary room illumination would be more suitable for the study of dosage forms (35). This type of light source should approximate more closely the light falling on products kept in usual storage areas. Several studies to be discussed subsequently employed the above-mentioned light source as a standard for testing.

Cabinets for housing a suitable light source, whatever its nature, are available in a multiplicity of designs. Numerous patents (53–57) have been issued for various installations depending upon the desired end use. The basic design consists of a housing to contain the sample at a fixed distance from a light source. In some instances provisions are made for humidity and/or temperature control while, in other cases, only the character of the radiation is regulated. The degree of control varies with the intended end use of the data obtained but, in almost all situations, an attempt is made to extrapolate the information derived to some extended time interval.

Chemical and Physical Stability Considerations.—Certain general statements can be made about the chemical and physical behavior of certified colorants in pharmaceutical systems. Changes in dyes resulting either in complete or partial loss, or in alteration of color, may occur for several reasons. Some of the more common causes for the color change are exposure to light, the action of oxidizing or reducing agents, and the action of acids or alkalies. Peacock (7) has tabulated data on the resistance of the certified colorants to a wide range of reactive agents and conditions. The summary gives an indication of dye resistance to sunlight, to organic and inorganic acids, alkalies and some metallic salts, and to oxidizing and reducing conditions.

Inskeep and Kretlow (14) have also summarized the relative stabilities of the FD&C colorants. They note that the degree of fastness of various synthetic dyes may vary with the dye itself, the nature and intensity of light, the amount of moisture present, and the vehicle in which the dye is employed. They have presented the following general information:

"*A common property of dyestuffs is their ability to take up hydrogen with the formation of colorless compounds. In nitro and azo dyes, amino compounds are produced, whereas other classes are converted into so-called leuco-compounds which contain two more atoms of hydrogen than the original dye from which they are derived. They are reconverted into the original dye on oxidation.*

"*Most of the certified colorants are very unstable in the presence of reducing agents. The same is true in the presence of oxidizing agents, although the red colors are slightly more stable than the others. The most common type of reduction encountered in the use of FD&C colors involves the action of a metal such as tin or iron in an acid medium. The acid acts on the metal, liberating hydrogen, which in turn reacts with the dye, to bring about a reduction. The result is a loss of color.*

"*The certified colorants vary considerably in their action towards acids and alkalies. FD&C Blue No. 2, for example, fades rapidly in an acid medium; FD&C Red No. 3 is completely precipitated and should not be used in any product where acid is present. The azo dyes are comparatively stable in weak acids, but some of them should not be used in a basic environment.*"

Evenson (60) has studied the effect of light on FD&C Red No. 3 and D&C Red No. 21. His study has shown that the addition of small amounts of FD&C Blue No. 2 greatly accelerates the fading of FD&C Red. No. 3 in solutions. As a result, he points out that care should be taken to select mixture components of approximately equal resistance to light, if possible.

Several studies involving pharmaceutical systems have been reported by Lachman and colleagues (61–66). One such investigation was conducted in an effort to determine the light stability of 10 certified water-soluble dyes when used in tablet dosage forms (62). No effort was made in the study to elucidate the specific fading mechanisms of the several colors; rather, an attempt was made to determine the relative stability of the colors under normal and exaggerated illumination. The relationship between fading and dye structures as well as fading and light intensity was discussed. The extent of dye fading beneath the surface of the tablet was also measured. The authors concluded that the fading rate is most rapid during the initial stages of irradiation. Of significance is the observation that the exaggeration of color fading produced by the intensified illumination source employed did not follow a particular pattern for the dyes studied.

In another study using identical exaggerated lighting conditions, Lachman (63) evaluated the relative light fastness of several water-soluble dyes and their corresponding lakes. Employing initial fading rate constants as criteria for de-

termining light fastness, the lakes studied exhibited less photostability than the dyes in the tablet systems studied. As an example of the variations in data that may result when different lighting systems are employed for exaggerated testing, Tucker (33) reported that enhanced light stability resulted from the use of lakes as colorants for pan coated tablets. There are no established standardized conditions for light stability testing in the pharmaceutical industry, and correlation of data is hardly possible. Thus, literature reports such as the aforementioned pair must necessarily be treated individually. It must also be remembered that the lakes were applied, in one instance, in conjunction with pan coating techniques and, in the other case, the lakes were blended directly into a granulation prior to compressing tablets.

In another study the influence of temperature and pH on the surface color and total dye content of tablets colored with certified dyes was investigated (66). Samples of tablets colored with three dyes and buffered at several pH levels were stored at elevated temperatures and tested for both residual dye content and surface fading. The results of the study disclosed no relationship between the fading at the surface of the tablets and the actual loss in colorant concentration at elevated temperatures.

The same authors have also evaluated the effect of ultraviolet absorbers on the photostability of colored tablets (65). These studies were performed under light sources simulating the spectral energy distribution of sunlight and normal and exaggerated room illumination. The use of the ultraviolet absorber was most effective against color fading in tablets exposed to simulated sunlight. Signore and Woodward (67) studied the stabilizing effects of ultraviolet absorbers such as 2-hydroxy-benzophenone derivatives on dyes in solution. They found that significant protection was afforded to selected dyes in 50% ethanol solutions irradiated in the presence of low concentrations of U.V. absorbing materials. However, U.V. absorbers do not universally protect all dyestuffs in solution as has been illustrated in papers by Hardy and Coleman (68) and Gantz and Sumner (69).

The protective influence of glass of various spectral transmission characteristics on the light-induced fading of colored tablets has been investigated by Swartz (64). The apparent rates of fading of the tablets irradiated through the various glass samples were determined following exposure of the tablets to intensified fluorescent illumination.

The observation that common pharmaceutical materials may react with dyes to promote fading in solution prompted Scott, *et al.* (70), to investigate the color loss of certified dyes in the presence of nonionic surfactants. The retention of color in aqueous buffered solutions containing certified dyes and nonionic surfactants was measured after 14 days storage at elevated temperatures. In all but four of the 30 systems examined, accelerated fading was noted over that obtained with solutions of the dye alone. The intensity of this effect was found to vary from one dye-surfactant system to another and was not generally predictable. Kuramoto and co-workers (71) determined the stability of FD&C Blue No. 2 in a buffered aqueous solution in the presence of several commonly employed pharmaceutical materials. They found that sugars such as dextrose, lactose, and sucrose increase the rate of fading, whereas sugar alcohols such as mannitol and sorbitol do not appreciably affect the rate. Numerous antioxidants were also tested in the system and found not to appreciably retard the fading. By means of phase studies using cloudpoint titration techniques, Lachman (72) studied the interaction between several quaternary ammonium compounds and certified dyes. It was demonstrated that three commonly employed cationic surfactants formed insoluble complexes with FD&C Red No. 1, FD&C Blue No.1, and D&C Yellow No. 10. Although the report was limited to data on only three certified dyes, the same phenomenon was found to occur with several other dyes.

Another study concerning itself with the mechanism of color fading in pharmaceutical formulations was presented by Garrett and Carper (73). This paper reported on the color stability of a liquid multi-sulfa preparation by kinetic investigation of the thermally accelerated degradation of the color. The colorant employed was a combination of FD&C Yellow No. 6 and D&C Red No. 33. The authors did not attempt to determine the actual mechanism of the reaction of the ingredients which were responsible for fading. They were principally interested in predicting the extended shelf color stability of a formulation in a brief period.

Though of less immediate value to workers in the pharmaceutical sciences, numerous reports have appeared in the literature of the textile and paper processing industries concerning dye stability. A group of the more pertinent of these will be commented upon in the following paragraphs.

A study of the oxidation of the azo dyes and

its relationship to light fading was carried out by Desai and Giles (74). They employed various oxidizing reagents including ceric sulfate, potassium dichromate, and hydrogen peroxide to disrupt the azo group in an effort to find if any correlation exists between resistance to oxidation and light fastness on textiles. However, following extensive experimental trials, the authors concluded that it seemed unlikely that a chemical agent could be found to fade dyes in the same manner as light exposure and thus be suitable for a rapid and reproducible screening test.

Atherton and Seltzer (75) attempted to correlate the fastness of dyes in cellulose acetate films to dye properties when deposited on textiles. They based their experiments on measurements made over the initial stages of the reaction in order to minimize the possibility of reactions between the dye and its decomposition products. The light source employed was an enclosed carbon arc projector. A series of simple monoazo dyes were selected because of their ease of synthesis, low light fastness, and colorless decomposition products. The results of these experiments did not permit the correlation hoped for. However, the workers were able to determine the influence of the chemical nature of substituent groups and their position relative to the azo linkage on the light fastness of the parent compound. This permitted them to propose a relationship between chemical structure and order of light fastness of these dyes under the specific conditions studied.

Other authors attempted to determine the influence of the substrate on the light fading of azo dyes and the influence of the physical state of the dyes upon their fastness properties in dyed textiles (76–79). Following a review of the data in every instance, only very limited correlations were possible. Desai and Vaidya (80) studied the action of light on certain triphenylmethane dyes, and by the use of both chemical and spetrophotometric methods were able to determine the photodecomposition products. They further showed that the same photochemical changes take place when the dyes are exposed to the action of different light sources. Various aspects of the fading of colored materials as a result of temperature, humidity, and light have been reviewed by Cunliffe (81), Morton (82), Taylor and Pracejus (83), and Barker (84). A review of the mechanisms of the free radical reactions which might take place in photosensitized oxidations of colorants in solutions has been reported by Weiss (85).

Rather than base the effects of light on dyes in solution on a systematic accumulation of practical data as has been done above, Bowen (86) has attempted to apply theoretical concepts in photochemistry to help clarify mechanisms in fading reactions. He has noted that many of the photo reactions of dyes have been interpreted as "electron transfer" reactions and suggests that experiments to elucidate some of the following properties would be helpful: "(*a*) precise measurements of the effects of oxygen (even in traces) on the photochemical change; (*b*) similar measurements with deliberately added oxidizing and reducing agents; (*c*) determinations of the temperature coefficient of photochemical reactions, without and with air present, to throw light on the nature of the processes limiting the efficiency; (*d*) examination of the effect of moisture on the reactions, in case liquid diffusion of substances should control the rate; (*e*) precise work on the detailed shapes of absorption bands of dyes both in solution and solid systems which might lead to a fuller understanding of the nature of the light absorbing process."

A more complete knowledge of the above should permit the active application of theory to the photodegradative processes of dyes.

APPLICATION PROPERTIES OF COLORANTS

It has been pointed out earlier in this report that quantitative data on the light and thermal stability of the certified dye is not readily available in published reports. Nevertheless, some information can be obtained from general reviews prepared by the various dye manufacturers (3, 6, 7) but these data are only qualitative in nature. Scott (70) has observed that the interactions between dyes and other pharmaceutical reagents leading to poor color stability in finished products have received little attention.

An excellent bibliography on color matching and its practical aspects has been prepared by Peacock (87). Color matching in the cosmetic industry is discussed by Stearns (88) who concludes that "color matching is very definitely an art, and the man who does color matching of cosmetics must be a highly skilled artisan." To give credence to this he states that there are 32 important factors involved in the judging of color effects, all interacting to various degrees.

The solubility properties of certified dyes are discussed in numerous trade articles. Upon observation of these values, variations in results that cannot be attributed exclusively to experimental error are sometimes found. Zuckerman

(89) determined that the maximum solubility of the dyes, at constant temperature, varied with with the quantity of excess solute and proceeded to develop a procedure for determining the maximum solubility of all the water-soluble FD&C colorants based on this.

An excellent review entitled, "Colour and Its Measurement" (90) has summarized many newer instrumental techniques of color measurement as applied to the textile industry. The bibliography contains 45 references in the general field of color perception, color application, and measurement.

THE REGULATION OF COLOR ADDITIVES

Following the discovery of mauve in 1856 by Sir William Perkin, the development of available colors with varied hues increased rapidly. For many years little attention was paid to the toxicology of these substances but by 1900 Congress was ready to appropriate funds to enable the Secretary of Agriculture to investigate the nature of "coloring matters" in order to establish the principles enabling their safe use in foods, drugs, and cosmetics. Before the passage of the Federal Food and Drug Act of 1906, seven colors were accepted as harmless and a voluntary system of certification based upon physiologic tests was set up. During the 32 years which elapsed before the new Food, Drug, and Cosmetic Act replaced the 1906 law, an additional 15 colors were certified for food, drug, and cosmetic use.

The 1938 Act provided more extensive and elaborate provisions for regulating the use of color additives with tests for toxicity, purity, stability, and local irritation. It also required that the structure of certified colors must be known and the purity determined by appropriate analytical methods. Certification was now divided into three classes: FD&C colors for foods, drugs, and cosmetics; D&C colors for drugs and cosmetics, and Ext. D&C colors for external use only.

Under the powers granted the FDA, decertification of previously approved colors has become increasingly frequent in recent years as more intensive pharmacological testing was applied to these substances. In addition, attitudes resulting from the controversy involving the safety of food additives were reflected in an increasingly critical and cautious attitude toward the use of color additives. In a report discussing Bill S2197 (Color Additive Amendments of 1959) Senator Hill (91) urged the replacement of the previous color additive regulations with the new "sound and uniform system for the listing of color additives of any kind which may be safely used in foods, drugs, or cosmetics subject, when necessary, to appropriate tolerance limitations and other conditions of use. . . ." Senator Hill was emphasizing the importance of the tolerance provision as an answer to a Supreme Court decision which defined the "harmless" principle (of the 1952 Act) as meaning harmless regardless of the quantity of the coal-tar color which is being used.

Williams (92), in analyzing from a legal point of view the color additive bills submitted to Congress, showed concern for the hazards associated with the procedures for listing and exempting safe color from certification. The absence of a practical jurisdictional test which would exclude from the statute colors known to be harmless contributed a burdensome character to the procedural requirements of the proposed legislation. Schramm (93), in a similar review of the bills before Congress in 1959, stated that the basic principles involved in these bills met the approval of the Certified Color Industry Committee. An objection of the Committee to the mandatory requirements for analytical methods as a condition for listing a color additive was resolved in the Senate bill on the basis of an industry and Department of Health, Education, and Welfare discussion. The Committee also objected to the specific inclusion of cancer since there was no logical reason to separate this pathology from other adverse physiological effects. Dohl (94), in discussing the proposed bills from the point of view of the pharmaceutical industry, while objecting to the Delaney Cancer Clause and to several less important aspects of the legislation, nevertheless supported the Senate bill as better than no legislation at all. Similar support, including the reminder that the pharmaceutical industry is accustomed to control, came from Goodrich (95).

On July 12, 1960, the Color Additive Amendments of 1960 became law and, following the expiration of a transitional period, all colors will become subject to uniform statutory rules. The disappearance of the term "coal tar colors" will not be mourned while its more inclusive replacement "color additives" must still find its place in the everyday vocabulary of pharmacy and the pharmaceutical industry. A section by section analysis of the new law has been published and should be very helpful to those responsible for conformance with the provisions of the law (96). Briefer commentaries (97, 98) reviewing the overall significance of the law have also made their appearance in literature.

Failure of the pharmaceutical industry to demonstrate the safety of D&C colors by 1963 will result in automatic decertification of these colors unless an extension is granted on the basis of studies initiated but not completed before the deadline. Many product development pharmacists and control chemists are of the opinion that permissible FD&C colors are inadequate for all pharmaceutical requirements. It is necessary to recognize the fact, and many pharmaceutical executives have not done so, that eliminating the use of colors in tablets, syrups, elixirs, etc., will not necessarily provide uniform, colorless, products. Variations in raw materials and intermediates are difficult or costly to control and lack of product uniformity will undoubtedly engender complaints. Significant protection against change in product appearance due to aging could also be provided by suitable coloring agents. The new color additives law regulates the production of pharmaceuticals in an important way and industry may find it advisable to invest in the acquisition of scientific information in order to assure compliance.

A remarkably thorough compilation and review of legislation regarding the available colorants for use in most of the nations of the world has been assembled by J. PlaDelfina (99, 100). In addition, this comprehensive report discusses the chemical structure and reactivity, toxicology, and pharmaceutical applications of all colorants available for both internal and external use. The review is appended by a series of outlines in the form of a catalog which summarizes and also completes the text making it useful for those not very familiar with the field. The six-column summary lists the chemical classification and structure, commercial and legal aspects, as well as pharmacologic data on all the material cited in the paper.

CONCLUSION

Research pharmacists and others concerned with the formulation of pharmaceutical products and the avoidance of confusion and errors in manufacturing and dispensing are dismayed and alarmed at the nonchalance with which many scientists and executives in the pharmaceutical industry have accepted recent decisions involving the decertification of important colorants. Any degree of reflection on the realities of a situation permitting only "colorless" or "naturally colored" pharmaceuticals, as has been blithely proposed by some, would bring into focus a host of new problems of disturbing significance. It is impossible to conceive of responsible individuals experienced in the development of pharmaceutical products who would solve problems at the expense of present or potential risk to patients. Scientists should, however, be prepared to fight off ill-conceived decisions based upon unknown fears or political advantages.

In spite of the lengthy history of the use of colorants in pharmaceuticals, a review of the literature brings out the fact that relatively little attention has been given to investigations of the behavior of colorants in pharmaceutical systems. Basic studies are needed in the field of chemical reactivity of colorants with other components of medications, the stability of individual or mixed colorants in varying environments, and the relative toxicity of color additives. As with all substances entering into biological systems, it is necessary to relate the quantity of agent administered with the response. Toxicology, like pharmacology, is dependent upon posology.

As is evident from this review, the research pharmacist planning investigations of the physical and chemical properties of colorants can lean upon the experiences of scientists in other fields whose experiments have yielded knowledge applicable to the use of such substances in drugs. The basic chemistry of dyestuffs, the application properties of colorants, and instrumentation for measuring color and color changes have been probed with concentrated intensity by workers in food processing, textiles, photography, and protective coating. The fruit of their labors provides a solid foundation for the development of needed knowledge in the formulation of pharmaceuticals.

Solid State Stability of Some Crystalline Vitamin A Compounds

By J. KEITH GUILLORY† and TAKERU HIGUCHI

Theoretical and experimental studies relating the relative stability of solid vitamin A derivatives to their melting points have shown that, in general, resistance toward degradation increases with fusion temperature. This is attributed to the part that crystal lattice energy plays in stabilizing these compounds, and is supported by the fact that the solution stabilities of the derivatives appear to be generally comparable. Of the several compounds studied, vitamin A benzhydrazone and vitamin A succinate triphenylguanidine salt exhibited the greatest stability.

THE PRESENT investigation has been concerned with the experimental examination of the relationship between fusion temperature and the rate of chemical degradation of certain susceptible solid drugs. Although it has been known that the stability of many solids is closely related to their melting points, rational application of this condition to stabilization of drugs has not been generally recognized by pharmaceutical investigators, and therefore has been quite limited. Specifically, several vitamin A derivatives of widely differing melting points have been prepared and their relative stability evaluated. The compounds studied in detail included vitamin A acetate, vitamin A benzhydrazone, vitamin A nicotinate, vitamin A phthalimido-N-acetate, vitamin A succinate triphenylguanidine salt, and vitamin A 3,4,5-trimethoxybenzoate.

The stability of organic compounds to degradation in the solid state is intimately related to the strength of the crystal lattice. Since the forces between molecules in a crystal are small compared with the energy required to break bonds, liquefaction normally occurs before degradation begins. As a general rule, reactions proceed at a much faster rate in liquids and in solution than in solids; consequently the melting point of a compound is a very important factor in determining stability.

The surfaces of higher melting crystals are a strong barrier to penetration of external agents responsible for degradation of chemicals in the dry state. The resistance of a crystalline compound to fusion can therefore be taken as a crude, but useful, index of its general stability.

Received April 20, 1961, from the School of Pharmacy, University of Wisconsin, Madison 6.
Accepted for publication June 26, 1961.
This study was supported in part by a grant from the Roche Laboratories, Nutley, N. J.
Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.
† Present address: School of Pharmacy, Washington State University, Pullman.

Past Work on Degradation of Solids.—Most studies on reactions which occur in the solid state have dealt with inorganic solids and, in particular, with oxidation taking place at the surface of metals. Nearly all organic compounds, including drugs, are apparently essentially stable within their crystalline structure. Degradation, when it is observed, usually occurs in the surface film phase. Bawn (1) points out that decomposition of solid explosives, for example, is usually accompanied by the formation of a liquid phase at temperatures below the normal melting point of the pure solid. As a consequence, there is a rapid increase in the reaction rate. In the absence of melting, the formation of product molecules is assumed to induce a strain in the crystal which produces cracks and thus forms fresh surfaces on which decomposition can occur. Degradation of explosives usually leads to the formation of gaseous products. The rate of the process can therefore be most conveniently followed by measuring the pressure developed in a constant volume system. A sigmoid shaped pressure-time curve is often obtained experimentally.

Wobbe and Noyes (2) studied the solid state decomposition of anhydrous oxalic acid into gaseous formic acid and carbon dioxide at temperatures just below its melting point. The reaction was again shown to occur largely on the surface of the crystals. When small amounts of solid were used, the reaction could be better represented by a zero-order than by a first-order equation. For large amounts of solid, the constants were always high, however.

Garrett (3), studying the solid state decomposition of aspirin anhydride, found that the degree of degradation could be qualitatively correlated with the amount of liquefaction in the samples at the various temperatures studied.

Micronization, drying, and avoidance of contact with alkali increased the thermal instability of the anhydride. The unusual observation that small crystals were more stable than larger ones was explained by the fact that the large crystals were probably solvates or contained trapped solvents.

Past Work on the Stability of Vitamin A.—Details of the early work on the stability of vitamin A, particularly in the form of oily concentrates, have been described elsewhere (4–6) and will not be discussed extensively here. Certain aspects of this work are, however, pertinent to the present investigation.

For many years after its isolation from fish liver sources no crystalline derivatives of vitamin A were available. It was not until 1935 that Hamano (7) succeeded in crystallizing the first derivative of the vitamin, vitamin A β-naphthoate. Vitamin A alcohol itself was not obtained in the form of solvent-free crystals until 1942. In 1942, Baxter and Robeson (8) prepared crystalline vitamin A acetate, vitamin A palmitate, and divitamin A succinate; and they studied the relative stability of these compounds in the solid state. Thin layers of the crystals were exposed to air at 5° in darkness. The percentage decomposition at various times was determined by the percentage decrease in the extinction coefficient. Vitamin A β-naphthoate was included in the stability study. The apparent order of stability of the compounds studied was: vitamin A acetate, vitamin A β-naphthoate, vitamin A palmitate, vitamin A succinate. The greater stability of vitamin A acetate was attributed to its crystal size. Apparently other factors were involved, however, for the authors could not explain with this hypothesis the exceptional stability of vitamin A β-naphthoate.

In recent years studies on the solid state stability of vitamin A and its compounds have been largely concerned with the effectiveness of various antioxidants. Some work has also been done on the preparation of protein complexes (9, 10), inclusion compounds (11, 12), and coatings (13–15). Few new crystalline derivatives of vitamin A have been reported.

The mechanism by which crystalline vitamin A compounds degrade has not yet been completely elucidated. This degradation is probably similar to the changes which occur in the drying of oils and in the polymerization of similar conjugated polyolefinic molecules. Two related types of reactions probably are involved: (*a*) free radical catalyzed autoxidative polymerization occurring at the surface of the crystal, and to as great a depth in the liquid film covering the crystal as oxygen can penetrate, and, less likely, (*b*) polymerization involving carbon-carbon linkages beyond the depth of penetration of oxygen.

Reinstein (16) has studied the degradation of vitamin A alcohol, vitamin A acetate, and vitamin A palmitate at 25° and 90° in heptane and ethanol, in the presence and in the absence of air. In the presence of air, the two esters degraded at similar rates, while the alcohol form decomposed approximately three times faster than the esters. The order of the reaction with respect to vitamin A was 1.3 to 1.5, indicating that very concentrated solutions lose vitamin A at a much faster rate than dilute solutions. When air was excluded, the rate of degradation was barely detectable, indicating that the degradation of vitamin A in heptane was essentially oxygen initiated.

EXPERIMENTAL PROCEDURE

Reagents.—Crystallize vitamin A alcohol was obtained by base-catalyzed hydrolysis of vitamin A acetate (Hoffmann-LaRoche). Benzhydrazide, potassium phthalimide, 1,2,3-triphenylguanidine, and dichloromethane were used as obtained (Eastman Organic Chemicals Co.). Chloroacetyl chloride and methyl formate (Eastman Organic Chemicals) were redistilled. Skellysolve A, Skellysolve B, and petroleum ether were used without purification. Manganese dioxide was obtained from General Metallic Oxides Co. All other solvents and chemicals were reagent grade.

Apparatus.—All ultraviolet spectra were determined in chloroform on a Cary recording spectrophotometer model 11MS. Infrared spectra were determined using a Beckman model IR-5 double-beam infrared spectrophotometer. Melting points were determined in capillary tubes, using a 3-inch immersion thermometer.

Analyses.—The microanalyses were performed by Dr. Stephen M. Nagy, Microchemical Laboratory, Massachusetts Institute of Technology.

Synthesis of Compounds

Vitamin A Benzhydrazone.—This compound precipitated when a solution of benzhydrazide in methanol was added to vitamin A aldehyde. The vitamin A aldehyde was prepared from vitamin A alcohol by oxidation with manganese dioxide, a method first used by Ball, *et al.* (17).

Activated manganese dioxide (28 Gm.) was added to a solution of 4 Gm. vitamin A alcohol in 40 ml. petroleum ether. The solution was agitated from time to time for 20 hours at room temperature. The ether solution was filtered off and evaporated to a yellow oil. Benzhydrazide (1.9 Gm.) dissolved in 50 ml. methanol was added to the vitamin A aldehyde. After a few minutes crystals formed in the solution. The crystals were filtered off, washed with petroleum ether, and recrystallized from methanol, m. p. 181–182°.

Anal.—Calcd. for $C_{27}H_{34}N_2O$: C, 80.5; H, 8.5; N, 7.0. Found: C, 78.9; H, 8.7; N, 7.1.

Vitamin A Nicotinate.—This ester was prepared by alcoholysis from Vitamin A alcohol and methyl nicotinate in Skellysolve B, with sodium methoxide as catalyst.

Crystalline vitamin A alcohol (18 Gm.) and crystalline methyl nicotinate (10 Gm.) were dissolved in 200 ml. Skellysolve B. Sodium methoxide (0.1 Gm.) was added and the mixture was heated at 60° for 2 hours. Skellysolve B was collected as it distilled in a Barrett trap, and fresh solvent was added to the reaction vessel as required. The flask was protected from light and moisture, and nitrogen was bubbled into the solution throughout the reaction. After the heating period the solution was extracted several times with water until the washings were neutral to litmus. The Skellysolve layer was dried over sodium sulfate, filtered, and refrigerated at 0°. Crystals formed in the solution overnight. The yield of vitamin A nicotinate was 8.5 Gm. An additional 4 Gm. of nicotinate was obtained from the mother liquor after concentration. Vitamin A nicotinate was recrystallized from methyl formate, m.p. 93–94°.

Anal.—Calcd. for $C_{26}H_{33}NO_2$: C, 79.7; H, 8.5; N, 3.6. Found: C, 77.1; H, 8.2; N, 3.8.

Vitamin A Phthalimido-N-acetate.—Vitamin A chloroacetate and potassium phthalimide afforded this compound in dimethylformamide.

Vitamin A chloroacetate was prepared by a modification of the procedure of Baxter and Robeson (8) for preparing esters of vitamin A from acid chlorides. Chloroacetyl chloride (4 Gm.) dissolved in 50 ml. dichloromethane was added dropwise from a dropping funnel into a solution of vitamin A alcohol (10 Gm.) in 100 ml. dichloromethane and 30 ml. pyridine. Nitrogen was bubbled into the solution throughout the reaction, and the mixture was kept at 0–5°. After the acid chloride was added, the solution was stored in the dark at room temperature for 2 hours. A saturated aqueous solution of oxalic acid was added and the solution was extracted with petroleum ether. After several washings with oxalic acid solution the ether layer was washed with water until neutral to litmus, then dried over sodium sulfate. The solvent was removed under reduced pressure and nitrogen, and potassium phthalimide (3 Gm.) dissolved in 50 ml. dimethylformamide was added. The solution was stored in the dark at room temperature for 12 hours. Water (100 ml.) was added, and the solution was extracted with ethyl ether. The ether layer was washed several times with water, then with 5% sodium hydroxide solution, and finally with water again, until neutral to litmus. The ether solution was dried over sodium sulfate, filtered, and refrigerated at 0°. Vitamin A phthalimido-N-acetate crystallized from the ether solution was filtered off and recrystallized from anhydrous ethyl ether, m.p. 111–112°.

Anal.—Calcd. for $C_{30}H_{35}NO_4$: C, 76.1; H, 7.5; N, 3.0. Found: C, 75.8; H, 7.6; N, 3.4.

Vitamin A Succinate Triphenylguanidine Salt.—Vitamin A succinate half ester was prepared by heating vitamin A alcohol and succinic anhydride in pyridine. 1,2,3-Triphenylguanidine was added to the ester in saturated ether solution and the salt precipitated.

Vitamin A alcohol (11.5 Gm.) and succinic anhydride (4.0 Gm.) were dissolved in 50 ml. pyridine in a flask protected from light. The solution was heated at 75° for 1 hour. Nitrogen was bubbled through the solution throughout the reaction while the mixture was cooled to room temperature. The pyridine solution was transferred to a low-actinic separator and 50 ml. petroleum ether was added. The ether solution was extracted four times with 75-ml. portions of saturated aqueous oxalic acid solution, then washed with distilled water until washings were neutral to litmus.

Five per cent sodium hydroxide (40 ml.) was added in 10-ml. portions with shaking. The ether layer contained unreacted vitamin A alcohol and was discarded, while the aqueous layer contained the sodium salt of vitamin A succinate. This was washed four times with 50-ml. portions of petroleum ether, which were discarded. The aqueous layer was acidified with saturated oxalic acid solution, and the vitamin A succinate was taken up with 50 ml. petroleum ether. The ether layer was washed again with 50-ml. portions of distilled water until neutral. It was then dried over anhydrous sodium sulfate and filtered. The ether solution was evaporated to a yellow oil by distillation from a 40° water bath under reduced pressure and nitrogen. The product obtained (13 Gm.) had an ester peak in the infrared at 5.81 μ. There was no alcohol peak.

Triphenylguanidine (4 Gm.) dissolved in 125 ml. anhydrous ether was added to 5 Gm. vitamin A succinate dissolved in 25 ml. ethyl ether. A white precipitate formed within 2 minutes at room temperature. After 15 minutes the precipitate was filtered off, washed several times with anhydrous ether, then dried in a vacuum desiccator, m.p. 140–140.5°. Vitamin A succinate triphenylguanidine salt was recrystallized from methyl formate without change in melting point.

Anal.—Calcd. for $C_{43}H_{51}N_3O_4$: C, 76.6; H, 7.6; N, 6.2. Found: C, 75.9; H, 8.0; N, 6.2.

Vitamin A 3,4,5-Trimethoxybenzoate.—This ester was prepared in the same way as vitamin A nicotinate, i. e., by alcoholysis from vitamin A alcohol and methyl-3,4,5-trimethoxybenzoate in Skellysolve B, with sodium methoxide as catalyst.

When crystals of vitamin A 3,4,5-trimethoxybenzoate were obtained from the Skellysolve B solution from which they were crystallized, they were washed with Skellysolve A, then recrystallized from Skellysolve B, m.p. 85–86°.

Anal.—Calcd. for $C_{30}H_{40}O_5$: C, 75.0; H, 8.4. Found: C, 75.0; H, 8.2.

Stability Studies

Solid State Studies.—Samples of 3×10^{-5} moles of each crystalline vitamin A compound were weighed into 1-dr. vials. The vials, open to air, were placed in a thermostated oven at 50 ± 1°. At intervals, sample vials were withdrawn and their contents transferred quantitatively into 100-ml. volumetric flasks. Samples of vitamin A nicotinate, phthalimido-N-acetate, succinate triphenylguanidine salt, 3,4,5-trimethoxybenzoate, and acetate were scanned in the ultraviolet region from 400 to approximately 280 mμ. All these compounds exhibited a peak at 333 mμ in chloroform, the only readily available solvent in which all the derivatives

were soluble. Vitamin A benzhydrazone solutions were scanned in the visible region, from 500 to 350 mμ. The vitamin A benzhydrazone peak was at 398 mμ. As degradation proceeded, the decrease in height of the respective peaks was noted.

Solution Studies.—Samples of each vitamin A compound were dissolved in chloroform, and aliquots containing 4×10^{-4} moles/L. were pipetted into 100-ml. volumetric flasks. The flasks were stored open to air in a dark cabinet. Periodically samples were removed, the proper dilution made, and the samples analyzed in the same way as in the case of the solid state studies.

RESULTS AND DISCUSSION

For the purpose of the present investigation the synthesis of a large number of derivatives was attempted. These derivatives are listed in Table I. Because of the extreme susceptibility of vitamin A to isomerization, polymerization, dehydration, and other chemical changes, these attempts led, in many instances, to reaction products contaminated with side products. Many of the derivatives successfully prepared were hygroscopic and, therefore, unsuitable for the planned studies. Stability investigations were limited to those compounds, marked with a superscript *a* in Table I, which were recoverable as sharply melting, nonhygroscopic crystals.

Relative Stability of the Derivatives in the Solid State

Results of studies on the relative stabilities of several vitamin A derivatives in the solid state are shown in Fig. 1. The data collected were based on spectrophotometric determinations of the absorption peak in the ultraviolet of separate solid samples kept for varying periods of time at 50°. Since there was a loss of less than 33% of the vitamin during the period of study, it is presumed that the data provide a fair representation of the stabilities of these derivatives.

No serious attempt was made to control the size of the crystals employed in these studies. The compounds, listed in order of decreasing crystal size were: vitamin A nicotinate, vitamin A acetate, vitamin A 3,4,5-trimethoxybenzoate, vitamin A phthalimido-N-acetate, vitamin A benzhydrazone, and vitamin A succinate triphenylguanidine salt. No marked correlation is apparent between crystal size and stability for these compounds, as shown in Fig. 1.

In the discussion of possible mechanisms of degradation of vitamin A it was postulated that degradation probably occurs almost exclusively in a liquid film at the surface of the crystal. A difference in reactivity of substances in the solid and liquid state is to be expected since there is a difference in internal energy between the two states equal to the latent heat of fusion (1). The relative amount of material in the liquid state may be expected in these instances to determine, in some large measure, the rate of degradation. The fraction of material in the liquid state is related to the melting point of the pure crystalline solid by the following equation

$$\ln x_l = \frac{-L_f}{R}\left(\frac{1}{T} - \frac{1}{T_m}\right)$$

where x_l is the mole fraction of the solvent, here the liquid phase, L_f is the molar heat of fusion, R is the gas constant, and T_m is the melting point of the pure solid.

It would appear for these systems then, that the relative rates of degradation of series of similar solid derivatives measured at any temperature, T, would be such that the logarithm of the rates would be, to a first approximation, a linear function of the reciprocal of their melting points. This would assume, of course, that the heat of fusion changes relatively slowly compared with $(T_m - T)$. That this general relation does, in fact, hold for the present situation is evident from Fig. 2.

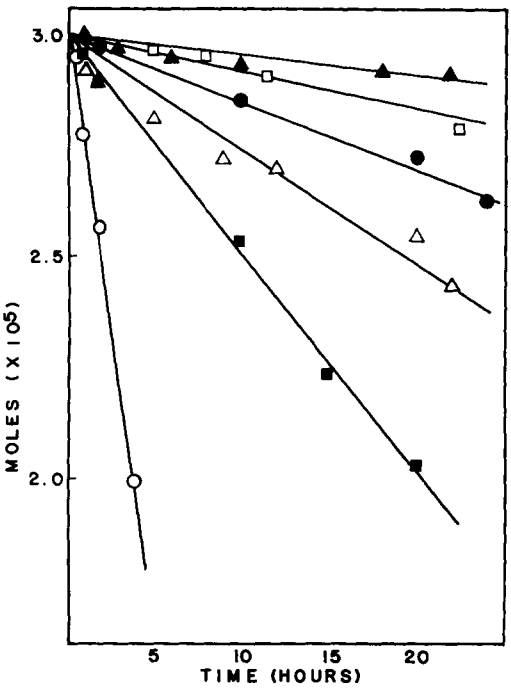

Fig. 1.—Solid state degradation of vitamin A compounds at 50°. ▲ Vitamin A benzhydrazone, m.p. 181–182°; □ vitamin A succinate triphenylguanidine salt, m.p. 140–140.5°; ●, vitamin A 3,4,5-trimethoxybenzoate, m.p. 85–86°; △ vitamin A nicotinate, m.p. 93–94°; ■ vitamin A phthalimido-N-acetate, m.p. 111–112°; ○ vitamin A acetate, m.p. 57–58°.

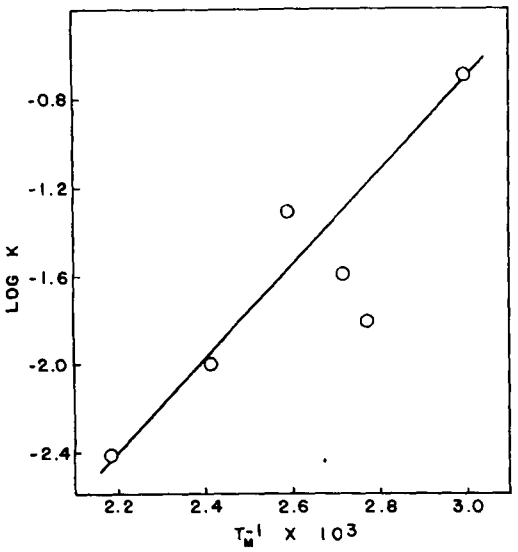

Fig. 2.—Relationship between zero-order rate constant and melting point for vitamin A derivatives.

From the slope of the line in this plot, an approximate mean value of 10 Kcal./mole is obtained for the compounds employed in this study. The heats of fusion of these vitamin A derivatives have not been determined experimentally, but they can be expected to be in the range of 10–18 Kcal./mole by comparison with similar compounds. This is in reasonable agreement with the mean value indicated by the slope and, therefore, supports the general line of reasoning presented above.

All points obviously cannot be expected to fall consistently on the average line in plots such as that shown in Fig. 2. Indeed, the effects of such uncontrolled factors as particle size, relative purity, and presence of catalytic species would also strongly influence the relative rates of degradation. The nature of the derivatives certainly must have some effect. It would appear, for example, that the greater stability of vitamin A 3,4,5-trimethoxybenzoate may be related to the fact that the acyl portion of the molecule may impart some free radical scavenging property to the whole molecule. This is suggested by the behavior of the ester in solution. The incorporation of even a mild antioxidant into the vitamin A molecule should increase its stability considerably.

None of the derivatives tested showed an appreciable induction period before degradation. Induction periods are often observed in reactions which proceed by free radical mechanisms. In such systems, nucleation is often a slow process, and some time elapses before foci of initiation reactions are developed. Many free radical processes show no induction period however, due to the reactivity of the molecules, involved.

Relative Stability of the Derivatives in Solution

The solution stabilities of the several vitamin A derivatives would not be expected to differ appreciably, particularly if the dissimilar portions of the molecule do not participate significantly in any free radical reactions. This is borne out in the data presented in Fig. 3.

These results were obtained in chloroform solution at room temperature. Measurements were carried out on solutions of essentially the same molar concentration since polymerization reactions have been shown to be approximately 1.5 order with respect to vitamin A (16). The pertinent measurements were limited to the initial stages of degradation just as they were in the case of the solid state study.

In contrast to its behavior in the solid state, vitamin A acetate appears to exhibit stability in solution comparable to that of other esters. The stabilizing effect of the strong lattice, which is apparently an important factor in determining the relative stability of the compounds in the solid state is, of course, no longer effective in solution. In fact, five of the compounds studied showed almost parallel decomposition rates. This finding appears to support the contention that the stability of compounds in the solid state is directly related to the strength of the crystal lattice.

The unusual stability of vitamin A benzhydrazone in solution is probably a reflection of its different structure. This difference in structure was not important in the solid state studies, where the principal degradative routes are probably autoxidation and polymerization; but in solution it becomes a determining factor in stability.

In solution, two reactions, in addition to autoxidation and polymerization, appear to participate in the degradation of vitamin A compounds. Isomerization of the polyolefin and formation of anhydro-

vitamin A are indicated in the ultraviolet spectra of partially degraded samples. Both reactions are associated with the double bond system of the molecule. Vitamin A benzhydrazone has an additional double bond in conjugation with the double bonds in the vitamin A carbon chain. This additional double bond probably greatly influences the reactivity of the compound to isomerization and anhydrovitamin A formation.

PHARMACEUTICAL SIGNIFICANCE

It is likely, on the basis of present findings, that in a series of vitamin A derivatives, the compound having the highest melting point will be the most stable, all other factors being equal. Stability is not, however, the only criterion employed in selecting a vitamin A derivative for use in solid formulations. Equally important to the manufacturer and user of vitamin A products is the biological activity, or "availability," of the compound. Biological availability of many compounds is determined by the solubility of the substances in water and in fats and oils.

The same equation which was used to describe the influence of the melting point of a compound on its stability in the solid state can be used to correlate solubility with melting point. From this equation it is evident that for compounds having similar molar heats of fusion, those with lower melting points will have the higher solubilities. Thus, if all other factors are equal, compounds with high melting points will have lower solubilities, and hence, frequently lower biological availabilities.

The conclusions reached in this study with regard to vitamin A may also be applied to other unstable compounds. Pharmaceutical chemists have applied their energies toward the goal of increasing the solubility of compounds and of improving their taste by chemical modification. The suggested approach of using chemical alteration to provide derivatives having high melting points and hence, greater stability, should also prove useful in those instances where drug degradation poses a serious problem.

Discoloration of Tablets Containing Amines and Lactose

By ROBERT A. CASTELLO and ALBERT M. MATTOCKS

It has been noted by several workers that tablets of amine salts combined with lactose darken in color with aging, and this problem has been investigated. Results show that the darkening is due to a reaction occurring in the presence of amine base and not in the presence of the salt. The reaction in tablets can be accelerated with elevated temperature and high humidity. The release of free base from the amine salt is shown to be due to reaction of the alkaline lubricant, such as magnesium stearate, which removes hydrogen ion with the formation of stearic acid, furnishing an alkaline medium in the adsorbed moisture. The change in pH with time was recorded to illustrate the effects occurring in tablets. The use of neutral or acidic lubricants, such as glyceryl monostearate or stearic acid, prevents the discoloration from occurring. These findings are thought to be applicable to any combination of amine salt and lactose.

THOUGH lactose has long been used as a tablet excipient, the recent finding that spray-dried lactose can be compressed without granulation has greatly increased the use of this material in tablet-making. This has made more important the recognition and avoidance of incompatibilities of lactose, combinations with amines being, perhaps, the one most commonly encountered.

A number of workers have found that tablets of amine salts combined with lactose as a filler have discolored slowly on storage to become tan in color. The intensity of color generally has been dependent on the amount of amine present and the humidity and time of storage, 6 months often being required for the discoloration to be distinct. It is of concern to learn whether the reaction occurring involves decomposition of the active ingredients, the lactose, or both, and how this reaction may be prevented. For these purposes the work presented in this paper was undertaken. Amphetamine sulfate was selected as the amine salt for most of this work.

EXPERIMENTAL

Materials Used.—Spray-dried lactose,[1] amphetamine sulfate, and various lubricants and excipients used were of U.S.P., N.F., or pharmaceutical grade. All chemicals used were of reagent grade.

A series of tablets were prepared of lactose with a relatively high percentage of amphetamine sulfate and with various lubricants, the combinations being selected so as to determine the ingredients necessary for reaction. Tablets were placed on watch glasses in a humidity cabinet at 40° and 85% relative humidity, conditions previously found to cause distinct discoloration in a commercial tablet in 1–2 days. Results are given in Table I.

Received April 28, 1961 from the College of Pharmacy, University of Michigan, Ann Arbor.

Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.

[1] Western Condensing Co., Appleton, Wis.

These results indicated several possibilities for reaction: (*a*) the free amine may be necessary for reaction, in which case the reaction may occur between the amine and lactose, or the free base may simply be undergoing alkaline oxidation, (*b*) the reaction may be a general base-catalyzed reaction of lactose.

To demonstrate clearly the alkalizing effects of the lubricants, excess amounts of lubricant (3%) were added to a 1% solution of amphetamine sulfate, the mixture was stirred continuously, and the pH was recorded over a period of several hours. Curves of pH *vs.* time are shown in Fig. 1.

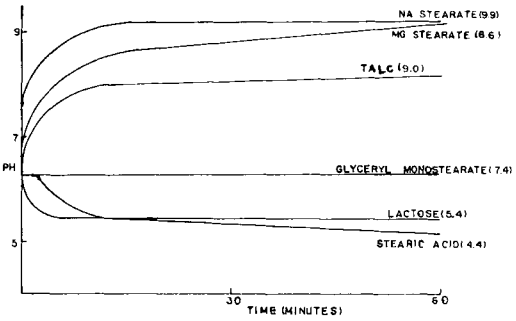

Fig. 1.—Effect of lubricants on solutions of amphetamine sulfate. Figures in parentheses are pH of suspensions of lubricants alone.

From Fig. 1 it is seen that the substances promoting discoloration, sodium stearate, magnesium stearate, and talc shifted the pH of the solution from 6.3 to values well on the alkaline side.

Results to this point indicated that the discoloration reaction required moisture, and it was concluded that the possibility of occurrence of reaction could be predicted from results with solutions. The use of solutions allowed observations to be made more quickly with discoloration being more distinct.

Results obtained with a series of solutions are shown in Table II. These data demonstrate that if an amine base or other alkali is present, the discoloration occurs. Further, it is seen that discoloration occurs only in the presence of lactose. Thus, it is clear that the discoloration is a base-catalyzed reaction of lactose.

TABLE I.—DISCOLORATION OF AMINE-LACTOSE TABLETS AFTER 48 HOURS AT 40° AND 85% RELATIVE HUMIDITY

Amine	Lubricant	Visual Observation
Amphetamine SO_4 10%	Mg Stearate 1%	Discoloration
Amphetamine SO_4 10%	Na Stearate 1%	Discoloration
Amphetamine SO_4 10%	Talc 2%	Discoloration
Amphetamine SO_4 10%	Stearic acid 1%	No discoloration
Amphetamine SO_4 10%	Glyceryl monostearate 1%	No discoloration
Amphetamine SO_4 10%	None	No discoloration
Amphetamine base 10%	None	Strong discoloration

TABLE II.—DISCOLORATION OF AQUEOUS SOLUTIONS AFTER 48 HOURS AT 60°

	Components		
Amine	Lactose, %	Other	Visual Observations
Amphetamine SO_4	10	...	No discoloration
.....	10	...	No discoloration
Amphetamine base, 1%	..	...	No discoloration
Amphetamine base, 1%	10	...	Severe discoloration
Ammonia buffer pH 9.5	10	...	Slight discoloration
.....	10	NaOH, 1%	Severe discoloration
.....	10	Mg stearate, 3%	No discoloration
Amphetamine SO_4, 1%	10	Mg stearate, 3%	Severe discoloration
Desoxyephedrine HCl, 1%	10	...	No discoloration
Desoxyephedrine base, 1%	10	...	Severe discoloration
Desoxyephedrine HCl, 1%	10	Mg stearate, 3%	Severe discoloration

The fact that the reaction product is from lactose alone and does not contain amine was substantiated by extraction and examination of the colored material. A solution of lactose, 10%, and amphetamine base, 1%, was allowed to react at 60° for several days, and the colored material was extracted with *n*-butanol. The butanol solution was washed thoroughly with water, dilute hydrochloric acid, and again with water, little or none of the color being removed in the washings. The butanol solution was then dried over anhydrous sodium sulfate and evaporated to leave a dark, tarry residue of the colored product. This material could not be recrystallized but was found to be free of nitrogen. Treatment with phenylhydrazine yielded yellowish crystals, recrystallized from methanol-water, which melted at 186–188°. This derivative has not yet been identified.

DISCUSSION

Reactions of carbohydrates with amines are well known and have been reviewed by Pigman (1). It has been found that reactions occur with aldehyde groups of open chain forms of the carbohydrates to form Schiff bases, as well as with ring forms to produce glycosylamines or N-glycosides. The reaction causing formation of a colored product, however, is more likely the browning reaction described by Maillard in 1912 (2). Beacham and Dull (3) investigated the browning of glucose, 2,3,4,6-tetramethyl-D-glucose, glyceric aldehyde, glycoaldehyde, and a number of glycoaldehyde ethers in the presence of amines. They observed that the susceptibility to browning of the D-glycosyl derivatives of the various amines was directly proportional to the basic strength of the amine. From the work of Mitts and Hixon (4) it is seen that the glucosyl derivatives of the more basic amines were most highly dissociated in aqueous solution, while those amines which formed condensation products resistant to hydrolysis did not readily cause browning. The amine derivatives of glyceric aldehyde and glycoaldehyde browned readily, indicating that furfurals are not necessary intermediates in the browning reaction. Derivatives formed from etherified glycoaldehyde and 2,3,4,6-tetramethylglucose were resistant to browning, supporting the necessity of the α-hydroxyl group in the reaction. This was in agreement with Hurd and Kelso (5) who reported that 2,3,4-tridesoxyaldopentose did not brown in the presence of glycine while 3,4-didesoxyaldopentose did. Results of these workers indicate that although a reaction of sugar with amine may be an intermediate step, it is not a necessary step in the browning reaction.

The reaction occurring between the amine salt and the basic lubricants, sodium stearate for example, may be postulated as

$$RN^+H_3 = RNH_2 + H^+ \qquad \text{(Eq. 1)}$$

$$\text{Stearate}^- + H^+ = \text{HStearate} \qquad \text{(Eq. 2)}$$

$$RN^+H_3 + \text{Stearate}^- = RNH_2 + \text{HStearate} \qquad \text{(Eq. 3)}$$

In the reaction mixture excess stearate is available; therefore, the alkali stearate is maintained at saturation. The reaction causes the solution to become saturated with stearic acid, as well, providing sufficient hydrogen ion is released from the amine salt. The equilibrium pH of the mixture may be approximated by the Henderson-Hasselbalch equation

$$\text{pH} = \text{pKa}_{(\text{HStearate})} + \log\left(\frac{\text{Stearate}^-}{\text{HStearate}}\right) \qquad \text{(Eq. 4)}$$

The theoretical value calculated by Eq. 4 was 8.49, which does not agree with the observed value of 9.2 for the sodium stearate mixture (see Fig. 1). It was felt, therefore, that either the proposed mechanism was incorrect or the pH measurements of the mixture were in error. It was noted that Jenny, *et al.* (6), reported the development of a liquid junction potential when measuring the pH of slurries and colloidal systems. This potential was said to be due

to a change in transference numbers of the potassium and chloride ions in the solution being measured. They demonstrated this effect by observing a potential drop across two calomel electrodes, one immersed in the suspension, the other in the supernatant liquid.

To eliminate this error, an equilibrium mixture of amphetamine sulfate and sodium stearate was centrifuged to remove the suspended material. The pH was again determined and found to be 8.6, which is in reasonable agreement with the calculated value, 8.49, from Eq. 4.

From these results it is proposed that Eq. 3 is descriptive of the system, and that the role of basic lubricants is the removal of hydrogen ion to promote the base-catalyzed browning of lactose. These findings coupled with later tests using inorganic alkalies indicate that the reaction is a general base-catalyzed reaction and not limited to amine bases.

It should be noted that the pH values shown in Fig. 1 are those of suspensions and contain the errors discussed above.

Results of this work furnish a practical means for predicting discoloration of tablets containing lactose with a few short-term tests. It is suggested that a new formulation be tested simply by preparing a solution or slurry of the ingredients, placing it in a bath at 60° for 2 or 3 days, and then observing the color. In this way one can determine whether the formulation is satisfactory before preparing tablets. Also, it is demonstrated that lactose should not be utilized in combination with bases, and when lactose is combined with amine salts, alkali stearates and talc should be avoided.

Synthesis of α- and β-Amino Ketone Analogs of Amino Acids as Antibacterial Agents

By SHU-SING CHENG†, SIGURDUR JONSSON‡, and FRED T. SEMENIUK

α- and β-Amino ketone analogs of amino acids were synthesized as potential antagonists of amino acids in microbial metabolism. The hypothetical mechanism of antibacterial activity for certain analogs is proposed. The successful use of organocadmium reagents for the synthesis of the aliphatic and aromatic series of α- as well as β-amino ketones indicates a wider scope of applicability than by the method of Dakin-West or by Friedel-Crafts acylation. These series of compounds show antimicrobial activity *in vitro*.

THE ANTIBACTERIAL activity (1) reported for β-amino ketone analogs of β-alanine suggested that α-amino ketone analogs of α-amino acids might possess similar activity. Due to the structural similarity between amino ketone analogs and the natural amino acids, one may assume that these analogs function as antagonists to amino acids, thus interfering with biochemical reactions in which individual amino acids or related peptides participate.

The cell walls of most Gram-positive bacteria consist primarily of components linked together as the following sequence: 3-O-carboxyethyl-hexosamine-*dl*-alanine-*d*-glutamic acid *l*-lysine-*dl*-alanine-*dl*-alanine (2). It could be assumed that an amino ketone analog of α-alanine would interfere with the formation of this peculiar amino-sugar peptide, thus inhibiting the cell wall synthesis. Many species of bacteria are able to grow on simple media containing ammonium and other inorganic salts, plus a single organic carbon source such as glucose. Some species require the addition of certain amino acids, simple peptides, and vitamins for growth. It is obvious that many bacteria can synthesize a majority of amino acids from ammonium salt and glucose. Two ways are recognized by which a bacterium can assimilate ammonia and convert it to α-amino groups in amino acids. These are the fumarate and the α-ketoglutarate pathways (3). The fumarate pathway is dependent upon a condensation reaction between fumaric acid and ammonia to yield aspartic acid. The α-ketoglutarate pathway is

based upon a reaction involving α-ketoglutarate and ammonia, the product being *l*-glutamic acid. Both aspartic and glutamic acids can serve as an amino group "pool" from which various amino acids are derived through transamination reaction between the pool and a variety of α-keto acids under the catalysis of transaminases. It follows that amino ketone analogs of aspartic acid or glutamic acid would block the formation of most amino acids.

Glycine combines with cysteine and glutamic acid to yield a tripeptide, γ-glutamylcysteinylglycine (glutathione). Glutathione functions as an important prosthetic group in the enzyme glyceraldehyde-3-phosphate dehydrogenase (4) which catalyzes the dehydrogenation and phosphorylysis of glyceraldehyde-3-phosphate, thus converting it to 1,3-diphosphoglyceric acid in the anaerobic breakdown of glucose (5). The amino ketone analogs, H_2NCH_2COR, of glycine conceivably might condense with cystein and glutamic acid to form a pseudo tripeptide, $HOOCCH(NH_2)CH_2CH_2CONHCH(CH_2SH)CONHCH_2COR$, with a ketone fragment instead of a carboxyl group at one end of the peptide chain. This analog of glutathione might compete with glutathione for the enzyme glyceraldehyde-3-phosphate dehydrogenase. In this fashion, the conversion of glyceraldehyde-3-phosphate to 1,3-diphospho-glyceric acid is preventable, and the microbial utilization of glucose may be interrupted. Phenylalanine, tyrosine, and leucine have been shown to be essential amino acids for the growth of psittacosis virus in chick embryo tissue (6). Presumably, amino ketone analogs of these amino acids might inhibit the growth of this virus. In addition to the proposed hypothetical mechanism for the antibacterial activity of each particular amino acid, the amino ketone analogs might interfere with peptide formation in protein synthesis in general.

Most of the aliphatic and aromatic amino ketone analogs of glycine, α-alanine, leucine, phenylalanine, tyrosine, and aspartic acid were synthesized by the hydrolysis of acylamido or phthalimido ketones obtained by the Dakin-West method or by Friedel-Crafts acylation, respectively. The heterocyclic β-aminoethyl ke-

[a] Analyses by Weiler and Strauss, Oxford, England.

tone analogs of β-alanine were synthesized by the hydrolysis of phthalimido ketones obtained from the condensation of thiophene or furan and β-phthalimido-propionic acid under the catalysis of phosphorus pentoxide. These heterocyclic analogs have not been reported previously.

The adaptation of organocadmium reagent by Cheng and Jonsson (1) for the preparation of alkyl β-aminoethyl ketones proved feasible. It therefore seemed of some interest to study the possibility of utilizing this reagent for the preparation of α-amino ketone analogs of amino acids.

The above mentioned amino ketone analogs were prepared as summarized by the reaction schemes. In scheme I, the aliphatic series of α-amino ketones are prepared by the hydrolysis of acylamido ketones, obtained conveniently by heating an α-amino acid with an aliphatic acid anhydride in pyridine according to Dakin and West (7). Since excessive amounts of acid anhydride are required for the formation of the acylamido ketone, the high cost of the higher member acid anhydride would render the preparation of acylamido ketone impractical. Furthermore, alkyl aminomethyl ketones are not attainable by the treatment of glycine with acid anhydride in pyridine. Glycine is subject to decomposition by the action of acetic anhydride and its higher homologs after a short period of heating in pyridine. These difficulties encountered in the synthesis of amino ketone analogs of α-amino acids by the Dakin-West method were overcome by the use of organocadmium reagent as illustrated in scheme IV.

In scheme III, the aromatic series of α-amino ketones are prepared by the hydrolysis of phthalimido ketones obtained from the condensation of phthalimidoacyl chlorides and aromatic hydrocarbons under the catalysis of anhydrous aluminum chloride according to Friedel-Crafts acylation reaction. The yields range from 60 to 80%. Unfortunately this reaction failed to yield β-phenyl α-phthalimidopropiophenone when β-phenyl α-phthalimidopropionyl chloride was treated with anhydrous aluminum chloride in dry benzene, 2-phthalimido-1-indanone being obtained instead. This unexpected compound was formed from the intramolecular acylation of the β-phenyl nucleus by the acyl carbonyl of the same molecule. The tendency of five-membered ring closure was so pronounced that the competitive intermolecular acylation reaction was overwhelmed, so that the expected product was not formed. A study of the factors which govern the pattern of the reactions reveals the operation of the inductive as well as of the

mesomeric effects. The difficulty however, in obtaining the desired intermediate for the preparation of β-phenyl-α-aminopropiophenone was overcome by the use of organocadmium reagent as outlined in scheme IV, where R is a benzyl and R′ phenyl, respectively.

The successful preparation of aliphatic and aromatic series of α-amino ketone analogs of amino acids by the use of organocadmium reagent demonstrates the wide scope of applicability and the advantage of this method over that of the Dakin-West method and of Friedel-Crafts acylation. 1-Phenyl-2-phthalimido-3-nonanone was prepared in a yield of 15%, comparable with 14–20% for the alkyl β-phthalimidoethyl ketones prepared from β-phthalimidopropionyl chloride by the same method (1). This reveals that the bulky α-phthalimido as well as the β-phenyl group exerts no steric hindrance on the condensation of the phthalimidoacyl chloride with either the alkyl or aryl organocadmium reagent.

The isolation of biphenyl from a reaction using phenylcadmium for the preparation of β-phenyl-α-phthalimidopropiophenone reveals the decomposition of organocadmium reagent in the course of reaction. This probably accounts for the low yield of amino ketone prepared by this method. The probable formation of the aliphatic hydrocarbons has not been demonstrated, perhaps due to the high volatility of the alkanes. The overall yield of amino ketones prepared by this method ranges from 20 to 40%, whereas it ranges from 32 to 34%, and 40 to 50% by Dakin-West and Friedel-Crafts methods, respectively.

These series of α- and β-amino ketones have been found to be active *in vitro* against the growth of bacteria and fungi when tested by the serial broth dilution and agar diffusion methods. The results of *in vitro* screening will appear in a subsequent paper.

EXPERIMENTAL

The chemical procedures used for the preparation of the various intermediates and products are illustrated by the following examples:

Phthalimidocarboxylic Acids.—Phthalimidoacetic, α-phthalimidopropionic, β-phthalimidopropionic, β-phenyl-α-phthalimidopropionic, and phthaloylaspartic acids were prepared according to Gabriel's method (8), with modification in the process of purification as described for β-phenyl-α-phthalimidopropionic acid: 100 Gm. of *dl*-phenylalanine (0.60 mole) and 90 Gm. phthalic anhydride (0.60 mole) were melted together at 210°, and the melt was maintained at this temperature for one-half hour. The product was cooled to room temperature and then dissolved in 150 ml. alcohol by refluxing. White crystalline powder, 165 Gm., was obtained after the solution was cooled to room temperature, corresponding to a yield of 82%. Recrystallization from alcohol gave large rhombic crystals, m.p. 177–178°.

Phthalimidoacyl Chlorides.—Phthalimidoacetyl, α-phthalimidopropionyl, β-phenyl-α-phthalimidopropionyl, and phthaloylaspartyl chlorides were prepared by the procedure described for β-phenyl-α-phthalimidopropionyl chloride: a mixture of 110 Gm. β-phenyl-α-phthalimidopropionic acid (0.5 mole), and 148 Gm. thionyl chloride (1.24 moles) was refluxed until all the solid dissolved. The excess thionyl chloride (25 ml.) was recovered by distillation under reduced pressure. The dark brown residue from the distillation was repeatedly extracted with petroleum ether (30–60°) by refluxing. A 102-Gm. quantity of chloride was obtained, corresponding to a yield of 85%, m.p. 73°.

Aliphatic Series of Acylamido Ketones. (See Table I).—4-Butyramido-2-methyl-5-octanone, 1-phenyl-2-butyramido-3-hexanone, 1-(*p*-hydroxy)phenyl-2-butyramido-3-hexanone were prepared by the procedure described for 1-(*p*-hydroxy)phenyl-2-butyramido-3-hexanone: a mixture of 10 Gm. of *dl*-tyrosine (0.055 mole), 300 ml. pyridine, and 43 ml. of *n*-butyric anhydride was refluxed for 8 hours. The excessive *n*-butyric anhydride and pyridine were removed by distillation under reduced pressure. The residual liquid was poured, with stirring, into 400 ml. petroleum ether (b.p. 30–60°). Six grams of 1-(*p*-hydroxy)phenyl-2-butyramido-3-hexanone was isolated, corresponding to a yield of 39%. It melted

at 108–109° after recrystallization from a mixture of benzene and petroleum ether.

Alkyl and Aryl α-Phthalimido Ketones (See Table II).—The aryl phthalimido ketones were prepared by Friedel-Crafts acylation, excepting β-phenyl-α-phthalimidopropiophenone, not obtainable by Friedel-Crafts acylation, which was prepared by the condensation of β-phenyl-α-phthalimidopropionyl chloride and phenylcadmium according to the procedure (1) described for the synthesis of alkyl β-phthalimidoethyl ketones. The procedure for the alkyl and aryl α-phthalimido ketones is essentially the same as that for the β-phthalimidoethyl ketones, except for the process of purification, as described for 1-phenyl-2-phthalimido-3-nonanone: the organocadmium reagent was prepared from 36.6 Gm. of *n*-hexyl bromide (0.22 mole), 5.3 Gm. magnesium turnings (0.22 mole), and 16 3 Gm. anhydrous cadmium chloride (0.22 mole) in anhydrous ether. After the solvent was replaced with dry benzene, 42 Gm. β-phenyl-α-phthalimidopropionyl chloride (0.134 mole) in benzene was added to the mixture. The reaction was completed and the product isolated in the usual way. The thick oil obtained after the removal of benzene was distilled under reduced pressure, yielding a yellowish oil at 70–240°/0.5 mm. Crystals, 7.6 Gm., were obtained from the alcoholic solution of the oil, corresponding to a yield of 15%. The crystals melted at 86–87° after two recrystallizations from alcohol.

Heterocyclic β-Phthalimidoethyl Ketones (See Table III).—2-Furyl, and 2-thienyl β-phthalimidoethyl ketones were prepared by the procedure described for 2-thienyl β-phthalimidoethyl ketone: a mixture of 22 Gm. β-phthalimidopropionic acid (0.1 mole) and 100 ml. dry benzene was refluxed for 1 hour with constant stirring. The mixture was cooled to room temperature, and 10 Gm. phosphorus pentoxide was added in one portion. The mixture was stirred for 1 hour at room temperature and then refluxed for 5 hours, following which it was filtered, and the filtrate washed successively with 10% sodium carbonate and water, and dried over anhydrous sodium sulfate. A syrupy liquid, obtained when the solvent was removed from the benzene solution, crystallized as a white powder, weighing 6.25 Gm. and corresponding to a yield of 37.5% based upon the quantity of β-phthalimidopropionic acid actually consumed (12.3 Gm.). The white powder crystallized from boiling alcohol as short needles, m.p. 154–155°.

Amino Ketone Hydrochlorides (See Table IV).—Amino ketone hydrochlorides were prepared by the hydrolysis of the phthalimido or the acylamido ketones in a mixture of glacial acetic and concentrated hydrochloric acids under refluxing conditions according to the procedure described in the previous paper (1).

Solvolysis of Symmetrical and Mixed Aspirin Anhydrides in 75% Dioxane–25% Water

By EDWARD R. GARRETT†

The neutral solvolysis of aspirin anhydride, I, and the mixed anhydrides of aspirin and acetic acid, II, of acetylsalicoylsalicylic and acetic acids, III, have been studied as functions of temperature in 75% dioxane by volume so as to compare them with the literature values on *m*- and *p*-substituted benzoic anhydrides studied in the same solvent. There is very little change in the heats of activation but large increases in the frequency factors of the *ortho*, mixed or symmetrical, over the *meta* and *para*. The mixed anhydrides of an *o*-acylbenzoic acid and acetic acid have higher solvolysis rates by virtue of lower frequency factors than the symmetrical aspirin anhydrides.

RECENT STUDIES (1) have demonstrated the presence of all possible products of acyl transfer in a melt of aspirin anhydride, I. Identification of these products necessitated the synthesis of several mixed anhydrides of aspirin and aspirin derivatives with acetic acid, *viz.*, the mixed anhydride of aspirin and acetic acid, II, and the mixed anhydride of acetylsalicoylsalicylic acid and acetic acid, III.

I

II

III

Since a significant amount of data has been obtained on the neutral hydrolysis of *m*- and *p*-substituted benzoic anhydrides in 75% dioxane-25% water solutions (2), studies on the symmetrical *ortho*-substituted benzoic anhydride, aspirin anhydride, and other unsymmetrical anhydrides of this type under the same conditions are of interest.

EXPERIMENTAL

Comparative Solvolysis Rates of Symmetrical and Nonsymmetrical Anhydrides in 75% Dioxane.—The general procedure for the hydrolysis studies in aqueous dioxane was to take a weighed amount of the anhydride up to a given volume with 75% dioxane. Prior to use, the dioxane was refluxed at least 24 hours over sodium to destroy peroxides, distilled, and the first fractions discarded. Both the dioxane and the distilled water used were thoroughly purged with nitrogen. The studies were made on the Cary model 11 recording spectrophotometer in 75% dioxane on aliquots of the solutions maintained in constant temperature baths.

The aspirin anhydride (3), I, aspirin, and salicylic acid were dried under high vacuum for several days before use.

The aspirin anhydride solutions were 2.142×10^{-4} *M*, the mixed anhydride of acetylsalicoylsalicylic acid and acetic acid, III, solutions were 3.827×10^{-4} *M*, and the solutions of the mixed anhydride of aspirin and acetic acid, II, were 6.274×10^{-4} *M*. The preparation of these latter compounds, II and III, has been previously described (1).

The ultraviolet spectra of these compounds are given in Fig. 1 and are plotted as the appropriate multiple of the molar absorptivity against wavelength in mμ since hydrolysis of one-half mole of aspirin anhydride would give one mole of aspirin and subsequently one mole of salicylic acid.

The high spectrophotometric purity of the mixed anhydrides was assured by the fact that the ultraviolet spectra of the hydrolyzing mixed anhydride of acetic acid and aspirin became the ultraviolet spectra of aspirin. The latter, as given in Fig. 1, had been determined from pure aspirin solution in 75% dioxane.

Salicylic acid production did not interfere with the determination of the rates of anhydride hydrolysis. For example, the rate constant for the hydrolysis of aspirin in 75% dioxane at 70.0° is 3.14×10^{-6} sec.$^{-1}$, which is 100 times slower than the hydrolysis of the mixed anhydride of aspirin and

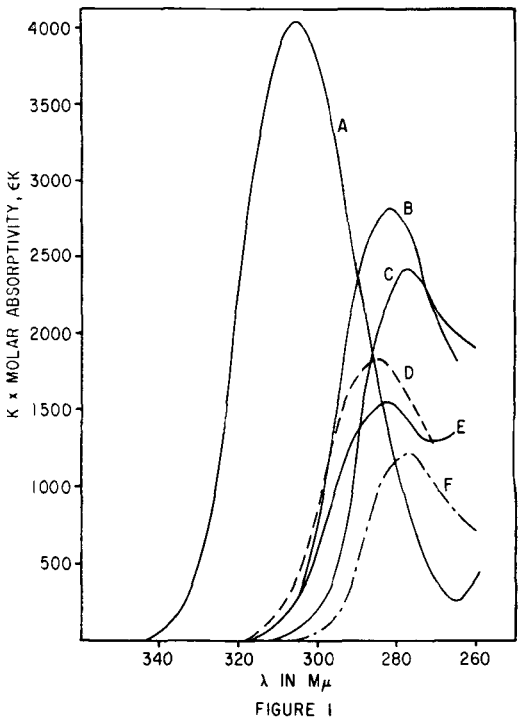

Fig. 1.—Ultraviolet spectra of anhydrides and their hydrolytic derivatives in 75% dioxane-25% water. *A*, Salicylic acid, $K = 1$; *B*, mixed anhydride, acetic and acetylsalicoylsalicylic acids, $K = 1$; *C*, acetylsalicoylsalicylic acid, $K = 1$; *D*, aspirin anhydride, $K = 1/2$; *E*, mixed anhydride, acetic acid, and aspirin, $K = 1$; *F*, aspirin, $K = 1$.

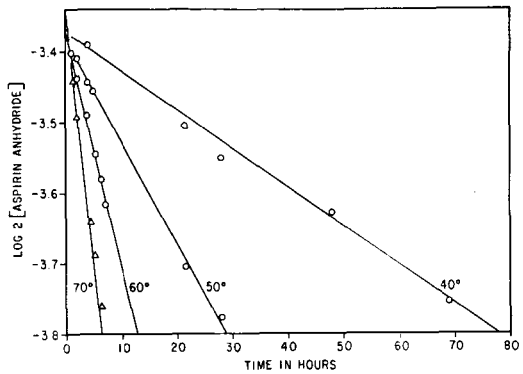

Fig. 2.—First-order plots of the hydrolysis of aspirin anhydride in 75% dioxane-25% water. Initial concentration 2.20×10^{-4} *M*.

acetic acid, II, and more than 12 times slower than the hydrolysis of aspirin anhydride, I, under the same conditions (see Table I).

However, since the spectra of the resultant highly chromophoric salicylic acid might interfere with the calculations for the aspirin anhydride to aspirin hydrolysis rates, the concentration of aspirin anhydride was calculated from the expression

$$[\text{Aspirin Anhydride}] = \frac{A'_{292.5}\,\epsilon^{ASP}_{277.5} - A'_{277.5}\,\epsilon^{ASP}_{292.5}}{\epsilon^{AA}_{292.5}\,\epsilon^{ASP}_{277.5} - \epsilon^{ASP}_{292.5}\,\epsilon^{AA}_{277.5}} \quad \text{(Eq. 1)}$$

TABLE I.—APPARENT FIRST-ORDER RATE CONSTANTS IN SEC.$^{-1}$ AND THERMODYNAMIC QUANTITIES FOR THE HYDROLYSIS OF VARIOUS ANHYDRIDES IN DIOXANE-WATER SOLUTIONS

	Aspirin Anhydride	Mixed Anhydride of Acetylsalicoylsalicylic Acid and Acetic Acid	Mixed Anhydride of Acetylsaliylic Acid and Acetic Acid
10^4 k at 27.0° in 10% dioxane	8.5[b]	62.0	24.0
10^4 k at 70.0° in 75% dioxane	0.474	5.18	5.62
10^4 k at 60.0° in 75% dioxane	0.216	2.08	2.81
10^4 k at 50.0° in 75% dioxane	0.0944	1.08	1.38
10^4 k at 40.0° in 75% dioxane	0.0351	0.52	0.78
S_a[a]	3,890	3,503	3,413
ΔH_a(Kcal./mole)	17.8	16.0	15.6
log P[a]	7.02	6.89	6.70

[a] The quantities are derived from the logarithmic form of the Arrhenius relation: $\log k = -(\Delta H_a/2.303R)(1/T) + \log P = S/T + \log P$ where ΔH_a is the heat of activation in cal./mole, R is the gas constant in cal./degree, T is the absolute temperature, and S is the slope of the Arrhenius plot. [b] As previously determined (3).

where ϵ is the equivalent absorptivity at the subscripted wavelength in mμ for aspirin anhydride (AA) or for aspirin (ASP) and where A′ is the corrected absorbance at the subscripted wavelength. The true absorbance, A, at the subscripted wavelength was corrected for the interfering absorption of the highly absorbing salicylic acid (SAL) to A′ by

$$A'_{292.5} = A_{292.5} - \epsilon^{SAL}_{292.5}[Sal] \quad \text{(Eq. 2)}$$

$$A'_{277.5} = A_{277.5} - \epsilon^{SAL}_{277.5}[Sal] \quad \text{(Eq. 3)}$$

where the salicylic acid concentration [Sal] was obtained from the absorbance at 320 mμ

$$[Sal] = A_{320}/\epsilon^{SAL}_{320} \quad \text{(Eq. 4)}$$

The logarithmic values of the calculated aspirin anhydride concentrations were plotted against time according to the first-order expression

$$\log [AA] = -kt/2.303 + \text{constant} \quad \text{(Eq. 5)}$$

and the derived first-order rate constants are given in Table I. Such plots are given in Fig. 2.

The other anhydrides studied hydrolyzed at such rates so that the spectral appearances of derived salicylic acids were no problem. The logarithm of the difference between the absorbances at any time, A, and the asymptotic value with time, A_∞, were plotted according to

$$\log [A - A_\infty] = -\frac{kt}{2.303} + \text{constant} \quad \text{(Eq. 6)}$$

and the derived first-order rate constants are also given in Table I. Such plots are given in Figs. 3 and 4.

The Arrhenius plots for the hydrolyses of these anhydrides in 75% dioxane are given in Fig. 5 and the thermodynamic quantities are given in Table I. The relation used is

$$\log k = -(\Delta H_a/2.303\text{R})(1/T) + \log P = -S/T \log P \quad (7)$$

where ΔH_a is the heat of activation in cal./mole, R is the gas constant in cal./degree, T is the absolute temperature, and S is the slope of the Arrhenius plot.

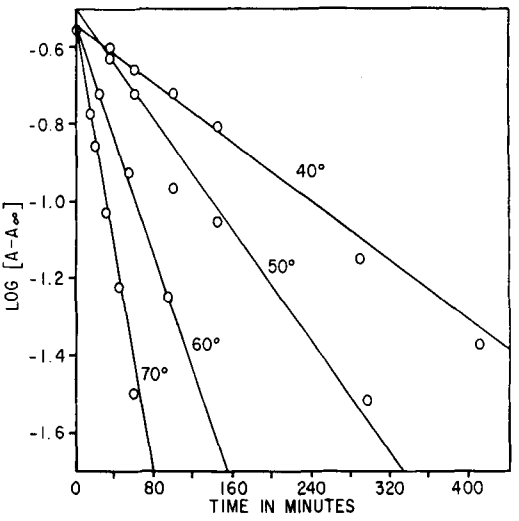

Fig. 3.—Apparent first-order plots of the loss of absorbance at the 283 mμ maximum of the mixed anhydride of aspirin and acetic acid in 75% dioxane-25% water. The A_∞ at 283 mμ (i.e., the absorbance for aspirin) for the 6.27×10^{-4} M solutions was 0.700.

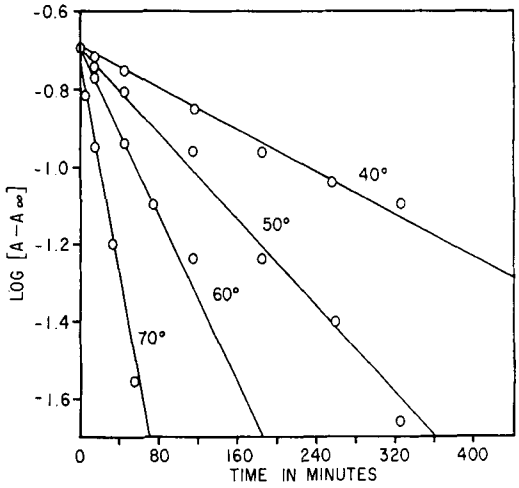

Fig. 4.—Apparent first-order plots of the loss of absorbance at the 282 mμ maximum of the mixed anhydride of acetylsalicoylsalicylic and acetic acids in 75% dioxane-25% water. The A_∞ at 282 mμ for the 3.83×10^{-4} M solutions was 0.870.

DISCUSSION

Comparison of Neutral Solvolyses of Anhydrides of *o*-Acetoxybenzoic Acid with *m*- and *p*-Substituted Benzoic Anhydrides.—In general, the neutral sol-

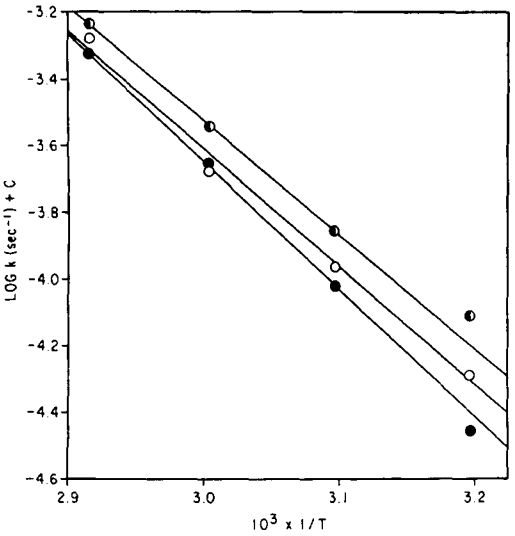

Fig. 5.—Arrhenius' plots for the hydrolysis of anhydrides in 75% dioxane-25% water. ⊙ Mixed anhydride, acetic and acetylsalicoylsalicylic acids, C = 0; ◐ mixed anhydride, acetic acid and aspirin, C = 0; ● aspirin anhydride, C = 1.

volyses of substituted benzoic anhydrides should be favored by electron withdrawing groups since nucleophilic attack is rate determining (2–6).

The acetoxy group in aspirin anhydride should possess less electron withdrawing properties than a methyl substituent (7). The *ortho* position had little effect on the heat of activation for the neutral hydrolysis of aspirin anhydride in 75% dioxane in comparison to the other *m*- and *p*-substituted benzoic anhydrides (2). The ΔH_a of 17.8 Kcal. is the same as that given for the neutral hydrolysis in 75% dioxane of the *m*- and *p*-alkyl benzoic anhydrides (2).

The unsymmetrical mixed anhydride of aspirin and acetic acid, II, and of acetylsalicoylsalicylic and acetic acids, III, may have slightly less heat of activation for their hydrolyses (see Table I).

Although this difference is not of a high order of significance, it may imply that the attack of the water molecule on the carbonyl carbon, which attack requires most of the activation energy, is slightly more facile in the case of the mixed anhydrides.

The most dramatic difference introduced by the *ortho* substituent, as expected by virtue of the proximity effect (8), is in the frequency factor. The log P value for aspirin anhydride hydrolysis is relatively quite high (see Table I) compared to all the *m*- and *p*-substituted benzoic anhydride hydrolyses listed by Berliner and Altschul (2).

The high frequency factor, or the less change in the entropy of activation, may be explained by the restricted rotation in aspirin anhydride due to the bulky *ortho* groups. On activation, the activated state has less degrees of freedom to lose compared to most *m*- and *p*-substituted benzoic anhydrides.

The lower frequency factors in the hydrolysis of the mixed anhydrides account for their higher reactivity over the symmetrical aspirin anhydride (see Table I). This difference from aspirin anhydride may be attributed to the loss in greater degrees of freedom on the preferential attack of the nucleophile on the acetyl carbonyl carbon rather than on the *o*-acetoxyphenylcarbonyl carbon. It may be expected that nucleophilic attack should take place at the acyl group of higher reactivity (4). Thus, since ethyl acetate has a greater alkaline hydrolysis rate under comparable conditions than ethyl benzoate (9), nucleophilic attack on the acetyl carbonyl carbon may be predicted.

Coulometric Titration of Various Organomercurials and Mercury Containing Compounds

By F. HENRY MERKLE and CLARENCE A. DISCHER

The feasibility of using constant current coulometry for the analysis of various pharmaceutical compounds containing mercury has been demonstrated. Electrolytically generated thioglycollic acid served as the titrant. No preliminary treatment of the mercury compound was necessary except for those substances in which the mercury is completely bound to carbon. These latter compounds were treated with concentrated hydrochloric acid to cleave the carbon to mercury bond. The mercury content was determined with samples in the milligram range with an indicated deviation of less than one per cent from the theoretical values.

COULOMETRIC titrations are rapidly taking an important place among the instrumental techniques. Applications and advantages of this technique have been recently reviewed (1). Coulometric methods are dependent on the stoichiometry existing between the quantity of electricity and the quantity of electroactive substance transformed at an electrode during the electrolysis. The amount of material that has reacted is computed using Faraday's law.

The internal generation of a reagent by constant current coulometry has made available many unstable but potentially useful reagents for chemical analysis. One of these, organically bound sulfhydryl, has been used by Miller and Hume for the quantitative determination of different metal ions; namely, mercury (II), copper (II), gold (III), and hexacyanoferrate (III) (2, 3). It was thought that their basic technique of generating the sulfhydryl group electrochemically should be of value in the determination of mercury, organically bound, in compounds of pharmaceutical interest.

The method of Miller and Hume employs mercury (II) thioglycollate, a soluble sulfhydryl compound, as the reagent precursor for the coulometric generation of free sulfhydryl. The mercury (II) thioglycollate-thioglycollic acid couple was found to be coulometrically suitable in terms of current efficiency and potentiometric reversibility, enabling efficient titration to proceed with accurate end point detection. The reaction which supplies the reagent sulfhydryl, occurs at the mercury-pool cathode. It may be expressed by the following equation

$$Hg(RS)_2 + 2H^+ + 2e^- = Hg^0 + 2RSH \quad \text{(Eq. 1)}$$

Received January 4, 1961, from Rutgers, The State University, College of Pharmacy, Newark 4, N. J.
Accepted for publication April 7, 1961.
Abstracted from a thesis submitted to the Graduate School of Rutgers, The State University, by F. Henry Merkle in partial fulfillment of the requirements for the Master of Science degree.

and is completely reversible. This indicates that one sulfhydryl group per electron is made available by the deposition of mercury. Any free sulfhydryl may be reacted and, thus, effectively removed by reversing the current and generating mercury (II) from the mercury-pool anode according to the following equation (4)

$$Hg^0 = Hg^{++} + 2e^- \quad \text{(Eq. 2)}$$

The reactions that occur in the bulk of the solution may be described by the following equations

$$RSH + R'Hg^+ = R'HgSR + H^+ \quad \text{(Eq. 3)}$$

$$2RSH + Hg^{++} = Hg(RS)_2 + 2H^+ \quad \text{(Eq. 4)}$$

where $R'Hg^+$ represents the monoalkyl or monoaryl mercury (II) ion arising from the dissociation of the organomercurial in the untreated sample (e.g., chlormerodrin in aqueous solution). The mercury (II) in reaction (4) represents the mercury set free from organic combination by treating the sample with a strong mineral acid.

EXPERIMENTAL

Apparatus.—The constant current source described by W. N. Carson, Jr., was used (5). The circuit was so designed that a single switch synchronously controlled the flow of generating current through the cell and the timer. The electric timer[1] used is calibrated to one-tenth of a second. Potentials were measured with a pH meter[2] with a saturated calomel reference electrode and an amalgamated silver wire indicator electrode. The titration cell was a 50-ml. Pyrex beaker, to the bottom of which a side arm (glass tubing, O.D. 0.75 cm.) was fused. A platinum wire served as the electrical contact to the mercury pool through this side arm. A platinum wire helix served as the nonworking electrode. It was separated from the working solution by an agar plug containing sodium nitrate. A block diagram of the titration assembly is shown in Fig. 1.

Reagents and Solutions.—All chemicals used were reagent grade unless otherwise specified. Thiogly-

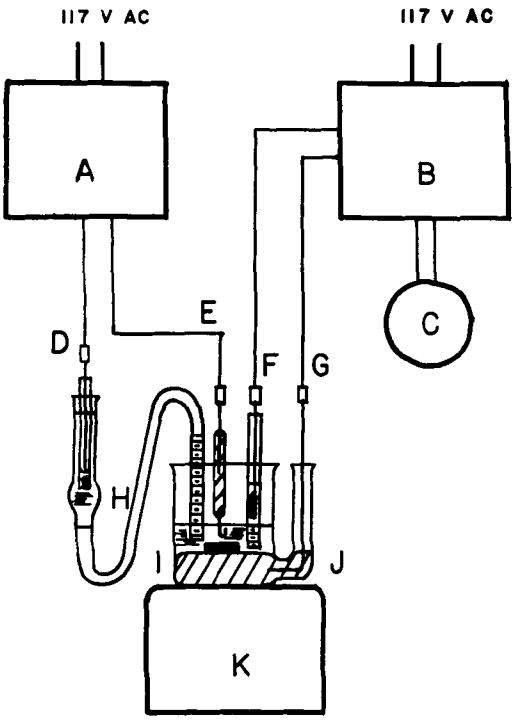

Fig. 1.—A block diagram of the titration apparatus. *A*, Beckman model H-2 pH meter; *B*, constant current source and integral milliameter; *C*, synchronous timer; *D*, saturated calomel reference electrode; *E*, mercury indicating electrode; *F*, platinum wire helix generating electrode; *G*, platinum wire contact to mercury pool electrode; *H*, saturated potassium chloride salt bridge; *I*, generating solution 5 to 7 ml.; *J*, side arm for mercury pool contact; *K*, magnetic stirrer.

collic acid (Eastman Kodak Co.), 70% practical grade and 80% analytical grade; phenylmercuric nitrate, phenylmercuric acetate, powder (The Matheson Co.); meralluride acid, powder;[3] meralluride, injectable solution; chlormerodrin, powder;[4] mercaptomerin sodium, crystals for injection[5] and injectable solution; mercury (II) salicylate powder U.S.P.; mercury (II) oxide (red) powder N.F.; ammoniated mercury powder U.S.P.

A solution of mercury (II) acetate, 0.1 *M* in acetic acid, was standardized against a standard disodium EDTA solution. The buffer used in this work (approximate pH = 5) was a solution 1.0 *M* in acetic acid and also 1.0 *M* in sodium acetate. The mercury (II) thioglycollate was prepared by mixing stoichiometric quantities of thioglycollic acid and mercury (II) chloride. The resulting precipitate was filtered and washed, and then treated with 6.0 *N* sodium hydroxide, dropwise, until completely dissolved (approximate pH = 5). This stock solution was then diluted with distilled water to 0.1 *M* with respect to mercury (II) thioglycollate.

Equal volumes of the buffer solution and the stock mercury (II) thioglycollate solution were mixed to produce the generating solution.

[3, 4] The authors wish to thank Lakeside Laboratories, Milwaukee, Wis., for the donation of these materials.

[5] The authors wish to thank Wyeth Laboratories, Philadelphia, Pa., for the donation of this material.

General Procedure.—The titration was carried out by placing about 5 to 7 ml. of the previously prepared supporting electrolyte-generating solution into the titration cell. Nitrogen was bubbled through this solution for about 5 minutes to remove any dissolved oxygen. A slow flow of gas was continued during the entire titration procedure in order to maintain an inert atmosphere. The point of maximum potential inflection was determined by generating an excess of mercury (II), then reversing the current and back titrating with sulfhydryl (Eqs. 2 and 1, respectively). Before the addition of the sample, the solution was pretitrated to the potentiometric inflection point to remove any slight excess of mercury (II) or sulfhydryl that might be present. The unknown sample was then introduced into the cell and the generating current maintained using appropriate time intervals until the original inflection point was passed (Eq. 1). After each generation period, the indicator potentials were read after equilibrium was reached. Equilibrium was attained quite rapidly, all cases requiring less than 1 minute. The end point time was then calculated from the point of maximum potential inflection. In all the titrations that were performed, the end point was necessarily overrun; and before a new sample was added, the excess sulfhydryl generated was back titrated to the potentiometric inflection point by reversing the current (Eq. 2).

Successive titrations are possible with a given portion of the supporting electrolyte-generating solution. However, the volume increase by the addition of the samples into the titration cell was found to limit the number of successive titrations that could be conducted. By maintaining a small volume in the cell, a sharper inflection point was obtained. In the case of the treated materials, the acidity of the samples added was also found to be a limiting factor. The titration curve shown in Fig. 2 is typical of all the titrations that were performed with the treated and untreated samples.

Samples Titratable without Preliminary Treatment.—The following solutions were prepared by dissolving the compounds in distilled water: phenylmercuric nitrate 0.5 Gm./L., phenylmercuric acetate 1.0 Gm./L., chlormerodrin 0.2 Gm./100 ml. A suitable sample of each solution, 1 to 2 ml., was then taken, pipetted directly into the cell, and titrated according to the procedure outlined.

Preliminary Treatment of the Samples.—The treatment of the various mercury-containing compounds varied only slightly depending on their nature. In preparing the mercury compounds, concentrated hydrochloric acid was used to cleave the mercury-carbon bond, thus releasing the mercury so that it could react with the generated sulfhydryl. The reaction that occurred with the acid for most of the alkyl and aryl salts investigated, of the type RHgOH, RHgX, and R_2Hg, is expressed by the following reaction (6)

$$R_2Hg \xrightarrow{HCl} RH + RHgCl \xrightarrow{HCl} RH + HgCl_2 \quad \text{(Eq. 5)}$$

Previous workers have accomplished similar bond cleavage by employing 50% sulfuric acid and then titrating with potassium thiocyanate (7). However,

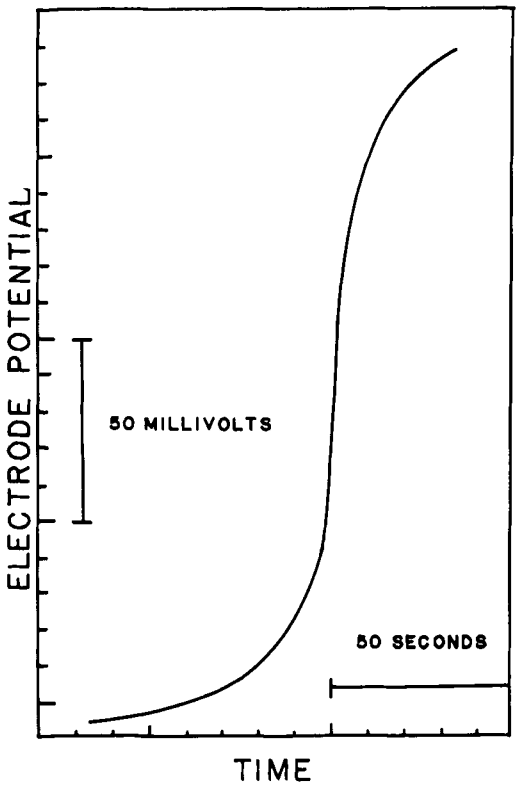

Fig. 2.—Typical titration curve obtained for chlormerodrin treated sample.

this earlier method is not applicable when hydrochloric acid or chloride ions are present.

With the following substances, it was necessary to vary the procedure as follows: 50 ml. of phenylmercuric nitrate solution (0.05%) and phenylmercuric acetate solution (0.10%) were pipetted into separate 100-ml. volumetric flasks. The solutions were boiled down to approximately 25 ml., and 5 ml. of concentrated hydrochloric acid was added, dropwise. After carefully boiling until complete solution was accomplished (usually 10 to 15 minutes), the solutions were neutralized with 6 *N* sodium hydroxide to a pH of approximately 5. Upon cooling, the solutions were diluted to the mark with distilled water.

Any loss of mercury (II) chloride, due to volatilization during the boiling procedure, was found to be negligible.

The two injectable solutions were sampled with a micrometer syringe.[6] Predetermined volumes (0.5 or 1.0 ml.) of these solutions were introduced into 50-ml. volumetric flasks containing 1 to 2 ml. of the concentrated acid. Distilled water, 10–15 ml., was added to the solutions before they were gently boiled. After solution was accomplished, they were cooled to room temperature and diluted to the mark with distilled water.

When solid materials were to be analyzed, appropriate samples (100 or 200 mg.) of the dry materials were weighed and then washed into a 100-ml. volumetric flask containing 2 ml. of the concentrated acid with 15 ml. of distilled water. In the case of mercury (II) salicylate, more distilled water was added and the heating time extended to dissolve the material completely. After cooling the solutions, they were diluted to the mark with distilled water. In the case of the samples of the injectable solutions and the dry materials, the neutralization step was found unnecessary since a minimum of acid was used.

Titration of Treated Samples.—The treated samples (1 to 2 ml.) were taken from the solutions, prepared as previously described, and pipetted directly into the titration cell.

[6] "Agla" brand micrometer syringe, Wellcome Research Laboratories, Beckenham, Kent, England (0.5-ml. capacity, with the precision of delivering 0.01 ml. to ±0.5%).

RESULTS AND DISCUSSION

Titration Data.—Tables I and II indicate typical data obtained in the titration of chlormerodin, untreated and treated samples, respectively. Table III is a summary of all the data obtained in titrating the various organomercurials.

Conclusions.—The experimental data indicated that electrolytically generated sulfhydryl can serve as a titrant in the determination of mercury (II) released from organic combination. In the samples treated with concentrated hydrochloric acid, the total mercury can be determined with the exception of mercaptomerin sodium. In the latter case, only half the total mercury content can be titrated. This indicates that the hydrochloric acid treatment is effective in cleaving the mercury-carbon bond, rendering the mercury available for reaction with the generated sulfhydryl, while insufficient to disrupt the mercury-sulfur bond.

A significant advantage to the general application of this method is the possibility of titrating the material directly without any preliminary treatment. The direct titration of the untreated solutions of chlormerodrin, phenylmercuric acetate, and phenylmercuric nitrate showed that this was possible. In these determinations, one-half the total mercury was titratable.

The chief difficulty with methods now generally available, involving direct titration with thiocyanate is the presence of chlorides. This drawback is overcome with the present procedure. In addition, the drastic heating usually necessary to decompose organic mercurials is eliminated since the hydrochloric acid treatment is effective in the carbon-mercury bond cleavage.

Although interferences by such ions as copper (II), gold (III), and hexacyanoferrate (III) are possible, their presence in the compounds studied is virtually nonexistent and, therefore, introduce no difficulty in the analyses.

The precision of the titrations is as good as, or better than, that with the methods ordinarily used for other mercury compounds.

Biosynthesis of Hyoscyamine and Scopolamine in *Datura stramonium*

By E. W. UNDERHILL† and H. W. YOUNGKEN, Jr.

Datura stramonium L. plants were allowed to metabolize certain C^{14}-labeled compounds for 10 days following which hyoscyamine and scopolamine were isolated and purified. Of the compounds employed, phenylalanine-3-C^{14}, phenylacetic acid-1-C^{14}, and sodium acetate-2-C^{14} were the most efficient precursors, followed by sodium propionate-2-C^{14}, sodium formate-C^{14}, and serine-3-C^{14} in that order; zinc lactate-2-C^{14} proved to be a comparatively inefficient precursor. The distribution of C^{14} within the alkaloids was entirely in their tropic acid moiety when phenylalanine and phenylacetic acid were used as precursors, and almost entirely in their tropine or scopine portions when acetate, propionate, formate, and serine were employed. The samples of tropic acid obtained, following administration of phenylalanine and phenylacetic acid, were degraded and the location of the C^{14} determined.

A NUMBER of theories on the biosynthesis of of the tropane moiety of hyoscyamine and scopolamine have been proposed and these have recently been reviewed (1). Experiments involving C^{14}-labeled compounds as precursors of this portion of the alkaloids have provided positive results in the case of ornithine-2-C^{14} (2), methionine-C^{14} (3), and acetate-C^{14} (4, 5), while negative results have been obtained when putrescine-1,4-C^{14} (6) and citric acid-3-C^{14} (7) were employed. Recently attention has been focused upon the formation of the tropic acid moiety of these alkaloids. Trautner (8) has suggested that tropic acid, itself possessing an isopropylbenzene skeleton, may be derived from the the terpenes, limonene and terpinene. Shortly after this work was commenced, Wenkert (9) suggested that this aromatic branched-chain acid may be derived from an aldol product of formaldehyde and prephenic acid. A number of routes leading from such an aldol product to tropic acid are possible and these have been elaborated upon in the experimental work reported by Leete (10), who administered DL-phenylalanine-3-C^{14}, sodium formate-C^{14}, and formaldehyde-C^{14} to *Datura stramonium*. Of the compounds employed by Leete, only phenylalanine was a precursor of tropic acid and in this instance the activity resided in the carbon adjacent to the aromatic group. Goodeve and Ramstad (11) have found that the administration of tryptophan-3-C^{14} to *D. stramonium* yielded hyoscyamine with the totality of its activity in the carboxyl carbon of tropic acid.

In the present paper experiments are reported in which the validity of the following three hypotheses for tropic acid biosynthesis was determined: (*a*) Acetate, an effective precursor of isoprenoid compounds might also be expected to become incorporated into tropic acid via the terpene pathway suggested by Trautner (8). (*b*) The aromatic branched-chain structure of tropic acid may be formed through the condensation of shikimic acid with the alpha carbon of a 3-carbon acid such as lactate or propionate. (*c*) Tropic acid may be formed by the attack of such an "active" 1-carbon compound as formate or the beta carbon from serine at the alpha carbon of phenylacetic acid or its coenzyme derivative (derived by oxidative decarboxylation of the transaminated product of phenylalanine, *viz.*, phenylpyruvic acid).

EXPERIMENTAL

C^{14}-Sample Preparation and Counting.—Radioactive samples were assayed by combustion of the material to carbon dioxide and converting the evolved gas to barium carbonate. The Van Slyke-Folch wet combustion mixture, prepared according to Calvin, *et al.* (12), was employed in an apparatus similar to that described by Claycomb, *et al.* (13). Barium carbonate samples were counted in a windowless flow counter at a finite thickness and the activity corrected to infinite thinness.

Cultivation of Plants.—*Datura stramonium* plants were grown in soil until the most mature plants bore flower buds (44 days). The roots of 24 plants of uniform size and appearance (no flower buds appearing) were washed free of soil and the plants placed in hydroponic culture. After the plants had remained in the hydroponic culture for 1 week, the roots of each plant were removed to within approximately $^1/_8$ inch of the crown. The purpose of the root excision was to provide a soil-free root system wherein a high rate of alkaloid synthesis might be expected to occur in the abundant quantity of young, actively metabolizing root tissue which formed during the following 10 days.

Administration of C^{14}-Labeled Compounds to Plants.—At the end of the 10-day root regeneration

Received April 7, 1961, from the College of Pharmacy, University of Rhode Island, Kingston.
Accepted for publication June 6, 1961.
Based in part, on a Ph.D. dissertation submitted by E. W. Underhill to The Graduate School, University of Rhode Island, June 1960.
This study was supported in part by United States Public Health Service grant MY3319 and in part by a grant from the Smith, Kline and French Foundation.
† Recipient of a National Research Council of Canada Special Scholarship and Edwin Leigh Newcomb Award in Pharmacognosy for 1961.

period, the C^{14}-labeled compounds were administered to the plants. Eight groups of three plants each were employed as follows: one group was selected as a control and as such received no radioactive compounds; the remaining seven groups were separately fed the following radioactive compounds, purchased from commercial sources: *dl*-phenylalanine-3-C^{14}, phenylacetic acid-1-C^{14}, sodium acetate-2-C^{14}, sodium propionate-2-C^{14}, sodium formate-C^{14}, *dl*-serine-2-C^{14}, and *dl*-zinc lactate-2-C^{14}.

The plants were individually placed in small beakers containing equal quantities (0.07 m*M* per plant) of the C^{14}-labeled compounds dissolved in 2 to 3 ml. of water. The illuminated plants absorbed their respective solutions within 20 minutes; the last traces were washed into the plant by addition of at least 12 successive 2-ml. portions of water to the beaker as it approached dryness. The plants were then transferred to hydroponic culture and were allowed to metabolize in a greenhouse under ordinary conditions of sunlight for a further period of 10 days.

Isolation and Purification of Alkaloids.—The plant material was dried at 65° for 36 hours and then ground in a semimicro Wiley mill to a No. 40 powder. The powdered material was extracted with ether in a Soxhlet apparatus according to the method described for this plant in the N.F. X (14). Further purification of the combined alkaloids was effected by extraction of the bases from the ethereal solution into acidulated water and then into chloroform. Hyoscyamine was separated from scopolamine by countercurrent liquid-liquid extraction using a phosphate buffer (0.2 *M*, pH 6.8) and chloroform as the two phases (15). Final purification of the individual alkaloids was carried out on Celite[1] columns after the method of Evans and Partridge (16). The amount of column-purified alkaloid was determined by colorimetric assay (17).

Hydrolysis of Alkaloids.—Those alkaloids possessing sufficient radioactivity to warrant further study were hydrolyzed to tropine or scopine and tropic acid in order to determine the distribution of C^{14} between these two portions of the alkaloids.

Sufficient nonradioactive alkaloid was added to the column-purified alkaloids to provide a sample of known weight between 100 and 150 mg. Complete hydrolysis was accomplished by dissolving the alkaloid in 35 ml. of water to which was added 10 ml. of 2 *N* sodium hydroxide and heating the mixture on a water bath for 2 hours. Tropine or scopine was extracted from the hydrolysate with five 25-ml. portions of chloroform. Following acidification of the hydrolysate, tropic acid was recovered by extraction with several portions of a mixture of isopropanol (1 part) and chloroform (3 parts).

Evaporation of the isopropanol-chloroform mixture yielded a light brown residue from which tropic acid was recovered by sublimation at 114–115° and 1–2 mm. Hg pressure. Crystallization of the sublimed acid gave pure tropic acid, m.p. 117–118°; yield based on the alkaloid was 80% or more.

Tropine was purified by formation of its picrate derivative and recrystallization of tropine picrate from water, m.p. 290–293°; yield 30 to 40% based on hyoscyamine. Repeated attempts to form the picrate of scopine failed to provide a derivative with a sharp melting point.

Degradation of Tropic Acid.—Two methods of degradation were employed. The first involved permanganate oxidation of tropic acid to benzoic acid while the second involved the decarboxylation of the branched-chain acid and recovery of the liberated carbon dioxide.

Tropic acid (30 to 50 mg.) was refluxed with 250 mg. of potassium permanganate and 50 mg. of sodium hydroxide in 5 ml. of water for 2 hours. The hot solution was filtered, acidified, and then extracted with successive 20-ml. portions of ether. Removal of the solvent left a light brown residue which, on sublimation, yielded 10 to 15 mg. of long, colorless crystals of benzoic acid, m.p. 122°.

Decarboxylation of tropic acid was accomplished by refluxing 10 to 20 mg. of the acid with 10 mg. of cupric oxide in 3 ml. of quinoline for 1 hour. The reaction was carried out in an atmosphere of nitrogen and the evolved carbon dioxide was collected in carbon dioxide-free sodium hydroxide. The yield of carbonate ranged from 95 to 110% of the theoretical after allowance was made for the carbonate which formed when appropriate blanks were employed.

The styrene and/or polystyrene, which would be expected to be formed as a result of tropic acid decarboxylation, was recovered from the reaction mixture in the following manner. The quinoline solution was acidified and then extracted with seven successive 10-ml. portions of ether. The combined ether extract was washed several times, first with acidulated water and then with dilute sodium hydroxide. Evaporation of the washed ether extract left a brown residue.

RESULTS

The relative effectiveness of the administered compounds as precursors of hyoscyamine and scopolamine can be seen by comparing the dilution values given in Table I. Phenylalanine, phenylacetic acid, and sodium acetate, which gave hyoscyamine and scopolamine showing the least dilution of C^{14}, were the best alkaloid precursors of the seven compounds tested. Sodium propionate, sodium formate, and serine were less efficient precursors, while the radioactive carbon from zinc lactate was only slightly incorporated into the alkaloids. The similarity in dilution values for the two alkaloids, upon administration of any one precursor, suggests that both hyoscyamine and scopolamine were being formed at the same time within the plants.

Tables II and III show the distribution of C^{14} within the alkaloids as determined by the specific activities of the hydrolysis products, tropic acid and tropine. The specific activity for scopine could not be determined due to the questionable composition of its picrate derivative and the specific activity values listed for this base have been derived by calculation. It is apparent from the results that, of the seven compounds administered to the plants, only phenylalanine and phenylacetic acid were precursors of tropic acid specifically. The radioactivity derived from sodium propionate also occurred to a limited extent in the acid but the majority of its activity, like that of acetate, formate, and serine, was located in tropine or scopine.

[c] Insufficient material or radioactivity to permit hydrolysis.

While all of the tropic acid obtained following hydrolysis of the alkaloids possessed radioactivity, only four samples were sufficiently active to be considered for degradation; these were obtained when phenylalanine and phenylacetic acid were used as precursors. The original hypothesis concerning the biosynthesis of tropic acid from phenylalanine suggested that the carbon skeleton of this amino acid would go to form the phenyl, alpha, and carboxyl carbons of tropic acid. On this premise, the activity within tropic acid should be located in the carbon adjacent to the benzene ring since phenylalanine-3-C^{14} was employed as the precursor. This hypothesis is supported by the results of permanganate oxidation of tropic acid to benzoic acid (Table IV) wherein essentially all of the activity present in the tropic acid obtained from both alkaloids was contained in the benzoic acid.

The tropic acid recovered following administration of phenylacetic acid was decarboxylated since, according to the starting hypothesis, the C^{14} from

phenylacetic acid-1-C^{14} should be present in the carboxyl carbon of tropic acid. However, the liberated carbon dioxide, collected and counted as barium carbonate, proved to be nonradioactive. The decarboxylation products, believed to be styrene and polystyrene, were recovered from the reaction mixture and their total activity determined. Table V shows the radioactivity recovered in these styrene products expressed as a percentage of the total radioactivity present in the tropic acid samples prior to decarboxylation. While most of the radioactivity was recovered, failure to obtain complete recovery is believed to be due to incomplete extraction of the degradation products into ether and also incomplete decarboxylation.

DISCUSSION

In view of Leete's success (10), as well as that reported here, in isolating both radioactive hyoscyamine and scopolamine, it would now appear that the failure of earlier workers (2, 3) to obtain radioactive scopolamine in the presence of C^{14}-labeled hyoscyamine was a function of the maturity of the plants in relation to the time of precursor administration. Preliminary experiments to those reported in this paper have shown that hyoscyamine contained most, if not all, of the C^{14} within the two alkaloids when these same seven radioactive compounds were administered to mature *D. stramonium* (plants bearing fruit). The failure to obtain radioactive scopolamine in the presence of C^{14}-labeled hyoscyamine using mature *D. stramonium* plants has been demonstrated by Romeike and Fodor (18).

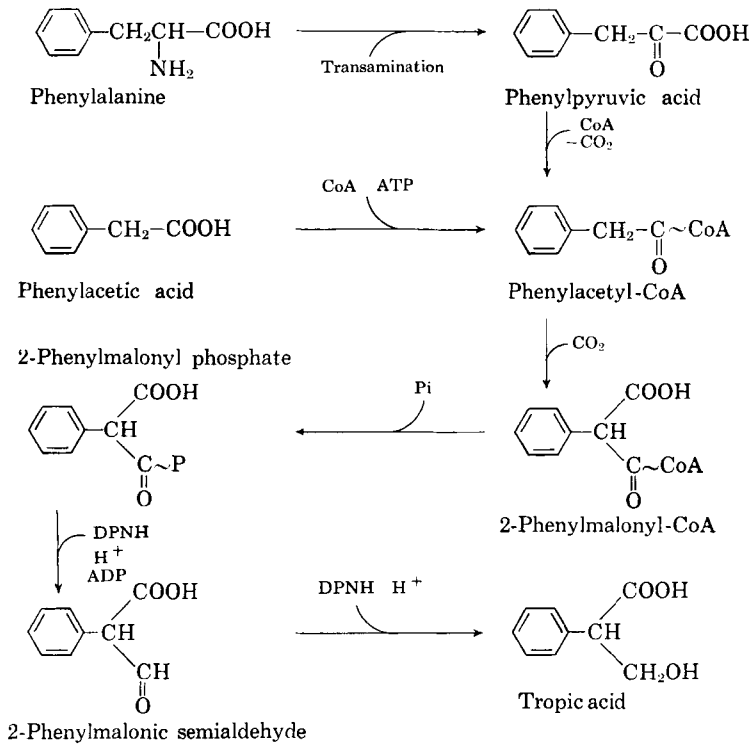

Fig. 1.—Proposed pathway for tropic acid biosynthesis.

The foregoing results provide no evidence which would support two of the proposed hypotheses for tropic acid biosynthesis, namely, the participation of acetate via the isoprene pathway suggested by Trautner (8) and the condensation of shikimic acid with lactate or propionate. The third hypothesis involved the formation of phenylacetic acid or its coenzyme derivative from phenylalanine followed by a 1-carbon attack at its alpha carbon by formate or the beta carbon of serine. This hypothesis has been substantiated in part by the results obtained in that both phenylalanine-3-C^{14} and phenylacetic acid-1-C^{14} were efficient precursors of tropic acid.

Two major discrepancies in the experimental results and the third hypothesis were met. First, the activity derived from formate-C^{14} and serine-3-C^{14} was not found in tropic acid but rather in the tropane moiety of the alkaloids. The second discrepancy, and the one which has provided the greatest interest and speculation, was that the radioactivity present in tropic acid derived from phenylacetic acid-1-C^{14} was not in the carboxyl group as was expected but is believed to have been present in the hydroxymethyl carbon.

These findings have led us to propose the following pathway for tropic acid biosynthesis (Fig. 1) which, in addition to accounting for the experimental findings, suggests the direct participation of carbon dioxide in the formation of the branched chain. The essential points in this proposal are as follows: (*a*) the addition of carbon dioxide to phenylacetyl-Co.A in a manner analogous to the formation of malonyl-Co.A from acetyl-Co.A in fat biosynthesis (19); (*b*) reduction in two stages of 2-phenylmalonyl-Co.A to tropic acid.

Degradative studies were not carried out to ascertain the location of the C^{14} which was predominantly incorporated into tropine and scopine upon administration of formate, serine, acetate, and propionate; hence, the full significance of these results is not possible to determine. It was not surprising that the C^{14} derived from formate-C^{14} and serine-3-C^{14} was incorporated into these bases since these compounds are known precursors of N-methyl groups in alkaloids. Leete (10) administered formaldehyde-C^{14} and formate-C^{14} to *D. stramonium* in addition to phenylalanine-3-C^{14}, and found that the activity from formate did in fact reside in the N-methyl of hyoscyamine. Acetate-2-C^{14} and propionate-2-C^{14} were very efficient precursors of tropine and scopine. Wenkert (9) and Birch (20), have suggested acetate as a possible precursor of the "acetone" moiety of tropine and scopine. Recently, Kaczkowski, Schütte, and Mothes (4, 5) have clearly demonstrated the participation of acetate in the formation of the tropine portion of hyoscyamine. Degradation of the alkaloid showed that the radioactivity, derived from acetate-1-C^{14}, was in carbon atom 3 while that derived from acetate-2-C^{14} was in carbon atoms 2 and 4. A further possibility of the location of C^{14} from both acetate-2-C^{14} and propionate-2-C^{14} stems from work on the biosynthesis of nicotine. Griffith and Byerrum (21) found that, following administration of these similarly labeled compounds to *Nicotiana rustica*, half of the C^{14} within nicotine was located in the pyrrolidine ring.

Work is continuing to provide more definitive information concerning the participation of propionate and carbon dioxide in the biosynthesis of hyoscyamine and scopolamine.

Influence of Nonequilibrium Sample Temperature on Stability Predictions Extrapolated from Elevated Temperature Studies

By MORTON W. SCOTT† and LEON LACHMAN‡

Assay results for a single sample stored in an elevated temperature oven for a known period of time may be in error if instantaneous heating and cooling of the sample is not achieved. For usual kinetic studies however, the storage behavior of a group of samples which have been placed in the oven at the same time is followed. Theoretical and experimental considerations are presented to show that in the case of apparent first-order reactions the assay values for all samples in the group are subjected to the same degree of error. Rates of degradation calculated from the assay data are identical to those measured under isothermal conditions. Consequently, decomposition rates obtained under the usual oven storage conditions, where time lags in heating and cooling samples exist, give useful information for estimating product stability.

CONSIDERABLE PROGRESS has been made in recent years in applying chemical kinetic principles for the prediction of the shelf life of pharmaceutical products. The techniques employed are gaining general acceptance in the pharmaceutical industry and have been the subject of an increasing number of literature reports.

In one early investigation, Garrett and Carper (1) predicted the color stability of a multisulfonamide preparation using colorimetric measurements of samples subjected to thermally accelerated degradation. Later, Swintosky, *et al.* (2), used chemical kinetics in predicting the shelf life of oral penicillin G procaine suspensions. In another report, Garrett (3) examined the thermal degradation of ascorbic acid, vitamin B_{12}, folic acid, and other components of a multivitamin preparation. The author was able to arrive at satisfactory estimates of room temperature stability from data obtained under accelerated test conditions. McLeod (4) used a similar approach to predict expiration dates for other multivitamin preparations.

These reports and others on the subject (5–7) have suggested a simple experimental procedure for the evaluation of product stability. The procedure generally followed involves storing the product, preferably packaged in its final market container, in three or four individual ovens maintained at constant elevated temperature. Periodically samples are removed from these ovens and assayed. The loss of active ingredient is calculated, and rates of decomposition for the

Later, Swintosky, *et al.* (2), used chemical kinetics in predicting the shelf life of oral penicillin G procaine suspensions. In another report, Garrett (3) examined the thermal degradation of ascorbic acid, vitamin B_{12}, folic acid, and other components of a multivitamin preparation. The author was able to arrive at satisfactory estimates of room temperature stability from data obtained under accelerated test conditions. McLeod (4) used a similar approach to predict expiration dates for other multivitamin preparations.

These reports and others on the subject (5–7) have suggested a simple experimental procedure for the evaluation of product stability. The procedure generally followed involves storing the product, preferably packaged in its final market container, in three or four individual ovens maintained at constant elevated temperature. Periodically samples are removed from these ovens and assayed. The loss of active ingredient is calculated, and rates of decomposition for the

several temperatures are obtained. These rates are plotted according to the Arrhenius relationship. Extrapolation of the Arrhenius plot gives the estimate of room temperature stability.

Errors which may arise in this procedure were recently discussed (8). In particular, it was observed that considerable time may elapse before samples placed in elevated temperature ovens reach thermal equilibrium. A time lag also may occur while the sample returns to room temperature after it is removed from the oven. These time lags lead to incorrect estimates of the actual storage interval at elevated temperature to which the samples are exposed. In order to correct for these errors, the concept of "Equilibrium Temperature Time Equivalent" or ETTE has been introduced. The ETTE is defined as the effective time of storage at oven temperature. It is calculated from the assay data by computer techniques, provided that an estimate of the heat transfer coefficients can be obtained.

Because of the increasing importance of accelerated testing procedures in industry, it seemed appropriate to explore in detail the errors introduced in stability predictions by heating and cooling lag times. This was done by using a theoretical and experimental approach to the problem.

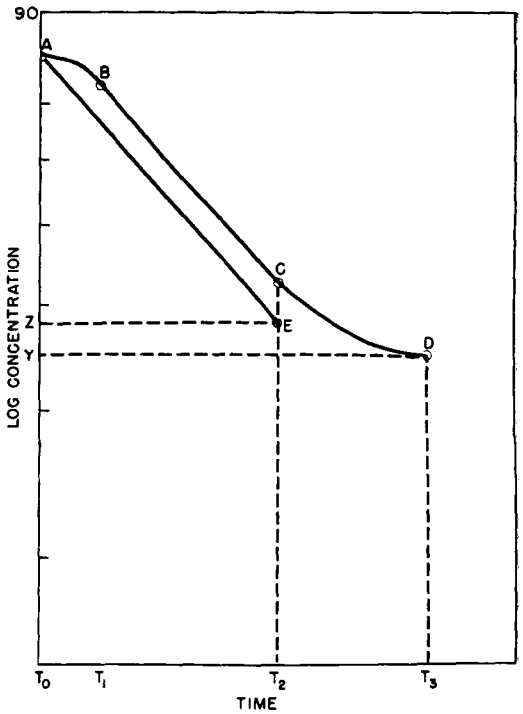

Fig. 1.—Time-concentration history for apparent first-order decomposition with heating and cooling lags, line *A-D;* and without lag, line *A-E.*

THEORETICAL TREATMENT

Figure 1 illustrates the decomposition history of a hypothetical pharmaceutical product stored at elevated temperature when degradation occurs by apparent first-order reaction. At zero time (T_0) the sample is placed in the storage oven and proceeds to warm to the equilibrium storage temperature at time T_1. During this heating interval the product temperature rises continuously, and breakdown occurs at an increasing rate. This is indicated by the changing slope of the line *A-B*. At time T_1, the sample temperature has reached its equilibrium value, and decomposition has reached its limiting rate. This maximum rate of breakdown continues at a constant level over the remaining time interval of actual storage in the oven. This period is indicated by the line *B-C*. At time T_2, the sample is removed from the oven and cooled to room temperature. While cooling, the decomposition rate gradually decreases as indicated by the changing slope of line *C-D*. The assay value obtained at the conclusion of the study, time T_3, is found to be Y units.

A hypothetical situation where the product is instantly heated to oven temperature, held at this temperature over the entire storage interval, and then instantly cooled back to room temperature is shown as a dashed line in Fig. 1. In this case, the rate of decomposition is constant and results in an assay value of Z units at time T_2. This value is higher than that obtained in the first example (Y units). The difference between Y and Z represents the error arising because of heating and cooling lag times. The presence of this $Y-Z$ error was illustrated in a similar fashion by Erickson, *et al.* (8), and served as the starting point for the development of the ETTE concept.

It is important to recognize, however, that in the usual kinetic study we are not primarily interested in the absolute assay value of any one particular sample. What is desired for the stability prediction are the rates of decomposition at the various elevated temperatures. These rates are obtained generally by following the decomposition history of a series of samples which have been placed in oven storage.

Figure 2 illustrates a theoretical decomposition history for a series of samples stored at oven temperature for various time intervals. First-order kinetic principles have been assumed to apply. It was also assumed that all samples were placed in the oven at the same time and heated at the same rate to the equilibrium oven temperature. Further, it was assumed that all samples cool to room temperature at the same rate after they are removed from the oven. These assumptions are completely in accord with industry practice and are justified by the results of Erickson and co-workers (9). It is important to note that in the present study no assumptions were made (or required) that the rates of heating (to oven temperature) or cooling (to room temperature) are equal to each other.

For the analysis shown in Fig. 2, all samples are placed in the oven at time T_0 and heated to equilibrium oven temperature at time T_1. The first sample is held in the oven until time T_2 and then cooled to room temperature by time T_3 giving an assay

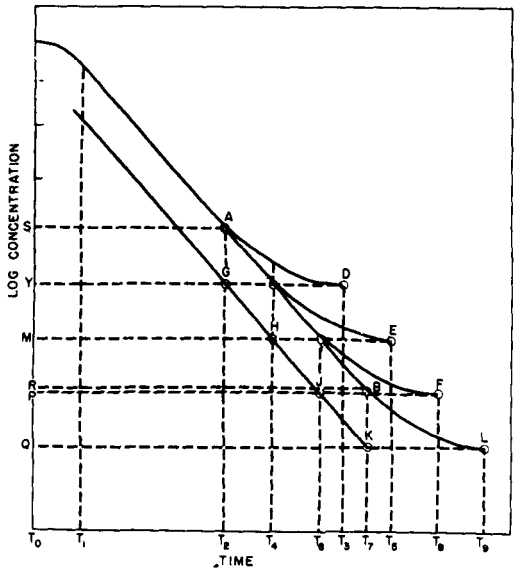

Fig. 2.—Time-concentration history for a series of samples decomposing under apparent first-order kinetics.

value of Y units. This plot is identical with that shown in Fig. 1.

The second sample is held at oven temperature until time T_4 and then removed from the oven and cooled to room temperature at time T_5, giving a final assay value of M units. Similarly, samples 3 and 4 are held at oven conditions for times T_6 and T_7, respectively, and then allowed to cool to room temperature to yield final assay values of P and Q units, respectively.

The individual assay values of Y, M, P, and Q units, together with the respective storage time intervals for each sample, constitute the entire data collection obtained for this particular temperature condition. It must be noted, however, that although assays are normally performed on samples which have cooled to room temperature, the storage interval is usually measured to the time the sample is actually removed from the oven. The data points used to plot the breakdown rates will therefore have the coordinates of (Y, T_2), (M, T_4), (P, T_6), and (Q, T_7) for the first, second, third, and fourth samples, respectively. These points have been designated in Fig. 2 by the letters G, H, J, and K.

A straight line has been drawn through the points G, H, J, and K in Fig. 2. Further, the slope of this constructed line has been set equal to the slope of the line A-B, which in turn equals the slope of line B-C in Fig. 1. The analysis which follows shows that points G, H, J, and K do fall on a straight line with a slope equal to that of line A-B. It should be emphasized that the slope of line A-B is equal to the rate constant for decomposition at constant temperature and is the parameter required for the Arrhenius plot. The slope of line A-B can be set equal to

$$\frac{R - S}{T_7 - T_2} = k \qquad \text{(Eq. 1)}$$

In coordinate notation, point G has been written as (Y, T_2) while point K has the coordinates of (Q, T_7). These points can be denoted also as ($S-X$, T_2) and ($R-Z$, T_7), respectively, where X and Z are concentration units such that

$$\ln S - \ln X = \ln Y \qquad \text{(Eq. 2)}$$

$$\ln R - \ln Z = \ln Q \qquad \text{(Eq. 3)}$$

For first-order and pseudo first-order rate mechanisms, the change in the logarithm of concentration is independent of initial concentrations and dependent only on the time interval during which the reaction occurs. This is true regardless of the temperature at which the reaction takes place. Consequently, if the rate of cooling from oven to room temperature is assumed to be equal for all samples, all samples will show an equal and constant change in the logarithm of concentration during the cooling step. Thus, the fall of X units in the logarithm of concentration from S to Y during the cooling of sample 1 will equal the fall of Z units in the logarithm of concentration from R to Q during the cooling of sample 4. Therefore, X and Z are equal to each other. Points G and K can now be expressed as ($S-X$, T_2) and ($R-X$, T_7), respectively. The slope of line G-K therefore becomes

$$\frac{(R - X) - (S - X)}{T_7 - T_2} = \frac{R - S}{T_7 - T_2} \qquad \text{(Eq. 4)}$$

This slope is identical to that for line A-B as shown in Eq. 1.

By repeating this procedure, it can be established that lines G-H, H-J, and J-K also have slopes equal to that for line A-B. Since G-H, H-J, J-K, and G-K can be shown to have the same slope and have points in common, points G, H, J, and K must be on the same line.

Individual assay points collected after sample decomposition at elevated temperatures do not recognize the errors introduced by heating and cooling lags. The foregoing theoretical analysis demonstrates however that the slope of the line drawn through these points represents, without error, the rate constant of decomposition desired for the Arrhenius plot.

EXPERIMENTAL

In order to illustrate the validity of the preceding theoretical treatment, two experiments were performed on a simple dye system degrading according to apparent first-order kinetics. The color stability at 87 ± 0.5° of aqueous solutions of FD&C Blue No. 2 (0.002%) in phosphate buffer, pH 6.72, was investigated. Residual color was measured spectrophotometrically at 610 mμ with a Cary model 11 recording spectrophotometer. Beer's law held for the dye in buffer solutions over the concentration range studies. Two different procedures were used to bring the color solutions to thermal equilibrium.

Experiment A—Instantaneous Heating and Cooling.—A 2.0-ml. aliquot of a concentrated stock solution of the dye at 25° was pipetted into 300 ml. of buffer solution preheated to 87 ± 0.5° and maintained at this temperature in a constant temperature bath. The solutions were mixed for 20 seconds to obtain uniform color distribution. The temperature of the buffer solution was not lowered by the

addition of the dye solution, thereby indicating instantaneous attainment of thermal equilibrium. At selected time intervals, 25-ml. aliquots of the solution were removed from the reaction mixture and quickly transferred to a glass-stoppered 50-ml. Erlenmeyer flask. These flasks were placed immediately into a dry ice-acetone bath at −67°. Cooling of the sample to 25° was obtained within 20 seconds by this procedure. Absorbance measurements were performed at 610 mμ for residual color. The change in the observed absorbance with time for this system is plotted in Fig. 3 as line *A*.

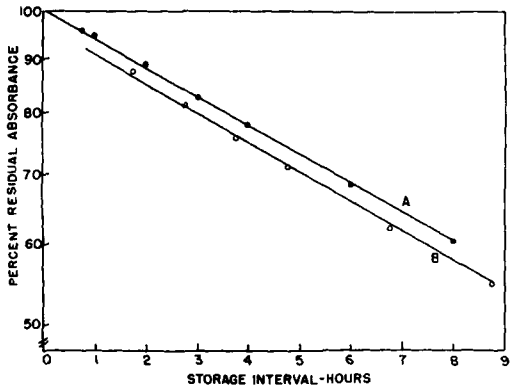

Fig. 3.—Apparent first-order plots for loss in absorbance of FD&C Blue No. 2 aged at 87°. Curve A, instantaneous heating and cooling; curve B, heating lag, 45 minutes, cooling lag, 105 minutes.

Experiment B—Slow Heating and Cooling.—This experiment was designed to introduce significant lags in both the heating and cooling of the dye solution. For this work a 2-ml. aliquot of concentrated stock solution of dye at 25° was pipetted into 300 ml. of buffer solution at 25°. The solutions were mixed to give uniform color distribution. The mixed solution was then placed in a constant temperature bath and heated to 87°. The solution required 45 minutes to reach an equilibrium temperature of 87 ± 0.5°. Periodically, 25-ml. aliquots of the solution were removed from the reaction flask and placed into a 50-ml. glass-stoppered Erlenmeyer flask. These samples were stored at room temperature to cool. A period of 105 minutes was required for the samples to reach 25°. Absorbance measurements were then taken. The data collected in this study are presented in Fig. 3 as line *B*. Storage intervals plotted in Fig. 3 were measured from the time samples were placed in the elevated temperature bath to the time they were removed.

DISCUSSION AND CONCLUSIONS

From the data shown in Fig. 3 it is evident that the rate of color loss follows first-order kinetics for experiment A (instantaneous heating and cooling). The rate constant at 87° for the isothermal reaction is expressed by the slope value of line *A* and is equal to 4.21×10^{-2} hr.$^{-1}$. It is also possible to read a $t_{80\%}$ value (3.6 hours) and other $t_{\%}$ values directly from the curve. These parameters often are used as convenient indexes of decomposition rate in the Arrhenius plot.

The degradation observed in experiment B (slow heating and cooling) also follows first-order kinetics once isothermal storage conditions are achieved (after 45 minutes). The data obtained in this experiment lie on a straight line (line *B*) which is parallel to that for the isothermal reaction. The rate constants as measured by the slopes of the lines therefore are equal. The experimental study thereby confirms the theoretically derived conclusion that valid rates of degradation can be measured directly from assay data which may be subject to (absolute) error as a result of heating and cooling lag times. Results obtained from customary stability testing of pharmaceutical dosage forms stored in constant temperature ovens therefore can be used with confidence to give accurate estimates of product stability.

Although data collected in such studies will give linear relationships with correct slope, the line constructed through the individual data points may be displaced from that obtained under isothermal conditions. Extrapolation of the decomposition data generally will not give a concentration intercept value equal to the experimentally determined concentration at zero time (100%). The rate of decomposition therefore cannot be correctly expressed in terms of $t_{\%}$ values which assume a linear relationship whose intercept on the concentration axis is equal to 100% (zero % decomposition).

When heating and cooling lags occur during the course of a stability study at elevated temperature, rate constants must be obtained from the slope of decomposition line. This slope should be calculated directly from the coordinates of two points which actually fall on the line. Although a high level of confidence is generally placed on the initial (zero time) assay value of the product, this value should not be employed in establishing the rate of decomposition.

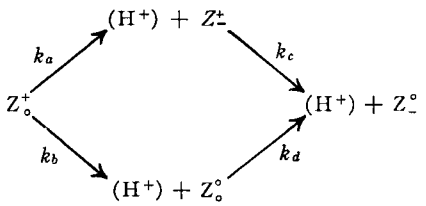
Acid Dissociation Constants of Phenylalkanolamines

By S. RIEGELMAN, L. A. STRAIT, and E. Z. FISCHER†



The acid dissociation constants of phenylephrine, synephrine, and tyramine were investigated by the new spectrophotometric method of Edsall. Epinephrine was studied by a titration and complexation method. It is concluded from analysis of the spectral data that the phenolic function is a stronger acid than the alkylammonium group. This is contrary to the accepted assignment of acid strengths to these acid functions. The spectrophotometric data were analyzed for the individual microscopic dissociation constants and the degree of dipolar character is reported.

THE ACCURATE evaluation of the dissociation constants of phenylalkanolamines is important to an understanding of their association and chelation reactions, their stability, and their comparative biological activity. Phenylalkanolamines may be considered initially as substituted phenols and compared to the acid strength of *o*-, *m*-, and *p*-cresol, whose dissociation constants are 10.32, 10.09, and 10.27, respectively (1). In contrast, the acidic dissociation constants of primary and secondary phenylalkylammonium groups vary from 9.8 to 10.8. Alkanolamines are somewhat stronger acids, i. e., ethanolamine has a pKa of 9.44 (2).

By analogy to these compounds, one would consider the first ionization step during the titration of a phenylalkanolamine salt to be related to the amine while the overlapping second dissociation step would be assigned to the phenol. However, evidence will be reported in this paper which will prove that the phenol group in these compounds is a stronger acid than is the alkanolammonium group.

It must be noted also that the ratio of the two successive dissociation constants obtained by pH titration may be as small as tenfold. A conventional titration, in which pH is determined as a function of the mean number of protons removed from the compound by the addition of hydroxyl ions, is not easily analyzed when the dissociation constants overlap. It is particularly difficult when the ratio of the constants for the two successive dissociation steps is 100 or less. Even when the ratio of the first dissociation constant to the second is as high as 500, one of the constants cannot be evaluated without correcting for the effect of the other, inasmuch as some simultaneous dissociation occurs. Bates (3) has stated that, under these conditions, accurate values may be unobtainable by the usual experimental procedures and has made use of the Speakman method (4) to analyze the data.

When both the phenolic and the alkylamine groups are found in the same molecule, they will not coexist without a degree of internal neutralization. Therefore, the compounds will be partly dipolar in character, depending on the relative strengths of the individual groups. At varying acidities, the molecules will exist in four different species. These may be represented as shown below

where Z^+_o = the phenylalkanolammonium ion, Z^- = the phenolate ion, and Z^+_- and Z°_o = the dipolar ion and uncharged molecule, respectively. The individual stages in the ionization result in individual or microscopic dissociation constants. These are noted as k_a, k_b, k_c, and k_d in the above diagram. The macroscopic or titration constants K_1 and K_2 bear a definite relation to the microscopic constants[1]

$$K_1 = k_a + k_b \qquad \text{(Eq. 1)}$$

$$K_2^{-1} = k_c^{-1} + k_d^{-1} \qquad \text{(Eq. 2)}$$

$$K_1K_2 = k_ak_c = k_bk_d \qquad \text{(Eq. 3)}$$

The assignment of K_1 or K_2 as determined from a titration of a compound to their corresponding dissociation function may be difficult on the basis of this information alone.

Spectrophotometry offers an alternative approach to this problem. It requires that one of the acidic groups in the molecule shall have an

[1] All the constants listed in the foregoing equations are acid dissociation constants. The existing literature citations are by no means uniform in the assignment of symbols for the microscopic acid dissociation constants. We have chosen to use the subscripts *a* to *d* rather than Arabic or Roman numerals to denote the different constants. It should be pointed out, however, that k_b represents an acid dissociation constant for the reaction shown in the diagram given above.

absorption spectrum distinguishable from its conjugate base. This is the case with the phenylalkanolamines. The phenol peak of the three phenylalkanolamines studied has an adsorption maximum in the region 2,720 to 2,750 Å. and shifts to 2,900 to 2,930 Å. upon complete conversion to the phenolate form. The molar extinction coefficient at 2,940 to 3,000 Å. is negligible for the forms in which the OH group is unionized, whereas it is large in the forms in which $-OH$ has been converted to the anion ($-O^-$). See Fig. 1. At pH values below 12.0, there are two forms in which the $-O^-$ exists, i. e., Z^+_- and Z°_-.

Edsall has shown that it is possible to obtain the individual constants for tyrosine by appropriate analysis of the ultraviolet absorption spectra over a wide range of pH values (5). He defined a function α_{OH}, which represents the fraction of all the phenolic hydroxyl groups in the solution which are ionized

$$\alpha_{OH} = \frac{\text{concn. of all molecules with ionized OH}}{\text{concn. of all molecular species}} = [Z^+_-] + [Z^\circ_-]/[Z^+_-] + [Z^\circ_-] + [Z^\circ_\circ] + [Z^+_\circ] = \frac{k_a(H^+) + k_ak_c(H^+)^2}{1 + (k_a + k_b)/(H^+) + k_ak_c/(H^+)^2} \quad \text{(Eq. 4)}$$

Edsall further defined M_{OH}

$$M_{OH} = \frac{(H^+)\alpha_{OH}}{(1 - \alpha_{OH})} = \frac{k_a(H^+) + k_ak_c}{(H^+) + k_b} \quad \text{(Eq. 5)}$$

or from Eq. 3

$$M_{OH} = \frac{k_a(H^+) + k_bk_d}{(H^+) + k_b} \quad \text{(Eq. 6)}$$

or in the logarithmic form

$$pM_{OH} = pH + \log(\alpha_{OH}/1 - \alpha_{OH}) \quad \text{(Eq. 7)}$$

$$= -\log \frac{k_a(H^+) + k_bk_d}{(H^+) + k_b} \quad \text{(Eq. 8)}$$

It is apparent from Eqs. 7 and 8 that a plot of pM_{OH} *vs.* α_{OH} will extrapolate to pk_a when $\alpha_{OH} = 0$ ($[H^+] \rightarrow \infty$) and to pk_d when $\alpha_{OH} = 1$ ($[H^+] \rightarrow 0$).

Once pk_a and pk_d are known, it is possible to obtain pk_b from the best fit to the experimental data. From Eq. 7, one will note that at $\alpha_{OH} = 0.5$, $pM_{OH} = pH$. Substituting this value for pM_{OH} in Eq. 8 and solving for k_b gives

$$k_b = \frac{(H^+)[k_a - (H^+)]}{(H^+) - k_d}, \text{ at } \alpha_{OH} = 0.5 \quad \text{(Eq. 9)}$$

Alternatively, a second approach leads to the value of k_b. Considering the value of α_{OH} corresponding to the point at which $pM_{OH} = (pka + pkd)/2$, then for this particular value of $M = (k_ak_d)^{1/2}$ we obtain from Eq. 6

$$pk_b = \log \frac{\alpha_{OH}}{1 - \alpha_{OH}} + pk_a \quad \text{(Eq. 10)}$$

The above calculation is exact if the molar extinction coefficient of the two phenolate forms Z^+_- and Z°_- are identical at the wavelengths chosen for the analysis. At the worst, it is a close approximation for the phenylalkanolamines. The same applies to the free phenol forms Z°_+ and $Z^\circ_\circ$, but is less significant since they make a very small contribution to the total results. If either assumption were incorrect, repeating the analysis at several different wavelengths should result in different values for the derived constants. The data obtained for the three phenylalkanolamines herein reported met this critical test.

EXPERIMENTAL

Apparatus.—Melting points were determined on a Kofler melting point apparatus. Polarimetric measurements were done on a Rudolph research polarimeter. The pH measurements were made on a Beckman model G pH meter. The ultraviolet absorption spectra were measured on a Cary model 11 recording spectrophotometer.

Materials.—l-Phenylephrine hydrochloride U. S. P. (Gane and Ingram Co., N. Y.) was used; m. p. 134–144°; specific rotation $[\alpha]^{25}_D$ −43°. Tyramine monohydrochloride (Nutritional Biochemicals Corp.), m. p. 269°. Synephrine tartrate was furnished by Dr. M. L. Tainter of Sterling Winthrop Research Institute. In several instances, the free bases were recovered, recrystallized, and used for the studies. There appeared to be no difference in extinction coefficients relative to the original salts. Epinephrine base (Desmo Chemical Corp.) meeting U. S. P. specifications was used as received.

Procedure.—Stock solutions were freshly prepared and diluted to approximately 3×10^{-3} to $4 \times 10^{-4} M$. All solutions were adjusted to a constant ionic strength of 0.1 *M* by the addition of potassium chloride. The recording spectrophotometer was carefully adjusted to zero absorbance prior to the determination and verified regularly between determinations. The instrument was carefully adjusted to wavelength and to zero absorbance at 3,500 Å. where the solutions were optically transparent.

The solutions were neutralized directly in the cell by the addition of a 5 *M* solution of acid or base using a micropipet. A range of pH values from less than 4.0 to greater than 12.5 was covered. The Beckman model G pH meter with a type E-2 electrode was checked for calibration, using the appropriate primary or secondary buffer standard recommended by the National Bureau of Standards, immediately before and after each pH reading. Complete neutralization of the sample modified the volume less than 0.5%. In all instances, the pH of the solution being studied was determined directly in the cell before and after analysis of its U. V. ab-

sorption. The values rarely differed more than 0.02 pH unit. It was found necessary to add a buffer to the synephrine solutions in order to stabilize the pH values in the intermediate range. Tris-(hydroxymethyl)-aminomethane was used as the buffer at a concentration of approximately tenfold of the drug concentration. The buffer is optically transparent in the region of study. In the acidic range, a more concentrated solution of the phenylalkanolamine was used when necessary in order to increase the accuracy of the determination of the absorbance of the solutions predominately containing the free phenol forms. However, in order to calculate the fraction in the phenolate ion form, the solution had to be brought to the pH >12.5. A carefully calibrated spacer was used to reduce the path length in order to obtain the absorbance of the highly absorbing phenolate ion form. In order to reduce the effect of oxidative changes, all solutions were freshly prepared just prior to the study. The solutions remained colorless throughout the study. The absence of oxidative changes was proved by checking whether or not the original spectrum was recovered by conversion of the alkaline solution back into the free phenol form.

Calculations of pM_{OH} values were made at three wavelength values in the region of 2,920 to 3,000 Å. where the extinction coefficient of the free phenol form is minimal, but the phenolate forms result in a high extinction. Within experimental error, the results reported are independent of the wavelength selected.

The titrations of epinephrine in the presence and absence of boric acid were run in a four-neck, round-bottom flask of 500-ml. capacity. The epinephrine base was dissolved with a slight excess of hydrochloric acid adjusted to 0.1 *M* with potassium chloride, and titrated with carbon dioxide-free potassium hydroxide. The titrating solution and the flask were flushed free of dissolved oxygen by passing oxygen-free nitrogen through the solution. The nitrogen flushing was continued during the run. Only an insignificant discoloration appeared at the end of the titration. The nitrogen was freed of residual oxygen by passing the gas through a gas purification train containing vanadous sulfate (6) and 2,6-anthroquinone disulfonate as oxygen getters.

RESULTS AND DISCUSSIONS

Figure 1 illustrates a typical determination of ultraviolet absorption data of phenylephrine. It is generally recognized that binary mixtures of compounds will possess isosbestics at points of intersection when only the mole fraction is varied. Examination of the graphs indicate that the solutions do not possess perfect isosbestic points; they have slightly varying points of intersection. These results were demonstrated not to arise from errors in the measurement procedure. This indicates that there are three or more absorbing species present in the majority of the solutions studied. Imperfect isosbestic points may be seen in the published data of Edsall, *et al.*, on glycyl-L-tyrosine at various pH values (7); however, they did not comment on the significance of this phenomenon.

The ultraviolet absorption data were converted to the appropriate form according to Eq. 7. The results are plotted in Fig. 2 in the form of pM_{OH}

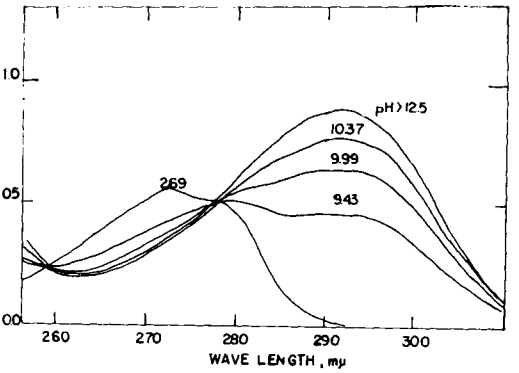

Fig. 1.—Ultraviolet absorption spectrum of phenylephrine hydrochloride at various pH values; temperature 22–23°; ionic strength 0.10.

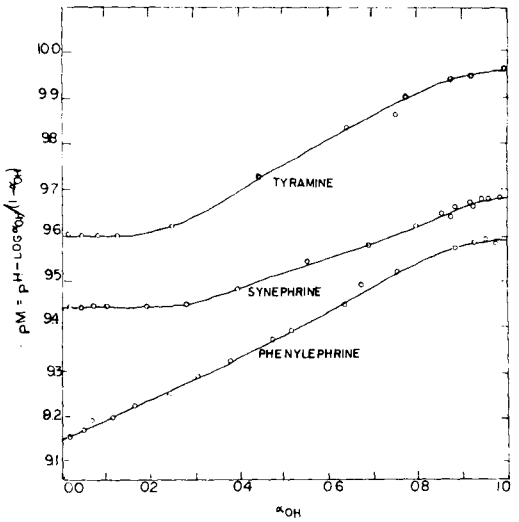

Fig. 2.—Values of pM_{OH} as a function of α_{OH} for phenylephrine, synephrine, and tyramine, respectively (see Eqs. 7 and 8).

vs. α_{OH}. As discussed above, the extrapolation to $\alpha_{OH} = 0$ and $\alpha_{OH} = 1$ results in the determination of pk_a and pk_d, respectively. These assignments are explicit from the equations listed earlier. Equations 9 and 10 were both used for the estimation of pk_b. The values were in good agreement. The solid line drawn through the points is the result of the substitution of the three microscopic constants into Eq. 8. Modification of the experimental microscopic constants by ±0.02 results in theoretical curve which deviates markedly in the sensitive portion of the graph.

Table I summarizes the data on the macroscopic and microscopic acid dissociation constants for the compounds studied. Both Fig. 2 and Table I indicate that the *meta*-substituted compound possesses ionization properties which differ from those of the *para*-substituted compounds. It is well recognized that several resonant forms of phenols exist with centers of high electron density at the *ortho* and *para* positions relative to the phenol group. Thus, phenylephrine with its *meta* substitution possesses carbons of increased negative charge density on

TABLE I.—NEGATIVE LOGARITHMS OF IONIZATION CONSTANTS

Constant[a]	Compound: Phenylephrine	Synephrine	Tyramine

either side of the alkanolamine chain, while synephrine does not. An atomic model of the compounds indicates that the secondary amine group can make contact with these carbon atoms. The values listed for the pk_a, pk_b, and pk_c for phenylephrine show increased acidity relative to the analogous *para*-substituted compounds. In contrast the values for the pk_d of phenylephrine and synephrine show a smaller difference, more analogous to that shown by *m*-cresol when compared with *p*-cresol.

Table I includes the macroscopic acid dissociation constants as calculated by Eqs. 1 and 2. A similar spectrophotometric study was conducted in 1954 by Lewis (8) who determined the ionization constants of sympathomimetics including the drugs used in this study. He calculated the phenolic dissociation constants, pK_1, on the basis of an assumption that only one species contributed to the phenolate spectrum or to the free phenol spectrum. Our data, however, show the failure to produce unequivocal

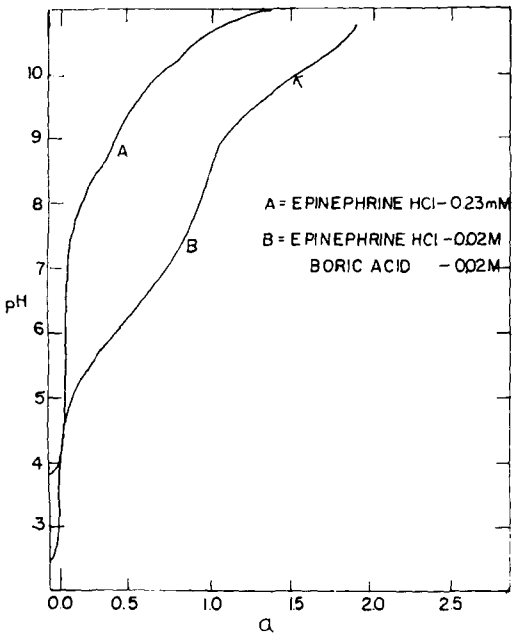

Fig. 3.—Titration of epinephrine hydrochloride with KOH, in the absence (*A*) and presence (*B*) of equimolar boric acid; ionic strength = 0.1; "a" denotes moles of base used per mole of epinephrine added.

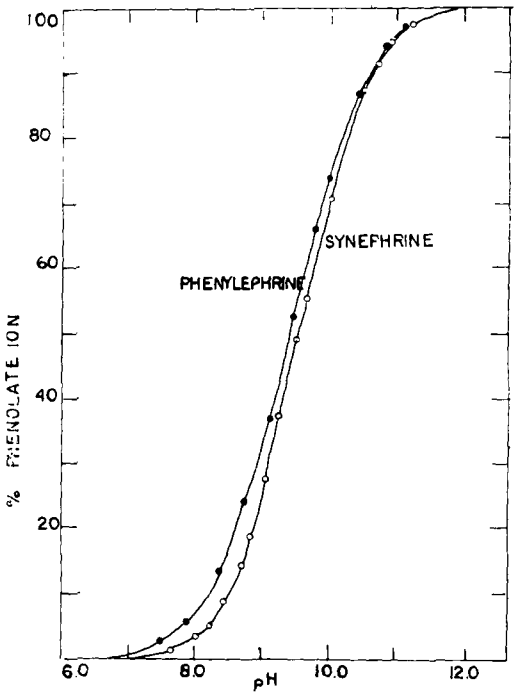

Fig. 4.—The degree of ionization of the phenol group of phenylephrine and synephrine (α_{OH}) as a function of pH.

isosbestic points in these systems. Therefore, the assumption of Lewis is unwarranted for these compounds and probably for the other dibasic compounds so calculated. Lewis then used the value obtained to estimate the pK_2 of the amino group from titration studies. Although both pK's are quantitatively inexact, they do confirm our conclusion that the conjugate acid of the amine is a weak acid relative to the phenol group. For experimental and theoretical reasons discussed in this paper, the acid dissociation constants (titration constants) determined by Tuckerman, *et al.* (9), using the approximation method of Parke and Davis (10) are invalid relative to their assignment of the particular dissociation constant to the amino group as well as to the relative accuracy of calculated constants.

The complication ensuing in the assignment of the titration acidity constants is illustrated in Fig. 3, the plot of our titration data of epinephrine in the absence (*A*) and presence (*B*) of equimolar concentration of boric acid. Boric acid is known to form chelates with adjacent or *cis* oriented hydroxy groups. In this manner, it is possible to block the normal ionization characteristics of phenolic groups. The first dissociation step in curve *B* of Fig. 3 is believed to be due to the second reaction represented below

$$H\,B + E \rightleftarrows H\,B\,E$$

$$H\,B\,E \rightleftarrows H^+ + B\,E^-$$

where HB = boric acid and E = epinephrine. Since the hydroxyl groups are blocked and no excess of boric acid is present, the second equivalent of base

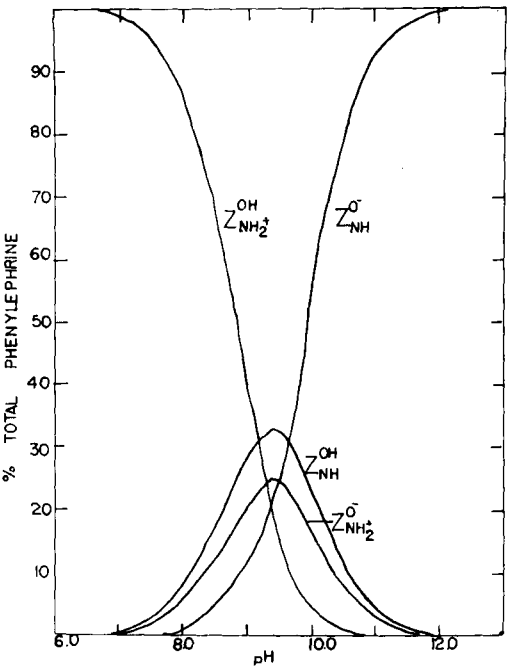

Fig. 5.—Relative concentrations of different microscopic forms of phenylephrine at different pH values.

which is utilized in the reaction must be assigned to the ionization of the secondary alkylammonium group of epinephrine. This leads to a pK_- of approximately 9.9. Tuckerman, *et al.*, incorrectly assigned a value of 8.55 to this functional group in epinephrine. Our titration value for epinephrine is in good agreement with the value of Lewis (7). It should be noted also that the pK's obtained by Albert (11) for tyramine of $pK_1 = 9.3$, $pK_2 = 10.9$ are in fair agreement with our results as shown in Table I considering the ionic strength effect and the differences in the method of calculation.

Table I also includes the ratio of the number of molecules in the dipolar ion form to the number in the uncharged form. This ratio gives no indication of the absolute amount of any of the species. However, these may be derived by further analysis of the absorption spectra data according to the procedures used by Benesch and Benesch (12). Figure 4 represents the degree of ionization of the phenol group (α_{OH}) of phenylephrine and synephrine as a function of pH, which is the sum of $Z^{\pm}_{-}$ and Z°_{-}. The data in Fig. 4, along with the fact that the ratio of the dipolar to the uncharged molecule is constant at all pH values, provide two simultaneous equations and to solve them for the relative concentrations of the different microscopic forms at different pH values. Figure 5 illustrates such an analysis of the data found for phenylephrine. It should be noted that the compound possesses significant concentrations of all species in the pH range from 8 to 10.5. At pH 9.35 where the dipolar ion form reaches its maximum concentration, the solution contains approximately 25% $Z^{\pm}_{-}$, 33% $Z^{\circ}_{\circ}$, 21% Z°_{-}, and 21% $Z^{+}_{\circ}$. It has been assumed, on occasion, that the evaluation of the ratio of $Z^{\pm}_{-}/Z^{\circ}_{\circ}$ was identical with a complete calculation of the per cent of the dipolar ion form. Such as assumption would lead to a conclusion that phenylephrine was 43% in the dipolar form. The more definitive analysis as given above shows that phenylephrine possesses a maximum of 25% in the dipolar ion form and this only at a pH of 9.35.

Postulation as to the significance of the individual microscopic dissociation constants on the stability and on the association or chelate formation properties of phenylalkanolamines will be left to a later publication.

Ion Exchange Resin Salts for Oral Therapy I

Carbinoxamine

By DAVID A. SCHLICHTING

Six new carbinoxamine cation exchange resin salts have been prepared. The degree of dissociation under simulated gastrointestinal tract conditions has been studied. It has been found that salts formed with resins having a pKa less than 5.2 are most adaptable to slow elution and, hence, sustained release of carbinoxamine. A more detailed investigation of salts of polystyrene sulfonic acids was made. Conditions regarding resin loading, per cent of cross linking of resin, efficiency of exchange, and the presence of added free acid resin were considered for attaining slow dissociation characteristics. Pharmacological tests of antihistamine activity are described. A new *in vivo* method of determining total drug release from an ion exchange salt is described and related to an *in vitro* method. The preparation of dosage forms and their stability is briefly discussed.

MOST ANTIHISTAMINIC agents have a central nervous system side effect. Frequently, a parasympatholytic effect is associated with them. The majority of these agents have a duration of action of about 4 hours or less (1). In the treatment of many conditions requiring antihistamines, a sustained antihistaminic effect is sought. If near optimal release of medicament can be achieved, then sustained drug blood levels and a reduction in side effects would be anticipated. Consequently, the possibility of achieving controlled and sustained release of the antihistamine carbinoxamine, 2-[*p*-chloro-α-(2-dimethylaminoethoxy)benzyl]pyridine, was investigated. A study was made of insoluble cation exchange resin salts, their formation, and dissociation under *in vitro* simulated gastrointestinal tract conditions and an *in vivo* test. Carbinoxamine maleate is a water-soluble, readily absorbed amine salt of proved clinical utility as an antihistaminic agent. A 4 to 8-mg. dose gives an effective clinical response and is recommended by the manufacturer to be taken three to four times a day.

Use is made of insoluble, synthetic cation exchange resins for salt formation and release-rate evaluation. They allow for utilization of numerous variables. Resins of varying functional anions, pKa values, cross linkages, and particle sizes are available. These variables are utilized in the following experiments in an attempt to prepare salts of carbinoxamine that release the drug slowly.

EXPERIMENTAL

Materials.—The insoluble, synthetic cation exchange resins used are described in Table I with information from the manufacturers as to their characteristics.[1] Future reference to these resins by capital letter will refer to Table I.

Resin Salt Formation.—Preparation of the carbinoxamine salts of the various resins was accomplished in the usual manner employing either batch or column processes (2). Carbinoxamine, its maleate, and its hydrochloride were used in aqueous and water-alcohol solutions in concentrations varying from about 1 to 20%. Quantities of carbinoxamine varying from two and one-half times the theoretical capacity to one-fourth of the capacity were used. Figure 1 exemplifies the rate of salt formation and is typical of this specific reaction as well as others studied.

Assay.—Assay of the various salts formed was accomplished by column elution with 5 to 10% hydrochloric acid. Elution with 2–300 ml. of acid over about a 24-hour period of time was found to be adequate. A Beckman spectrophotometer, model DU, was used for assay, reading at 263 mμ. Minor modifications were necessary when the resin salt was formulated in tablet and suspension dosage forms. Table II gives the results of the assays of carbinoxamine salts of the resins described in Table I.

Release Rates.—Time-release relationships were studied by subjecting a 40–100 mg. sample of the resin salt to 75 ml. of U.S.P. simulated gastric fluid without pepsin for one hour at 37.5 ± 3°. After 1 hour, the eluate was removed and assayed and was replaced by 75 ml. of U.S.P. simulated intestinal fluid without pancreatin. Aliquots, 5 to 10 ml., of this latter fluid were removed and assayed periodically and fresh replacement samples were added. The method is of the type described by Chaudhry and Saunders (3) as the replacement closed tube method.

The test apparatus used for time-release rates utilized 2.2 × 9-cm. glass tubes. They were fitted with 100-mesh stainless steel screens at the bottom and hooks at the top. Test samples were placed in such tubes. The tubes were hooked onto the arm of a U.S.P. device for raising and lowering tubes (4).

Received April 19, 1961, from McNeil Laboratories, Inc., Philadelphia, Pa.
Accepted for publication May 8, 1961.

[a] A 0.5-Gm. sample studied for 4½ hours in gastric fluid and 1½ hours in intestinal fluid.

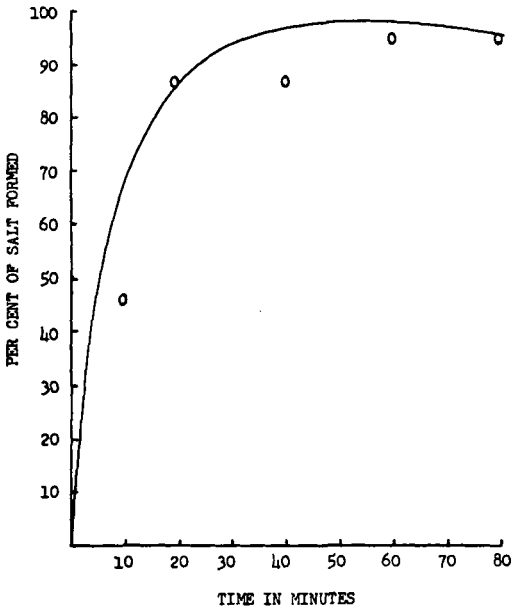

Fig. 1.—Reaction rate at room temperature between a 2.8% aqueous carbinoxamine maleate solution, equivalent to 25% of the theoretical capacity of the resin, and resin A.

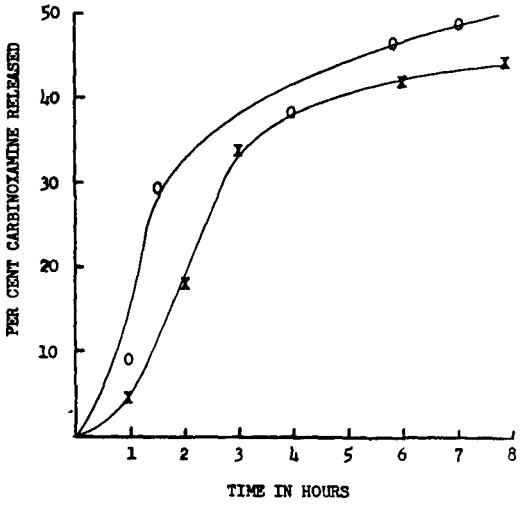

Fig. 2.—Rate of dissociation of two salts assaying 25.0 and 25.6% carbinoxamine, respectively. O, Surface area = 1,463 mm.²/100 mg.; X, surface area = 758 mm.²/100 mg.

The tubes containing samples were allowed to move up and down in individual 4 × 15-cm. test tubes containing 75 ml. of eluant maintained at 37.5 ± 3°. Table II describes the release rates of the various resins described in Table I.

In 5 morphine-chloralose anesthetized dogs, a 0.7 mg./Kg. dose of carbinoxamine, given intraduodenally as the maleate salt, showed maximal response to intravenous histamine in an average time of 33 minutes. The elapsed time from the average maximal response until histamine response returned to one-half the control response averaged 101 minutes. In 4 morphine-chloralose anesthetized dogs, a 2 mg./Kg. dose of carbinoxamine on resin, intra-

duodenally, showed maximal response to intravenous histamine in an average time of 74 minutes. The elasped time from the average maximal response until histamine response returned to one-half the control response averaged one 106 minutes.[2] Assuming about 50% dissociation of the resin salt, the prolonged protection is significant.

An *in vivo* study of total release of carbinoxamine from polystyrene sulfonic acid in a healthy adult male was accomplished. A sample of resin A salt, shown in Fig. 2 as X—X, containing 33 mg. of carbinoxamine was ingested 5 hours after the evening meal and 8 hours before the morning meal. A portion was recovered from the feces about 24 hours later and was isolated and assayed for carbinoxamine remaining on the resin. It was found that this dose released 53% of the carbinoxamine in a normal gastrointestinal tract compared to 44% released by the *in vitro* test method reported.

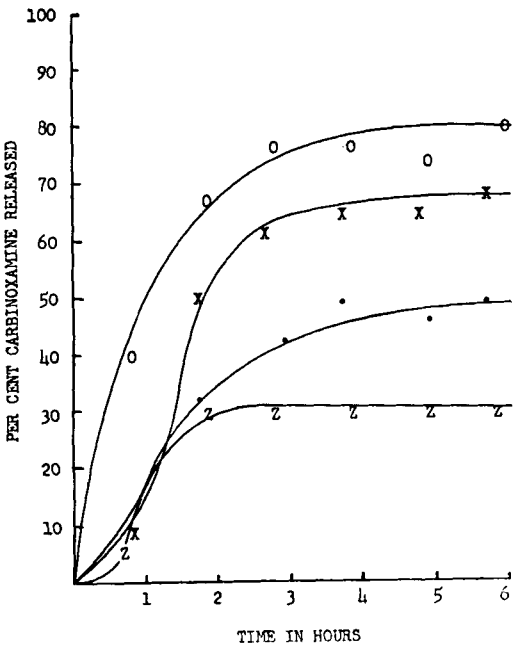

Fig. 3.—Rate of dissociation of smaller than 80-mesh samples. O, Sample 65% converted to salt form; X, same salt plus equal weight of resin A acid; Z, same salt plus three times the weight of resin A acid; ●, sample 47% converted to salt form.

RESULTS AND DISCUSSION

Several variables were shown to have important effects on dissociation of the resin salts as reported in Table II. Resins having a pKa 5.2 or greater release carbinoxamine too rapidly for sustained action, e.g., resins E, F, and G. Resins having a pKa less than 5.2 release carbinoxamine in a more desirable manner for sustained release effect, e.g., resins A, B, C, D, and H. For those resins having two pK values, the overall effect is between the two values. Resin A gives time-release characteristics closest to a straight line function and reacts efficiently with carbinoxamine. Increase in cross linkage of the polymers reduces both the efficiency of salt formation and of dissociation. Figure 2 shows the effect of surface area on release characteristics. Doubling of the surface area increased the dissociation *in vitro* by about 5% in this test. Figure 3 shows that partial loading of resin A or introduction of acid resin A in the presence of resin salt A gives results similar to those reported by Chaudhry and Saunders (3). However, the salt plus equal weight of resin releases more than expected.

Tablets were formulated and it was found that the salt of resin A, ground to smaller than 40 mesh, could be compressed well when aluminum hydroxide or dicalcium phosphate was used as the main tablet diluent and gelatin solution was used in granulation. Such tablets, colored with pigments or other tablets coated with sugar, showed no alteration in assay or release characteristics on storage for 3 months at about 40°.

It was found that the salt of resin A, ground to smaller than 80 mesh, could be suspended well in tragacanth or Carbopol 934[3] sols. The effect of pH on release was studied and indicates that a weak ionic aqueous suspension would release little or no carbinoxamine between pH 3 and 5. Assay and release characteristics of suspensions showed no alteration on storage for 3 months at about 40°.

SUMMARY AND CONCLUSIONS

Six new insoluble synthetic cation exchange resin salts of carbinoxamine have been prepared and evaluated. Salt formation and dissociation were studied and polystyrene sulfonic acid was found to be superior. Retardation of dissolution occurred, however, with all salts made from resins having a pKa less than 5.2. For the preferred acid salt it was found that: particle size plays a minor role in dissolution rate, partial salt formation or the presence of added free acid markedly alters dissolution rate, and increased crosslinking of the resin reduces the dissolution rate. In anesthetized dogs it was shown that the resin salt protected against histamine for a significantly longer time than carbinoxamine maleate. A new *in vivo* test method of total release was compared with the *in vitro* test method used and they were found to be of the same order of magnitude. Tablets and suspensions of the resin salt have been prepared and found to be stable over a period of 3 months at about 40°.

Peptide Studies V

Synthesis and Racemization of Some Optically Active Tripeptides of L- and D-Leucine and L- and D-Valine

By S. SHANKMAN and S. HIGA

Seven tripeptides of leucine and valine of the optical configuration L-L-D were synthesized by the mixed anhydride procedure. Configuration of each amino acid in the peptides was established bacterimetrically. Racemization was found on the internal amino acid.

IN PREVIOUS investigations of antibacterial peptides (1, 2), we found that the L-L-D structure of the 8 valine tripeptides was unique in its ability to inhibit growth of lactic acid bacteria. Synthesis of other tripeptides was desirable to determine further the relation of structure to inhibitory activity. We now report that the 7 other possible L-L-D tripeptides of leucine and valine have been synthesized via the mixed anhydride procedure (3) by the sequence Z.A.B. + C. ester → Z.A.B.C. ester. All di- and tripeptide intermediates were obtained in the crystalline state. The phthalyl valyl-valyl esters were previously reported (4) as uncrystallizable oils.

In the synthesis of carbobenzoxy-leucyl-valyl-leucine methyl ester and carbobenzoxy-leucyl-valyl-valine methyl ester, both the desired L-L-D structure and an L-DL-D mixture were isolated. The latter was formed by racemization of the central amino acid. This mixture, which melted sharply, is composed of two compounds, L-L-D and L-D-D, which crystallized together but are not optical enantiomorphs. The L-DL-D mixtures contained approximately equal amounts of L-L-D and L-D-D isomers for both the Z.leu.val.-val.ester and the Z.leu.val.leu.ester.

The optical purity of peptides has been established classically by rotation of the protected peptide after synthesis by two procedures. Several workers (5–10) have evaluated coupling procedure for racemization by using model systems with isolation of the optically active and racemic compounds. The coupling of acylamino acid to the peptide esters has been recommended to avoid racemization (11, 12). Z-blocked dipeptides may racemize during *p*-nitrophenyl ester formation (13). Racemization of an internal amino acid may occur during exposure of the peptide to base (14) during the saponification of peptide esters.

Biologic evaluation of optical purity has proved useful when the peptide can be compared to natural all L isolated material (15, 16). In one case, however, presence of D-amino acid did not destroy or prevent biologic activity (17). Enzymatic methods, employing leucine aminopeptidase (18) and chymotrypsin (19), have been used to establish optical purity after decarbobenzoxylation of peptides. Still another method for proving optical purity of peptides is the bacterimetric determination of the free L-amino acids after hydrolysis (4). Here we report the application of the bacterimetric procedure to determine the configuration of each amino acid in the free tripeptides of leucine and valine and two carbobenzoxy-tripeptide esters.

EXPERIMENTAL

Carbobenzoxy-valyl-valyl-methyl ester.—Z.L-valine (0.138 mole) (m.p. 59–60°) in cold (−10°) ether was condensed via the chlorcarbonate (3) with valine methyl ester (0.153 mole) freshly distilled. The mixture was washed with water, 0.1 N hydrochloric acid, water, 5% potassium carbonate, water, with appropriate backwashes, dried over sodium sulfate, and evaporated to dryness. The compound solidified after the residual solvent was removed *in vacuo*. The peptide was recrystallized from chloroform:petroleum ether. Yield 37.5 Gm., 75%, m.p. 109–110°. The other three protected dipeptides were similarly made. Yields and m. p. are given in Table I.

Carbobenzoxy-valyl-valine.—Z.val.val.OMe (0.088 mole) was dissolved in a minimal amount of methanol at RT and sodium hydroxide (0.096 mole) (2 *N* in water) was added. After 4 hours water was added and the methanol was removed *in vacuo*. The unsaponified residue was removed by filtration. The aqueous filtrate was treated with about 1 Gm. of activated carbon, filtered, and acidified with 1 *N* hydrochloric acid to Congo red. The Z.val.val was extracted into ethyl acetate, washed with water, dried, evaporated to dryness, and recrystallized from chloroform:petroleum ether. Yield 26.9 Gm., 88%, m.p. 140–141.5°. The remaining Z.dipeptides were similarly made.

Received April 20, 1961, from Pasadena Foundation for Medical Research, Pasadena, Calif.
Accepted for publication May 24, 1961.
This work was supported in part by Grants CY-3609 and CY-4318 of the National Institutes of Health.
The authors wish to thank Mrs. V. Gold for assistance with the analyses.

TABLE I.—CARBOBENZOXY DIPEPTIDES OF L-LEUCINE AND L-VALINE

Compound	Z. Dipeptide Ester			Z. Dipeptide

Leu.val	70	...	...	80	109–110	109–110(25)

[a] Uncorrected.

Carbobenzoxy-tripeptide Esters.—Z.leu.leu, 2.5 Gm. (6.6 mmole) in cold ether (−5°) was condensed via the chlorcarbonate (3) with 7.3 mmole of D-valine ester freshly distilled. Some precipitation occurred on standing overnight. To the entire mass was added sufficient ethyl acetate to form one phase, and the ethyl acetate was washed with water, 0.1 *N* hydrochloric acid, water, 5% potassium carbonate, and water, with appropriate backwashes. The ethyl acetate-ether phase was dried over sodium sulfate and evaporated to dryness *in vacuo*. The residue was dissolved in chloroform and fractionally precipitated with petroleum ether (30–60°). The first and second crops were recrystallized repeatedly from the same solvent pair to constant melting point before any analysis. The remaining six compounds were similarly prepared unless noted. Yields and analytic data are given in Table II.

On the Z.leu.val.val.OMe and Z.leu.val.leu.OMe, the above procedure gave the sharp melting material which melted intermediate to the compounds in Table III.

Fractionation of Z.leu.val.val.OMe.—The first crop, 1.5 Gm. of product from chloroform:petroleum ether crystallization, had a wide melting range 130–150°. This material was very slowly crystallized five times from ethanol:water to yield 0.5 Gm. of material, m.p. 131–132°, which proved by analysis to be a mixture of L-L-D and L-D-D. The second crop from the chloroform:petroleum ether was obtained by evaporating the filtrate from crop No. 1 to dryness. It was recrystallized three times from ethanol:water to yield 0.4 Gm. of material, m.p. 162–163°, which proved on analysis to be chiefly L-L-D.

Fractionation of Z.leu.val.leu.OMe.—The crude tripeptide ester (3.2 Gm.) was recrystallized from methanol:water to give 2.4 Gm., m.p. 130-153°. After two recrystallizations from chloroform:hexane and one from alcohol:water, 1.0 Gm. of material, m.p. 126–127.5°, was obtained, which was by analysis a mixture of L-L-D plus L-D-D. The second crop from chloroform:hexane was obtained by evaporating the filtrate from crop No. 1 to dryness. It was recrystallized very slowly three times from ethanol:water to give 0.8 Gm., m.p. 162–164°, which proved to be the L-L-D compound.

Carbobenzoxy Tripeptides.—These compounds were saponified as above, but overnight. The methanol was reduced to one-fourth volume *in vacuo*, and water was added to precipitate completely the unsaponified starting compound. The filtrate was stripped of methanol on a rotary evaporator, extracted with ethyl ether, treated with charcoal, and acidified with 0.1 *N* hydrochloric acid to Congo red. The Z.tripeptides were filtered off and recrystallized from chloroform:petroleum ether. Ethanol:water was used only when material with wide melting range was obtained.

Tripeptide Acetates and Tripeptides.—The Z.tripeptide (0.5 Gm.) was dissolved in 30 ml. methanol and 0.1 ml. acetic acid, 2 ml. water, and 0.17 Gm. palladium oxide catalyst (26) was added. Hydrogen was passed in until carbon dioxide was no longer evolved. The catalyst was removed and the filtrate was evaporated to dryness *in vacuo*. The residue was dissolved in water, filtered, and again evaporated to dryness. This procedure gave tripeptide acetates. The tripeptide acetates were put on a Dowex-50-X-8 column and eluted with 4 *N* ammonium hydroxide. The eluate was taken to dryness *in vacuo*.

Analytic Procedures.—*L. plantarum* was used to assay L-valine under conditions in which D-valine was inactive. *P. cerevisiae* parent (ATCC 8081) or *L. casei* was used to assay for L-leucine, since *L. plantarum* can utilize the D-form. Media and test conditions have been reported (27). The growth period was 3 days. Several commercial D-leucines had variable amounts (3–11%) of L-leucine under our conditions. The lot used for synthesis assayed 0.1–0.3% L-leucine in several trials. The D-valine employed assayed about 0.1% L-valine. The L-amino acids from Calbiochem or Mann assayed about 100% of control by bacterimetry. Possible impurities, such as tyrosine in L-leucine, were negligible. D-Amino acid in L-valine or L-leucine was not determined.

Free peptides were hydrolyzed overnight in 4 *N* hydrochloric acid, in sealed tubes, at 116°, which is conveniently maintained by refluxing *n*-butanol. Z.peptides or Z.peptide esters were treated first with hydrogen bromide in dioxane, taken to dryness, then hydrolyzed with hydrochloric acid. Hydrochloric acid treatment alone led to charring of sample and poor assays.

Rotations were measured with the Keston polarimetric attachment to the Beckman DU spectrophotometer, employing Aminco 5.00-cm. cells of 2.6 ml. volume. The technique for inhibition measurements has been described (2). All samples were autoclaved with the test medium.

DISCUSSION

The bacterimetric procedure, applied to any all L-peptide, gives (as a measure of optical purity of a given amino acid) the L-amino acid found compared with theory for that amino acid. In the L-L-D peptides described here, the bacterimetric procedure is applicable to each amino acid residue with maximum accuracy when used to determine the C-terminal amino acid with D-configuration. Any L-amino acid in the C-terminal position is determined

directly, without interference from the existing D-amino acid. The limit of the detection is determined by the extent of racemization under the hydrolytic conditions employed. The determination of the D-amino acid which is present due to racemization of the L is made by subtracting the L found from that which should be theoretically present when no racemization occurs.

Maximal assay values for all peptides were obtained after hydrolysis with 4 *N* hydrochloric acid in sealed tubes, after 12–24 hours at 116°, in contrast to the 60 hours at 126° needed for D-valyl-L-valine (4). Increasing the hydrolysis time to 48 hours or longer did not give increased leucine or valine assay values in the peptides val.leu.val, leu.leu.val, or leu.val.leu. The free amino acids D-leucine and D-valine gave 0.7% and about 0.2%, respectively, of the L-forms when hydrolyzed 12 hours, and 3.5% and 1.0% of the L-forms at 60 hours. Approximately 10–20 γ of L-amino acid per ml. in the sample was sufficient for analysis.

Yields of the Z.dipeptide esters of valyl-valine, valyl-leucine, leucyl-valine, and leucyl-leucine were satisfactory. Alkaline saponification of these Z. dipeptide esters also proceeded smoothly and in good yield (Table I).

In the Z.tripeptide series (Table II), yields of the crude Z.tripeptide esters were from 60–80% of crystalline material. However, after several recrystallizations (needed to obtain constant melting point and analytic purity, indicated by amino acid analysis) the yields of pure Z.tripeptide esters were from 25–35%. Saponification proceeded quite slowly compared with the Z.dipeptide esters. After 16 hours, yields of Z.tripeptides from 25–60% were obtained, with most of the remaining Z.tripeptide ester recoverable. There were distinct differences in the yields of the free tripeptides after hydrogenation. N-Terminal leucine peptides were obtained in 60–90% yields; N-terminal valine peptides in 20–55% yields. The N-terminal valine tripeptides which are reported here were obtained optically pure after recrystallization, but this is not conclusive proof of absence of racemization on synthesis (28).

Two of the four protected N-terminal leucyl peptides were obtained in both optical forms. Previously (4), with the phthaloyl blocking group and carbodiimide coupling, the eight optically active tripeptides of L- and D-valine were obtained pure. This probably was due in large part to the use of valine in the N-terminal position, as has been noted above, since Anderson (6) has reported that the carbodiimide procedure also permits racemization to occur.

The data in Table II indicate that no significant racemization occurred on the N-terminal or C-terminal amino acids during coupling, saponification, or hydrogenation. However, leu.val.val was found to be low in L-valine. A second coupling was fractionally crystallized as the Z.tripeptide ester, and yielded both the desired L-L-D peptide ester and the mixture of L-L-D and L-D-D. The Z.L-L-D peptide esters melted some 30° higher than the mixture of L-L-D and L-D-D (Table III).

Rotations, R_f values, and inhibitory powers of the free peptides are given in Table IV. No resolution of the mixtures of L-L-D and L-D-D occurred in the butanol:acetic acid:water system used. Previously (4), we obtained R_f's of 0.70 and 0.73, respectively, for the L-L-D and L-D-D trivalines.

SUMMARY

Seven possible tripeptides of leucine and valine of the L-L-D configuration were synthesized.

Their optical purity was determined bacterimetrically.

These peptides were not effective as antibacterial agents compared with L-valyl-L-valyl-D-valine.

Stability of Pyridine-2-aldoxime Methiodide II

Kinetics of Deterioration in Dilute Aqueous Solutions

By ROBERT I. ELLIN, JAMES S. CARLESE, and ALBERT A. KONDRITZER

The decomposition of 2-PAM was studied at pH values 0.5 to 13 and at temperatures ranging from 37 to 87°. At constant pH and temperature, the observed rate of deterioration of 2-PAM was first order with respect to drug concentration. Below pH approximately 4, hydrogen ion catalysis of the acid form of oxime occurs; above pH 4, the reaction is either an hydroxyl ion catalysis of the acid form of oxime or is noncatalytic in which there is a direct attack on the oximate species. Two mechanisms have been postulated for the breakdown of 2-PAM. Specific velocity constants, energies of activation, and frequency factors have been determined for both mechanisms. The pH of maximum stability has been determined from initial rate constants over the entire pH range. General equations relating the half-life of 2-PAM solutions to temperature and pH have been derived.

DURING the past few years a group of new drugs, of which the best known is pyridine-2-aldoxime methiodide (2-PAM, 2-formyl-1-methylpyridinium iodide oxime), has been introduced which is capable of reversing neuromuscular block caused by organophosphates and may be of clinical value in the treatment of intoxication by these compounds (1–6). Aqueous solutions of 2-PAM, contained in injector items, may be used for purposes of self-aid and first-aid. Therefore, knowledge of the stability in water is essential. The object of this study was to establish a basis for predicting the rate of decomposition of 2-PAM at various hydrogen and hydroxyl ion concentrations and temperatures.

The hydrolysis and pyrolysis of acylated oximes have been the subject of many investigations (7–9). The hydrolysis of free oximes in acid solution has been well investigated (10). However, relatively few references are available on the alkaline decomposition of the free oxime. For the most part, these reports were not concerned with the kinetics of the process or predictions based on such data. Benger and Brady (11) presented various mechanisms for the alkaline hydrolysis of acyl benzaldoximes. Two of the mechanisms described were attack by hydroxyl ions: (*a*) at the methine hydrogen atom resulting in formation of the corresponding nitrile and (*b*) at the carbonyl carbon resulting in the formation of free oxime. In general, aldoximes on reaction with alkali do not give rise to the corresponding nitrile because the high electron density on the oxygen prevents attack by hydroxyl ions at the methine hydrogen atom. Replacement of the hydrogen of the hydroxyl group of the oxime by an acyl group establishes a relative positive charge at the oximino oxygen, thereby reducing the electron density sufficiently to permit hydroxyl ion attack at the methine hydrogen atom (11, 12). This mechanism is considered to involve removal of the methine hydrogen atom as a proton accompanied or followed by release of the acylate anion (11, 13). On the other hand, the free aldoxime, *o*-nitrobenzaldoxime, on heating with aqueous sodium hydroxide gives rise to the corresponding nitrile. Here the negative inductive effect of the nitro group facilitates the removal of a proton at the methine hydrogen atom (14, 15).

The decomposition of 2-PAM takes place by two mechanisms. Below pH approximately 4, 2-PAM is hydrolyzed to pyridine-2-carboxaldehyde methiodide and hydroxylamine (reaction 2, Fig. 1). Above pH 4, 2-PAM is dehydrated to 2-cyanopyridine methiodide, which is converted to 2-hydroxypyridine methiodide, which rearranges to N-methyl-alpha-pyridone (16) (reaction 1, Fig. 1). The latter reaction may follow a mechanism similar to the one mentioned above. The nitrogen on the pyridine ring, being strongly electrophylic, would have an effect similar to that of a nitro group and thereby facilitate hydroxyl ion attack on the methine hydrogen atom.

The kinetics of the decomposition of 2-PAM was studied over the pH range 0.5 to 13 and at the temperatures 37, 57, and 87°. Kinetic constants, determined at the various temperatures, were used to calculate the activation energy for each of the two mechanisms. From these values an equation was derived for predicting the decomposition of 2-PAM at any particular temperature and pH. By taking into account the effects of both hydroxyl and hydrogen ions, the pH of minimum decomposition at various tem-

Accepted for publication March 28, 1961.
Part I was published in *J. Am. Chem. Soc.*, **80**, 6588(1958).

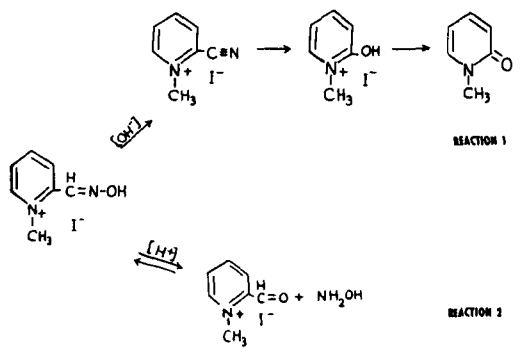

Fig. 1.—Reactions involved in the decomposition of 2-PAM.

peratures and the decomposition rates at these minimum pH values were calculated. By using initial rate constants, the half-life of 2-PAM solutions have been calculated for various pH values and temperatures.

EXPERIMENTAL

The method of analysis consisted of making a series of ultraviolet measurements of 2-PAM solutions undergoing decomposition. (2-PAM, purchased from Aldrich Chemical Co., Milwaukee, Wis., was twice recrystallized from ethyl alcohol and has a melting point of 228–230°.) Ultraviolet absorption spectra of 2-PAM and its acid and base decomposition products were determined in acid and alkaline solutions and indicated that 2-PAM can be determined quantitatively in the presence of its decomposition products at 335 mμ in 0.1 *N* sodium hydroxide (17).

The hydrogen and hydroxyl ion concentrations of the system were maintained by using buffer solutions or an excess of acid and base. The pH change during the experimental period was limited to 0.1 pH unit. Buffer systems used in the study are listed in Table I. From pH 0.4 to 1.2, the pH was controlled by an excess of perchloric acid; at pH 13, by an excess of sodium hydroxide. The pH of each buffer was determined at the temperatures at which the experiments were carried out.

Table I.—List of Buffers Employed and Composition of Each

pH	Composition	Dilution
2	5.0 ml. 0.2 *M* KCl + 10.6 ml. 0.2 *N* HCl	to 200 ml.
3	3 Gm. glacial acetic acid	to 500 ml.
4	16 ml. 0.1 *N* acetic acid + 4 ml. of 0.1 *N* sodium acetate	as is
5	6 ml. of 0.1 *N* acetic acid + 14 ml. of 0.1 *M* sodium acetate	as is
6	11.6 Gm. KH_2PO_4 + 2.15 Gm. Na_2HPO_4	to 500 ml.
7	4.55 Gm. KH_2PO_4 + 9.45 Gm. Na_2HPO_4	to 500 ml.
8	5.9 Gm. boric acid + 4.55 Gm. borax	to 500 ml.
10	3.25 Gm. $NaHCO_3$ + 6.6 Gm. Na_2CO_3	to 500 ml.
12	12.3 Gm. Na_3PO_4	to 500 ml.

Buffer solutions were placed in a thermostatically controlled bath, and allowed to reach the temperature of the bath. A volume of standard solution, containing 25 mg./ml. of 2-PAM, was then added to give the reaction mixture a concentration of 1 mg./ml. The decomposition of 2-PAM was determined by periodically removing 1-ml. samples, diluting to 100 ml. with 0.1 *N* sodium hydroxide, and following the disappearance of the oxime grouping with a Beckman DU quartz spectrophotometer at 335 mμ.

RESULTS AND DISCUSSION

The observed degradation of 2-PAM under various conditions, examples of which are given in Figs. 2–4, conform to the classical first-order equation, $\ln c = kt +$ constant, where k is the first-order rate constant at a constant pH. 2-PAM as the free oxime represents the protonated form of the oxime and will be designated (OxH). The protonated form is positively charged as the nitrogen of the pyridine ring of 2-PAM is in the charged form. The basic or oximate species of 2-PAM may be considered to be electrically neutral as the negative charge on the oximino oxygen internally neutralizes the positive charge on the pyridine ring nitrogen. The oximate species will be designated (Ox).

From the pH profile shown in Fig. 5 we can assume that the hydrolysis of 2-PAM at pH values 0–4 is due to the hydrogen ion catalysis of the protonated species. At pH values 4 to 8, the mech-

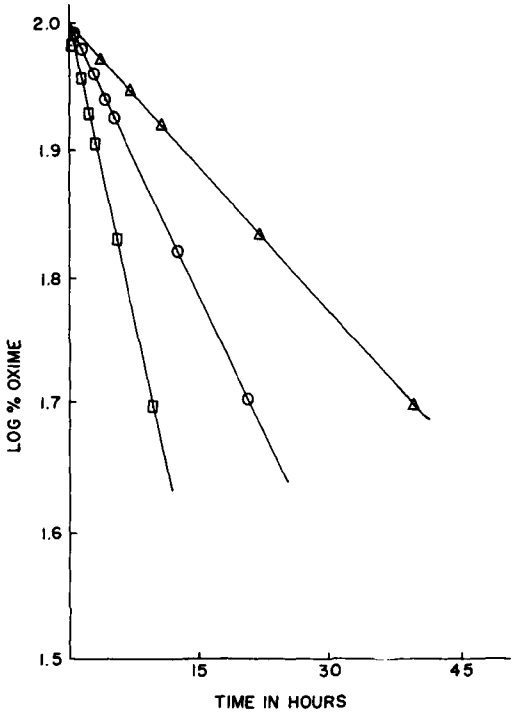

Fig. 2.—Typical first-order rate plots for the acid catalyzed decomposition of 2-PAM at 57°. △, 0.096 *N*; ○, 0.191 *N*; □, 0.383 *N* perchloric acid.

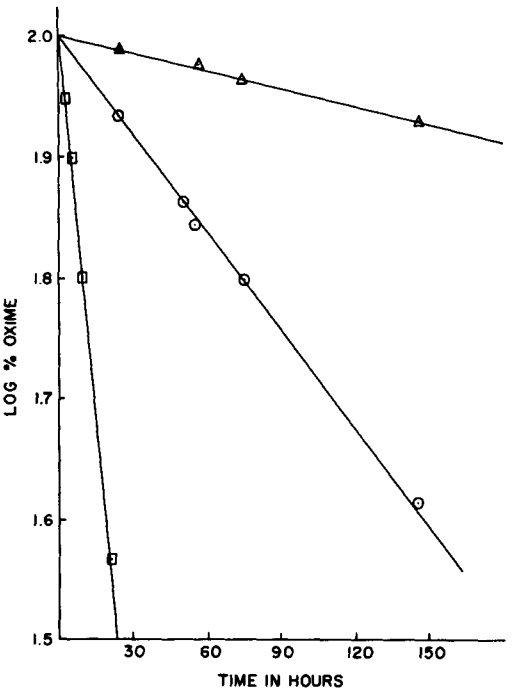

Fig. 3.—Typical first-order rate plots for the decomposition of 2-PAM at pH values 5 to 7 at 57°. △, pH 5; ○, pH 6; □, pH 7.

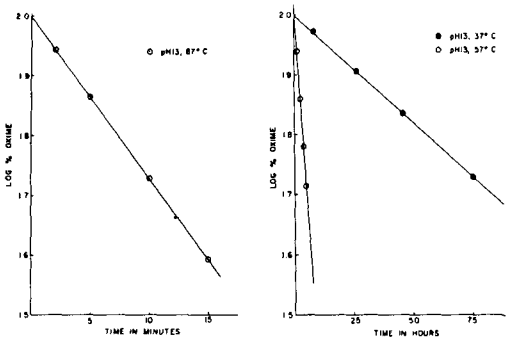

Fig. 4.—Typical first-order rate plots for the decomposition of 2-PAM at pH 13 at various temperatures.

anism appears to involve hydroxyl ion catalysis of the oxime species of 2-PAM. However, a pH independent region is observed at the pH values approximately 8–13. Thus at pH values 4 to 13, equations can be derived to show the mechanism of degradation involves either hydroxyl ion catalysis of the oxime species or a direct attack on the oximate species of 2-PAM, in which there is no catalysis.

The symbol k_{H^+} represents the catalytic rate constant or catalytic coefficient for the hydrogen ion catalysis of the protonated species, k_{OH^-} represents the catalytic constant for the hydroxyl ion catalysis of the protonated species, k_{Ox} represents the degradation constant acting directly on the oximate species of 2-PAM, a is the total drug concentration, and Ka

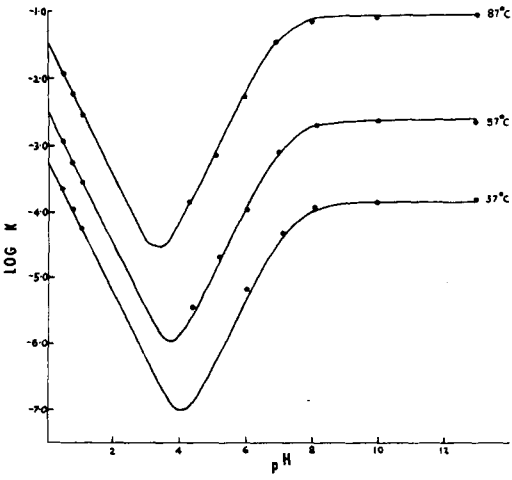

Fig. 5.—The pH profile of the logarithm of initial first-order rate constants for the breakdown of 2-PAM at 37, 57, and 87°. The curves represent values calculated from the equation derived from experimental data. The illustrated points represent experimental values.

and Kw are the acid and water dissociation constants, respectively. Then

$$\frac{d \ln a}{dt} = k_{H^+}(H^+)\frac{(H^+)}{Ka + (H^+)} + \frac{k_{OH^-}\, kw}{Ka + (H^+)} \qquad \text{(Eq. 1)}$$

or

$$\frac{d \ln a}{dt} = k_{H^+}(H^+)\frac{(H^+)}{Ka + (H^+)} + \frac{k_{Ox}\, Ka}{Ka + (H^+)} \qquad \text{(Eq. 2)}$$

The right sides of Eqs. 1 and 2 are constant at any given pH. The overall rate of degradation is first order with respect to oxime concentration and $(d \ln a/dt)\text{pH} = k$, the overall pseudo first-order rate constant at a constant pH.

Whenever the first term of Eqs. 1 and 2 is important, that is, the value of the hydrogen ion concentration is much larger than the value of Ka, the oxime exists in the protonated form. Therefore, at any pH the equations reduce, respectively, to

$$k = k_{H^+}(H^+) + \frac{k_{OH^-}\, kw}{Ka + (H^+)} \qquad \text{(Eq. 3)}$$

and

$$k = k_{H^+}(H^+) + \frac{k_{Ox}\, Ka}{Ka + (H^+)} \qquad \text{(Eq. 4)}$$

Hence, k_{OH^-} will be related to k_{Ox} at any given pH and temperature by the statement

$$k_{Ox} = k_{OH^-}\, Kb \qquad \text{(Eq. 5)}$$

where Kb is the basic dissociation constant of 2-PAM.

At relatively high pH values, approximately 10 to 14, Eq. 3 reduces to $k = k_{OH^-}$ Kb and Eq. 4 reduces to $k = k_{Ox}$. At relatively low pH values below 3, Eqs. 3 and 4 reduce to $k = (k_{OH^-}\, Kw)/Ka + (H^+)$ and Eq. 4 reduces to $k = k_{Ox}Ka/Ka + (H^+)$.

100	3.20	5 days

Between the regions of high and low pH the reaction velocity will pass through a minimum at a hydrogen ion concentration which is found by differentiating k with respect to (H^+) in Eqs. 3 or 4, and equating to zero. For Eq 3

$$k\,H^+ - \frac{k_{OH^-}\,Kw}{(Ka + H^+)^2} = 0 \qquad \text{(Eq. 6)}$$

At the observed pH of minimum decomposition, shown to be about pH 4, Ka is small compared to H^+ and can be dropped from the equation. Then

$$(H^+_M)^2 = \frac{k_{OH^-}\,Kw}{k_{H^+}} \qquad \text{(Eq. 7)}$$

For Eq. 4

$$(H^+_M)^2 = \frac{k_{Ox}\,Ka}{k_{H^+}} \qquad \text{(Eq. 8)}$$

The value k_M, the velocity constant at $(H^+)_M$, is obtained by substituting in Eqs. 3 and 4 the corresponding values of $k_{OH^-}\,Kw$ in Eq. 7 and $k_{Ox}\,Ka$ in Eq. 8. In either case

$$k_M = 2\,k_{H^+} + (H^+)_M \qquad \text{(Eq. 9)}$$

Temperature Dependency of the Reactions.—Velocity constants were determined at 37, 57, and and 87° in acid solutions which were approximately 0.1, 0.2, and 0.4 N with respect to hydrogen ion concentration. These measurements, which represent a type 2 reaction, were used to calculate the kinetic constants at 1 N hydrogen ion concentration for each of the temperatures used. See Table II. The values obtained for the latter constant are: k_H at 37° = 5.84×10^{-4} min.$^{-1}$; k_{H^+} at 57° = 2.97×10^{-3} min.$^{-1}$; and k_{H^+} at 87° = 2.98×10^{-2} min.$^{-1}$. In Fig. 6, the velocity constants are plotted against the reciprocal of the absolute temperatures. The straight line relationship indicates that the mechanism responsible for the oxime hydrolysis is not altered with change in temperature. The relationship between temperature and velocity constants is shown by the Arrhenius equation

$$k_{H^+} = Ze^{-Ea/RT} \qquad \text{(Eq. 10)}$$

On calculating the slope and setting it equal to $-Ea/2.303$ RT, the energy of activation, Ea, was found to be approximately 17,400 calories per mole. The frequency factor in the Arrhenius equation, Z, was found by substituting the conditions at the three experimental temperatures. The average Z was found to be 1.024×10^9 min.$^{-1}$.

It is evident from Fig. 5 that above pH 4, the

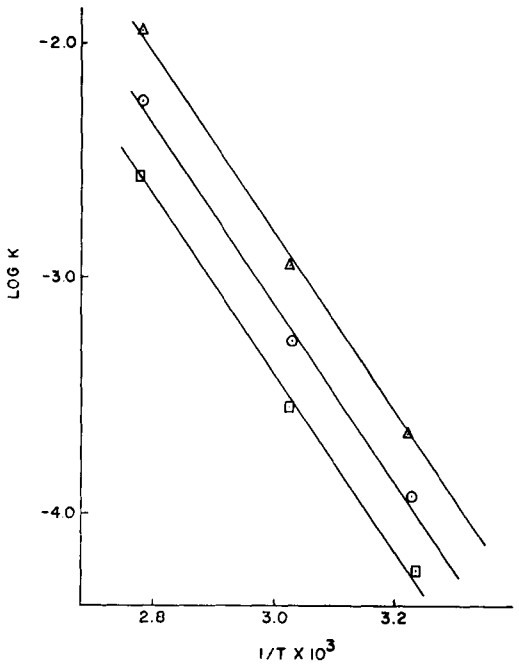

Fig. 6.—Temperature dependency of reaction 1 the hydrolytic reaction of 2-PAM, catalyzed by hydrogen ions, logarithm of k min.$^{-1}$ plotted against the reciprocal of the absolute temperature. △, 0.383 N; ○, 0.191 N; □, 0.096 N perchloric acid.

overall reaction is essentially that of reaction 1. As the exact mechanism by which reaction 1 progresses has not been established, two energy of activation constants were determined, one for the potentially base catalyzed and one for the potentially uncatalyzed reaction. The logarithms of velocity constants for each mechanism, determined at pH values 5 to 13, were plotted against the reciprocals of the absolute temperature. Representative results, shown in Fig. 7, again indicate that neither mechanism for the dehydration reaction is altered with change in temperature. The average slope of the uncatalyzed reaction was found to be 6,200, the activation energy, *Ea*, being 28,500 calories per mole. The energy of activation of the base catalyzed reaction was found to be 17,000 calories per mole. By

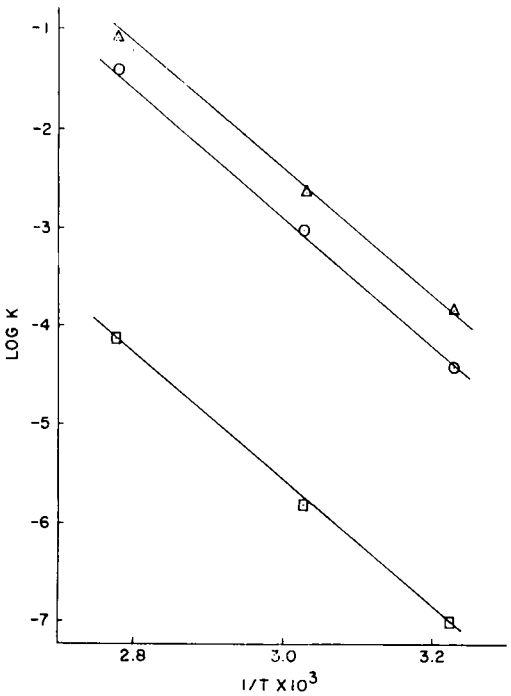

Fig. 7.—Temperature dependency of reaction 2, the dehydration reaction of 2-PAM at pH values 4, 7, and 10. □, pH 4; ○, pH 7; △, pH 10.

substituting the value of k_{Ox} and of k_{OH^-} at various experimental temperatures in the Arrhenius equation, the frequency factors come out to be 1.797×10^{16} min.$^{-1}$ and 3.144×10^{14} min.$^{-1}$, respectively.

The overall equation for the breakdown of 2-PAM at various pH values is either

$$k = 1.02 \times 10^{9}\, e^{-17,400/RT}(H^+) + 1.8 \times 10^{16}\, e^{-28,500/RT} \frac{Ka}{Ka + (H^+)} \quad \text{(Eq. 11)}$$

or

$$k = 1.02 \times 10^{9}\, e^{-17,400/RT}(H^+) + 3.1 \times 10^{14}\, e^{-17,000/RT} \frac{k_{OH^-}\, Kw}{Ka + (H^+)} \quad \text{(Eq. 12)}$$

pH of Minimum Hydrolysis.—The hydrogen ion concentration at which minimum decomposition occurs is found at the point where the first term of the right-hand side of Eq. 11 or 12 equals the second term. On substituting into Eq. 8 the values of k_{H^+} and k_{Ox}, the equation for the pH of minimum decomposition pH_M, may be expressed as

$$pH_M = {}^1/_2 \left(pKa - 7.246 + \frac{2436}{T}\right) \quad \text{(Eq. 13)}$$

The pH of minimum decomposition changes inversely with changes in temperature, ranging from 4.68 at 0° to 3.32 at 87° (Table III). The pKa values at various temperatures may be estimated by substituting the corresponding experimental values into Eq. 4. As the pKa values for 2-PAM were found experimentally to be between 7 and 8, the $k_{H^+}(H^+)$ becomes small and may be eliminated. Thus

$$Ka = \frac{k_{H^+}}{k_{Ox} - k} \quad \text{(Eq. 14)}$$

Using Eq. 11 or 12 the half-lives of 2-PAM can be calculated at any pH value and temperature. Predicted stability data over the region of pH 3 to 8 at temperatures from 10 to 87° are given in Table IV. The half-lives near the pH of minimum decomposition were, in most instances, extrapolated from initial rate constants as the half-lives are so long that experimental determinations were not practical.

Equilibrium.—In addition, we encountered in the acid region of pH 1 to 3, various conditions of equilibrium between 2-PAM and its hydrolysis products, pyridine - 2 - carboxaldehyde methiodide

TABLE IV.—PREDICTED STABILITY OF 2-PAM IN AQUEOUS SOLUTION, $t^1/_2$ (HALF-LIFE)

(PCAM) and hydroxylamine. An equilibrium constant, $k_{eq.}$, can be determined at any pH value. The equilibrium constant for reaction 2 is

$$k_{eq.} = \frac{(PCAM)(NH_2OH)}{(2\text{-}PAM)} \qquad \text{(Eq. 15)}$$

The basic dissociation constant for hydroxylamine may be arranged as

$$\frac{(NH_2OH)}{(NH_3OH)^+} = \frac{(OH^-)}{Kb} = \frac{Kw}{Kb\,(H^+)} \qquad \text{(Eq. 16)}$$

Substituting Eq. 16 into Eq. 15 and since the concentration of $(NH_3OH)^+$ is equal to the concentration (PCAM)

$$k_{eq.} = \frac{Kw\,(PCAM)^2}{Kb(H^+)\,(2\text{-}PAM)} \qquad \text{(Eq. 17)}$$

The value of $k_{eq.}$ for the reactions in our study at 87° was approximately 20.

Synthesis of Some N-Aralkyl-N-methylaminoethyl Carbanilates

By ROGER W. BARNES and WILLIAM J. ROST

In an attempt to correlate the basicity of local anesthetics with their activity, 21 substituted carbanilates of N-benzyl-N-methylaminoethanol, N-phenethyl-N-methylaminoethanol, and N-phenpropyl-N-methylaminoethanol were prepared. Substitutions on the carbanilic acid portion of the molecule were designed to study possible resonance effects. The compounds showed topical local anesthetic properties, but infiltration anesthetic properties were almost absent. No correlation between basicity and local anesthetic properties could be made. The relatively high acidity of the hydrochloride salts tested might account for the irritation commonly found.

CARBANILIC ACID esters of aminoalcohols have been reported to have marked local anesthetic activity (1, 2). Carbanilates with alkyl, chloro, amino, and alkoxy substitutions have been shown to possess a fair to high degree of local anesthetic activity (3–11). The position of the substitutions on the phenyl group have favorably affected the activity of the compounds in some cases (4, 6, 9). Sekera and Vrba have concluded that the more stable carbamates had a greater activity (6).

Aralkyl substitution on the nitrogen of aminoalkyl esters has given compounds with marked local anesthetic action. A 2% solution of γ-(2-benzylpiperidino)propyl benzoate or γ-(2-phenethylpiperidino)propyl benzoate gave a corneal anesthesia lasting 5 to 6 days (12). β-(N-Methyl-N-phenethylamino)ethyl carbanilate administered intracutaneously to a guinea pig in 0.5% concentration, gave an anesthetic effect lasting more than 24 hours. The local anesthetic effect of this compound lasted 84 minutes when used on the rabbit cornea (13).

Because the aromatic substitutions gave a marked increase in the activity of dialkylaminoalkyl carbanilates and because N-aralkylation of the aminoalkyl benzoates, *p*-aminobenzoates, and the carbanilate proved effective, it was thought to be of interest to investigate the N-aralkylation of aminoalkyl esters of substituted carbanilic acids. Tolstoouhov has postulated that the local anesthetic effect of a molecule is related to the basicity of the amine nitrogen it contains (14). The N-aralkyl groups chosen for investigation were benzyl, phenethyl, and phenpropyl. The N substitutions might then vary the basic charac-

Synthesis of Some N-Aralkyl-N-methylaminoethyl Carbanilates

By ROGER W. BARNES and WILLIAM J. ROST

In an attempt to correlate the basicity of local anesthetics with their activity, 21 substituted carbanilates of N-benzyl-N-methylaminoethanol, N-phenethyl-N-methylaminoethanol, and N-phenpropyl-N-methylaminoethanol were prepared. Substitutions on the carbanilic acid portion of the molecule were designed to study possible resonance effects. The compounds showed topical local anesthetic properties, but infiltration anesthetic properties were almost absent. No correlation between basicity and local anesthetic properties could be made. The relatively high acidity of the hydrochloride salts tested might account for the irritation commonly found.

CARBANILIC ACID esters of aminoalcohols have been reported to have marked local anesthetic activity (1, 2). Carbanilates with alkyl, chloro, amino, and alkoxy substitutions have been shown to possess a fair to high degree of local anesthetic activity (3–11). The position of the substitutions on the phenyl group have favorably affected the activity of the compounds in some cases (4, 6, 9). Sekera and Vrba have concluded that the more stable carbamates had a greater activity (6).

Aralkyl substitution on the nitrogen of aminoalkyl esters has given compounds with marked local anesthetic action. A 2% solution of γ-(2-benzylpiperidino)propyl benzoate or γ-(2-phenethylpiperidino)propyl benzoate gave a corneal anesthesia lasting 5 to 6 days (12). β-(N-Methyl-N-phenethylamino)ethyl carbanilate administered intracutaneously to a guinea pig in 0.5% concentration, gave an anesthetic effect lasting more than 24 hours. The local anesthetic effect of this compound lasted 84 minutes when used on the rabbit cornea (13).

Because the aromatic substitutions gave a marked increase in the activity of dialkylaminoalkyl carbanilates and because N-aralkylation of the aminoalkyl benzoates, *p*-aminobenzoates, and the carbanilate proved effective, it was thought to be of interest to investigate the N-aralkylation of aminoalkyl esters of substituted carbanilic acids. Tolstoouhov has postulated that the local anesthetic effect of a molecule is related to the basicity of the amine nitrogen it contains (14). The N-aralkyl groups chosen for investigation were benzyl, phenethyl, and phenpropyl. The N substitutions might then vary the basic charac-

Received April 28, 1961, from the School of Pharmacy, The University of Kansas City, Kansas City 10, Mo.
Accepted for publication June 20, 1961.
Presented to the Scientific Section, A. PH. A., Chicago meeting, April 1961.

ter of the amine and therefore vary the activity of the compounds as local anesthetics. Carbanilates, methylcarbanilates, chlorocarbanilates, methoxycarbanilates, and nitrocarbanilates of the N-phenalkyl-N-methylaminoethanols were prepared. The nitrocarbanilates could then be reduced to the amino derivatives after the initial reaction. These substituted carbanilates were chosen to vary the resonance effects of the carbamic acid esters. *Meta-* and *para-*substitutions were chosen to contrast the different resonance effects. *Ortho-* substituted carbanilates were not studied because of the possible steric hindrance.

The purpose of this paper is to report the synthesis of 21 compounds, report their basicities, and to give a preliminary evaluation of their local anesthetic activities.

EXPERIMENTAL

N - Phenalkyl - N - methylaminoethanols.—The proper phenalkyl halide was condensed with two equivalents of N-methylaminoethanol in the absence of a solvent. The exothermic reactions were first cooled in an ice bath and then allowed to stand at room temperature for varying lengths of time. After treatment with aqueous sodium hydroxide, the reaction mixture was extracted with ether. The ether was evaporated, and the aminoalcohol was distilled under reduced pressure. The products are described in Table I.

Carbanilates.—A solution of 0.066 *M* of the appropriate isocyanate dissolved in 30 ml. of dry toluene was slowly added to 0.06 *M* of the N-phenalkyl-N-methylaminoethanol. After the initial heat of reaction had subsided, the mixture was refluxed for 3 hours and allowed to stand at room temperature for 2 days. At the end of this period, the urea which had formed was filtered from the solution. Anhydrous hydrogen chloride was passed into the filtrate to obtain an oil which changed on standing to the solid hydrochloride salt. The crude product was recrystallized from acetone to which a trace of ethanol had been added.

Reduction of Nitrocarbanilates.—The nitrocarbanilates on reduction with hydrogen under low pressure with platinum oxide yielded an oil which solidified on standing. Attempts at recrystallization were unsuccessful.

The carbanilates prepared are listed in Table II.

Comparison of Basicities of Derivatives.—The basicities of the various compounds were compared using the method of Tolstoouhov (14). The pKb of each compound was also determined. A solution of the amine hydrochloride was dissolved in water. The salt was half neutralized by the addition of 0.01 *N* sodium hydroxide. Because of the insolubility of the free base, alcohol was added to facilitate solution. The pH of the resultant solution was determined, and the pKb calculated. The results of the above determinations are reported in Table III.

[a] Done according to method of Tolstoouhov (14).

PHARMACOLOGY

The local anesthetic activity of the compounds was determined on the mouse cornea. With two exceptions, the compounds were active in concentrations of 0.5% or less. N-Benzyl-N-methylaminoethyl *p*-methylcarbanilate and N-benzyl-N-methylaminoethyl *m*-methylcarbanilate were active in concentrations as low as 0.05%. Irritation was commonly found. Only the N-benzyl-N-methylaminoethyl carbanilate, *m*-methylcarbanilate, and *p*-methylcarbanilate showed local anesthetic activity when injected intradermally into the guinea pig back. Irritation was commonly found when this method of testing was used.

The N-benzyl-N-methylaminoethyl carbanilate, *m*-methylcarbanilate, and *p*-methylcarbanilate were tested for any possible action they might have on the rat intestine. A decrease in motility was observed with the most marked decrease being with the N-benzyl-N-methylaminoethyl *p*-methylcarbanilate.

The minimum lethal doses of these compounds was of the order of 200 mg./Kg.

DISCUSSION

Tolstoouhov has postulated that compounds whose basicity fell within a certain range would be local anesthetics (14). Local anesthetic salts which start to separate from solution as the free base at pH 5.93–6.36 were claimed to have the highest order of activity. Compounds possessing a basicity outside of this optimum range were shown to have a gradually diminishing activity. The above postulation was not found to hold in this series of carbanilates. The best local anesthetic activity was found in the N-benzyl-N-methylaminoethyl carbanilates. Although compounds in the other series possessed a basicity which fell within the optimum range suggested by Tolstoouhov, they showed no intradermal local anesthetic activity. Almost all of the compounds, however, did show a topical activity. No correlation between basicity and local anesthetic activity was possible.

The pKb of the compounds indicated that they were relatively weak bases. The acidity of the hydrochloride salts tested could then explain the irritation commonly found in this series. A similar explanation might be given for the irritant compounds reported by Sievers and McIntyre (13).

The electronic influences of the aromatic substitutions on the carbanilic acid portion of the molecules seemed to have no effect on the local anesthetic activity.

SUMMARY

The syntheses and properties of 21 N-aralkyl-N-methylaminoethyl carbanilates were described.

The compounds tested possessed a topical local anesthetic effect in concentrations of 0.5% or less. Infiltration anesthetic properties were almost absent.

The relative basicities of the compounds were determined, but no correlation with local anesthetic activity could be made. The relatively high acidity of the hydrochloride salts tested might account for the irritation commonly found.

Coumarins I

Isolation, Purification, and Structure Determination of Pteryxin and Suksdorfin

By ROBERT E. WILLETTE† and TAITO O. SOINE

Pteryxin and suksdorfin were isolated from petroleum ether extracts of *Pteryxia terebinthina* (Hook.) Coulter and Rose var. *terebinthina* and *Lomatium suksdorfii* (Wats.) Coulter and Rose, respectively. A suitable chromatographic procedure was developed for their purification. Upon hydrolysis, these coumarins yielded the same isomeric alcohols obtained from visnadin and samidin. In addition, an alcohol and its acetate which had not been reported previously were obtained and assigned the structures (+)-*cis*-ethylkhellactone and (−)-*cis*-acetylethylkhellactone. Pteryxin, during the hydrolysis, yielded angelic and acetic acids. Quantitative hydrolytic studies, optical rotations, isolation of the partially hydrolyzed coumarins as acetates, and ultraviolet and infrared absorption studies led to the establishment of the following structure for pteryxin: 3′-acetyl-4′-angeloyl-(+)-*cis*-khellactone; and for suksdorfin: 3′-acetyl-4′-isovaleryl-(+)-*cis*-khellactone. The probable conformation of these substances is discussed.

THE PRESENT investigations were stimulated by the recent interest in the isolation and characterization of various naturally occurring chromones and coumarins from *Umbelliferae* possessing certain and distinct pharmacological activities. The chromone khellin, which is obtained from the umbellifer *Ammi visnaga*, has had some clinical success (1). From the strongly vasodilatory oil which remains after the isolation of khellin, Smith and co-workers reported the isolation and structural determinations of the coumarins visnadin, samidin, and dihydrosamidin (2). Visnadin has undergone clinical studies under the registered name Provismine (3). The absolute configurations of these latter substances were established by Schmid and co-workers (4).

In an extensive pharmacognostical investigation of *Pteryxia terebinthina* (Hook.) Coulter and Rose var. *terebinthina*, Call (5) isolated a low-melting solid, which he named pteryxin, and which exhibited antispasmodic activity (6). Preliminary characterization studies by Pettinato (7) indicated pteryxin to be a coumarin containing two alkali-consuming groups in addition to the expected lactone grouping.

Call (8) isolated another crystalline substance from the fruit of *Lomatium suksdorfii* (Wats.) Coulter and Rose which he named suksdorfin A. He also showed that it possessed antispasmodic properties. A preliminary phytochemical study (9) and an analysis of the volatile oil content (10) of this plant have been reported.

The investigation reported here concerns the isolation, purification, and determination of structure of pteryxin and suksdorfin.

Detailed pharmacological studies will be reported at a later date.

EXPERIMENTAL

Melting points were determined in capillary tubes in an oil bath with a thermometer that read accurately for a set of standard samples. Values of $[\alpha]_D$ have been approximated to the nearest degree. Infrared spectra were determined on a Perkin and Elmer spectrophotometer, model 137. Ultraviolet spectra were determined in 95% ethanol on Cary recording spectrophotometers, models 11 and 14.

Material.—Dried roots of *Pteryxia terebinthina* (Hook.) Coulter and Rose var. *terebinthina*, collected at an elevation of 400 ft. near Rufus, Oreg., and dried fruits of *Lomatium suksdorfii* (Wats.) Coulter and Rose, collected at an elevation of 1,200 ft. near Klickitat, Wash., were ground in a Jacobsen laboratory mill to an approximately No. 20 powder in preparation for extraction.[1]

Isolation of Pteryxin (I) from *P. terebinthina*.—The ground root (1 Kg.) was washed with two 2-L. portions of ice-cold petroleum ether (b.p. 30–60°), which were discarded. The washed root was boiled with three 2-L. portions of Skellysolve B (b.p. 65–70°); the menstruum after each extraction was filtered into a large beaker. Upon cooling, a resinous, oily deposit separated, from which the clear liquor was decanted. The liquor became cloudy on pouring and, after standing overnight, was decanted

Received March 31, 1961, from the Department of Pharmaceutical Chemistry, College of Pharmacy, University of Minnesota, Minneapolis.

Accepted for publication May 4, 1961.

Abstracted in part from a dissertation presented to the Graduate School, University of Minnesota, by Robert E. Willette in partial fulfillment of the requirements for the degree of Doctor of Philosophy, July 1960.

Presented to the Scientific Section, A.PH.A., Washington, D. C., meeting, August 1960.

† Rowell Laboratories Fellow, 1957–1958 and 1958–1959. Present address: The John Curtin School of Medical Research, The Australian National University, Canberra, Australia.

The authors are indebted to The Upjohn Co., Kalamazoo, Mich., for making available the instruments used for much of the spectroscopic data.

[1] The authors are indebted to Dr. T. G. Call, 115 W. Rancho Rd., Corona, Calif., for collection and identification of the plant materials, and to Dr. G. B. Ownbey, Botany Department, University of Minnesota, Minn., for confirmation of the identities. Suitable specimens have been placed in the herbarium of the Botany Department, University of Minnesota.

from the oil deposit which again separated. After this process had been repeated several times, large tetragonal crystals formed on the bottom of the beaker. The crystals were collected in successive crops to yield 15.3 Gm. of crude pteryxin. The resinous, oily deposits were combined, dissolved in boiling Skellysolve B, and treated in the same manner. An additional 4.7 Gm. was obtained for a total of 20 Gm. (2%) of crude pteryxin. Recrystallization from Skellysolve B gave slightly yellow tetragonal prisms melting at 79–81°. The melting point was not depressed on admixture with a sample of pteryxin previously isolated by Call.

A twice recrystallized sample of pteryxin, dissolved in Skellysolve B, was spotted on several chromatostrips.[2] Each chromatostrip was developed in an ascending manner in a stoppered test tube containing about 2 ml. of solvent. Of the several solvent systems tried, only 10% anhydrous ethanol in Skellysolve B separated the sample into four fluorescent spots.

Twice recrystallized pteryxin (500 mg.) dissolved in anhydrous ethanol (5 ml.) was added to the top of a column of silica gel (150 Gm., Davison, commercial grade) prepared in a slurry with 10% anhydrous ethanol in Skellysolve B. Development with the same solvent separated the material into four zones which were eluted. Evaporation of the first two and last fractions gave only trace residues. The third fraction afforded a colorless resin (420 mg.), which was dissolved in boiling Skellysolve B. The solution was filtered, concentrated to about two-thirds its volume, and allowed to stand in a stoppered flask. After several days small colorless prisms began to form. The stopper was removed and the flask covered with a piece of filter paper. After four days, pteryxin crystallized as large, colorless, tetragonal prisms which were filtered off and dried at room temperature in vacuum for several days, m.p. 81.5–82.5°; $[\alpha]_D^{22}$ +10° (c 0.650, C_2H_5OH); ultraviolet spectrum (Fig. 1): $\lambda_{min.}$ 252 (log ϵ 3.57) and 263 mμ (3.20); $\lambda_{max.}$ 218 (4.31) sh., 244 (3.71) sh., 255 (3.60), 300 (3.92) sh., and 323 mμ (4.11); infrared spectrum (Nujol mull) (Fig. 2): 1757–1745 (α-pyrone and α,β-unsatd. ester C=O), 1637 (α-pyrone ring C=C), 1621, 1502 (aromatic C=C), 1587 (aromatic ring with conjugated C=C), 1321, 1107 (α,β-unsatd. ester C—O), 1122 (Ar—O—CR_3), 908 [$(CH_3)_2C$—O], 846 (1,2,3,4-aromatic substitution) and 839 cm.$^{-1}$ (trisubstituted ethylene C—H); (c 2.0, CH_2Cl_2): 1393 and 1377 cm.$^{-1}$ ([$CH_3)_2C$=]. [3] Development of it on a chromatostrip with 10% anhydrous ethanol in Skellysolve B gave a single homogeneous spot.

Anal.[4]—Calcd. for $C_{21}H_{22}O_7$: C, 65.27; H, 5.74; mol. wt., 386.39. Found: C, 66.18; H, 6.11;[5] mol. wt. (Rast), 339.

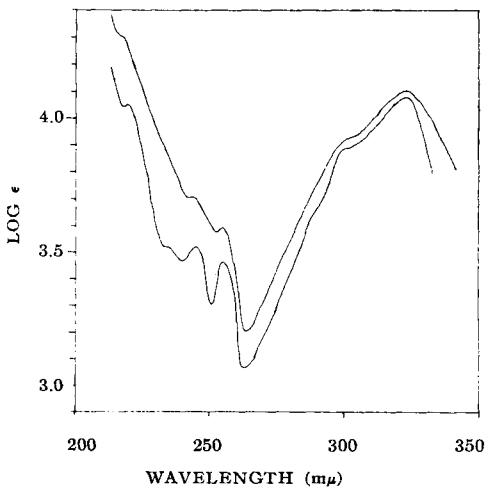

Fig. 1.—Ultraviolet absorption spectra in 95% ethanol. Upper curve, pteryxin; lower curve, suksdorfin.

Isolation of Suksdorfin (II) from *L. Suksdorfii*.—The ground fruit (500 Gm.) was extracted continuously for two days in a Soxhlet apparatus with Skellysolve B (b.p. 65–70°). The colorless crystalline deposit which formed in the concentration flask was filtered off, rinsed with Skellysolve B, and air-dried to give 6 Gm. (1.2%) of suksdorfin, m.p. 130–135°. Five recrystallizations from Skellysolve B afforded fine colorless needles (2 Gm.), m.p. 140–141°. The melting point was not depressed on admixture with a sample of suksdorfin A previously isolated by Call.

A sample of recrystallized suksdorfin was spotted on several chromatostrips which were developed as before, using various solvent systems. Only 30% acetone in Skellysolve B was found to separate a sample into three fluorescent spots.

Recrystallized suksdorfin (0.5 Gm.) was chromatographed on a column of silica gel (150 Gm., Davison, commercial grade) prepared in a slurry with Skellysolve B. Development was conducted with Skellysolve B to which acetone was added gradually (1% increase every 10 ml.) until a concentration of 30% acetone was reached. The major fraction was eluted; the column extruded; and the two remaining zones separated and eluted from the adsorbent with acetone, which was evaporated to give only faint traces. Two recrystallizations of the major fraction from Skellysolve B followed by drying at 100° in vacuum overnight afforded fine colorless needles, m. p. 140.5–141°; $[\alpha]_D^{24}$ + 4° (c 0.500, C_2H_5OH); ultraviolet spectrum (Fig. 1): $\lambda_{min.}$ 240 (log ϵ 3.47), 251 (3.30) and 263 mμ (3.07); $\lambda_{max.}$ 219 (4.05), 234 (3.52) sh., 245 (3.52), 255 (3.46), 300 (3.88) sh., and 323 mμ (4.07); infrared spectrum: (Nujol mull) (Fig. 3): 1754 (ester C=O), 1736 (α-pyrone C=O), 1631 (α-pyrone ring C=C), 1610, 1493, 1445 (aromatic C=C), 1572 (aromatic ring with conjugated C=C), 1250, 1120 (Ar—O—CR_3), 902 [$(CH_3)_2C$—O] and 856 cm.$^{-1}$ (1,2,3,4-aromatic substitution); (c 2.0, CH_2Cl_2): 1395 and 1376 cm.$^{-1}$ [$C(CH_3)_2$]. A sample developed with 30% acetone in Skellysolve B on a chromatostrip showed only one distinct spot. In a volatile acid

[2] The chromatostrips consist of glass strips, 13 × 136 mm., coated on one surface with a thin film of silicic acid containing 5% starch and 0.1% each of zinc silicate and zinc-cadmium sulfide. Their preparation and development procedure is essentially the same as described by Stanley (11).

[3] The assignment of groups responsible for some of the absorption bands in the infrared spectra of the compounds discussed in this paper are in agreement with the findings of Schroeder, *et al.* (4).

[4] Microanalyses were determined by the Microanalytical Laboratory of the School of Chemistry, University of Minnesota, Minneapolis, or by Drs. Weiler and Strauss, 164 Banbury Rd., Oxford, England.

[5] Average percentages. All attempts to prepare a sample which analyzed accurately were unsuccessful.

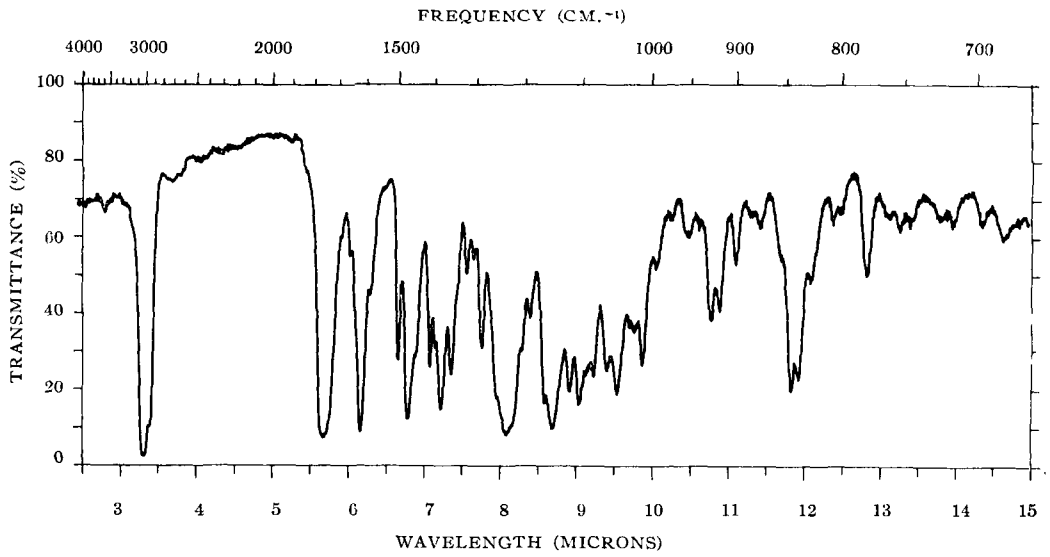

Fig. 2.—Infrared absorption spectrum of pteryxin (Nujol mull).

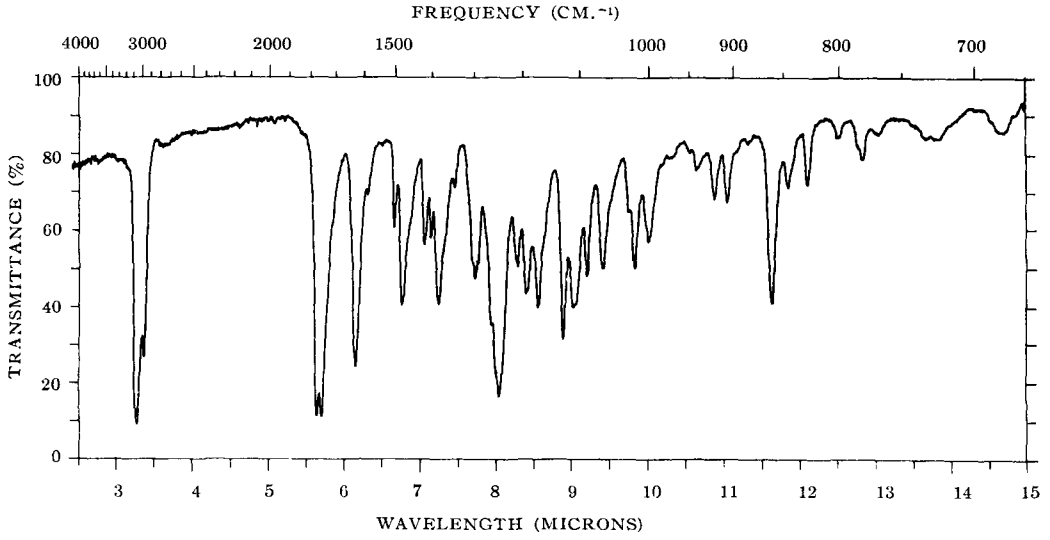

Fig. 3.—Infrared absorption spectrum of suksdorfin (Nujol mull).

determination suksdorfin yielded an amount of acid equivalent to 38.42 ml. of 0.01 *N* sodium hydroxide; calcd. for two acids, 41.89 ml.

Anal.—Calcd. for $C_{21}H_{24}O_7$: C, 64.95; H, 6.23; mol. wt., 388.30. Found: C, 64.88; H, 6.31; mol. wt. (Rast), 357.

Hydrogenation of Pteryxin.—Chromatographically pure pteryxin (77.2 mg., 0.2 mmole) was dissolved in ethanol (10 ml.) and hydrogenated at atmospheric pressure in the presence of platinum oxide (20 mg.). After 20 minutes, 0.17 mmole of hydrogen was consumed, the hydrogenation was interrupted, the catalyst filtered off, and the filtrate evaporated on a steam bath. Two crystallizations of the oily residue from dilute ethanol followed by drying at 78° in vacuum gave dihydropteryxin as fine colorless needles, m.p. 103–104°; ultraviolet spectrum: $\lambda_{min.}$ 262 mμ (log ε 3.20); $\lambda_{max.}$ 218 (4.23) and 322 mμ (4.15); infrared spectrum (Nujol mull): 1172 cm.$^{-1}$ (satd. ester C—O).

Anal.—Calcd. for $C_{21}H_{24}O_7$: C, 64.95; H, 6.23. Found: C, 65.09; H, 6.04.

Chromatographically pure pteryxin (77.2 mg., 0.2 mmole) was treated as above. After 3 hours, 0.36 mmole of hydrogen was consumed, the hydrogenation interrupted, and the product worked up as above. Recrystallization from dilute ethanol and drying for several hours at 100° in vacuum afforded tetrahydropteryxin as fine colorless needles, m.p. 115–115.5°; ultraviolet spectrum: $\lambda_{min.}$ 262 (log ε 2.92) and 301 mμ (3.64); $\lambda_{max.}$ 243 (3.50) sh., 255 (3.22), 284 (3.72) sh., 291 (3.76), and 323 mμ (3.82); infrared spectrum (Nujol mull): 1764 (γ,δ-unsatd. δ-lactone C=O) and 1739 cm.$^{-1}$ (satd. ester C=O).

Anal.—Calcd. for $C_{21}H_{26}O_7$: C, 64.60; H, 6.71. Found: C, 64.21; H, 6.64.

Ethanolic Alkaline Hydrolysis.—Crude pteryxin (15 Gm.), dissolved in 95% ethanol (150 ml.), was mixed with 1 *N* ethanolic sodium hydroxide (150 ml.) and allowed to stand at room temperature for 30 minutes. The mixture was poured into water (2.5 L.), acidified with concentrated sulfuric acid (4 ml.), and extracted with six 500-ml. portions of ether. The combined ether extract was backwashed with three 200-ml. portions of 5% sodium carbonate solution, dried over anhydrous sodium sulfate, and evaporated to dryness. The residue crystallized from dilute ethanol as colorless needles (4.1 Gm.). A sample of it separated into five distinct fluorescent spots on a chromatostrip developed with 50% ethyl acetate in Skellysolve B. Recrystallization from dilute ethanol gave colorless needles (2.5 Gm.) which separated into three spots on a chromatostrip. A portion of these needles (1.0 Gm.) was chromatographed on a column of silica gel (100 Gm., Davison, commercial grade) prepared in a slurry with Skellysolve B. Elution with 20% ethyl acetate in Skellysolve B gave, after recrystallization from dilute ethanol, 0.8 Gm. of colorless needles m.p. 143–144°, which separated into two spots on a chromatostrip. One other zone was eluted in trace amounts.

(+)-*Cis*-**ethylkhellactone (XI).**[6]—The material obtained above (0.8 Gm.) was rechromatographed on a similar column. Development with 10% ethyl acetate in Skellysolve B separated two zones. Elution of the lowest zone with the same solvent gave (+)-*cis*-ethylkhellactone. Repeated crystallizations from dilute ethanol and drying at 78° in vacuum overnight afforded fine colorless needles, m.p. 127–128°; $[\alpha]_D^{24}$ +136° (c 1.00, C_2H_5OH); ultraviolet spectrum: $\lambda_{min.}$ 243 (log ε 3.47), 253 (3.44), and 266 mμ (3.18); $\lambda_{max.}$ 218 (4.12) sh., 247 (3.51), 258 (3.48); 300 (3.93) sh., and 327 mμ (4.19); infrared spectrum (Nujol mull): 3521 (OH), 1716 (α-pyrone C=O), 1626 (α-pyrone ring C=C), 1608, 1490 (aromatic C=C), 1567 (aromatic ring with conjugated C=C), 1342, 1104 (O—H deformation and C—O stretching), 1121 (Ar—O—CR_3), 1057 (ethyl ether), 889 [$(CH_3)_2C$—O] and 838 cm.$^{-1}$ (1,2,3,4-aromatic substitution).

Anal.—Calcd. for $C_{16}H_{18}O_5$: C, 66.19; H, 6.25; mol. wt., 290.30. Found: C, 65.75; H, 6.14; mol. wt. (Rast), 285.

(−)-*Trans*-**ethylkhellactone (IX).**—Further elution of the above column afforded (−)-*trans*-ethylkhellactone. Recrystallization from dilute methanol and drying at 100° in vacuum overnight gave fine colorless needles, m.p. 161–162°; $[\alpha]_D^{23}$ −64° (c 0.5, C_2H_5OH) [lit. m.p. 161–162°, $[\alpha]_D$ −59° (c 0.9, C_2H_5OH) (2)]; ultraviolet spectrum: $\lambda_{min.}$ 266 mμ (log ε 3.18); $\lambda_{max.}$ 327 mμ (4.19); infrared spectrum (Nujol mull) was similar to that of the (+)-*cis*-isomer except for the following major differences: 3636 (OH), 1323 and 1082 cm.$^{-1}$ (OH deformation and C—O stretching.)

The melting point was not depressed on admixture with an authentic sample of (−)-*trans*-ethylkhellactone.[7] Its ultraviolet and infrared spectra were identical to those of the authentic sample. This same compound was obtained by refluxing suksdorfin with 0.5 *N* ethanolic sodium hydroxide for 30 minutes, followed by the same work-up, and purified by repeated crystallizations from dilute methanol.

Anal.—Calcd. for $C_{16}H_{18}O_5$: C, 66.19; H, 6.25; mol. wt., 290.30. Found: C, 66.06; H, 6.40; mol. wt. (Rast), 286.

Isolation and Identification of Acids.—The rapid, horizontal paper chromatographic method of Roberts and Bucek (12) was used to obtain a preliminary characterization of the acids released by hydrolysis. Samples of pteryxin and suksdorfin (25 mg.) were refluxed with 1 *N* sodium hydroxide in 75% ethanol for 30 minutes. The solutions were acidified with concentrated sulfuric acid, adjusted to pH 8 with 33% aqueous ethylamine, and spotted on the paper. After development with a butanol-water solvent system, the acid spots were located by spraying the paper with 0.2% ethanolic chlorophenol red. Pteryxin gave two spots which corresponded quite closely with control samples of acetic and angelic acids, and suksdorfin, with acetic and isovaleric acids.

Pteryxin (1.0 Gm.) was refluxed with 1 *N* ethanolic potassium hydroxide (20 ml.) for 1 hour. The reaction mixture was diluted with water (50 ml.), freed of ethanol under reduced pressure, adjusted to pH 8 with concentrated sulfuric acid, and extracted with ether. The ether extract was evaporated to dryness. The *p*-phenylphenacyl esters were prepared from the residue and chromatographed on a silicic acid-Celite (3:1) column in the manner described by Klohs, *et al.* (13). Elution of the column with 1:1 benzene-petroleum ether (60–110°) yielded in the first fraction unreacted bromide, m.p. 124°. The second fraction afforded colorless crystals which, after recrystallization from ethanol, gave *p*-phenylphenacyl angelate as shiny platelets, m.p. 87–88° [lit. m.p. 90–91° (14)]. The melting point was not depressed on admixture with an authentic sample of *p*-phenylphenacyl angelate.[8]

Anal.—Calcd. for $C_{19}H_{18}O_3$: C, 77.53; H, 6.16. Found: C, 77.54; H, 6.16.

Further elution with 2:1 benzene-petroleum ether (60–110°) yielded colorless needles. Recrystallization from ethanol and drying at 100° in vacuum gave *p*-phenylphenacyl acetate as fine colorless needles, m.p. 109–110° [lit. m.p. 110–111° (13)]. The melting point was not depressed on admixture with the same derivative prepared from acetic acid.

Anal.—Calcd. for $C_{16}H_{14}O_3$: C, 75.58; H, 5.55. Found: C, 75.37; H, 5.73.

The *p*-phenylphenacyl esters of the acids obtained from suksdorfin in the same manner afforded *p*-phenylphenacyl acetate, m.p. 109–110°, no depression on admixture with the authentic sample, and *p*-phenylphenacyl isovalerate as shiny platelets, m.p. 78.5–79° [lit. m.p. 78° (15)]. The melting point was not depressed on admixture with the same derivative prepared from isovaleric acid.

Anal.—Calcd. for $C_{19}H_{20}O_3$: C, 77.01; H, 6.80. Found: C, 76.94; H, 6.94.

(−)-*Cis*-**acetylethylkhellactone (VII).**—A mixture of (+)-*cis*-ethylkhellactone (230 mg.), acetic anhydride (2 ml.), and dry pyridine (2 ml.) was heated on a steam bath for 1 hour and poured into water

[6] The compounds described in this paper have been named according to the scheme followed by Schroeder, *et al.* (4).

[7] Graciously supplied by Dr. Eric Smith, S. B. Penick and Co., New York, N. Y.

[8] Graciously supplied by Dr. S. W. Pelletier, the Rockefeller Institute for Medical Research, New York, N. Y.

(40 ml.). Upon standing overnight fine needles formed and were filtered from the liquor, leaving a clear viscous oil which had separated on the bottom of the beaker. The needles were recrystallized twice from dilute methanol and dried at 78° in vacuum to give (−)-*cis*-acetylethylkhellactone as colorless prisms, m.p. 122–123°; $[\alpha]_D^{25}$ −15° (c 0.527, C_2H_5OH); ultraviolet spectrum: $\lambda_{min.}$ 263 mμ (log ε 3.20); $\lambda_{max.}$ 325 mμ (4.18); infrared spectrum (Nujol mull): 1247 and 1043 cm.$^{-1}$ (acetate C—O).

Anal.—Calcd. for $C_{18}H_{20}O_6$: C, 65.05; H, 6.07. Found: C, 64.67; H, 6.26.

(−)-*Trans*-**acetylethylkhellactone (V).**—The residual oil obtained above crystallized upon rubbing with methanol. Three recrystallizations from dilute methanol followed by drying at 78° in vacuum gave (−)-*trans*-acetylethylkhellactone as colorless needles, m.p. 168–168.5°; $[\alpha]_D^{24}$ −39° (c 1.77, C_2H_5OH) [lit. m.p. 170–172°, $[\alpha]_D$ −40.6° (c 0.6, C_2H_5OH) (2)]; ultraviolet spectrum: $\lambda_{min.}$ 264 mμ (log ε 3.26); $\lambda_{max.}$ 325 mμ (4.20); infrared spectrum (Nujol mull): 1245 and 1042 cm.$^{-1}$ (acetate C—O).

Anal.—Calcd. for $C_{18}H_{20}O_6$: C, 65.05; H, 6.07. Found: C, 64.90; H, 6.14.

This acetate was obtained from (−)-*trans*-ethylkhellactone in the same manner.

Methanolic Alkaline Hydrolysis.—Crude pteryxin (15 Gm.) dissolved in methanol (60 ml.) was mixed with 1 *N* methanolic sodium hydroxide (60 ml.) and refluxed 90 minutes. The brown mixture was diluted with water (300 ml.) and the methanol removed under reduced pressure. The aqueous solution was extracted with three 100-ml. portions of methylene chloride, which were combined and evaporated to dryness. The light brown residue (4.0 Gm.) was recrystallized from methanol, then ether-Skellysolve B as colorless needles (2.5 Gm.), which separated into two spots on a chromatostrip developed with 50% ethyl acetate in Skellysolve B; m.p. 159–160°; $[\alpha]_D^{24}$ +37° (c 1.00, CH_3OH), corresponding to a mixture of 40% (+)-*cis*- and 60% (−)-*trans*-methylkhellactone.[9]

(+)-*Cis*-**methylkhellactone (XII).**—The above mixture (731 mg.) was chromatographed on neutral alumina (25 Gm., Woelm, activity III, prepared according to Brockmann). Elution with benzene gave (+)-*cis*-methylkhellactone (295 mg.), m.p. 126–127°; $[\alpha]_D^{23}$ +88° (c 0.752, C_2H_5OH) [lit. m.p. 127°, $[\alpha]_D^{22}$ +97° (c 0.628, CH_3OH) (4)]; ultraviolet spectrum: $\lambda_{min.}$ 266 mμ (log ε 3.18); $\lambda_{max.}$ 329 mμ (4.21); infrared spectrum (Nujol mull): 3521 (OH), 1351 and 1111 cm.$^{-1}$ (OH deformation and C—O stretching).

Anal.—Calcd. for $C_{15}H_{16}O_5$: C, 65.19; H, 5.84. Found: C, 65.20; H, 6.01.

(−)-*Trans*-**methylkhellactone (X).**—Further elution of the above column with 1:4 ether-benzene gave (−)-*trans*-methylkhellactone (313 mg.) which was recrystallized from ether-petroleum ether (30–60°) as colorless needles, m.p. 160–161°; $[\alpha]_D^{25}$ − 8° (c 0.793, C_2H_5OH) [lit. m.p. 161.5–162.5°, $[\alpha]_D^{24}$ −3° (c 1.374, CH_3OH) (4)]; ultraviolet spectrum: $\lambda_{min.}$ 265 mμ (log ε 3.32); $\lambda_{max.}$ 328 mμ (4.21); infrared spectrum (Nujol mull): 3571 (OH), 1328 and 1101 cm.$^{-1}$ (OH deformation and C—O stretching).

Anal.—Calcd. for $C_{15}H_{16}O_5$: C, 65.19; H, 5.84. Found: C, 65.44; H, 6.03.

On acetylation, the methyl ether mixture (300 mg.) gave, after recrystallization from dilute methanol and drying at 100° in vacuum, (+)-*trans*-acetylmethylkhellactone (VI) as colorless needles (200 mg.), m.p. 148–149° [lit. m.p. 152.5° (4)]; ultraviolet spectrum: $\lambda_{min.}$ 263 mμ (log ε 3.14); $\lambda_{max.}$ 325 mμ (4.18).

Anal.—Calcd. for $C_{17}H_{18}O_6$: C, 64.14; H, 5.70. Found: C, 64.14; H, 5.68.

Quantitative Hydrolytic Experiments.—Samples of recrystallized pteryxin (61.8 mg.), suksdorfin (61.4 mg.), visnadin[10] (51.5 mg.), and (+)-*trans*-acetylmethylkhellactone were each dissolved in 0.25 *N* ethanolic sodium hydroxide (10.0 ml.) at room temperature. Aliquots (1.0 ml.) taken at various intervals were diluted with carbon dioxide-free water (15 ml.) and titrated with 0.0243 *N* sulfuric acid to pH 7 on a Beckman Zeromatic pH meter. A blank determination of the alkali solution was made at the same time. The results expressed as mole equivalents plotted against time in minutes are shown in Fig. 4.

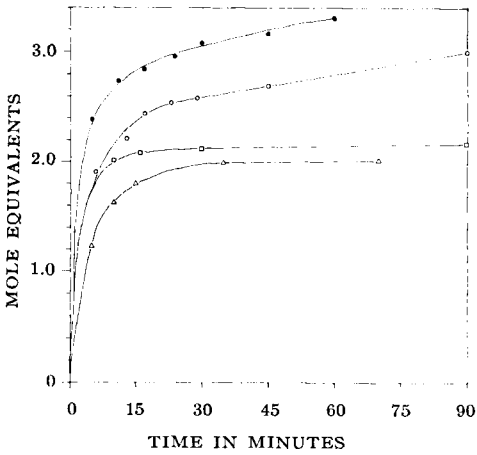

Fig. 4.—Hydrolysis rates in 0.25 *N* ethanolic sodium hydroxide at room temperature. ●, suksdorfin; ○, pteryxin; □, visnadin; △, (+)-*trans*-acetylmethylkhellactone.

Controlled Hydrolysis of Pteryxin.—Recrystallized pteryxin (1.0 Gm., 2.6 mmole) was dissolved in 0.25 *N* ethanolic sodium hydroxide (25.0 ml.) at room temperature and the rotation taken every 30 seconds. The rotation decreased rapidly for 8 minutes, remained constant for the next 4 minutes, and then started to decrease. An aliquot (1.0 ml.) was taken quickly and added to water (15 ml.) as the remaining solution was simultaneously added to an equivalent amount of sulfuric acid (6 meq.) in water (250 ml.). The reaction period was 13 minutes. The diluted aliquot was titrated im-

[9] It should be pointed out that Smith, *et al.* (2), obtained from samidin a methyl ether which melted at 158–159° and gave a rotation of $[\alpha]_D$ +14°, which is a mixture of approximately 83% *trans*- and 17% *cis*-isomers. Schroeder, *et al.* (4), have drawn attention to the fact that in no case did these workers report isomeric pairs, even though the isomers had been previously characterized in a preliminary report by the Swiss workers (16).

[10] Graciously supplied by Dr. Hamed Abu-Shady, Pharm. Chem. Department, Cairo University, Cairo, Egypt.

mediately with 0.0243 *N* sulfuric acid; a blank of the alkali solution was titrated at the same time. The alkali consumed was 1.75 mole equivalents. The aqueous acid solution of the reaction mixture was extracted with five 25-ml. portions of 3:1 ether-methylene chloride. The combined ethereal extract was washed with 10% sodium bicarbonate solution followed by saturated sodium chloride solution. The washed extract was dried over anhydrous sodium sulfate and evaporated to dryness. The residue was dried to constant weight in vacuum (680 mg.) and chromatographed on a column of neutral alumina (15 Gm., Woelm, Brockmann activity III). Elution with benzene yielded a crystalline residue from the first fraction (20 ml.). Recrystallization from methanol and drying at 78° in vacuum overnight afforded (−)-*trans*-acetylethylkhellactone (V), m.p. 167–168°. The melting point was not depressed on admixture with the acetate prepared from (−)-*trans*-ethylkhellactone. Their infrared spectra were superimposable.

Anal.—Calcd. for $C_{18}H_{20}O_6$: C, 65.05; H, 6.07. Found: C, 64.90; H, 6.15.

Continued elution with benzene, after removal of a dark zone, yielded a second crystalline fraction which was recrystallized from dilute methanol and dried at 78° in vacuum to give (+)-*cis*-ethylkhellactone (XI) as very fine colorless needles, m.p. 126–127°. The melting point was not depressed on admixture with a sample of (+)-*cis*-ethylkhellactone obtained previously from pteryxin. Their infrared spectra were identical.

Anal.—Calcd. for $C_{16}H_{18}O_5$: C, 66.19; H, 6.25. Found: C, 66.17; H, 6.36.

Further elution afforded only trace amounts of material.

Controlled Hydrolysis of Suksdorfin.—Suksdorfin (1.00 Gm., 2.58 mmole) was hydrolyzed in the same manner as above. The reaction period was 5 minutes with 1.65 mole equivalents of alkali being consumed. The reaction mixture was worked-up and the residue chromatographed as above. (−)-*Trans*-acetylethylkhellactone, m.p. 169–170°, and (+)-*cis*-ethylkhellactone, m.p. 127–128°, were obtained. Mixed melting points with samples obtained previously showed no depression and their infrared spectra were identical. Further elution of the column afforded only trace amounts of material.

3′-Keto-3′,4′-dihydroseselin (XIII).—Ethylkhellactone (2.18 Gm.) was treated with *p*-toluenesulfonic acid in boiling benzene in the same manner described by Schroeder, *et al.* (4). Recrystallization from 1:1 acetone-Skellysolve B gave 1.08 Gm. (59%) of light yellow prisms, m.p. 157–157.5° [lit. m.p. 156.5–157.5° (4)]; ultraviolet spectrum: $\lambda_{min.}$ 263 mμ (log ε 3.40); $\lambda_{max.}$ 321 mμ (4.10); infrared spectrum (Nujol mull): 1757 cm.$^{-1}$ (α- and β-pyrone C=O).

Anal.—Calcd. for $C_{14}H_{12}O_4$: C, 68.86; H, 4.95. Found: C, 68.65; H, 4.99.

(±)-3′-Hydroxy-3′,4′-dihydroseselin (XIV).—To a stirred solution of 3′-keto-3′,4′-dihydroseselin (488 mg.) in methanol (40 ml.), cooled to −10° in an ice-salt mixture, was added dropwise an ice-cold solution of sodium borohydride (530 mg.) in methanol (10 ml.) over a 15-minute period. The mixture was stirred an additional 45 minutes at room temperature. The yellow solution was made slightly acidic with 1 *N* hydrochloric acid and concentrated to 10 ml. Upon standing overnight fine red needles formed which were filtered off and air-dried to yield 422 mg. (86%) of product. Repeated crystallizations from dilute ethanol gave pale pink needles, m.p. 165–166°; infrared spectrum (Nujol mull): 3636 (free OH), 1720 (C=O), 1295 and 1090 cm.$^{-1}$ (O—H deformation and C—O stretching).

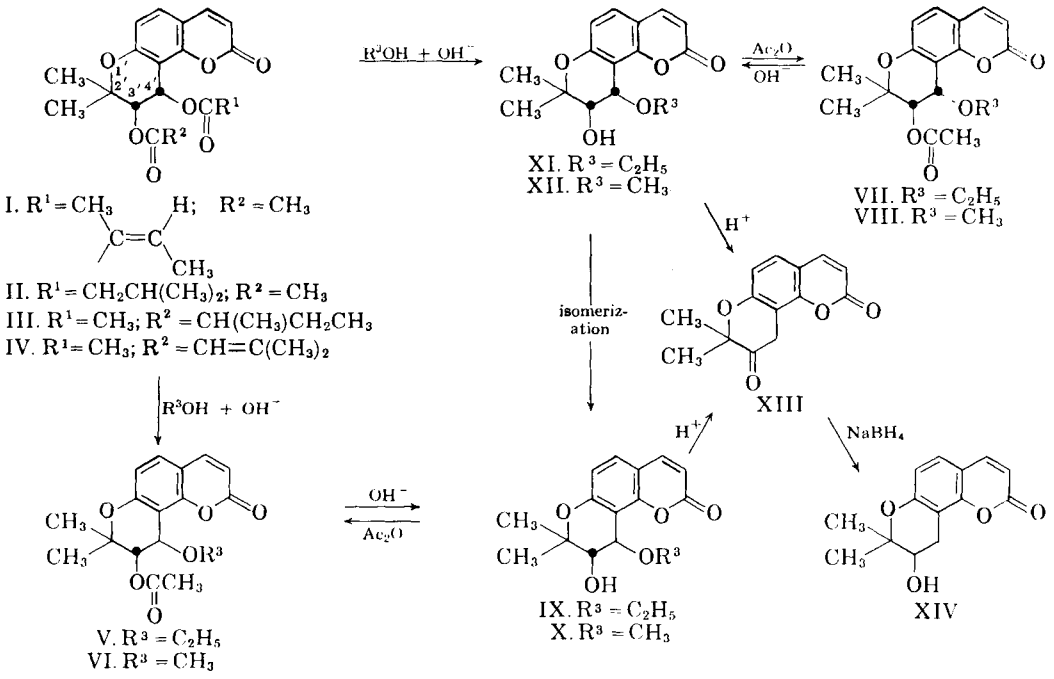
Anal.—Calcd. for $C_{14}H_{14}O_4$: C, 68.28; H, 5.73. Found: C, 68.00; H, 5.60.

Acetylation of 200 mg. of the alcohol XIV with acetic anhydride and pyridine gave 220 mg. (94%) of acetate. Recrystallization from dilute ethanol gave fine colorless needles, m.p. 172–173°; infrared spectrum (Nujol mull): 1752–1745 (α-pyrone and acetate C=O) and 1242 cm.$^{-1}$ (acetate C—O).

Anal.—Calcd. for $C_{16}H_{16}O_5$: C, 66.65; H, 5.59. Found: C, 66.50; H, 5.70.

The nuclear magnetic resonance (n.m.r.) spectra of the alcohol XIV and its acetate is in complete agreement with the assigned structures.[11]

DISCUSSION



Pteryxin (I) was isolated in 2% yield from dried roots of *P. terebinthina* and suksdorfin (II) in 1.2% yield from dried fruits of *L. Suksdorfii*. Chromatostrips were utilized in finding a satisfactory solvent system to purify these substances. Results obtained on the chromatostrips were readily adaptable to column chromatography and were a definite labor-saving device.

Ultraviolet spectra of these substances and their derivatives had absorption maxima at 322–329 mμ and minima at 263–266 mμ, which are in agreement with their assigned coumarin structures (2).

Upon hydrolysis with ethanolic alkali, pteryxin (I) and suksdorfin (II) both yielded the same isomeric alcohols, (−)-*trans*-ethylkhellactone (IX), which was shown to be identical to the hydrolysate obtained from samidin by Smith, *et al.* (2), and (+)-*cis*-ethylkhellactone (XI). In methanol, the corresponding methyl ethers (X and XII) were obtained. Absolute configurational formulas for the methylkhellactones were established by Schroeder, *et al.* (4). These ethers arise by means of a solvolysis of the 4′-position in the parent compounds, a finding substantiated by both Smith (2) and Schroeder (4). The 4′-position constitutes a benzyl ester, certain ones of which are known to undergo solvolysis with O-alkyl cleavage under acidic or basic conditions (17).

(+)-*Cis*-ethylkhellactone (XI) and its acetate (VII) have not been reported previously. We assigned absolute configurational structures to them on the basis of similarities to the established methyl ethers. The *cis* relationship of the adjacent hydroxyl and ethoxyl groups is indicated by the hydrogen bonding of the hydroxyl group evidenced in its infrared spectrum (3521 cm.$^{-1}$) as compared to the free hydroxyl shown by the *trans*-isomer (3636 cm.$^{-1}$). Additional evidence for hydrogen bonding in the *cis*-isomer is the location of its secondary hydroxyl OH deformation and C—O stretching absorption at 1342 and 1104 cm.$^{-1}$, whereas these peaks are at 1323 and 1082 cm.$^{-1}$ for the *trans*-

[11] The authors thank Mr. George Slomp, The Upjohn Co. Kalamazoo, Mich., for the determination and interpretation of the n.m.r. spectra.

isomer. Bonded hydroxyls are known to absorb at lower wavelengths (18). The same is true of the methyl ethers.

Ethylkhellactone (IX + XI) was dehydrated to form the ketone XIII, which was reduced with sodium borohydride to the alcohol XIV. The structures for alcohol XIV and its acetate were confirmed by nuclear magnetic resonance spectra.

Hydrolysis of pteryxin yielded angelic and acetic acids, and suksdorfin yielded isovaleric and acetic acids. These were characterized by paper chromatography and through their *p*-phenylphenacyl ester derivatives.

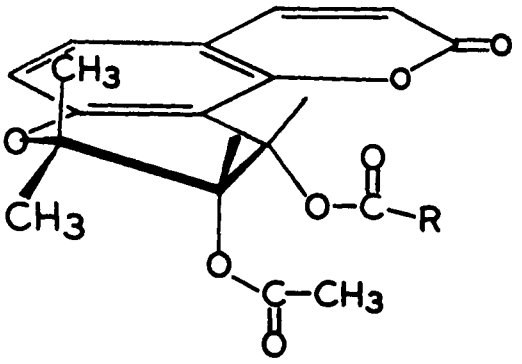
In a titration experiment measuring the rate of alkali consumption of visnadin (III) and samidin (IV) during room temperature hydrolysis in ethanolic alkali, Smith, *et al.* (2), reported these coumarins to consume only approximately two equivalents of alkali after 90 minutes. The third equivalent was consumed after refluxing. Also, they were able to isolate a room temperature hydrolysate which contained a five carbon acid moiety at the 3′-position. In a similar experiment, pteryxin (I) consumed all three equivalents at room temperature in 90 minutes, and suksdorfin (II) in 30 minutes.

Esters of α,β-unsaturated acids and higher saturated fatty acids hydrolyze in acid or base at a significantly slower rate than acetates (19). Clearly, the α,β-unsaturated angeloyl group in pteryxin and the isovaleryl group in suksdorfin are not on the 3′-oxygen, as is the case in visnadin and samidin, but are on the 4′-oxygen, where the solvolysis rate is not affected by the nature of the acid substituent. It follows therefore, that the acetoxy group is at the 3′-position and, inasmuch as it offers less resistance to hydrolysis, is cleaved at room temperature in a relatively short period of time.

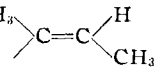
If the assignment of the acetoxy group to the 3′-position is correct, then the acetate of the intermediate ether (V or VII) should hydrolyze at a similar rate. Such was the case. Hydrolysis of (+)-*trans*-acetylmethylkhellactone (VI) was complete in 35 minutes.

By quenching the hydrolysis of the parent coumarins after 5 to 13 minutes, a mixture of (+)-*trans*-ethylkhellactone acetate (V) and (+)-*cis*-ethylkhellactone (XI) was obtained. Isolation of the intermediate acetate (V), which was identical to that prepared from the alcohol, conclusively proves pteryxin and suksdorfin to have structures I and II, respectively.

Migration of the acyl or acyloxy group from the 4′-position, to the 3′-position, which were arbitrarily designated as *trans*, was discussed by Smith, *et al.* (2), and the possibility eliminated. Establishment of their *cis* configuration makes a migration even more remote.



The hydrolytic studies indicated that the 3′-acetyl group was being hydrolyzed concomitantly, although at a slower rate, with the loss of the angeloyloxy group. As indicated above, the partial hydrolysis product was the *trans*-acetate (V) and the initial completely hydrolyzed one the *cis*-alcohol XI. If the reaction was allowed to proceed for an additional 15 minutes, the major product was the *trans*-alcohol IX, which arises by hydrolysis of the acetate V and by isomerization of the less stable *cis*-alcohol XI.



The hydrolytic results described above may be rationalized on the basis that the system is undergoing two different competitive processes, the one being kinetically controlled and relatively fast and the other being a slower equilibrium process. The former leads to the less stable *cis*-isomer and the latter predominantly to the more stable *trans*-isomer. It may be considered that the process, as postulated by Smith, *et al.* (2), involves first a fast S_N1 type expulsion of the 4′-acyloxy group initiated by the neighboring phenolic group. This leads to an enone intermediate which stabilizes the resulting carbonium ion. A study of structural models of the species involved leads us to suggest that the results of the

hydrolytic studies may be explained plausibly if one considers that the 3′-acetoxy group is undergoing continuous hydrolysis from the moment it is subjected to alkaline conditions. Thus, at all times, we can postulate two species of carbonium ion present, one with an acetoxy group and one with only a hydroxyl group at the 3′-carbon atom. The arrangement of groups on this carbon atom offers the strong possibility of a neighboring group type participation between the quasi-axially oriented acetoxy carbonyl and the carbonium ion center. Stabilization of the acetoxy group in this manner would reasonably promote ethoxide ion addition on the less hindered *trans*-side and lead to the *trans*-acetate V. On the other hand, the alcoholic species would no longer have this stabilizing influence and, therefore, both *cis*- and *trans*-addition can be envisioned. In this respect, the *cis*-addition, favored by a serious axial methyl (at the 2′-position) interference with *trans*-addition, is suggested as being quite rapid kinetically and would account for the isolation of the *cis*-alcohol XI when the reaction is quenched before equilibrium has been achieved. As the process proceeds, however, equilibration finally results in a preponderance of the *trans*-alcohol IX over the *cis*-alcohol, the former being obtained by hydrolysis of V as well as by isomerization of the less stable XI under alkaline conditions.

Pteryxin (I) and suksdorfin (II) have the same configuration as visnadin (III) and samidin (IV) at the 3′-position, as evidenced by the formation of the same hydrolytic products. The absolute configurational structures for the latter pair of compounds were established by Schroeder, *et al.* (4), on the basis of their (+)-rotation and the similarities of their infrared spectra in the 9 and 10 μ region to synthetic (±)-*cis*-diacetylkhellactone. Also, these infrared spectra differed significantly from those of synthetic (±)-*trans*-samidin and (±)-*trans*-diacetylkhellactone. Since pteryxin (I) and suksdorfin (II) possess these features too, they have the same configuration as visnadin (III) and samidin (IV) at the 4′-position, and are, therefore, established as (+)-*cis*-pteryxin and (+)-*cis*-suksdorfin.

We propose the following absolute conformational structures for (+)-*cis*-pteryxin (XV) and (+)-*cis*-suksdorfin (XVI) with the 3′-acetoxy and 4′-acyloxy groups in axial and quasi-equatorial positions, respectively. The arrangement of these two groups in molecular models is distorted from the normal axial and equatorial positions that would be encountered if the ring system were a cyclohexane type rather than the fused dihydro-pyrano system that actually exists. This, no doubt, is due to the different bond lengths and angles of the ether oxygen.

XV: R = 

XVI: R = $CH_2CH(CH_3)_2$

The mechanisms involved in the hydrolysis of these coumarin esters and additional stereochemical proofs are presently under further investigation.

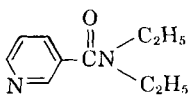
Central Stimulatory Activity of Vanillic Diethylamide



By JOSEPH P. BUCKLEY, MARIO D. G. ACETO, and WILLIAM J. KINNARD

Vanillic diethylamide produced central nervous system effects indicative of medullary stimulation when injected into frogs and rats. Vanillic diethylamide administered intravenously to anesthetized dogs and cats produced a marked increase in both the rate and depth of respiration, which was usually accompanied by the return of the corneal reflex and a mild, transient hypotensive effect. The transient hypotensive effect could be eliminated by administering the compound via a slow infusion at rates ranging between 1 and 8 mg./Kg./min. The compound produced identical responses prior to and after bilateral carotid sinus area denervation, and it appears that the compound acts mainly on the medullary centers and that the carotid sinus-body complex is not essential for the stimulatory activity. A 10 mg./Kg. quantity of vanillic diethylamide administered into the arterial inflow to the recipient's head in 2 dog cross-circulation experiments awakened the recipient animal and produced a transient pressor effect in the recipient.

IT HAS BEEN known for many years that the analeptic activity of the alkylated acid amides was due to the alkylation of the nitrogen of the acid amide group (1). The clinical success with nikethamide, an active member of the alkylated acid amide group, prompted further synthesis of related compounds. Vanillic diethylamide, 3-methoxy-4-oxybenzoic acid-diethylamide (see Fig. 1), was prepared and tested on experimental animals in an attempt to produce a more potent compound (2, 3). The object of the present study was to investigate certain central stimulatory actions of the compound and to study its possible sites of action.

Vanillic Diethylamide

Nikethamide

Fig. 1.—Chemical structure of vanillic diethylamide and nikethamide.

Received April 28, 1961, from the Department of Pharmacology, University of Pittsburgh, School of Pharmacy, Pittsburgh, Pa.

Accepted for publication June 22, 1961.

Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.

Supported in part by a research grant from U. S. Vitamin & Pharmaceutical Corp., New York, N. Y.

EXPERIMENTAL PROCEDURES

Preliminary CNS Screening in Frogs.—Doses of vanillic diethylamide, ranging between 10 and 50 mg./Kg., were administered into the ventral lymph sac of 12 frogs. General activity was noted and if hyperreflexia or convulsions occurred, either decerebration or decerebration and demedullation was performed.

Preliminary CNS Screening in Rats.—An aqueous solution of vanillic diethylamide was administered intraperitoneally to 16 rats in doses ranging from 25 to 75 mg./Kg., and the gross behavior of the animals recorded.

Effect on Anesthetized Dogs and Cats.—Mongrel dogs were anesthetized with an intravenous dose of 35 mg./Kg. of sodium pentobarbital. Cats were anesthetized by an intraperitoneal injection of the same dose of sodium pentobarbital. Blood pressure was recorded from a carotid or femoral artery via a Statham transducer, and respiration was recorded from a thermocouple wire in the tracheal cannula. The neural plexi surrounding both carotid sinuses and carotid bodies were stripped in three experiments. The elimination of the pressor response to bilateral carotid occlusion was utilized as one of the criteria for complete denervation of the carotid sinus area. Physiological responses were recorded on a Grass polygraph. Fresh aqueous solutions of vanillic diethylamide were administered intravenously in doses ranging from 2.5 to 25 mg./Kg.

Effect on Dogs and Cats under Severe Barbiturate Depression.—Dogs and cats were anesthetized and prepared for the recording of blood pressure and respiration as previously noted. The animals were further depressed by intravenous doses of sodium pentobarbital. At a point of severe respiratory depression, vanillic diethylamide was administered intravenously in an aqueous solution.

Effect of Vanillic Diethylamide Infusion on Depressed Cats.—Cats were anesthetized by an intraperitoneal injection of 35 mg./Kg. of sodium pentobarbital. Physiological recordings were made as previously noted. Vanillic diethylamide was infused intravenously into the depressed animal utilizing a microdrip apparatus.[1] Bilateral carotid

[1] Venopak microdrip, Abbott Laboratories.

sinus-body denervation was produced in three preparations.

Central Effects of Vanillic Diethylamide.—The central effects of vanillic diethylamide were investigated in two dog cross-circulation preparations. Mongrel dogs were anesthetized by an intravenous injection of pentobarbital sodium, 35 mg./Kg., and the vascularly isolated, neurally intact recipient head preparation was obtained utilizing the procedure described by Buckley, *et al.* (4). Donor and recipient femoral blood pressures were obtained, and electroencephalographic tracings were obtained from frontal electrodes in the recipient. Vanillic diethylamide, 10 mg./Kg., was administered in aqueous solution via the carotid artery to the recipient's head.

RESULTS

Preliminary CNS Screening in Frogs.—Doses of 10 and 25 mg./Kg. of vanillic diethylamide produced hyperreflexia which disappeared upon decerebration. Injection of 50 mg./Kg. produced clonic convulsions which were abolished by demedullation.

Preliminary CNS Screening in Rats.—The effects of vanillic diethylamide, in doses ranging between 25 and 75 mg./Kg., i.p., on the activity of albino Wistar rats are summarized in Table I and indicate that the compound is a potent stimulant of the central nervous system. The type of convulsions produced by the larger doses suggests the medulla as the possible site of stimulation.

TABLE I.—EFFECTS OF VANILLIC DIETHYLAMIDE ON ALBINO RATS

No. of Animals	Dose, i.p., mg./Kg.	Results
3	25	No effect
9	50	2 showed slight stimulation, 4 showed extreme excitement short of convulsions, 3 showed clonic convulsions and death within 5 minutes
4	75	3 showed mixed convulsions and death within 5 minutes, 1 showed slight stimulation

Effect on Anesthetized Dogs and Cats.—The intravenous administration of vanillic diethylamide, in the dose range of 10 to 25 mg./Kg., to dogs and cats produced general signs of central nervous system stimulation (See Table II). The common picture of initial apnea lasting 60 seconds or less followed by an increased rate and/or depth of respiration was observed in most of the experiments. The initial hypotensive effect followed by the return to the predrug level or slightly above that level was also seen in the majority of the experiments. Doses of 20 and 25 mg./Kg., i.v., into cats produced signs of arousal. The intravenous injection of vanillic diethylamide to three dogs having bilateral denervation of the carotid sinus-body complex produced the same physiological responses that were seen in animals having intact sinus areas. The administration of 10 mg./Kg. of vanillic diethylamide to the first dog produced a transient fall in blood pressure from 245/135 mm. Hg to 180/80 mm. Hg with a return to control levels within 2 minutes. The respiration was increased, following a transient apnea, to 17 per minute from an initial rate of 13 per minute. The blood pressure in the second dog showed a transient fall from 250/128 mm. Hg to 150/80 mm. Hg and a recovery to 195/120 mm. Hg within 80 seconds following the intravenous injection of 15 mg./Kg. of vanillic diethylamide. The respiration, following a short period of apnea, increased to 18 per minute from the control value of 4 per minute; the respiratory rate then slowed gradually to 7 per minute. The third dog showed an increase in respiratory rate to 63 per minute from the control level of 47 per minute following 10 mg./Kg. of the drug, i.v. The blood pressure followed the same pattern as was seen in the previous dogs.

Effect on Dogs and Cats under Severe Barbiturate Depression.—Vanillic diethylamide, in doses from 5 to 25 mg./Kg., produced in all experiments but one an increase in the rate of respiration (See Table III). Doses of 25 mg./Kg., i.v., in the cat generally produced signs of arousal from the anesthesia. Many of the cardiovascular responses were that of initial transient hypotension with a recovery to near normal levels of blood pressure within a few minutes.

Effects of Vanillic Diethylamide Infusion on Depressed Cats.—The administration of vanillic

TABLE II.—EFFECT OF VANILLIC DIETHYLAMIDE ON ANESTHETIZED[a] DOGS AND CATS

Animal	Initial Blood Pressure, mm. Hg	Initial Respiration, rate/min.	Dose, i.v., mg./Kg.	Effects	
				Respiration	Blood Pressure,[b] mm. Hg
Dog	190/135	18	2.5	17/min. with increased depth	205/145
Dog	250/140	72	10.0	Rate drop to 66/min., depth increased by 50%	Transient fall, then maintained at 260/150
Dog	130/75	31	10.0	Short period of apnea followed by increased rate and depth	Transient fall and then recovery
Dog	175/115	28	10.0	Initial apnea, then increased to 36/min.	Transient fall, followed by a slight hypertensive effect
Dog	200/120	5	15.0	Apnea for 60 sec., rate increased to 12/min., then back to normal in 4 min.	Fall to 104/42, then rise to 175/100 in 80 sec.
Cat	175/130	24	5.0	No change	No change
Cat	75/55	12	10.0	Transient increase	No change
Cat	193/140	19	20.0	Increased to 40/min.	Increased 25%, animal awoke
Cat	145/100	26	25.0	Increased to 50/min.	No change, motor activity of limbs

[a] Anesthetic—pentobarbital sodium, 35 mg./Kg., i.v., for dogs, i.p., for cats. [b] Motor activity also noted.

TABLE III.—EFFECT OF VANILLIC DIETHYLAMIDE ON DOGS AND CATS UNDER DEEP PENTOBARBITAL DEPRESSION

Animal	Additional Doses of Sodium Pentobarbital,[a] mg./Kg.	Blood Pressure, mm. Hg	Respiration, rate/min.	Dose, i.v., mg./Kg.	Effects	
					Blood Pressure, mm. Hg	Respiration,[b] rate/min.
Dog	22.5	155/105	2	10.0	Transient fall then rise to 175/120	Increased to 33
Cat	15.0	...	2–3	5.0	Transient fall then increased to 180/125	Increased to 11 with increase in depth
Cat	7.5	100/75	Stopped	5.0	Increased to 175/125	Increased to 10
Cat	11.0	128/80	20	6.0	Fall to 100/68	Transient apnea, then 15
Cat	9.0	147/108	15	10.0	Transient fall to 115/53 then returned to 151/113 in 3 min.	Increased to 21 for 1 min., then returned to 15
Cat	6.5	...	20	25.0	.....	Extremely rapid with convulsions
Cat	15.0	75/60	Stopped	25.0	160/100	Increased to 15 for 5 min., then stabilized at 8, then corneal reflex positive
Cat	18.0	...	2–3	25.0	Increased	Increased to 15

[a] Dogs anesthetized with pentobarbital sodium, 35 mg./Kg., i.v.; cats anesthetized with pentobarbital sodium, 35 mg./Kg. i.p. [b] Motor activity also noted.

[a] Anesthetic, pentobarbital sodium, 35 mg./Kg., i.p. [b] Peak hypertensive effect. [c] Cessation of infusion. [d] Bilateral carotid sinus-body denervation.

diethylamide by slow infusion produced pronounced CNS stimulatory effects in anesthetized cats, even when the carotid sinus-body complexes were denervated (See Table IV). In most cases, the blood pressure was elevated during initial stages of the infusion and then gradually fell after a period of time. When the infusion was stopped, arterial blood pressure usually increased or remained stable. The

peak hypertensive response usually occurred very close to the onset of visible motor movements. Since the arterial pressure began to drop shortly after motor activity was observed, it is entirely possible that pain stimuli might be responsible for this secondary depressor response. The respiratory rate generally increased during the initial phase of the infusion and then gradually decreased. The rate of respiration immediately increased when the infusion was stopped. The infusion of vanillic diethylamide into denervated cats produced the same effects as those seen during the infusion of the drug into cats having intact sinus areas (See Table IV).

Central Effects of Vanillic Diethylamide.—The administration of 10 mg./Kg. of vanillic diethylamide into the arterial inflow to the recipient's head in two cross-circulation experiments produced nearly complete arousal of the animals. The recipient animals blinked their eyes, wagged their tails, and attempted to move their heads. An initial apnea occurred in the recipient dogs which was followed by a resumption of respiration that was thoracic in nature as compared to the abdominal breathing observed prior to drug administration. The compound produced an initial hypertensive effect in the recipient dogs. There was little change in the blood pressure and respiration of the donor dogs although there was a slight transient hypotensive response in one dog. An electroencephalogram, obtained from frontal electrodes in the recipient dog, illustrated an increased activity immediately after the administration of vanillic diethylamide. Major analeptic effects were not seen in the donor dog.

DISCUSSION

The parenteral administration of vanillic diethylamide into frogs, rats, cats, and dogs produced definite signs of central nervous system stimulation. Injection of 50 mg./Kg. of the drug into the ventral lymph sac of frogs produced clonic convulsions which were abolished by demedullation, while 50 and 75 mg./Kg.-doses injected in rats produced tonic-clonic convulsions. Single doses of 5 to 25 mg./Kg. administered intravenously into anesthetized and deeply anesthetized dogs and cats generally produced a decrease in the depth of anesthesia. Following the injection of the drug, an initial phase of apnea and hypotension usually occurred; the respiration then increased in rate and/or depth while the blood pressure returned to normal or slightly hypertensive levels. Nikethamide is believed to stimulate respiration through stimulation of the carotid body (5). It has also been reported that vanillic diethylamide acts through stimulation of this receptor area (6); however, single and infused doses of vanillic diethylamide following bilateral denervation of the carotid body-sinus area produced similar effects to those seen prior to denervation. It would appear that the carotid body has little, if any, part in the mechanism of action of the compound.

The infusion of vanillic diethylamide into depressed cats decreased the depth of anesthesia in accordance with the rate of infusion. It would appear that this method of administration might lend itself well to clinical control of overdepressed patients, especially since vanillic diethylamide appears to be quickly metabolized.

The hypotensive effect of the compound produced by single intravenous injections into depressed animals was not observed following intra-arterial injection into the recipient animal in cross-circulation experiments. A hypertensive effect rather than the expected hypotensive response occurred in these animals. This might indicate that the hypotensive response was due to peripheral mechanisms rather than effects mediated through the central nervous system.

It appears that vanillic diethylamide is a potent central nervous system stimulant having primary effects on the medullary neural receptors with little or no effect taking place through the carotid body chemoreceptors or the carotid sinus receptors. It should also be noted that the cat appears to be extremely sensitive to the drug.

SUMMARY

1. The central stimulatory effects of vanillic diethylamide were studied in frogs, rats, dogs, and cats.

2. Vanillic diethylamide produced central stimulatory effects in all species tested.

3. The stimulatory action of vanillic diethylamide appears to be mainly due to direct stimulation of medullary receptor sites and not to stimulation of the carotid body-sinus complex.

4. Large doses of the compound produced transient hypotensive effects which could be eliminated by administering vanillic diethylamide by slow intravenous infusion.

Hydrocholeresis in the Isolated Perfused Rat Liver

By W. W. TUTTLE, L. L. EISENBRANDT, and P. M. SCOTT

The construction and operation of a simplified isolated rat liver perfusion apparatus consisting of readily available components are described. In 30 determinations this procedure successfully maintained isolated rat liver function to a degree equivalent to that obtained by other investigators.

PIONEER STUDIES with perfused livers as reported by Bauer, *et al.* (1), were made by Mautner and Pick in 1915. These early perfusions, which employed saline perfusates, lead to the more recent and refined investigations of Brauer, *et al.* (2), who used expanded blood perfusates. This latter procedure required considerable glass manipulation, for the apparatus was tailored to the morphology of the liver. Young, *et al.* (3), later developed a rabbit liver perfusion apparatus which had the advantage of being composed largely of standard glassware, facilitating initial construction and replacement. An adaptation of this sytem was used in the work herein reported.

Isolated liver perfusion as a means of studying liver function and metabolism is useful because it permits hepatic activity to be studied in the absence of extrinsic nerve supply and lymphatic plexus. Brauer, *et al.* (2), reported that maintenance of a liver in near physiologic state was excellent if a blood-containing perfusate were used.

METHODS AND MATERIAL

Perfusion Apparatus.—The perfusion apparatus (Fig. 1) consisted of a perfusate reservoir, oxygenating column, organ chamber, circulating pump and filter system, hydrostatic perfusate reservoir, and a thermostatically (37.5°) controlled thermal plywood cabinet with a glass door. Heat was supplied by four 100-watt shielded light bulbs.

The reservoir [1] was a 100-ml. three-neck distilling flask with a standard taper 24/40 center-neck. All other ground-glass joints in this apparatus were standard taper 24/40. The oxygenation system consisted of an oxygenating column [2] made by fusing an outer and inner Pyrex joint to give a column of 20 cm. total length. The connecting tubes [3] on either end of this column were Pyrex with 105° side arms. The Pyrex inner joint [4], above the upper connecting tube, was cut to fit the lower neck of the organ chamber [5] with the aid of a bored-rubber stopper gasket. The organ chamber consisted of two 150-mm. desiccator covers with greased, ground-glass surfaces to insure an air-tight seal for good oxygen circulation through the apparatus. A small hole in the lower cover allowed for egress of the bile duct cannula. The organ mounting cradle [6] was made of No. 50-mesh stainless steel screen. Special attention is directed to the cannula attachment [7, 8] which was fashioned by fitting a rubber stopper in the upper desiccator neck with a short length of 9-mm. Pyrex glass tubing which extended above the stopper $^1/_4$ inch. An 11.5-cm. length of 7-mm. Pyrex tubing was slipped into the 9-mm. length, and the upper juncture of these sealed with a short length of rubber tubing. This allowed for sliding the inner glass tubing leading to the portal cannula up or down for positioning the excised liver. The double perfusion valve [11] was available from the Macalister-Bicknell Co., Cambridge, Mass. The blood filters [10] were Baxter Filterdrip assemblies which were modified to reduce their volume by use of 7-mm. Pyrex glass tubing extensions [13]. These extensions were inserted into the top of the assemblies and terminated a few millimeters above the filter elements. The double filter system enabled transfer of filters should one become clogged during a perfusion. The pulsating tube [12] was made from a 2-inch length of 22-mm. Pyrex glass tubing joined to a $1^1/_2$-inch length of 7-mm. Pyrex tubing. The diaphragm of this pulsating pump was a large rubber finger cot which was folded over the large end of the pulsating tube and held in place by rubber cement and closed by the rubber adapter cap of a disposable Baxter blood administration set. A pipetting machine [21] with valves removed was fitted with a lubricated 30-ml. syringe to provide the reciprocating action necessary to expand and collapse the finger cot diaphragm of the pulsating chamber. The hydrostatic reservoir [15] was made from a $2^1/_2$-inch length of 22-mm. Pyrex tubing attached at the bottom to a short length of 7-mm. Pyrex tubing. The overflow arm was made from 9-mm. Pyrex tubing with its lower end reduced to 7 mm. This side arm was attached to the reservoir 1 inch from the top. The increase in tube size in this arm permitted a noncontinuous overflow of the perfusate which bipassed the liver. This reservoir was elevated to give 21.5 cm. of hydrostatic pressure from overflow arm to portal vein of the liver. The infusion system [17] consisted of a Phipps and Bird syringe driver adapter fitted to a kymograph and adjusted to deliver 0.012 ml./min. of infusate into the system via the latex tubing above the organ chamber. A few drops of Dow Corning antifoam B were added to the saline humidifier [16] to prevent excessive foaming. The rubber connecting tubing used throughout this system was amber latex rubber tubing with 5 mm. i.d. and 1.5 mm. wall thickness. Especially constructed glass cannulas were used for the portal and vena cava cannulations, as adapted from the work of Werthessen (4).

The entire system except for the pulsating tube

was steam sterilized prior to use, and the finger cot diaphragm of the pulsating tube was soaked with benzalkonium chloride 1:500 for 3 hours prior to assembly.

Perfusate.—The perfusate and infusate mixtures were adopted from Brauer, *et al.* (2), to give a basis for performance comparisons with his biliary flow rates. Perfusate solutions A (expanded physiologic saline)[1] and B (phosphate buffer system) were mixed, added to the reservoir and equilibrated with oxygen for 2 minutes, and then solution C (rat blood) was added. The infusate mixture consisted of an antibiotic and nutrient in an expanded saline medium.

Operative Technique.—Under ether anesthesia the bile duct of Sprague-Dawley rats was cannulated with P.E. 50 tubing. The inferior vena cava of the heparinized animal was ligated just superior to the right renal vein and divided. The inferior vena cava was cannulated just superior to the diaphragm and divided. The portal vein was cannulated last and severed. The organ was then removed by excising the diaphragm and dividing the suspensatory ligaments attached to the organ. The liver was mounted, diaphragm down, on the stainless steel cradle and attached to the filled perfusion system making sure all lobes were free for circulation. The bile duct cannula was placed through the hole in the organ chamber provided for it and positioned over the planchet magazine. Then the covers of the organ chamber were sealed. The thermocouple to the thermometer was then positioned to rest lightly on a lobe of the liver. Surface temperature varied from 38.5 to 39.5° which was within the temperature range of maximal bile production as reported by Brauer, *et al.* (5).

[1] The authors are indebted to the Armour Laboratories for the bovine plasma albumin used in the perfusate.

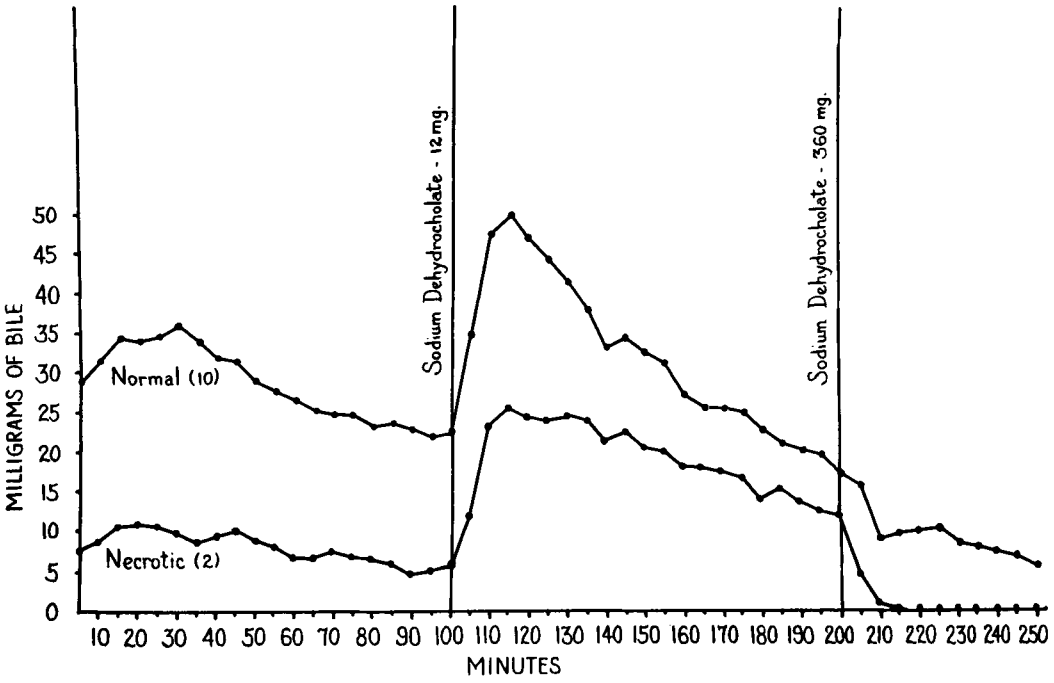

Fig. 2.—Bile flow of normal and necrotic isolated perfused rat livers.

Operation of Apparatus.—Oxygen flow was maintained at 2 L./min. The perfusate pumping rate was regulated to pass about one-half as much perfusate over the hydrostatic reservoir overflow as that which passed throuhg the organ. Perfusate flow varied somewhat in each individual organ, but the usual rate was 100 to 150 ml. per minute.

A properly functioning organ was evidenced by the gradual change in lobe color from dark to pink, as well as by the rate of bile flow. A nonperfusing lobe remained dark and required repositioning to initiate perfusion.

After an equilibration period of 15 minutes, bile was collected at 5-minute intervals in tared cup planchets and quickly weighed.

EXPERIMENTAL DATA

Fifteen Sprague-Dawley albino rats, ranging in weight from 350 to 400 Gm., served as liver donors in the early phases of the experiment where adjustment of the oxygenation rate was necessary, as well as the perfusion design and technique. In addition, 30 animals were used for varying periods of time. Of these, 12 were complete runs of 250 minutes and are included to illustrate the operation of the equipment. The high rate of failures indicates the technical complexities of isolated rat liver perfusion. Mean perfusion rates of 10 normal livers and two necrotic livers and their response to sodium dehydrocholate[2] are reported. The data are preliminary and are to be extended.

Twenty-four-hour liver necrosis was induced by an oral dose of 3 ml./Kg. of a 40% mixture of carbon tetrachloride in olive oil (6). Special care in handling these organs was needed because the carbon tetrachloride induced considerable fragility.

A rapid increase in bile flow occurred during the first 45 minutes of perfusion followed by a gradual decline for about the same time-interval, finally reaching a steady phase of flow of approximately 23 mg. per 5-minute interval (Fig. 2).

During the steady phase the initial 12-mg. dose of sodium dehydrocholate was given into the latex tubing of the hydrostatic reservoir overflow which allowed for maximal mixing with the perfusate before reaching the liver. The average bile flow (by weight) at the time of the dose was 22.2 mg., while the average peak bile flow 15 minutes later was 49.9 mg. per 5-minute interval, an increase of 125 ± 14.7%. During hydrocholeresis the perfusate flow was unchanged.

The initial high rate of bile flow was not as pronounced in the necrotic preparations but had the same general pattern as the normal. The necrotic livers exhibited considerably less biliary flow than their normal counterparts. The relative percentage response of the necrotic livers to the 12-mg. dose of sodium dehydrocholate was greater than in the normal livers. The average bile flow (by weight) of the necrotic livers at the time of the dose was 5.5 mg.; 15 minutes later the average peak bile flow was 25.3 mg. per 5-minute interval, a 360 ± 68.7% increase. Again the perfusate rate remained constant. The stimulated response was considerably more prolonged in the necrotic livers as compared to the normal.

After allowing 100 minutes for the initial response to sodium dehydrocholate (12 mg.) to subside, the 360-mg. dose was given as before. This dose was equivalent to the 200 mg./Kg. dose used routinely in this laboratory with *in situ* work.

[2] Appreciation is expressed to George A. Breon and Co. for the Dilabil-Sodium Injection.

The response from this massive dose resulted in an abrupt decrease in normal liver biliary flow from an average weight at the time of administration of 17.2 mg. to 5.9 mg. of bile per 5-minute interval at depth of depression, a 67.5 ± 11.8% decrease. Again the perfusate flow remained constant.

Although necrotic livers did not return to their stable biliary flow rate in 100 minutes, the 360-mg. dose of sodium dehydrocholate was given for experimental continuity. Bile flow decreased from an average flow at time of administration from 12.0 to 0.00 mg. of bile per 5-minute interval, a 100 ± 0.00% decrease. The perfusate flow remained constant as before. Obviously, the latter data are suggestive only.

DISCUSSION

The described liver perfusion unit differs from others in that standard glassware and simple cabinet construction were used. Using identical perfusate and infusate mixtures and the same hydrostatic pressure as Brauer, *et al.* (2), a normal bile flow pattern identical with his was found. However, the hydrocholeretic response was not proportionally as great as that from the 2 mg. of sodium dehydrocholate used by Brauer. Perhaps this was due to the addition of the drug by Brauer into the system just above the liver, which resulted in a greater initial hepatic concentration of drug.

The decrease in biliary flow due to the 360-mg. dose was apparently not a vascular response because the perfusate flow remained constant. During preliminary runs, large doses (360 and 840 mg.) of sodium dehydrocholate were found to elicit a depression of bile flow during the first hour of perfusion. Also, 2-mg. doses of sodium dehydrocholate given at 40, 95, 135, and 160 minutes resulted in equivalent increments in biliary flow indicating that the depressive response is a true reaction and not just the malfunction of a fatigued or subnormal organ. Goodman and Gilman (7) and Clark (8) noted that the toxic effects of bile salts resulted in inhibition of cholinesterase. Perhaps endogenously released acetylcholine caused a decrease in bile flow through biliary tract constriction.

The perfusion rate of the isolated perfused rat liver was considerably above the *in situ* rate of blood flow. Brauer, *et al.* (9), attributed this fivefold increase in flow rate to the inactivation of a hepatic vasoconstrictor factor resulting in full vasodilatation of the hepatic vascular tree.

The initial rise in bile flow may be due to a recovery from liver hypothermia following the surgical procedure. Brauer, *et al.* (10), noted that bile elaboration was depressed when liver temperature was reduced from its optimal value of about 40°. Upon rewarming, an excessive flow with increased bilirubin content resulted for a brief period. This surge was perhaps due to an accumulation of intermediate metabolites leading to excessive flow once metabolic balance was restored upon rewarming. The initial collections of bile in this work were noticeably darker, which quite possibly indicated an increment of bile salts.

It is quite apparent that necrotic liver data are insufficient for evaluation, but were included to indicate a trend.

SUMMARY

The assembly and operation of a functional isolated rat liver perfusion apparatus is described using simple materials and standard glassware. Preliminary data are included to illustrate the operation of the unit.

The mean per cent response of normal isolated perfused rat livers to 12 mg. of sodium dehydrocholate from point of administration to peak of hydrocholeretic rise was 125 ± 14.7% (22.2 to 49.9 mg. bile per 5-minute interval). The comparable response of necrotic livers was 360 ± 68.7% (5.5 mg. to 25.3 mg. bile).

The bile flow response to 360 mg. sodium dehydrocholate resulted in a decrease from point of administration to depth of depression of 67.5 ± 11.8% (17.2 to 5.9 mg. bile per 5-minute interval) for normal livers, and 100 ± 0.00% (12.0 to 0.00 mg. bile) for necrotic livers.

Manometric Method for the Evaluation of Preservatives

By JOHN L. WAILES

A manometric method using the Warburg apparatus has been investigated as a possible screening technique for the evaluation of agents used as preservatives in pharmaceutical preparations. This procedure also was utilized to determine the relative effectiveness of different preservatives, and preservative-surfactant combinations. The respiratory effects on baker's yeast were determined with methylparaben, propylparaben, and sorbic acid, separately, and each in the presence of polysorbate 80. Each of the three preservatives caused a decrease in oxygen consumption by baker's yeast. In general, the order of effectiveness was propylparaben > sorbic acid > methylparaben. Polysorbate 80 decreased the effectiveness of each of the three preservatives. Sorbic acid was the least affected, except at a preservative concentration of 0.025%. These manometric results are rapidly obtained, informative, and in general agreement with results found by more time-consuming procedures.

VARIOUS METHODS such as the agar-cup-plate, agar streak, agar-disk-plate, and direct inoculation, with and without complex nutrients, have been used to test preservatives against a variety of organisms. These methods, though informative, are time consuming. Also, some question may arise as to the interaction of preservative with the complex nutrients (1, 2) and the different rates of diffusion of preservatives in these nutrients.

This investigation was undertaken to determine the feasibility of using a Warburg manometric procedure as a screening technique for the evaluation of agents used as preservatives in pharmaceutical preparations. The method was devised to reduce the time element and to employ a simple medium, thus obviating complex nutrients and the varying rates of preservative diffusion in a medium. Also, it was of interest to determine whether or not the method would reveal the relative effectiveness of different preservatives and preservative-surfactant combinations.

Sabalitschka and Boehm (3) were among the first investigators to use the *p*-hydroxybenzoate esters as antibacterial and antifungal agents. Since that time these esters and many other substances have been investigated, compared, and recommended for their preservative activity (4–12). The evidence in the literature is abundant concerning the interaction between methyl- and propylparaben with nonionic surfactants (13–20).

The use of sorbic acid as a pharmaceutical preservative is relatively new compared with the parabens. Cosgrove, *et al.* (21), and later deNavarre (22) were among the first investigators to employ sorbic acid as a preservative in pharmaceuticals. In addition, deNavarre (19, 23), Barr and Tice (18), Charles and Carter (24), and recently Blaug and Ahsan (25) have investigated the effectiveness of sorbic acid in the presence of nonionic surfactants.

EXPERIMENTAL

The direct method of Warburg (26) was used to measure the amount of oxygen consumed by the yeast cells. The respiratory effects on baker's yeast were determined with methylparaben, propylparaben, and sorbic acid. Each preservative was tested separately with five different w/v concentrations: 0.025, 0.05, 0.1, 0.2, and 0.4%. In addition, each concentration of preservative was combined with five separate w/v concentrations of polysorbate 80:[1] 0.25, 0.5, 1.0, 2.0, and 5.0%. The oxygen uptake by the yeast cells in the presence of the preservative and the preservative-surfactant combination was compared with the control over a period of 90 minutes.

Each Warburg reaction flask contained a final volume of 3.0 ml. The center well of each flask contained 0.2 ml. of 20% potassium hydroxide in which a small, pleated, filter paper was inserted. The side arm contained 0.2 ml. of yeast, equivalent to 1.25 mg. of dried baker's yeast, suspended in sterile 0.05 *M* phosphate buffer (27) pH 6.0. The yeast suspension was prepared by adding 100 ml. of the sterile phosphate buffer to 625 mg. of dried yeast. The suspension was stirred for 30 minutes prior to pipetting to ensure an even dispersion of the yeast cells.

The main compartment of the flask contained 2.6 ml. of the preservative dissolved in an alcohol-phosphate buffer-dextrose solution. As an example, in order to prepare a 0.1% solution of the preservative, 107.7 mg. of the preservative was dissolved in 3.4 ml. of 95% ethyl alcohol and diluted to 100 ml. with sterile 0.05 *M* phosphate buffer, pH 6.0,

[1] Tween 80, Atlas Powder Co., Wilmington, Del.

This investigation was supported in part by a research grant, E-2788, from The National Institute of Allergy and Infectious Diseases, Public Health Service.

containing 5% dextrose. When 2.6 ml. of this solution was diluted with 0.2 ml. of the yeast suspension contained in the side arm, the resulting solution consisted of 0.1% of the preservative and 3.0% ethyl alcohol. The control flasks contained 2.6 ml. of the alcohol-phosphate buffer-dextrose solution in the main compartment in addition to the 0.2 ml. yeast suspension in the side arm, and the potassium hydroxide in the center well.

The flasks were placed in the constant temperature water bath. All tests were conducted at 37 ± 0.01°. The Warburg was adjusted to 120 cycles per minute with a 3-inch stroke. After a 10 minute equilibration period, the contents of the side arm were tipped into the main compartment of the reaction flasks. Manometer readings were recorded every 10 minutes for a 90-minute period.

At the end of 90 minutes, one standard loopful was transferred from the main compartment of each flask to 20 ml. of sterile Sabouraud maltose broth. These tubes were incubated at 37° for 18 hours, and then observed to determine either the absence or presence of growth. Those tubes that showed no growth were incubated for a total of 72 hours, and again observed.

All solutions and the yeast suspension were prepared immediately prior to use. Each concentration of preservative and preservative-surfactant combination was run in triplicate and each experiment repeated three times.

RESULTS AND DISCUSSION

It was considered necessary to determine the respiratory effects of each component of the substrate. Table I reveals that baker's yeast in phosphate buffer consumed very little oxygen over the 90-minute time period, thus showing little endogenous respiration. However, approximately a ninefold increase in oxygen consumption was observed with the addition of 5% w/v dextrose. Oxygen consumption was further increased by the addition of alcohol. The increase was observed with the subsequent addition of 1, 3, and 5% (v/v) alcohol. Therefore, alcohol at any one of these concentrations could be used as a solvent for the preservatives without any inhibition of respiration caused by the presence of alcohol. Three per cent alcohol was arbitrarily chosen as the solvent in this investigation.

It was observed that a 10% concentration of alcohol caused a decrease in oxygen consumption. Therefore, a 10% concentration is in itself inhibiting to yeast respiration. This inhibition was more pronounced at 15%, and complete inhibition was noted with 20% alcohol.

When polysorbate 80 was added to the phosphate buffer-5% dextrose-3% alcohol substrate, no significant change in oxygen consumption was observed during the 90-minute period. Barr and Tice (18), although using different organisms, concluded that microorganisms produce esterases that split the fatty acid from the surfactant. They also stated that the possibility of the microorganisms utilizing the surfactants for nutritive purposes was remote. The insignificant change in oxygen consumption by yeast cells in the presence of polysorbate 80 tends to confirm their work.

Table II reveals that propylparaben is superior to methylparaben in inhibiting the oxygen consumption of baker's yeast. These manometric results are in accordance with those obtained by Sabalitschka (5). Also, it may be seen that sorbic acid has a greater inhibitory effect than methylparaben, but not as great as propylparaben in the dextrose-alcohol substrate buffered at a pH of 6.0. These results are in agreement with those reported by Osman and El-Mariah (28). Methylparaben is superior to sorbic acid at the lowest preservative concentration of 0.025%. This exception was also observed when the preservatives were tested in the presence of polysorbate 80 (Tables III–V).

A comparison of the results found in Tables III–V shows that an increase in the percentage of polysorbate 80 causes a decrease in the effectiveness of methylparaben, propylparaben, and sorbic acid in inhibiting the respiration of the yeast cells.

Although sorbic acid is the least affected by the surfactant, propylparaben is superior in the presence of small quantities (0.25 and 0.5%) of polysorbate 80. Thus, in pharmaceutical preparations containing less than 1% polysorbate 80, propylparaben would be the best preservative for inhibiting the growth of yeast. In instances where the percentage of surfactant is greater than 1%, sorbic acid would be more effective. These results support the findings of Charles and Carter (24) in that sorbic acid in the presence of nonionic surfactants provided protection of cosmetic formulations against contamination by various organisms.

Experiments also were undertaken in an attempt to correlate either the killing or the inhibiting action with the per cent of respiratory inhibition. At the end of the 90-minute period, one standard loopful from the main compartment of each flask was transferred to a tube containing 20 ml. of sterile Sabouraud dextrose broth. The tubes were incubated at 37° for a period of 18 hours and then observed for growth. If no growth was apparent, the tubes were incubated for a total of 72 hours, and observed again for growth.

No growth appeared at the end of 72 hours in the tubes containing inoculum from the flasks that showed an inhibition of 95% or greater. Those preservatives that produced this degree of inhibition evidently killed the yeast cells within this 90-

minute period. This could be considered as self-sterilization.

In those experiments where the percentage of inhibition ranged from 86 to 92%, growth appeared in the tubes at the end of 72 hours, but not at 18 hours. This showed that there were some yeast cells living and able to reproduce in a favorable environment. Had the time limit been extended for more than 90 minutes, it is possible that those few remaining cells might have been killed.

All other tubes from the remaining experiments showed growth at the end of the 18 hours of incubation. Therefore, those results represent merely a degree of inhibition, but not one of self-sterilization.

CONCLUSIONS

1. A manometric method has been used to determine the relative effectiveness of preservatives, and preservative-surfactant combinations on the respiration of baker's yeast.

2. Propylparaben was superior to either sorbic acid or methylparaben in inhibiting yeast respiration in a substrate composed of 5% dextrose, 3% alcohol, and buffered at a pH of 6.0.

3. The activity of sorbic acid was the least affected in the presence of polysorbate 80.

4. In the presence of small quantities (0.25 and 0.5%) of polysorbate 80, propylparaben showed the greatest inhibitory powers. However in greater concentrations of the surfactant (1, 2, and 5%) sorbic acid was more effective.

5. Methylparaben was the least effective of the compounds tested, alone or in the presence of polysorbate 80.

6. On the basis of these manometric results using baker's yeast as the test organism, further investigation is considered justified using this technique with other organisms, preservatives, and surfactants.

Antiradiation Compounds I

Acylated Derivatives of β-Mercaptoethylamine

By WILLIAM O. FOYE, RONALD N. DUVALL, and JAMES MICKLES

A series of S-acyl derivatives of β-mercaptoethylamine (MEA) has been prepared in an attempt to provide compounds having protective effects in animal cells against ionizing radiation and which are less toxic than MEA itself. In general, toxicity to animals was reduced and good protective ability against X-radiation was retained in some of the esters. The dithiocarbamic acid of MEA was also prepared, but attempts to acylate this compound, which showed good antiradiation effects in close to toxic dose levels in mice, gave a variety of decomposition products.

Beta-Mercaptoethylamine (cysteamine, MEA) has been reported one of the most effective compounds discovered for protecting animal cells against the deleterious effects of ionizing radiation (1). This compound is somewhat toxic for human use (2), however, so an attempt has been made to mask the toxic effects by preparing derivatives subject to hydrolysis *in vivo* which would afford a liberation of MEA over a period of time. Several acylating agents were selected for this purpose.

Received April 28, 1961, from the Department of Chemistry, Massachusetts College of Pharmacy, Boston.
Accepted for publication June 16, 1961.
Presented to the Scientific Section, A. Ph. A., Chicago meeting, April 1961.
This project was carried out under a contract (DA-49-193-MD-2029) with the Office of the Surgeon General, U. S. Army Medical Research and Development Command.
The authors express their gratitude for this support as well as for the testing and toxicity data supplied by Dr. D. P. Jacobus.

The hydrochloride of MEA was utilized on the assumption that acylation of the nitrogen would be prevented. Conventional blocking agents would be difficult to remove in the presence of the thioester formed, and nonhydrolyzable substituents on the nitrogen have generally resulted in diminution or loss of radio-protective action. Attempts to prepare the S-carbobenzoxy derivative of MEA, furthermore, resulted in the formation of S-benzylmercaptoethylamine. Also, MEA hydrochloride failed to react with ethyl chloroformate. However, the use of the hydrochloride of MEA was successful in preventing formation of N-acyl derivatives.

Some difficulty was experienced in finding a suitable solvent for both MEA·HCl and the selected acyl chlorides, but the reaction was found to take place in either dimethylformamide or an

excess of the acyl chloride. Physical properties and reaction data for the esters prepared are listed in Table I.

Since dithiocarbamates have also shown relatively good protective effects against ionizing radiation, the dithiocarbamic acid of MEA was prepared, which may be considered an acylation with carbon disulfide. A two-phase system of carbon disulfide and ammonia water was applicable for this preparation; apparently the ammonium salt of the dithiocarbamic acid of MEA, which would be expected, was hydrolyzed under the reaction conditions, and the free acid was obtained.

Relatively good antiradiation properties in mice were found with the dithiocarbamic acid of MEA (see Table II), but the compound was found to be unstable in air, and close to toxic dosage levels were necessary for protection against lethal doses of X-radiation. Accordingly, attempts were made to acylate the β-mercapto group of this compound with the intention of increasing stability and reducing toxicity. Reaction of MEA dithiocarbamic acid with acetyl chloride at various temperatures, however, resulted in decomposition with the loss of hydrogen sulfide or carbon disulfide. Three products were identified from the attempted acetylation: 2-mercaptothiazoline, S-acetyl-β-mercaptoethylamine hydrochloride, and β-mercaptoethylamine disulfide dihydrochloride. See I. Attempted acylation in buffered aqueous solution also resulted in decomposition of the dithiocarbamic acid. The high degree of insolubility of this compound in organic media proved to be a major handicap.

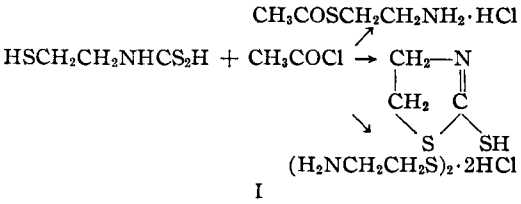
The reverse procedure of dithiocarbamation of an acyl derivative of MEA was also investigated. The reaction of S-benzoyl-β-mercaptoethylamine hydrochloride with carbon disulfide and ammonia water was accordingly carried out, but the major product proved to be N-benzoyl-β-mercaptoethylamine. The migration of the benzoyl group appeared to be nearly instantaneous, as shown by immediate ether extraction of a solution of S-benzoyl-β-mercaptoethylamine hydrochloride when made basic with ammonia water. Similar results were obtained when the S-acetyl, S-octanoyl, and S-myristoyl esters of MEA were made alkaline in ammonia water; no evidence of dithiocarbamation was found. See II. The desired reaction was therefore found to be im-

possible in either neutral, acid, or basic aqueous media. Similar acyl migrations from sulfur to nitrogen have been observed by others (3).

Reaction of the dithiocarbamic acid of MEA with acid chlorides in ether also gave products that decomposed either on storage in a desiccator or on suspension in water. The N-acyl derivatives were isolated from this reaction, however. Use of pyridine and acetic anhydride likewise resulted in the formation of N-acetyl-2-mercaptoethylamine, a known compound.

Antiradiation Properties.—Tests for the ability of these compounds to protect mice against X-radiation were carried out at the Walter Reed Army Institute of Research under the direction of Dr. D. P. Jacobus. The S-acetyl derivative of MEA was found to provide 60% protection over a 30-day survival period when the mice were irradiated at a dose of 800 r. An 80% survival was observed after a dose of 575 r, nontoxic doses of compound being injected in each case 15 minutes prior to exposure. The S-octanoyl ester gave similar results. The S-myristoyl ester provided 65% protection against a dose of 575 r, but was ineffective against 800 r. The dithiocarbamic acid gave 75% protection against 800 r, and 95% protection against 575 r, making this compound almost the equal of MEA itself. These results are summarized in Table II.

The benzoyl ester of MEA was not appreciably effective, affording only 10% protection from 800 r. The chloroacetyl ester, however, which would be expected to hydrolyze in water at a somewhat more rapid rate than the other esters tested (4), surprisingly gave no protection at all. It is possible that the compound underwent polymerization or cyclization before reaching the cells, when neutralized prior to injection.



The acute intraperitoneal toxicities in mice of several of the esters are recorded in Table III, where they may be compared to the toxicity of 2-mercaptoethylamine. It is apparent that a lowering of toxicity has resulted on ester formation. Although hydrochlorides of the esters were used, a valid comparison may be made with 2-mercaptoethylamine itself, since neutralization would be expected to occur fairly rapidly *in vivo*.

On the basis of the mixed disulfide hypothesis (5) of radiation protection by mercaptans, the S-acyl derivatives of MEA would be expected to suffer hydrolysis *in vivo*, thus liberating MEA to form mixed disulfides with vital thiol groups in the cells. However, rearrangement to the N-acyl derivatives may take place, which is shown here to occur quite readily at pH's above 7. This, too, would provide a free thiol group for mixed disulfide formation, but the basicity of the nitrogen, usually present in compounds possessing antiradiation ability, would be lost. Antiradiation tests on the N-acyl derivatives should help resolve the question of the necessity of a basic nitrogen in compounds of this type.

EXPERIMENTAL

Melting points were taken on a Fisher-Johns block and are uncorrected. Carbon-hydrogen analyses were done by Weiler and Strauss, Oxford, England, or by Carol K. Fitz, Needham, Mass.

2-Mercaptoethylamine Hydrochloride.—A modification of the procedure of Mills and Bogert (6) was used. Ethyleneimine (27.5 ml., 0.52 mole) dissolved in 205 ml. of absolute ethanol was added dropwise, with stirring, during 1 hour to 200 ml. of absolute ethanol. A stream of dry hydrogen sulfide was passed into the ice-cooled solution simultaneously. The resulting solution was partially dis-

tilled under nitrogen and reduced pressure, and dry hydrogen chloride was then bubbled through the remaining solution until it was acidic. The solvent was distilled under nitrogen and reduced pressure, and the resulting oil was allowed to crystallize by being chilled in tightly stoppered bottles. A 72% yield was obtained of material melting at 70°, which agrees with the reported value (7).

Esters of 2-Mercaptoethylamine Hydrochloride.—The following procedure is representative. A mixture of 2-mercaptoethylamine hydrochloride (4.5 Gm., 0.04 mole) and myristoyl chloride (15 ml., Eastman Organic Chemicals) was refluxed on a water bath for 2 hours or until the mixture solidified (the lower esters, with the exception of the benzoyl, gave solutions). The solid mass (which generally resulted on cooling) was pulverized, washed with benzene and ether, and recrystallized from absolute ethanol. Washing with water was possible in the case of the myristoyl ester. A yield of 75% was obtained of material melting at 126–128°.

Anal.—Calcd. for $C_{16}H_{34}ClNOS$: C, 59.2; H, 10.5; S, 9.9. Found: C, 59.3; H, 10.7; S, 10.2.

Reaction of 2-Mercaptoethylamine with Benzyloxycarbonyl Chloride.—2-Mercaptoethylamine hydrochloride (10.0 Gm., 0.09 mole) was refluxed with 25 ml. of benzyloxycarbonyl chloride for 20 hours on a water bath or 4 hours at 150°, when a clear solution resulted. Benzene was added, and an oil separated which soon crystallized. The product was recrystallized from absolute alcohol with the addition of a large amount of ether. The product, 2-benzylthioethylamine hydrochloride, which did not give a mercapto test with iodine, melted at 112–114° [Walton (8) reported 120–136°].

Anal.—Calcd. for $C_9H_{14}ClNS$: C, 53.1; H, 6.9; S, 15.7. Found: C, 52.6; H, 6.7; S, 15.7.

2-Mercaptoethyldithiocarbamic Acid.—A solution of 2-mercaptoethylamine hydrochloride (11.3 Gm., 0.1 mole) in 20 ml. of water was added dropwise, with stirring, to an ice-cooled mixture of 7 ml. of carbon disulfide (0.1 mole) and 22 ml. of ammonia water (0.32 mole). Stirring was continued for an hour after the addition was complete, and the yellow product was isolated and dried rapidly on blotting paper at room temperature. The product was stored in a desiccator under nitrogen at refrigerator temperature. The yield was 10 Gm. (65%) of material melting at 76–78°.

Anal.—Calcd. for $C_3H_7NS_2$: C, 23.5; H, 4.6; S, 62.7. Found: C, 23.7; H, 4.9; S, 61.9.

Acetylation of 2-Mercaptoethyldithiocarbamic Acid.—2-Mercaptoethyldithiocarbamic acid (2 Gm., 0.013 mole) was treated with excess acetyl chloride both at room temperature and at 0–5° and allowed to stand for a half-hour. Hydrogen sulfide was liberated and an oil was formed which was washed thoroughly with benzene and ether. The oil was dissolved in alcohol and pale yellow crystals appeared. The material melted at 127–130° and was identified as S-acetyl-2-mercaptoethylamine hydrochloride [lit. (9) m.p. 137°].

Anal.—Calcd. for $C_4H_{10}ClNOS$: S, 20.6. Found: S, 21.4.

A water-insoluble product that appeared in the original reaction melted at 101–103° and was identified as 2-mercaptothiazoline [lit. (10) m.p. 101–102°].

A small amount of material melting at 210° was also isolated from the alcohol extract of the oil. This proved to be 2-mercaptoethylamine disulfide dihydrochloride [lit. (6) m.p. 212–212.5°].

Acylation of 2-Mercaptoethyldithiocarbamic Acid in Ether.—Freshly prepared 2-mercaptoethyldithiocarbamic acid (2.0 Gm., 0.013 mole) was suspended in ether (100 ml.) surrounded by an ice pack. An excess of octanoyl chloride was added dropwise, and the yellow material turned to an orange color in a few minutes. The orange product was filtered and washed thoroughly with ether. As soon as the ether evaporated, however, the crystals turned yellow and became oily, which took place even on storage in a desiccator. After several days in a desiccator, the yellow product was dry and proved to be a mixture of N-octanoyl-2-mercaptoethylamine, m.p. 46–48°, and bis(2-aminoethyl) disulfide dihydrochloride, m.p. 209–210°.

N-Octanoyl-2-mercaptoethylamine.—S-Octanoyl-2-mercaptoethylamine hydrochloride (5.0 Gm., 0.02 mole) was dissolved in 50 ml. of water. The solution was made alkaline with ammonia water and an oily precipitate formed immediately. The mixture was extracted with two 100-ml. portions of ether, the extract was dried over sodium sulfate, and the ether was removed under a current of nitrogen. The gray-white product was recrystallized from 25% aqueous ethanol and 3.5 Gm. (82%) of material was obtained which melted at 46–48°. It decolorized iodine solution rapidly.

Anal.—Calcd. for $C_{10}H_{21}NOS$: C, 59.1; H, 10.3; S, 15.7. Found: C, 59.7; H, 9.9; S, 15.1.

N-Myristoyl-2-mercaptoethylamine.—This compound was prepared in the same manner as the N-octanoyl derivative.

Anal.—Calcd. for $C_{16}H_{33}NOS$: C, 66.9; H, 11.5. Found: C, 67.5; H, 11.4.

Attempted Dithiocarbamation of S-Acyl Esters of 2-Mercaptoethylamine Hydrochloride.—An ice-cooled aqueous solution of S-benzoyl-2-mercaptoethylamine hydrochloride (2.0 Gm.) was made basic with concentrated ammonia water and an equivalent of carbon disulfide was added dropwise with stirring. The yellow solution was made very slightly acidic with hydrochloric acid and extracted with ether. The ether extract was evaporated under a current of nitrogen and a colorless product crystallized, m.p. 65–67°. The product reduced iodine solution rapidly and was shown to be N-benzoyl-2-mercaptoethylamine [lit. (11) m.p. 69–71°].

Anal.—Calcd. for $C_9H_{11}NOS$: S, 17.7. Found: S, 17.8.

An identical product was obtained when an aqueous solution of S-benzoyl-2-mercaptoethylamine hydrochloride was made basic with ammonia water and extracted with ether.

Kinetics of Degradation in Solution of Epinephrine by Molecular Oxygen

By THEODORE D. SOKOLOSKI† and TAKERU HIGUCHI

The rate of degradation of epinephrine in aqueous solution at pH 5 by molecular oxygen has been shown to be extremely complex functions of both the amine and oxygen concentrations. The kinetic studies, based on chromatographic isolation of epinephrine as its triacetate, indicate that at the pH used (*a*) the degradation products had no detectable effect on the observed oxidative rate, (*b*) the dependency on the catecholamine ranged from 1.0 to 0.5 depending on oxygen tension, and (*c*) conversely, the dependency on oxygen varied from over 1 to less than 0.4 depending on epinephrine concentration.

THE MECHANISMS and kinetics of the reaction between molecular oxygen and epinephrine have presented a challenge to pharmaceutical workers ever since the isolation of the hormone in 1901 by Takamine. Despite the long history of effort made in these directions, however, only a few reliable basic landmarks have been established concerning the reaction system because of (*a*) the lack of a suitable analytical procedure for the intact catecholamine and (*b*) the complexity of the oxidative process involved. Such paramountly important information as the rate dependencies of the concentration of the amine and oxygen had not been previously determined. In the present report the results of an investigation into these basic relations are given.

The influence of various factors on the rate of loss of epinephrine from its solutions has been attempted previously by numerous workers using a number of different assay techniques. Berry and West (1) have investigated the stability of epinephrine at different hydrogen ion concentrations by using a bioassay based on the response of a frog's heart to the drug. Notable among those methods based on colorimetric determinations was that of Mazur, Green, and Shorr (2) who studied the effect of drug concentration. Probably the most widely used method has been one based on some oxygen uptake technique. Wang (3), Trautner and Bradley (4), and Chaix, Chauvet, and Jezequel (5) have offered contributions based on this method of study. In none of the earlier investigations, unfortunately, was the rate of disappearance of the catecholamine itself observed. Since the oxygen uptake technique measures gas consumption, not only by epinephrine but also by a number of its breakdown products which are even stronger reducing agents, results obtained cannot be directly related to the primary reaction. Bioassay methods when used to follow epinephrine concentration also suffer from the fact that oxidation products can interfere with the determination. Ruiz-Gijon (6) has pointed out that adrenalinequinone, an oxidation product of epinephrine, has the same physiological properties as epinephrine. The results of any method based on a colorimetric determination should properly apply only to the catechol chromophore or the presence of phenolic hydroxyl groups.

The present investigation offers, for the first time, experimental results concerning the rate dependencies on the concentration of epinephrine and oxygen, based on a method which follows the loss of the drug by a direct and reproducible analysis of the intact molecule. The procedure was based on a modification of the U.S.P. XV method which successfully determines epinephrine in the presence of its oxidation products (7). The advantages that such a method for determining drug concentration holds over those techniques used by earlier workers is obvious.

EXPERIMENTAL

The dependency of the rate of autoxidation of epinephrine with respect to drug and oxygen concentrations was studied by reacting solutions of the amine at pH 5.0, selected for a convenient rate of degradation, and an ionic strength of 0.5 μ under various oxygen pressures at 65°.

Solutions of epinephrine at concentrations between 5×10^{-3} M and 0.2 M were prepared by weighing amounts of epinephrine base,[1] reported by the manufacturer and found on analysis to be more than 98% pure, into 0.05 M acetate buffer. The pH was adjusted with acetic acid and the ionic strength brought to the desired value by adding calculated amounts of potassium chloride. All

hydrogen ion concentrations were measured at room temperature on the Beckman model H pH meter using a glass indicator electrode with a reference calomel electrode.

A reaction vessel containing the solutions of epinephrine was so designed as to permit equilibration with oxygen at a particular partial pressure, withdrawal of samples without disturbing that atmosphere, stirring of the solution, and storage in a constant temperature bath at 65.0 ± 0.2°. Figure 1 shows this apparatus. After the introduction of the solution into the vessel the atmosphere above the liquid was evacuated and the entire apparatus allowed to come to temperature equilibrium. The reaction was considered initiated with exposure to the oxygen atmosphere.

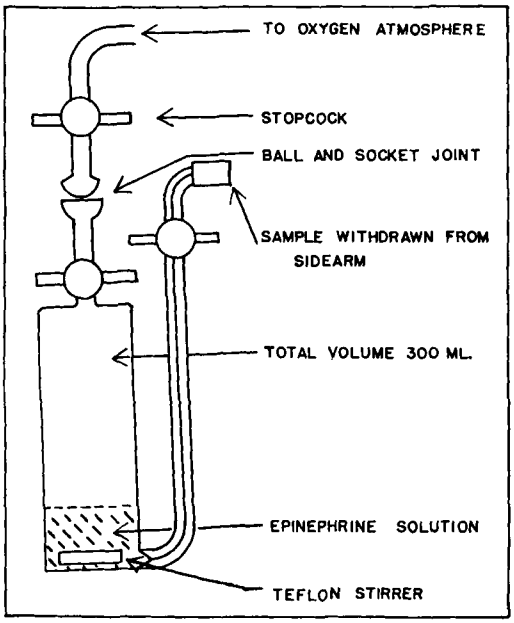

Fig. 1.—Schematic representation of the reaction vessel used in studying the rate of degradation of epinephrine at various drug concentrations and oxygen pressures.

A 5-gallon jar served as the oxygen source and was attached to the apparatus by glass tubing. By displacing known volumes of water with high purity oxygen and nitrogen, any desired partial pressure of oxygen could be obtained. A mercury manometer was attached to the system and the oxygen-nitrogen mixtures were maintained at a positive pressure of 3 to 4 cm. of mercury. This manometer served as a check to insure the maintenance of a constant oxygen pressure throughout any particular determination. The amount of oxygen added was such that if all of the epinephrine present were to degrade, there would be no more than a 15% decrease in the pressure above the solution. The error represented a maximum that was never realized since the epinephrine never completely degraded nor did the manometer indicate such a drastic change in pressure. For those studies above one atmosphere, the reaction vessel was attached directly to the oxygen tank through a trap and the gauge reading taken as the pressure above the solution.

After suitable lengths of time, samples of the desired volume were withdrawn quantitatively from the sidearm of the vessel into a pipet. The solution was then transferred to a beaker and frozen until the time of assay by the modified U.S.P. XV procedure (7). The amount of solution withdrawn depended on the concentration of the epinephrine and attempts were made so that the acylated solution initially contained the equivalent of 10 mg. of epinephrine prior to its transfer to a chromatographic column. For example, in the analysis of the 0.2 *M* epinephrine solution, 3 ml. of the solution was withdrawn, diluted to 25 ml. with distilled water, and 2 ml. of this solution acylated after adjusting the final volume to 5 ml. The acylated mixture was transferred to a column for chromatographic separation after mixing with 5.6 Gm. of Celite 545 as described in a previous study (7).

RESULTS

The dependence of the reaction with respect to the drug concentration was found to vary with the oxygen tension present and ranged from a simple proportionality at low oxygen pressures to a half-order at higher oxygen concentrations. When the oxygen tension was held at 0.13 atmospheres and the concentration of epinephrine followed as a function of time, plots represented by Fig. 2 were obtained. It should be noted that in this particular determination and in each of the other kinetic studies made, the degradation proceeded with no apparent lag phase. Reactions which follow a free radical path are often characterized by an initial lag time during which period intermediates accumulate.

Since it was not possible to determine clearly the dependency of the reaction with respect to the substrate by merely plotting various functions of the concentration against the time, the changes in the initial rate with initial concentrations of the drug

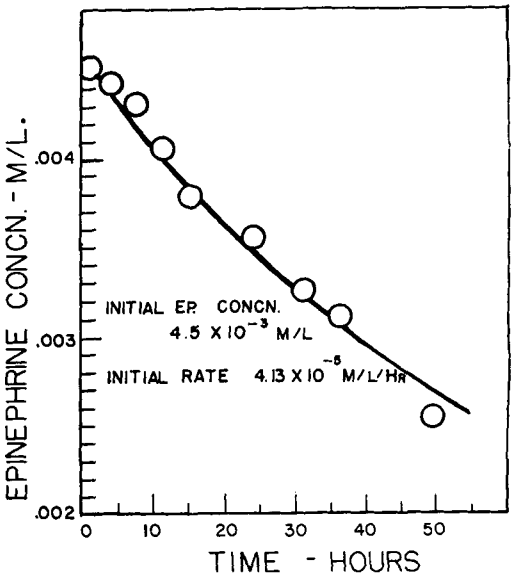

Fig. 2.—Epinephrine concentration (moles/L.) as a function of the time (hr.) at 0.13 atmosphere oxygen, pH 5, ionic strength 0.5 μ, and temperature 65° where the initial epinephrine concentration was 4.5 $\times 10^{-3}$ *M*.

43.6	1.5
183	1.1

were determined. The approach largely obviates participation of various degradation products in the epinephrine reaction *per se*, since these are assumed to be quite low in concentration in the beginning.

The initial rates were found by taking initial slopes of lines as shown in Fig. 2 expressed as moles/L./hr. By varying the initial concentration of the drug, the change in the initial rate as a function of drug concentration could be determined. The results of these determinations at 0.13 atmospheres oxygen appear in the first column of Table I. To determine the dependency of the rate with respect to the epinephrine concentration at this oxygen tension the data appearing in Table II were plotted on a log-log scale. It is evident in this type of plot that the slope of the line is identical with the dependency of the rate with respect to drug concentration.

By choosing six different oxygen pressures above the solutions and applying the same principles it was possible to determine the effect that oxygen had on the dependency with respect to epinephrine. These data are also summarized in the columns of Table I. The log-log plots establishing the dependency of epinephrine are given in Fig. 3. The manner in which the drug dependency is affected by the oxygen pressure is represented in Fig. 4. In this plot the order of the reaction with respect to the epinephrine concentration is shown as a function of the oxygen pressure and it is seen that the order changes quite rapidly initially as the oxygen pressure increases. At a value of about one atmosphere the order tended to level off and remained steady at about a half-order dependence.

At lower oxygen pressure the order with respect to the substrate is apparently first order. If the data of Fig. 2 were plotted on a semilogarithmic scale a straight line should be obtained, provided that degradation products did not alter the rate of reaction.

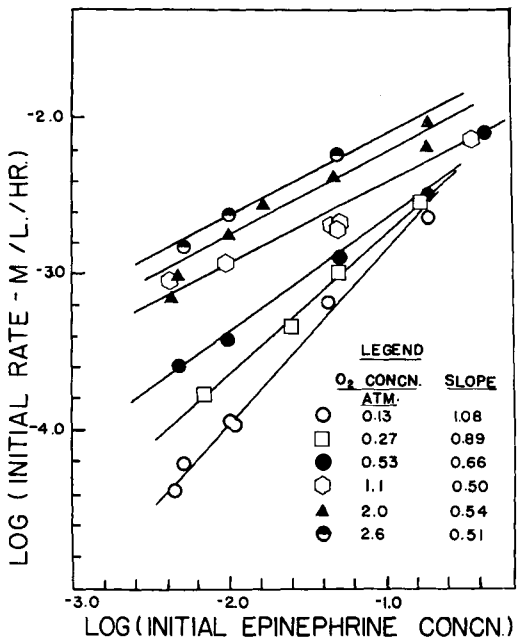

Fig. 3.—The logarithm of the initial rate of epinephrine degradation as a function of the logarithm of the initial epinephrine concentration at different oxygen pressures.

The logarithmic plot is presented in Fig. 5, and it is evident that the first-order dependency of the drug holds over a considerable loss of the substrate. The first-order rate constants calculated from plots as Fig. 5 should be independent of the initial epinephrine concentrations. Table II shows these rate constants obtained for different runs made at several initial concentrations of the drug. The variation observed here was only about 10% and well within the deviation to be expected.

The rate dependency of the catecholamine oxidation on oxygen tension above the solution was determined from data already presented in the preceding section. Since the initial rates of the loss of epinephrine having exactly the same initial epinephrine concentration were not determined under different oxygen tensions it was necessary to obtain these points by interpolation of such data as has been obtained. Each initial rate at a particular oxygen pressure and initial epinephrine concentration was interpolated from initial rates obtained for given different initial epinephrine concentrations

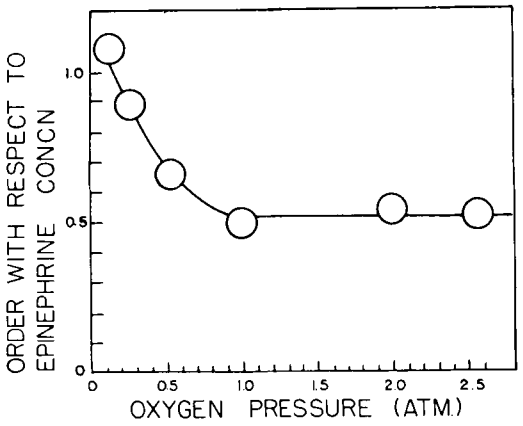

Fig. 4.—The order of the rate of epinephrine autoxidation with respect to drug concentration as a function of oxygen pressure (atmosphere).

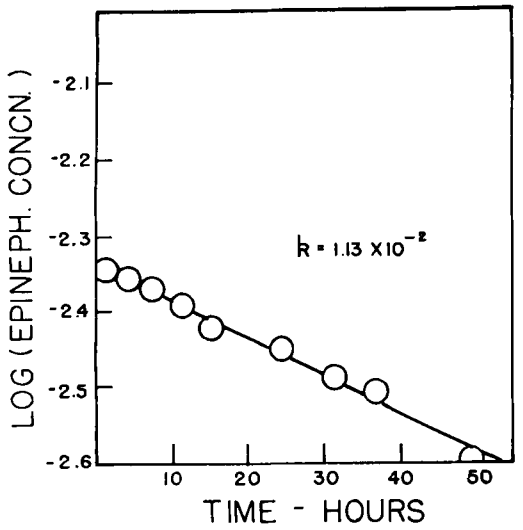

Fig. 5.—The logarithm of the epinephrine concentration as a function of the time (hr.) at 0.13 atmosphere oxygen, pH 5, ionic strength 0.5 μ, and a temperature of 65° where the initial epinephrine concentration was 4.5×10^{-3} M.

making use of Fig. 3. In this way the rates at six different oxygen pressures all at the same initial epinephrine concentration were found. Data were thus obtained for seven different initial epinephrine concentrations ranging from 0.0032 to 0.2 M. The interpolated data are shown plotted logarithmically in Fig. 6 as the initial rate against the oxygen tension. The slope of each line corresponds to the dependence of the autoxidative rate with respect to oxygen concentration at various initial epinephrine concentrations. It is apparent from Fig. 6 that as the concentration of epinephrine is increased, the slope or order with respect to oxygen concentration decreases. The apparent order is strongly affected by the epinephrine concentration as shown in Fig. 7, decreasing gradually at the higher levels of the drug. A fractional dependency with respect to oxygen concentration in an oxidative process is apparently not uncommon.

The effects of solutions of epinephrine initially at

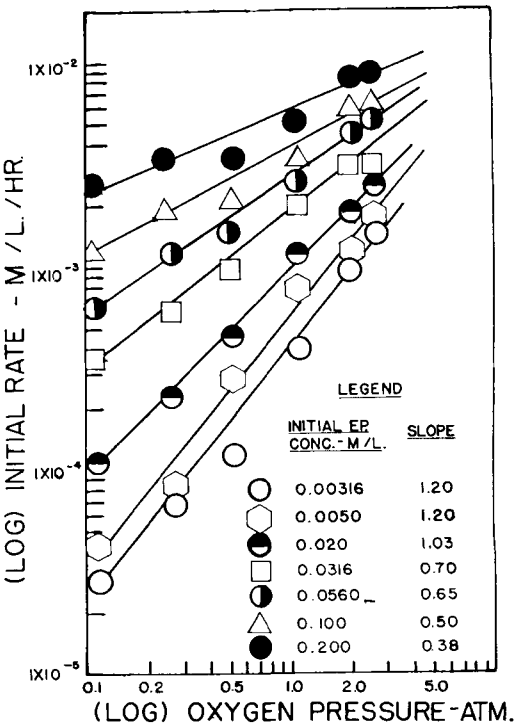

Fig. 6.—The logarithm of the initial rate of epinephrine degradation as a function of the logarithm of the oxygen pressure at different initial concentrations of epinephrine.

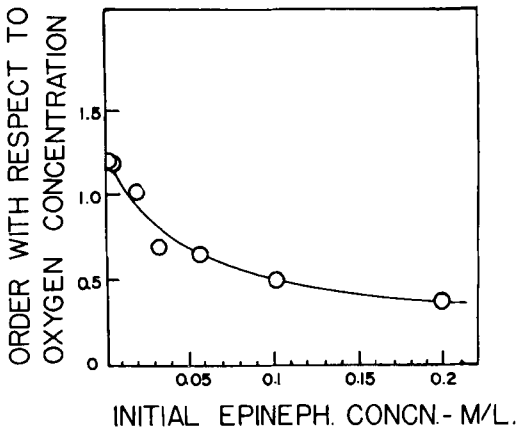

Fig. 7.—The order of the rate of autoxidation of epinephrine with respect to oxygen concentration as a function of the epinephrine concentration.

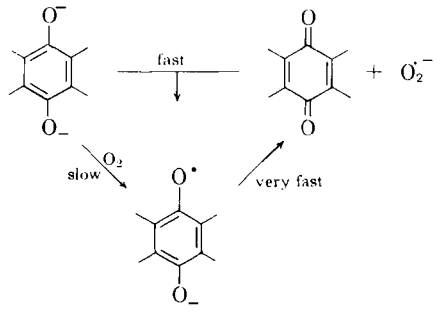
0.01 M and an ionic strength of 0.5 containing concentrations of 6.8×10^{-3} M potassium chloride, 2.2×10^{-4} M copper (II) acetate, and no copper or cyanide were compared. Oxidation appeared to take place even in the absence of copper although there can be no question that copper acted as an effective catalyst for epinephrine in aqueous solutions under the influence of oxygen. The graphs showing the dependence of the epinephrine concentration as a function of time did not exhibit a lag phase and thus were similar to those obtained in the epinephrine dependence study. The data

TABLE III.—EFFECT OF POTASSIUM CYANIDE AND COPPER (II) ACETATE ON THE DEGRADATION OF EPINEPHRINE

	Concentration of Additive, moles/L.	Half-Order Rate Constant $\times 10^2$, $(\text{moles/L.})^{1/2}$hr.
KCN	6.8×10^{-4}	1.0
KCN	6.8×10^{-3}	1.0
KCN	3.4×10^{-2}	1.2
KCN	6.8×10^{-2}	1.1
$Cu(OAc)_2$	2.2×10^{-4}	3.6
	0.00	0.8

yielded linear half-order plots. The resulting rate constants for each of the three solutions, potassium cyanide, copper acetate, and no copper or cyanide, are shown in Table III. It can be seen that the copper-containing solution degraded almost four times faster than the one containing potassium cyanide, and five times that of the one containing no copper or cyanide.



The rate of degradation of the solution containing the cyanide salt was more rapid than that containing none. This fact prompted a study of the effect of varying potassium cyanide concentrations investigating some possible catalytic action. The data, also shown in Table III, indicates, however, that even though the concentration of potassium cyanide was increased a hundredfold, no increase in rate constant was noticed.

DISCUSSION

The results of the studies on the kinetics of autoxidation of epinephrine as presented in the previous section are essentially summarized in Table IV. Orders referred to in the table were obtained from the dependencies of the initial rates of disappearance of the amine from solution.

At low concentrations of both reactants, the degradative reaction seems to be effectively second order. This simple dependence of the rate of reaction is not surprising but does not necessarily imply that the underlying mechanism is simple. Although Joslyn and Branch (8) reported that the oxidation of catechol proceeded with a first-order dependency on catechol concentration, this direct proportionality was apparently the consequence of a highly complex mechanism. Close analogies of the catechol degradation to the epinephrine oxidation cannot be made since in the case of epinephrine the intermediate species apparently involve the nitrogen. According to Wang (3) the rate of oxygen uptake is markedly reduced if a methyl radical replaces the primary nitrogen on epinephrine.

If the concentration of epinephrine and oxygen are both high, the rate of drug oxidation depends on the oxygen concentration raised to a fractional power and varies directly with the square root of the epinephrine concentration. The appearance of fractional orders strongly suggests that the degradative mechanism of epinephrine oxidation may be free radical mediated. This behavior is similar in some ways to the autoxidation of durohydroquinone, 2,3,5,6-tetramethyl hydroquinone, studied by James and Weissberger (9). According to their postulations the following scheme is indicated for this system

Such a scheme would rationalize the one-half power dependency of epinephrine at higher concentrations but, in turn, requires some sort of lag phase for the buildup of the quinoid species and a catalytic activity on the part of the oxidation products of the catecholamine. The present study gives neither any evidence of a lag phase nor data which suggests that the reaction is autocatalytic. The reaction seems to be totally unaffected by the accumulation of products during its course. This observation does not, of course, preclude the possibility that some highly unstable but dimerizable intermediate may play a catalytic role.

It should be pointed out that another work based on oxygen uptake by Trautner and Bradley (4) obtained evidence for major catalytic effects on the part of adrenochrome. The present results do not suggest that intermediate species cannot act catalytically but that these do not accumulate significantly in these solutions. It is interesting to note the part that the hydrogen ion concentration may contribute to the accumulation of intermediates. From experimental evidence it has been shown that an equilibrium exists between hydroquinone, quinone, and semiquinone according to the following scheme

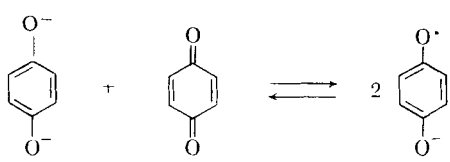


TABLE IV.—DEPENDENCE ON OXYGEN AND EPINEPHRINE CONCENTRATION OF THE INITIAL RATE OF EPINEPHRINE DISAPPEARANCE FROM SOLUTION AT HIGH AND LOW EPINEPHRINE AND OXYGEN CONCENTRATIONS

	Case	Order with Respect to Reactant: Oxygen	Order with Respect to Reactant: Epinephrine
I	Low epinephrine and low oxygen concentration	1^+	1.0
II	High epinephrine and high oxygen concentrations	Less than 0.5	0.5
III	High epinephrine and low oxygen concentration	Less than 0.5	1.0
IV	Low epinephrine and high oxygen concentration	1^+	0.5

The equilibrium favors a semiquinone formation when the divalent hydroquinone is the reactive species present, but in an acid solution the semiquinone is unstable and the reaction shifts considerably to the left. On the basis of these results, the studies of Trautner at pH 6–8 would apparently favor a stable semiquinone intermediate in contrast to the present studies made at pH 5 where the radical may possibly be more reactive and in lower concentration.

The results of Wang would tend to support the postulated rapid formation of radicals and may explain the apparent absence of a lag time. Her studies (3) show that oxygen was consumed in relatively short periods of time in comparison to the loss of epinephrine in the present investigation. At pH 4.9, 50°, and an epinephrine concentration of 0.001 *M*, Wang reports an oxygen consumption of 22.8 μl. after 0.6 hours, where a total of 224 was consumed after 9 hours.

It is possible to compare the results of the present investigation based on a chemical assay for the intact drug with that of Wang. By relating the rate of oxygen consumption to the rate of disappearance of epinephrine, Wang showed no lag phase present at pH 4.9 in a temperature range of 38 to 50°. However, at higher pH values a lag time was experienced. By interpolation of Wang's data the rate at which oxygen was consumed at 65° under air, where the initial epinephrine solution was 0.001 *M* at pH 4.9, was 9.5×10^{-6} moles/L./hr. By interpolating the data of the present study at approximately the same conditions, 0.001 *M* of epinephrine initially at pH 5 under 0.27 atm. oxygen, the rate was found to be 3.2×10^{-5} moles/L./hr. A close but not exact agreement suggests that perhaps the rate at which oxygen is consumed is some multiple of the rate of disappearance of the drug.

Under those conditions of high epinephrine concentration and low oxygen tension, the rate varies with a fractional-order dependency of oxygen and a first-order dependence with respect to epinephrine concentration. In contrast to this behavior we have the fourth case in which oxygen dependency is greater than unity and epinephrine is of a fractional order at low epinephrine and high oxygen pressure. Undoubtedly both oxygen and epinephrine are important reactants in the oxidation although their exact roles are not known. It is especially difficult to postulate the role of oxygen since indications are that, at low epinephrine concentrations, the oxygen dependence is greater than unity. There have appeared in the literature reactions which depend on a three-halves order with respect to oxygen but these were generally reactions in which metals were present as catalysts. In the present study oxygen dependence is shown only as a function of epinephrine concentration.

Chaix, Chauvet, and Jezequel (5) have said that in the absence of heavy metals an oxidation of epinephrine will not take place. The present studies have shown that although copper catalyzes the autoxidative degradation, the reaction probably takes place in their apparent absence. When the effect of various potassium cyanide concentrations was investigated, a small increase in rate over those solutions with no cyanide or copper was noticed, rather than the expected decrease. The cyanide has been known to act as a strong complexing agent for heavy metals and it was expected that it would act as a scavenger for the metals present in our system. The metals thus removed should have been unavailable for catalytic action. The small increase in rate is perplexing but demonstrates that heavy metals may not be needed for autoxidation.

Another evidence which suggests that trace amounts of metals in systems of the present study were not responsible for the degradation of epinephrine is based on the reproducibility that could be obtained. From Chaix's data an increase of copper ion concentration from 0 to 10^{-6} *M* or from 10^{-6} to 10^{-5} *M* would increase the rate of oxidation by a factor of two. Such increases in systems where the heavy metal concentration was not closely controlled would markedly affect reproducibility. The origin of free radicals may possibly come from oxygen and the organic species present and need not be initiated by heavy metals.

CONCLUSION

We are not prepared on the basis of the present work to present a complete mechanism sequence by which the observed results can be explained. The results suggest, however, that the overall reaction is an extremely complex one and, without question, involves free radical mediated sequences. The study appears to put to rest a number of previously unsupported concepts concerning the mode of oxidation of epinephrine at hydrogen ion concentrations approaching those commonly employed.

The behavior of this system as reflected in this study strongly points to formation of nonpersistent, dimerizable odd electron catalytic species. These probably act as the initial oxygen transfer agents. The results suggest, however, that none of the gross oxidation products possesses any significant catalytic effect.

From a purely practical and pharmaceutical standpoint it is evident from the data presented that for systems exposed to high oxygen tension the rate of degradation is always less than first order and that the percentage of the drug lost per unit time is always less per unit time at higher concentrations than at lower concentrations. These and other conclusions possible from these results may be of value in formulation of the drug.

Determination of *m*-Aminophenol (MAP) in *p*-Aminosalicylic Acid (PAS) and Sodium *p*-Aminosalicylate (PASNa)

By R. B. LUERS, Jr., and L. B. STADLER

The MAP test in the U.S.P. XVI monographs for PAS and PASNa has been re-evaluated. Experimental data based upon paper chromatography showed the test to be sound but in need of minor changes to correct sources of error. As a result of this study, recommendations are made to change the correction factor, to determine maximum absorbance through a range of 420 to 435 mμ, and to change the time allowed for development of color to 3 hours.

THE MAP TEST in the U.S.P. XVI monographs for PAS and PASNa (1) is based upon a color development shown by Pesez (2) to be the result of a series of diazotization coupling reactions. Seaman, *et al.* (3), refined the method which Pesez had published. The color reactions are comprehensively reviewed by Feiser and Feiser (4). The U.S.P. XVI test for MAP is basically a sound analytical procedure; however, experience has indicated that certain discrepancies exist in the test. It has been recognized for some time that absorbance values in the MAP test often were less than 0.372 (the quantity alleged to represent color formed by PAS itself in the test), resulting in apparent minus percentage values for MAP content. Furthermore, the absorbance values decrease during the first 3 hours after color development possibly as the result of a decrease in background color. In an effort to understand the apparent variables in this test for MAP better, an investigation was undertaken to study the various conditions involved in the U.S.P. XVI test for MAP.

In order to establish the absolute MAP content of some production samples of PAS and PASNa, a paper chromatographic procedure was developed in our laboratory. Briefly, the procedure consisted of chromatographic separation of the MAP from the PAS and PASNa using a benzene and methanol mobile solvent and the quantitative estimation of MAP by a spectrophotometric ultraviolet scanning technique.

EXPERIMENTAL

Proposed Modified Colorimetric Method for MAP in PAS and PASNa.—The proposed revisions of the U.S.P. XVI test for MAP, as described under *Procedures*, were performed on samples of PAS and PASNa. The basis for the revisions proposed are discussed under *Conditions Affecting the Colorimetric Determination of MAP*.

Reference PASNa.—The reference PASNa used in this investigation was a sample that was shown to contain less than 0.01% of MAP, as determined by the paper chromatographic method. When tested by the proposed revised colorimetric method described under *Procedures*, the reference PASNa showed an absorbance of 0.320. Repeating this test on the reference PASNa through a period of 20 different days, a range of absorbance values of 0.319 to 0.322 was obtained. In view of this, it was concluded that this sample represented reference quality PASNa in conjunction with this study.

A specially prepared sample of PASNa received from Dr. L. H. Welsh,[1] when tested by the paper chromatographic method and by the proposed revised colorimetric method, compared very closely with the reference PASNa used in this study.

CONDITIONS AFFECTING THE COLORIMETRIC DETERMINATION OF MAP

Effect of Time upon the Color Intensity Developed.—As discussed by Seaman, *et al.* (3), the time after addition of the sulfuric acid and sodium nitrite is quite critical. As the result of our investigations, it was found that after the addition of the sodium carbonate solution the intensity of the color decreased rapidly over a 3-hour period. After 3 hours the color intensity stabilized (See Fig. 1.). For this reason the time lapse between the addition of the sodium carbonate solution and the measurement of color intensity has been changed to 3 hours in the proposed modified colorimetric method described under *Procedures* for MAP determinations in PAS and PASNa. This characteristic of the color development was found evident in all samples of PAS and PASNa tested.

Effect of Change in Concentration of MAP upon the Absorbance Maximum of the Color Developed.—To confirm the absorbance peak of 440 mμ for the MAP color intensity produced by the U.S.P. XVI method, absorption spectra in the 350 to 700 mμ range were obtained from two samples of PASNa known to contain 0.20% and less than 0.01% of MAP, using a Cary recording spectrophotometer

Received February 24, 1961, from the Analytical Laboratories, Parke, Davis and Co., Detroit 32, Mich.
Accepted for publication May 2, 1961.
The authors are greatly indebted to Mr. F. A. Maurina for guidance and technical assistance given. The authors wish to express their gratitude to Mr. Carl E. Greco and Mr. Robert Eppler for paper chromatography, Miss Carolyn Holtrey and Mr. Richard Zingle for spectrophotometric curves, and to Dr. J. M. Vandenbelt and staff for spectrophotometric scanning of chromatographic strips.

[1] Department of Health, Education and Welfare, Food, and Drug Administration.

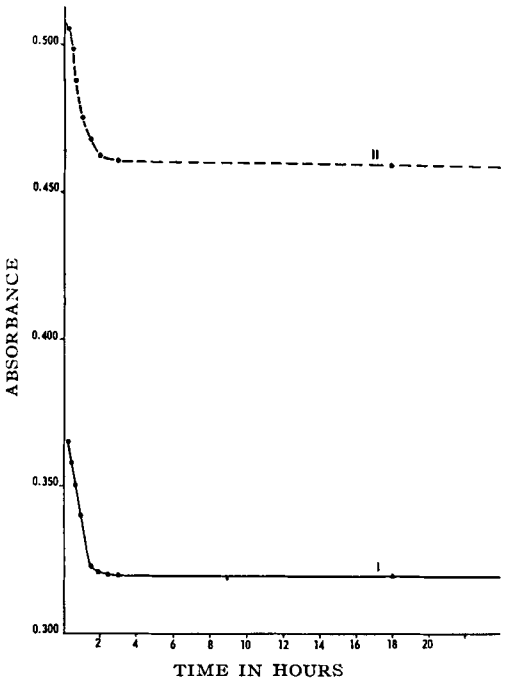

Fig. 1—Relationship of absorbance and time for PASNa samples. I, Reference quality PASNa containing less than 0.01% MAP; II, PASNa containing 0.12% MAP.

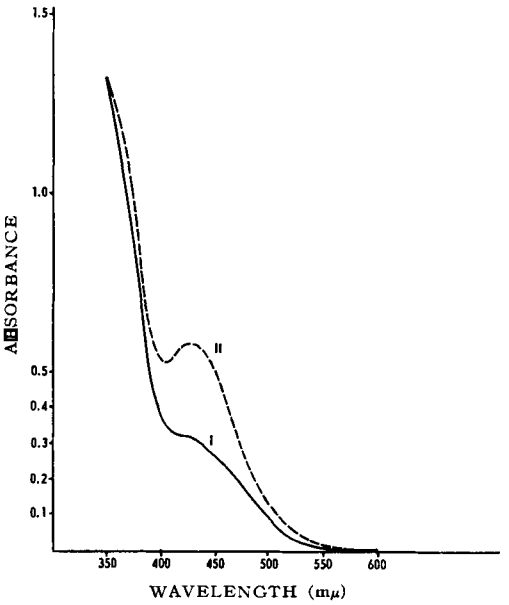

Fig. 2—Relationship of MAP concentration and absorption maxima. I, Reference quality PASNa containing less than 0.01% MAP; II, PASNa containing 0.20% MAP.

TABLE I.—EFFECT OF CHANGE IN CONCENTRATION OF MAP UPON ABSORBANCE MAXIMUM

Per cent of MAP in PASNa	Absorbance Maximum Found, mμ	Comment on Curve Characteristics
0.02	420–425	Plateau occurs
0.04	420–425	Plateau occurs
0.08	425	Round curve occurs
0.10	425	Sharper peak occurs
0.15	430	Sharp peak occurs
0.20	430	Sharp peak occurs
0.30	430	Sharp peak occurs
0.50	435	Sharp peak occurs
1.00	435	Sharp peak occurs

(model 11). As indicated by Figure 2, the PASNa containing less than 0.01% of MAP showed a plateau-like peak in the 420–425 mμ range, and the PASNa containing 0.20% of MAP showed a peak at 430 mμ. As a result, a series of determinations were conducted, using solutions of PASNa containing known quantities of MAP ranging from 0.02 to 1.0%. The absorbance maxima obtained for these concentrations of MAP are shown in Table I. These results indicate a shift in the absorbance maximum with increasing MAP concentrations and justify the use of a 420 to 435 mμ range for the measurement of the maximum absorbance of the color developed by the proposed modified colorimetric method described under *Procedures* for MAP in PAS and PASNa.

Based upon our study of a number of production samples of PAS and PASNa and the correlation of data between the proposed modified colorimetric method and paper chromatographic procedure (see Table II), the correction value for color produced other than by MAP should be 0.320 rather than 0.372. The absorbance values of our reference PASNa and the PASNa sample from Dr. Welsh also support the 0.320 value.

PROCEDURES

For PAS.—Weigh accurately 500 mg. of PAS and transfer to a 100-ml. volumetric flask with the aid of 5 ml. of sodium hydroxide T.S. and 5 ml. of water. Mix to dissolve the sample and dilute the solution with water to about 80 ml. Add 10 ml. of dilute sulfuric acid (1 in 10), add water to volume, and mix. Within 150 seconds from the time the acid is added, transfer 5 ml. of this solution to a second 100-ml. volumetric flask immersed in an ice bath and containing 50 ml. of water at 0 to 5°, and add 2.5 ml. of sodium nitrite solution (1 in 100). Mix and allow to stand in the ice bath for 3 minutes ± 5 seconds. Add 25 ml. of sodium carbonate T.S., mix, and place the flask in a water bath at 25° for 15 minutes. Add water to volume, mix, and allow the solution to stand at 25° for 3 hours. Determine the absorbance of the solution at the absorbance maximum observed in a range of 420 to 435 mμ in a 1-cm. cell with a suitable spectrophotometer, using water as the blank. Calculate the per cent of MAP by the formula $(A - 0.320)/0.84$, in which A is the absorbance of the solution, 0.320 is the absorbance correction factor representing color produced other than by the reaction of MAP initially present, and 0.84 is the factor converting absorbance to per cent of MAP in PAS.

For PASNa.—Weigh accurately 690 mg. of PASNa and transfer to a 100-ml. volumetric flask. Add 80 ml. of water and 1.8 ml. of sodium hydroxide

TABLE II.—PER CENT OF MAP FOUND BY THE DIFFERENT METHODS TESTED

Sample of PASNa Tested	Per cent MAP Found: By Paper Chromatography	By U.S.P. XVI Method	By Proposed Modified Method
Reference Sample	Less than 0.01	Negligible[a]	Less than 0.01
Sample A	0.04	Negligible	0.03
B	0.12	0.08	0.12
C	0.01	Negligible	0.01
D	...	Negligible	0.07

P	...	0.04	0.11
Q	...	0.01	0.09

[a] The term negligible denotes that the absorbance value for the sample was less than 0.372, which by the U.S.P. XVI method would result in a minus percentage value for MAP content.

T.S., and mix. Add 10 ml. of dilute sulfuric acid (1 in 10), add water to volume, and mix. Within 150 seconds from the time the acid is added, transfer 5 ml. of this solution to a second 100-ml. volumetric flask immersed in an ice bath and containing 50 ml. of water at 0 to 5°, and add 2.5 ml. of sodium nitrite solution (1 in 100). Mix and allow to stand in the ice bath for 3 minutes ± 5 seconds. Add 25 ml. of sodium carbonate T.S., mix, and place the flask in a water bath at 25° for 15 minutes. Add water to volume, mix, and allow the solution to stand at 25° for 3 hours. Determine the absorbance of the solution at the absorbance maximum observed in a range of 420 to 435 mμ in a 1-cm. cell with a suitable spectrophotometer, using water as the blank. Calculate the per cent of MAP by the formula (A − 0.320)/1.16, in which A is the absorbance of the solution, 0.320 is the absorbance correction factor representing color produced other than by the reaction of MAP initially present, and 1.16 is the factor converting absorbance to per cent of MAP in PASNa.

SUMMARY AND CONCLUSIONS

1. The MAP content found by the proposed modified colorimetric method was comparable to that found by paper chromatography for the PAS and PASNa tested in this study.

2. The color produced by both the U.S.P. XVI method and the proposed modified colorimetric method stabilized after standing 3 hours at 25°.

3. The absorbance spectra obtained from the U.S.P. XVI method and the proposed method showed the absorbance maxima to be between 420 and 435 mμ.

4. The correction factor for color produced other than that by MAP should be changed from 0.372 to 0.320.

5. The values of 0.84 and 1.16 for conversion of absorbance to per cent MAP are correct.

6. The U.S.P. XVI procedure for the determination of MAP in PAS and PASNa is basically reliable.

7. It is recommended that the modifications, as herein described, be adopted by the U.S.P. XVI to correct minor sources of error in the determination of MAP in PAS and PASNa.

In Vitro Testing of Timed Release Tablets and Capsules

By E. O. KRUEGER and E. B. VLIET

An apparatus, previously described (1), is recommended for *in vitro* testing of timed release dosage forms.

THE INCREASING use of timed release dosage forms (in particular, prolonged action tablets and capsules) was recognized by the Contact Section in the Fall of 1957. A special committee on timed release tablets and capsules was organized in the Spring of 1958 with the following objectives: to develop an apparatus and an *in vitro* procedure that might be generally useful as a routine control method to check the uniformity of drug release from lot to lot.

From the beginning, the committee limited its considerations to *in vitro* control procedures. Specifically, it has not attempted to develop methods that can be used in formulating timed release products. This must be done with appropriate *in vivo* studies.

During the past 4 years the committee has worked towards its objective through a series of collaborative efforts.

Much of the early stimulation and interest was provided by an apparatus and procedure used by Dr. Frank Wiley and his associates at the Food and Drug Administration (2). A description of this equipment and method was sent to interested PMA member firms with the request that they try it on their products. Laboratories that tried the method felt it was somewhat more complex and less convenient than is desired in a routine control method.

The subcommittee agreed that an effort should be made to determine whether the U. S. P. basket-rack assembly (U. S. P. XV, p. 937) might be adaptable as a suitable test apparatus. The first collaborative study using the modified U. S. P. equipment followed the Spring 1958 meeting of the Contact Section. Nine laboratories were equipped with metal cartridges designed to fit inside the tubes of the U. S. P. tablet disintegration apparatus. The cartridges were closed at each end with 30-mesh screens. Two products were tested. Data obtained from this study showed reasonable agreement among the collaborating laboratories.

As a result of comments arising from this work, slight modifications were made in the equipment and a second study was undertaken after the Fall 1958 meeting. In this study, metal cartridges of about the same size as the tubes in the U. S. P. tablet disintegration procedure were used to provide a better flow of the disintegrating fluid, and the 30-mesh screens were replaced with 40-mesh screens so as to retain finer particles better. The cartridges were supported on a basket-rack holder. Three different products were studied. Each of the products contained a single drug component readily soluble in water. The release pattern was determined in two ways: (*a*) by assaying the drug in the disintegrating fluid, and (*b*) by assaying the undisintegrated residue. This study showed good intra- and interlaboratory agreement in results, and established the interchangeability of determining the drug in the test fluid or in the residue. However, it was generally agreed that it was simpler to determine the drug in the residue, since this avoided any interference effects of the test fluid on the analytical procedures. A summary of this second study was published in *Drug Standards* (3).

At that time it was believed that the apparatus and method described in the second study might be generally useful and convenient for laboratory control of lot-to-lot uniformity for most timed release products.

One of the collaborating laboratories then studied this procedure further and compared the results obtained by using it with those by the rotating bottle method previously described in *Drug Standards* (1) and also with those found by using the initial procedure of the Food and Drug Administration laboratories (2). It became obvious that there were marked differences in release rates using the three methods, particularly with products containing sparingly soluble drugs.

Received November 11, 1961, from Abbott Laboratories, North Chicago, Ill.
Accepted for publication December 18, 1961.
Report of a special committee of the Contact Section of the Pharmaceutical Manufacturers Association, which included C. L. Graham, L. M. Lueck, C. M. Mitchell, A. Nutzul, E. B. Vliet, F. H. Wiley, and E. O. Krueger, chairman.

The rotating bottle method yielded values more usable for demonstrating timed release and completeness of release (hence, more suitable for control purposes) than did the other two methods.

As a result, a third study was set up testing four different products in eight laboratories. One product contained a readily soluble drug, whereas the other three contained drugs that were only sparingly soluble. Each sample was checked in each laboratory by five procedures as follows: (*a*) Rotating bottle procedure with a complete change from simulated gastric fluid T. S. to simulated intestinal fluid T. S. after 1 hour. (*b*) Rotating bottle procedure with a gradual pH change, accomplished by first using simulated gastric fluid T. S. and, at each subsequent time interval, withdrawing one-half of the fluid and replacing it with simulated intestinal fluid T. S. (*c*) Cartridge basket-rack procedure with a complete change from simulated gastric fluid T. S. to simulated intestinal fluid T. S. after 1 hour. (*d*) Cartridge basket-rack procedure with a gradual pH change effected as in (*b*). (*e*) FDA procedure.

The analyses were performed on the residue in methods *a*, *b*, *c*, and *d*, and on the extracting fluid in method *e*. The results from all laboratories on all four samples were in good agreement.

The product containing the freely soluble drug showed by all 5 procedures: (*a*) comparable results at all time intervals, (*b*) almost complete release after 8 hours, and (*c*) no differences in release, irrespective of whether the pH change was abrupt or gradual.

With the other three products the rate of release was greatest (nearly complete after 8 hours) with the rotating bottles; considerably less (from 35 to 65% released after 8 hours) with the cartridges and basket-rack; and least (from 10 to 50% released after 8 hours) by the FDA method. These differences seem to be in line with variation in the rate of flow of the fluids around the tablets or capsules. The flow is greatest in the rotating bottles, considerably less in the cartridges, and is quite restricted in the FDA apparatus. Results using the gradual pH change were, in general, only slightly different than those using the abrupt pH change technique.

It was decided to explore further the use of this *in vitro* rotating bottle procedure on a larger variety of timed release products to determine how extensively it might be applied and to ascertain whether the results obtained in different laboratories would be sufficiently consistent so that the method might be used for routine control testing.

THE NEW COLLABORATIVE STUDY

Scope.—In this study 12 different products were tested; 11 tablets and one capsule. Six had one drug component, while four contained two drugs each, one had three and one had four. There were at least five different types of release mechanisms in this group of samples and the drugs in the products varied from very soluble to sparingly soluble.

Eight laboratories participated in the study. All samples were sent to the laboratories on a coded basis along with the assay techniques to be used. These had been furnished by the firms that submitted the samples and were checked in other laboratories before and during the study. This, and the assays during the tests, entailed a great amount of work, especially in the multicomponent products. The release rates of each sample were generally determined in four different laboratories. One laboratory checked all of the samples.

Apparatus.—The apparatus used was described by Souder and Ellenbogen (1), was referred to in the previous report of this committee (4), and is shown in Figs. 1 and 2. Disintegration of samples is accomplished in 90-ml. bottles containing 60 ml. of disintegrating fluid revolving end over end in a 37° bath at 40–44 r. p. m.

Procedure.—It was realized that, in adapting a routine control testing method to a specific timed release product, the time intervals to be checked and the nature of the extracting fluid to be used would depend upon the release pattern the product was designed to give and upon the nature of the drugs and other components it contains. Nevertheless, it was decided that in this series of tests all laboratories would check the amount of drug released by all samples after intervals of 1, 2, 3.5, 5, and 7 hours. In all cases, simulated gastric fluid T. S. would first be used. At subsequent time intervals this would be replaced by mixtures of simulated gastric fluid T. S. and simulated intestinal fluid T. S. so that after 1 hour the pH would be 2.5, then 4.5 after 2 hours, and 7.0 after 3.5 hours. Simulated intestinal fluid T. S. at pH 7.5 would be used after 5 hours. The analysis would be performed on the residue in all cases.

The laboratory which tested all of the samples also checked each one using an abrupt pH change. Simulated gastric fluid was completely replaced by simulated intestinal fluid after the first hour.

TABLE I.—*In Vitro* RELEASE OF DRUG FROM PRODUCT A, REPORTED BY FIVE LABORATORIES

Laboratory No.	Per Cent of Drug Released After Elapsed Times, hr.				
	1	2	3.5	5	7
2	44	50	60	68	78
5	45	54	66	70	82
1	51	58	69	76	84
6	45	50	56	66	68
4	47	60	67	73	82

TABLE II.—*In Vitro* RELEASE OF DRUG FROM PRODUCT B, REPORTED BY FOUR LABORATORIES

Laboratory No.	Per Cent of Drug Released After Elapsed Times, hr.				
	1	2	3.5	5	7
3	30	50	59	63	75
2	37	53	60	68	79
1	35	54	63	72	81
7	46	56	64	74	83

RESULTS

Results obtained in the different laboratories on each sample using the prescribed procedure were in reasonable agreement. When the procedure was modified by abruptly changing the pH of the fluid after 1 hour, the release rates of pH-sensitive drugs were altered, as would be expected.

Of the 12 products tested, only one failed to release its drug as expected. The method, as applied in this study, would seem to be unsuitable for such a product, which depends upon a release mechanism considerably different than those used in the other products studied.

Data shown in Tables I, II, III, and IV, are typical of those obtained in the study and indicate how well results from different laboratories agreed. Results on the other products studied showed the same general degree of agreement.

CONCLUSION

After carefully considering the results obtained in this and the preceding collaborative study, and after communicating with those supplying the samples tested, the special committee made an observation and a recommendation to the PMA Contact Section at its meeting in October 1961. These were unanimously accepted and approved by the membership of the Section and are as follows:

1. The apparatus described in *Drug Standards* (1) and shown in Figs. 1 and 2 is more useful for the *in vitro* control testing of most timed release products now marketed than any other apparatus studied to date.

2. In the event the U. S. P. and N. F. should

Notes

Effect of Ionized Air on Early Growth of Black Mustard Seedlings

By ROBERTSON PRATT

Mammalian systems, bacteria, and fungi have previously been reported to be affected by ionized air. The present paper records an effect of such air on a spermatophyte, black mustard *Brassica nigra* (L.) Koch. Neither positive nor negative air ions influence germination of the seeds, but both types of ions depress the early growth of roots and shoots of the seedlings.

NUMEROUS EFFECTS of ionized air on biologic systems, including human beings, have been reported for more than 200 years, and attempts to apply some of these effects clinically were made as early as 1754. However, most of the reports must be classed as testimonial or, at best, speculative. Within the past decade possibly more reliable, but nonetheless subjective, clinical appraisals have indicated an ameliorating effect of negative air ions and an aggravating effect of positive ions on sinusitis, rhinitis, asthma, pollenosis, and related conditions. The literature up to 1935 has been reviewed extensively (1) and the more recent literature briefly (2).

Among quantitatively measurable effects of air ions on other biologic systems are reduction in succinoxidase content of the adrenal gland of the intact rat exposed to positively ionized air (3); killing of staphylococci by both positive and negative air ions (4); increase in ciliary movement in mammalian trachea, both *in vivo* and *in vitro*, when exposed to negative air ions and the reverse effect, or even abolition of movement, when exposed to positive ions (5–7); and reduction of germination of spores, growth of mycelium and elaboration of penicillin in cultures of *Penicillium notatum* exposed to an atmosphere enriched with air ions, negative ions having a greater effect than positive ones in reducing production of penicillin but positive ions exerting the greater depressing effect on spore germination and mycelial growth (2). The data below, taken from a larger continuing study, record a quantitatively measurable effect of air ons on early seedling growth of a spermatophyte, black mustard (*Brassica nigra*).

Accepted for publication December 11, 1961.

EXPERIMENTAL

Seeds, surface sterilized by immersion for 20 minutes in a dilute solution of calcium hypochlorite, were rinsed several times in sterile distilled water, then were soaked for 1 hour in same, and finally were placed aseptically on moist sterile filter paper strips about 2 cm. wide adhering to the inner surfaces of the germination chambers, consisting of 600-ml. Pyrex beakers. The strips (placed one in each beaker about 6 cm. from the top) were kept moist by a wick which consisted of a "tail" about 1.5 cm. wide that extended to the bottom of the chamber where it dipped into sterile distilled water. Seeds of black mustard are small enough to adhere easily to moist filter paper, even on a vertical surface. Soaking the seeds in water not only removed traces of hypochlorite, it also improved adhesiveness. Experiments were conducted in diffuse daylight; the temperature ranged from 20 to 23°.

A sterile ion generator head,[1] which has been described elsewhere (2), was supported about 1 cm. below the top of each beaker, and then the beaker was aseptically closed with sterile aluminum foil. The details and theory of the ion generators have been reviewed (8–10). At the rectifier voltage employed (860 v.), the atmosphere of the closed beakers was enriched with about 9.5×10^6 ions of appropriate charge/ml./sec. Radiation controls, similar to those run in earlier experiments on *Penicillium* (2), failed to reveal any evidence of direct radiation effects on the seeds or seedlings.

The data in Table I (averages computed from 5 replicate experiments totaling 500 seeds in each of the four environmental conditions) indicate that

Notes

Effect of Ionized Air on Early Growth of Black Mustard Seedlings

By ROBERTSON PRATT

Mammalian systems, bacteria, and fungi have previously been reported to be affected by ionized air. The present paper records an effect of such air on a spermatophyte, black mustard *Brassica nigra* (L.) Koch. Neither positive nor negative air ions influence germination of the seeds, but both types of ions depress the early growth of roots and shoots of the seedlings.

NUMEROUS EFFECTS of ionized air on biologic systems, including human beings, have been reported for more than 200 years, and attempts to apply some of these effects clinically were made as early as 1754. However, most of the reports must be classed as testimonial or, at best, speculative. Within the past decade possibly more reliable, but nonetheless subjective, clinical appraisals have indicated an ameliorating effect of negative air ions and an aggravating effect of positive ions on sinusitis, rhinitis, asthma, pollenosis, and related conditions. The literature up to 1935 has been reviewed extensively (1) and the more recent literature briefly (2).

Among quantitatively measurable effects of air ions on other biologic systems are reduction in succinoxidase content of the adrenal gland of the intact rat exposed to positively ionized air (3); killing of staphylococci by both positive and negative air ions (4); increase in ciliary movement in mammalian trachea, both *in vivo* and *in vitro*, when exposed to negative air ions and the reverse effect, or even abolition of movement, when exposed to positive ions (5–7); and reduction of germination of spores, growth of mycelium and elaboration of penicillin in cultures of *Penicillium notatum* exposed to an atmosphere enriched with air ions, negative ions having a greater effect than positive ones in reducing production of penicillin but positive ions exerting the greater depressing effect on spore germination and mycelial growth (2). The data below, taken from a larger continuing study, record a quantitatively measurable effect of air ons on early seedling growth of a spermatophyte, black mustard (*Brassica nigra*).

TABLE I.—PER CENT GERMINATION OF SEEDS AND ROOT AND SHOOT LENGTH OF SEEDLINGS OF BLACK MUSTARD EXPOSED TO IONIZED AIR

Ionization	Per Cent Germination	Average Root Length, mm. 48 hr.	72 hr.	96 hr.	120 hr.	Average Shoot Length, mm. 72 hr.	96 hr.	120 hr.	Root/Shoot Ratio 72 hr.	96 hr.	120 hr.
None (no unit)	89.7	9.4	27.1	63.0	93.0	6.0	16.9	19.7	6.5	6.0	5.1
None (unit not connected to power)	89.2	9.8	28.0	63.2	92.3	5.5	17.6	20.1	6.9	6.2	5.4
Negative	90.1	6.6	22.3	46.1	67.7	2.9	12.5	16.5	12.3	7.2	4.1
Positive	89.6	6.1	22.4	45.8	65.2	3.0	12.2	16.4	12.0	7.3	4.4

germination of black mustard seeds was not affected by an atmosphere enriched with ionized air (at the level employed), but that subsequent early growth of roots and shoots of the seedlings was depressed. The root/shoot ratios (last 3 columns of Table I) were obtained by dividing the total length of roots by the total length of shoots. The high values at 72 hours for plants exposed to ionized air (first of the 3 columns) reflect the delay in emergence of shoots in these seedlings. But, during the next 2 days, the increase in shoot length with respect to increase in total root length was greater for seedlings exposed to air ions than for control seedlings. Thus, the early differences in root/shoot ratio were eliminated, and there is indication of a reversal in the trend by the fifth day. For technical reasons, it was not practical to continue measurements beyond the fifth day.

DISCUSSION

Positive and negative air ions exerted qualitatively and quantitatively similar effects on seedlings of black mustard. This finding is similar to results obtained with staphylococci (4) but contrary to observations on succinoxidase content of rat adrenal gland (3), on ciliary movement in mammalian trachea (5–7), and on spore germination, mycelial growth, and penicillin production in cultures of *Penicillium* (2), in all of which significant differences were noted between the effects of negatively and positively charged air ions.

Effect of Small Variations in Heat Stimulus Temperature on the Tail Flick Response of Rats in Analgesimetry

By J. JUSZKIEWICZ-DONSBACH and GERHARD LEVY

The heat-induced tail flick reaction time of rats is affected by small changes in temperature of the heat stimulus. A crossover experiment, using temperatures of 48 and 50°, respectively, showed significant differences in reaction times in a group of 31 rats. The results demonstrate the need for accurate temperature control of heat sources.

VARIOUS METHODS employing thermal stimuli are used widely in some phases of the evaluation of analgesics (1). Such techniques include the use of electric hot plates, hot wires, and metal tubing heated by circulating hot water. In our hands, the determination of the reaction time after immersion of the rat's tail in a beaker of hot water maintained at constant temperature proved to be the most reproducible method.

In many instances, the thermal sources used in the methods cited above maintain a given temperature within a range of ±1 or ±0.5°. During preliminary experiments we found that such relatively small fluctuations in temperature of the heat stimulus appear to have a significant effect on the reaction time of the animals. In order to investigate this factor in greater detail, the heat-induced reaction time of a number of rats was determined at 48 and at 50°. Both temperatures were maintained within ±0.05°. It was also of interest to determine the effect of repeated stimuli at 15-minute intervals on reaction time as well as the likelihood of "conditioning" due to regular application of the heat stimulus over a period of several weeks.

EXPERIMENTAL

Female Wistar rats weighing 50–90 Gm., starved for about 12 hours, were placed in individual plexiglas holders (Fisher Scientific Co., item 1-280) for 30 to 60 minutes. After an animal had calmed

Effect of Small Variations in Heat Stimulus Temperature on the Tail Flick Response of Rats in Analgesimetry

By J. JUSZKIEWICZ-DONSBACH and GERHARD LEVY

The heat-induced tail flick reaction time of rats is affected by small changes in temperature of the heat stimulus. A crossover experiment, using temperatures of 48 and 50°, respectively, showed significant differences in reaction times in a group of 31 rats. The results demonstrate the need for accurate temperature control of heat sources.

VARIOUS METHODS employing thermal stimuli are used widely in some phases of the evaluation of analgesics (1). Such techniques include the use of electric hot plates, hot wires, and metal tubing heated by circulating hot water. In our hands, the determination of the reaction time after immersion of the rat's tail in a beaker of hot water maintained at constant temperature proved to be the most reproducible method.

In many instances, the thermal sources used in the methods cited above maintain a given temperature within a range of ±1 or ±0.5°. During preliminary experiments we found that such relatively small fluctuations in temperature of the heat stimulus appear to have a significant effect on the reaction time of the animals. In order to investigate this factor in greater detail, the heat-induced reaction time of a number of rats was determined at 48 and at 50°. Both temperatures were maintained within ±0.05°. It was also of interest to determine the effect of repeated stimuli at 15-minute intervals on reaction time as well as the likelihood of "conditioning" due to regular application of the heat stimulus over a period of several weeks.

EXPERIMENTAL

Female Wistar rats weighing 50–90 Gm., starved for about 12 hours, were placed in individual plexiglas holders (Fisher Scientific Co., item 1-280) for 30 to 60 minutes. After an animal had calmed

Received October 30, 1961, from the Biopharmaceutics Laboratory of the School of Pharmacy, University of Buffalo, Buffalo 14, N. Y.
Accepted for publication November 24, 1961.

down, one-third of the length of its tail was immersed in a beaker of water maintained at either 48 or 50 ± 0.05°. The beaker was an especially constructed, double-wall container of 400-ml. capacity, which permitted the circulation of water at constant temperature with a circulatory pump connected to a thermostatically controlled water bath. The water in the beaker was agitated with a magnetic stirrer to reduce any temperature gradient. The magnetic stirrer was stopped immediately prior to and during the time an animal's tail was immersed.

The animals reacted to the thermal stimulus with a typical contraction of their tails into circles. The time of this reaction was measured with a stop watch which was turned away from the operator to reduce a possible subjective influence upon him. Reaction times were determined at 15-minute intervals for a total of three determinations. The same individual carried out all measurements in order to assure proper interpretation of the end point. From 4 to 8 animals were used at a time. Half of these received a 50° heat stimulus; the others were subjected to a heat stimulus of 48°. Two days later the conditions were reversed, so that the response of each animal could be measured at both temperatures.

A number of animals were subjected to the described thermal stimulation twice a week for three weeks in order to determine a possible conditioning of their response.

RESULTS AND DISCUSSION

The first-week data obtained from several groups, totaling 31 animals, are shown in Table I. A significant difference ($P < 0.01$) in response to the 48° as compared to the 50° heat stimulus was observed. The reaction times during the third week of animals subjected to heat stimulation twice weekly for three weeks are listed in Table II. No significant differences between the first week and the third week reaction times of these animals at a given temperature were found, but the results obtained during the third week again show the effect of a 2° temperature difference on reaction time. It appears that the animals are not "conditioned" by repeated stimulation over a period of three weeks. This is in agreement with the findings of D'Amour and Smith (2).

TABLE I —TAIL FLICK REACTION TIME OF RATS AT 48 AND 50°

Time of Stimulus, min.	Reaction Time, sec.[a] 48°	50°
0	4.8(1.9)[b]	2.9(0.9)
15	5.4(1.5)	3.4(1.2)
30	5.4(1.7)	3.5(1.5)
Mean	5.2(1.7)	3.3(1.3)

[a] Average of 31 animals. [b] Standard deviation in parentheses.

TABLE II —TAIL FLICK REACTION TIME OF RATS AT 48 AND 50° AFTER REPEATED EXPOSURE TO STIMULUS FOR THREE WEEKS

Time of Stimulus, min.	Reaction Time, sec.[a] 48°	50°
0	5.6(1.5)[b]	3.3(0.7)
15	5.4(1.9)	3.5(1.0)
30	5.5(1.3)	3.9(1.1)
Mean	5.5(1.6)	3.6(1.0)

[a] Average of 21 animals. [b] Standard deviation in parentheses.

The animals used in this investigation neither were especially selected for their normal response, nor were trained in any special manner. According to some investigators (3–5), preselection and training of the experimental animals yields more consistent data, but even without these precautions it was possible in this study to demonstrate the effect of small temperature differences on reaction time. The results show that the temperature of the heat source used for thermal stimulation must be closely controlled if the sensitivity and reproducibility of thermal analgesimetric methods is to be assured.

Colorimetric Method for the Determination of Vinblastine, an Alkaloid from *Vinca rosea* I

By IVAN M. JAKOVLJEVIC

A reproducible colorimetric method is described for the determination of vinblastine, an antileukemic alkaloid from *Vinca rosea* Linn.

VINBLASTINE, an alkaloid from the ornamental shrub *Vinca rosea* Linn. was first reported as vincaleucoblastine[1] by Noble, Beer, and Cutts (1). On the basis of analytical and physical data the empirical formula of $C_{46}H_{58}N_4O_9$ (2) has been suggested for vinblastine. Spectral studies of this and parent alkaloids, catharanthine, and vindoline indicated that vinblastine represented a new type of dimeric alkaloid containing indole and indoline moieties (3). Vinblastine has been shown to contain the following functional groups: 2-$COOCH_3$, $OCOCH_3$, OCH_3 (aromatic), OH (free), OH (hydrogen bonded), NH (indole), and NCH_3. The appropriate derivatives of vinblastine as well as functional group analysis corroborate the presence of these groups (4).

Since some 20 different alkaloids have been obtained from this plant (5), a specific method for the detection and determination of vinblastine and its salts were highly desirable. The alkaloid produces color reactions with several reagents. If about 1 mg. of the alkaloid is heated with 50% hydrochloric acid containing 0.2% vanillin, a pink color is produced. With concentrated sulfuric acid containing traces of formaldehyde, a light wine color results. Concentrated sulfuric acid gives no color at room temperature; nitric acid gives a yellow color. A faint pink color is obtained with the alkaloid when heated with 40–60% sulfuric acid. Ten per cent sulfuric acid containing 1% of cerium sulfate gives a dark orange color which rapidly changes to yellow. A dark blue color is obtained by dissolving vinblastine in a 1% solution of ferric ammonium sulfate in 75% sulfuric acid. If vinblastine is dissolved in formic acid and several drops of 5% sodium hypochlorite solution are added, an orange color develops which fades to yellow.

After experimentation with many reagents, it was found that addition of vinblastine to an appropriate mixture of acetic anhydride, acetyl chloride, pyridine, and sulfuric acid followed by heating, produced a deep rose color. This color development is specific for vinblastine and, up to now, has not been observed with any other alkaloid reported from *V. rosea*. The specificity of this reaction has been corroborated qualitatively by paper chromatography of the alkaloids from *V. rosea* (6).

This paper describes the details for the colorimetric determination of vinblastine.

EXPERIMENTAL

Moisture Determination.—Vinblastine sulfate contains moisture which can be removed by vacuum drying at about 50° without damage to the alkaloid. The anhydrous material, however, is very hygroscopic and picks up about 2% moisture in 2 minutes when allowed to stand under room conditions. Equilibrium is reached in about 20 minutes, resulting in a moisture content of about 10%. The most convenient method of handling the compound is to allow it to reach equilibrium, at which time separate samples are weighed for the color assay and for the moisture determination. The moisture is determined by vacuum drying at 50° for 16 hours.

Apparatus and Reagents.—A Beckman model DU spectrophotometer with 1-cm. glass cells was used in this laboratory, but any suitable spectrophotometer may be used.

A constant temperature oil bath was used to insure the exclusion of condensation water during the heating period. The oil bath used was designed to hold eight 10-ml. volumetric flasks so that a standard and three samples, in duplicate, could be run simultaneously.

Care must be taken to insure the exclusion of water from the reagents and glassware.

Acetyl chloride, analytical reagent grade.

Acetic anhydride, analytical reagent grade. This reagent must contain a minimum of 97% $(CH_3CO)_2O$, and must pass the U.S.P. test for reducing substances. At least 24 hours before use, 0.25 ml. of acetyl chloride is added to each 500 ml. of acetic anhydride. The activated acetic anhydride can be stored for at least 3 months. The metallic lining of the acetic anhydride bottle cap should be replaced with an inert plastic material. A corroded metallic liner may indicate an undesirable reaction which reduces the color formation.

Pyridine, analytical reagent grade. Water content must be less than 0.1%.

Sulfuric acid, concentrated, analytical reagent grade.

Preparation of the Color Reagent.—The color reagent must be freshly prepared immediately prior to use as indicated in the procedure.

By means of a graduate, 35 ml. of acetic anhydride is transferred to a 100-ml. glass-stoppered Erlenmeyer flask and cooled under running water. While swirling and cooling, 1 ml. of concentrated sulfuric acid is added. With continued cooling and swirling, 35 ml. of pyridine is added in about three equal portions.

Procedure.—About 3 mg. of standard vinblastine sulfate, and about 3 mg. of the sample preparation are weighed accurately to the nearest 0.01 mg. Each is transferred quantitatively to separate 10-ml. volumetric flasks. From this point on, the assay should be performed without delay. The

Accepted for publication May 2, 1961.

The author wishes to express his indebtedness to Mr. Norbert Kuzel and Mr. LeRoy Springman for their suggestions, and to Dr. Norbert Neuss for helpful discussions concerning this paper. The author wishes to thank Mr. William Beach for the design of special equipment used, and Mr. William Shaffer for his assistance in the collection of the large amount of data necessary for the development of this method.

[1] In compliance with the A.M.A. Council on New Drugs, its name has been changed to vinblastine. The sulfate salt of this alkaloid under the name of Velban (vinblastine sulfate, Lilly) has recently been made available for the treatment of Hodgkin's disease and choriocarcinoma.

standard and sample are dissolved and diluted to the mark with the color reagent and well mixed. Two 2-ml. aliquots of the standard solution are transferred to separate 10-ml. volumetric flasks labeled "standard." Two 2-ml. aliquots of the sample solution are transferred to separate 10-ml. volumetric flasks labeled "sample." To each of the four flasks 3 ml. of the color reagent is added by pipet. The flasks are placed simultaneously in an oil bath which has been preheated to 80 ± 1°. After about 2 minutes of heating, the flasks are stoppered loosely with glass stoppers. The flasks are heated a total of exactly 20 minutes at 80 ± 1°, then removed from the bath and cooled to room temperature under running water. Each flask is diluted to the mark with color reagent and well mixed. The absorbance of each is measured on a suitable spectrophotometer in 1-ml. cells at 574 and 538 mμ, using distilled water as a reference.

The ratio A_{574}/A_{538} is determined. This value must be within the range of 1.20 to 1.25 for relatively pure vinblastine. Any value outside this range indicates the color has been incorrectly developed. In the case of crude alkaloid mixtures containing less than 30% vinblastine, the ratio may be slightly less than 1.20.

Calculations.—

$$\frac{\text{Abs.}_{574}\ \text{sample} \times \text{mg. standard}}{\text{Abs.}_{574}\ \text{standard} \times \text{mg. sample}} \times 100 = \%\ \text{vinblastine sulfate}$$

$$\frac{\%\ \text{vinblastine sulfate}}{1.000 - \frac{\%\ \text{loss of wt. on drying}}{100}} = \%\ \text{vinblastine sulfate, anhydrous}$$

DISCUSSION

Standard Curve.—A plot of the absorbance *versus* concentration was found to be linear and to pass through the origin, obeying Beer's law from 5–70 mcg. per ml. (Fig. 1). The reproducibility of the method is entirely satisfactory and will be discussed in a later paper.

Stability of the Color.—The color is stable for about 20 minutes after which time it begins to increase slowly at 574 mμ, and more rapidly at 538 mμ (Fig. 2). This differential rate of increase of the color at the two wavelengths was responsible for the choice of 574 mμ as the wavelength for quantitative measurements.

Influence of Sulfuric Acid.—One milliliter of sulfuric acid seems to be the optimum amount to add to the 70 ml. of 1:1 acetic anhydride:pyridine mixture. The addition of more or less sulfuric acid reduces the color intensity and conformity to Beer's law is reduced to a much narrower range of concentrations.

Influence of Acetyl Chloride.—Acetyl chloride has an important influence on the color development. Without acetyl chloride, the color develops a pronounced yellow tint and the absorption peak at 574 mμ is shifted to lower wavelengths. With a few lots of acetic anhydride it was not necessary to add acetyl chloride. In these cases it is supposed that trace amounts of acetyl chloride were present due to the method of synthesis of the anhydride.

Characterization of the Color Produced.—It is possible to isolate a deep rose oil from the reaction mixture after the color has been developed. The excess reagent was removed from the mixture by several washings and decantations with large amounts of ether. The oily residue rapidly changed to a bright brown color. When color reagent was added to the residue, the original rose color was reconstituted; however, the ratio A_{574}/A_{538} was slightly diminished.

The chemistry of the color formation is not clear at the present time. There is a possibility that the color is due to a halochromic effect of the reaction mixture. Clarification on this point may result from further elucidation of the structure of this alkaloid, presently being conducted in these laboratories.

Tetrazole Analogs of Various Amino Acids as Possible Bacterial Antagonists

By W. A. ZYGMUNT

RECENTLY, the synthesis of the tetrazole analogs of several amino acids was described by McManus and Herbst (1). Since we had an opportunity to obtain several of these compounds,[1] it was of interest to determine whether they had any activity as amino acid antagonists in bacteria.

The tetrazole analogs tested were as follows: I, 5-aminomethyltetrazole (glycine analog); II, 5-(1′-aminoethyl)tetrazole (DL-alanine analog); III, 5-(2′-aminoethyl)tetrazole (β-alanine analog); IV, 5-(1′-aminopropyl)tetrazole (DL-α-aminobutyric acid analog); and V, 5-(1′-amino-2′-phenylethyl)tetrazole (DL-phenylalanine analog).

Each of the compounds was tested with a microorganism which synthesizes its own amino acids, and certain compounds with microorganisms which require specific amino acids for growth. All compounds were tested for their ability to inhibit the growth of *Escherichia coli* W in the synthetic medium of Davis and Mingioli (2).

In addition, test compounds I and V were tested for their ability to inhibit utilization of glycine and phenylalanine in the amino acid basal medium of Barton-Wright (3) using *Leuconostoc mesenteroides* P60, an organism requiring these amino acids. Compound II was also tested for antagonism of DL-alanine utilization in the medium of Sauberlich and Baumann (4) using *Pediococcus cerevisiae* (ATCC No. 8081), an alanine-dependent organism. Neutralized solutions of test compounds, amino acids, and basal media were sterilized by Seitz filtration and portions added to previously autoclaved culture tubes containing graded levels of sterile, distilled water. Only freshly prepared solutions of the test compounds were used. Final assay volumes were 6 ml. per culture tube (18 × 150 mm.). In the preparation of the inocula, precautions were taken to minimize the carry-over of preformed amino acids by appropriate washing of the cultures and by the use of small inocula. Incubation periods of 24 hours were used with *E. coli* and *L. mesenteroides*, and 72 hours with *P. cerevisiae*. An incubation temperature of 35° was used with all cultures. Growth was measured turbidimetrically as absorbance using a Coleman junior spectrophotometer at a wavelength of 620 mμ.

All of the tetrazole analogs studied, at a final concentration of 1 mg. of test compound per ml. (molar range of 0.005 to 0.010), failed to inhibit the growth of *E. coli* in a 24-hour assay. This clearly indicates that these compounds (I through V) are not potent inhibitors of the synthesis and/or utilization of amino acids.

TABLE I.—ANTAGONISM OF DL-ALANINE UTILIZATION BY 5-(1′-AMINOETHYL)TETRAZOLE IN *P. cerevisiae*

Molarity 5-(1′-Aminoethyl)-tetrazole	Molarity DL-Alanine	Molar Ratio Antagonist to Metabolite	% Inhibition of Growth, 72 hours at 35°
0.022	0.000093	237/1	98
0.022	0.000186	118/1	38
0.022	0.000372	59/1	19
0.040	0.000093	430/1	99
0.040	0.000186	215/1	50
0.040	0.000372	108/1	10
0.040	0.000744	54/1	4
0.040	0.001488	27/1	3

Compound I at a 0.04 *M* concentration when tested with *L. mesenteroides* in the presence of 0.0004 *M* glycine (half maximal growth) inhibited the growth of *L. mesenteroides* by 28%. No inhibition of growth was observed at 0.005 *M*, 0.01 *M*, and 0.02 *M* concentrations. This low order of activity was not sufficient to warrant further studies.

In the presence of 0.0002 *M* DL-phenylalanine, the level required for half maximal growth, no inhibition of growth was observed at 0.05 *M* and 0.01 *M* concentrations of compound V. It was not possible to test higher concentrations due to the low solubility of this compound at a neutral pH.

5-(1′-Aminoethyl)tetrazole (compound II) was shown to be an antagonist of DL-alanine utilization with *P. cerevisiae*. This anatagonism was readily reversed by DL-alanine. The compound must be considered a weak inhibitor, however, in that approximately a 200–400 to 1 molar ratio of antagonist to metabolite was needed to obtain a 50 to 99% inhibition of growth (Table I).

Further tests on compounds I, II, and V with *L. mesenteroides* and *P. cervisiae* which require glycine, phenylalanine, or α-alanine, respectively, showed that the analogs did not support growth in place of the respective amino acids.

In summary, tetrazole analogs of five different amino acids were found to have little or no activity as inhibitors of bacterial growth in chemically defined media. As yet, none of the available tetrazole analogs have been studied in isolated enzyme systems.

Received August 14, 1961, from the Department of Nutritional and Biochemical Research, Mead Johnson Research Center, Evansville 21, Ind.

Accepted for publication November 8, 1961.

The author gratefully acknowledges the valuable advice of Drs. Herbert P. Sarett and Homer E. Stavely in these studies, and the test compounds kindly supplied by Dr. Robert M. Herbst.

Book Notices

Virus Meningo-Encephaltis. Edited by G. E. W. WOLSTENHOLME and MARGARET P. CAMERON. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1961. viii + 120 pp. 12.5 × 18.5 cm.

A compilation of 13 papers and discussions on subjects related to meningo-encephalitis which were presented at a study group in September 1960. References and a subject index are appended.

Quinones in Electron Transport. Edited by G. E. W. WOLSTENHOLME and CECILIA M. O'CONNOR Little, Brown and Co., 34 Beacon Street, Boston 6, Mass., 1961 xii + 453 pp. 13.5 × 20.5 cm. Price $11.

Reports on biochemical studies related to the quinones, particularly ubiquinone (coenzyme Q), and their part in electron transport are compiled in this book. Nineteen papers were contributed and discussed at the May 1960 Ciba Foundation Symposium.

Pharmacology and Oral Therapeutics. 12th ed. By EDWARD C. DOBBS. The C. V. Mosby Co., 3207 Washington Blvd., St. Louis 3, Mo., 1961. 578 pp. 16 × 24 cm. Price $10.

Revision of this authoritative textbook assures consideration of those drugs official in U.S.P. XVI and N.F. XI, as well as the drugs evaluated in the latest editions of "New and Nonofficial Drugs" and "Accepted Dental Remedies." The book is excellent for dental students and practitioners, and includes useful information for pharmacists.

Comparative Animal Physiology. 2nd ed. By C. LADD PROSSER and FRANK A. BROWN, JR. W. B. Saunders Co., West Washington Square, Philadelphia 5, Pa., 1961. ix + 688 pp. 16.5 × 25.5 cm. Price $15.50.

Intended as a text for upper-class undergraduates and first-year graduate students and as a reference volume, this edition reflects the additional knowledge and current views developed since the 1950 edition. The authors consider the reactions of animals to specific variations in a series of environmental factors and then consider effector and coordinating mechanisms in general.

Biochemists' Handbook. Edited by CYRIL LONG. D. Van Nostrand Co., Inc., 120 Alexander St., Princeton, N. J., 1961. xxii + 1192 pp. 15.5 × 25 cm. Price $25.

Compiled chiefly for biochemists and others in related sciences, this encyclopedia-type handbook is divided into six sections. Section 1 includes selected topics in physical and organic chemistry, with tabulated data. Section 2 discusses enzyme kinetics and describes about 300 enzymes. Metabolic pathways are treated in Section 3. Data on the chemical composition of animal tissues and plants are given in Sections 4 and 5, respectively. Section 6 gives information on some physiological and nutritional topics. The general index requires 64 pages.

Physical Chemistry of Macromolecules. By CHARLES TANFORD. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1961. xiv + 710 pp. 15 × 23 cm. Price $18.

Areas of physical chemistry in this book are taken up in the order: Molecular structure, with emphasis on X-ray diffraction; Statistics of linear polymers; Thermodynamics; Light scattering; Transport processes and viscosity; Electrostatic free energy and polyelectrolytes; Multiple equilibria; and Kinetics of macromolecular reactions. Fundamental theories are given and then modified or extended to apply to molecules of high molecular weight. Author and subject indexes are appended

Pharmacy Examination Review Book. Vol. 1. Medical Examination Publishing Co. Inc., P. O. Box 36, Fresh Meadows, Flushing 65, N. Y., 1960. 179 pp. 13.5 × 21.5 cm. Paperbound.

The purpose of this book is to reveal those areas of pharmaceutical knowledge that require further study by the individual preparing for examinations. It includes about 1,000 multiple choice questions (and answers) in sections on pharmacy, pharmacology, microbiology and public health, chemistry, biochemistry, and physiology.

Progress in Drug Research. Vol. 2. Edited by ERNST JUCKER. Interscience Publishers, Inc., 250 Fifth Ave., New York 1, N. Y., 1960, 636 pp. 16.5 × 24 cm. Price $22.50

The development of a reference work in the field of drug research is continued with the issuance of volume 2 in this series. The publication of volume 1 was noted in THIS JOURNAL, 49, 62(1960). Other volumes will appear annually. Extensive review articles cover nine subjects in volume 2. The articles are printed in the languages of the contributors. In this volume five articles are in English and four are in German. Indexes are not appended, but each article has a detailed table of contents.

Investigation of Rates and Mechanisms of Reactions. Part 1. 2nd ed. Edited by ARNOLD WEISSBERGER. Interscience Publishers, Inc., 250 Fifth Ave., New York 1, N. Y., 1961. xii + 713 pp. 15.5 × 22.5 cm. Price $23.50.

A revised and augmented edition of volume 8, part 1, in the series "Technique of Organic Chemistry." The first edition was reviewed in THIS JOURNAL, 42, 507(1953). The text should be extremely useful in the field of physical pharmacy. An index is appended.

Metabolic Pathways in Microorganisms. By VERNON H. CHELDELIN. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1961. ix + 91 pp. 12.5 × 18.5 cm.

A compilation of lectures on carbohydrate metabolism in microbial systems, emphasizing metabolic peculiarities of acetic acid bacteria.

The authors consider the reactions of animals to specific variations in a series of environmental factors and then consider effector and coordinating mechanisms in general.

Biochemists' Handbook. Edited by CYRIL LONG. D. Van Nostrand Co., Inc., 120 Alexander St., Princeton, N. J., 1961. xxii + 1192 pp. 15.5 × 25 cm. Price $25.

Compiled chiefly for biochemists and others in related sciences, this encyclopedia-type handbook is divided into six sections. Section 1 includes selected topics in physical and organic chemistry, with tabulated data. Section 2 discusses enzyme kinetics and describes about 300 enzymes. Metabolic pathways are treated in Section 3. Data on the chemical composition of animal tissues and plants are given in Sections 4 and 5, respectively. Section 6 gives information on some physiological and nutritional topics. The general index requires 64 pages.

Physical Chemistry of Macromolecules. By CHARLES TANFORD. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1961. xiv + 710 pp. 15 × 23 cm. Price $18.

Areas of physical chemistry in this book are taken up in the order: Molecular structure, with emphasis on X-ray diffraction; Statistics of linear polymers; Thermodynamics; Light scattering; Transport processes and viscosity; Electrostatic free energy and polyelectrolytes; Multiple equilibria; and Kinetics of macromolecular reactions. Fundamental theories are given and then modified or extended to apply to molecules of high molecular weight. Author and subject indexes are appended

Pharmacy Examination Review Book. Vol. 1. Medical Examination Publishing Co. Inc., P. O. Box 36, Fresh Meadows, Flushing 65, N. Y., 1960. 179 pp. 13.5 × 21.5 cm. Paperbound.

The purpose of this book is to reveal those areas of pharmaceutical knowledge that require further study by the individual preparing for examinations. It includes about 1,000 multiple choice questions (and answers) in sections on pharmacy, pharmacology, microbiology and public health, chemistry, biochemistry, and physiology.

Progress in Drug Research. Vol. 2. Edited by ERNST JUCKER. Interscience Publishers, Inc., 250 Fifth Ave., New York 1, N. Y., 1960, 636 pp. 16.5 × 24 cm. Price $22.50

The development of a reference work in the field of drug research is continued with the issuance of volume 2 in this series. The publication of volume 1 was noted in THIS JOURNAL, 49, 62(1960). Other volumes will appear annually. Extensive review articles cover nine subjects in volume 2. The articles are printed in the languages of the contributors. In this volume five articles are in English and four are in German. Indexes are not appended, but each article has a detailed table of contents.

Investigation of Rates and Mechanisms of Reactions. Part 1. 2nd ed. Edited by ARNOLD WEISSBERGER. Interscience Publishers, Inc., 250 Fifth Ave., New York 1, N. Y., 1961. xii + 713 pp. 15.5 × 22.5 cm. Price $23.50.

A revised and augmented edition of volume 8, part 1, in the series "Technique of Organic Chemistry." The first edition was reviewed in THIS JOURNAL, 42, 507(1953). The text should be extremely useful in the field of physical pharmacy. An index is appended.

Metabolic Pathways in Microorganisms. By VERNON H. CHELDELIN. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1961. ix + 91 pp. 12.5 × 18.5 cm.

A compilation of lectures on carbohydrate metabolism in microbial systems, emphasizing metabolic peculiarities of acetic acid bacteria.

Book Notices

Virus Meningo-Encephaltis. Edited by G. E. W. WOLSTENHOLME and MARGARET P. CAMERON. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1961. viii + 120 pp. 12.5 × 18.5 cm.

A compilation of 13 papers and discussions on subjects related to meningo-encephalitis which were presented at a study group in September 1960. References and a subject index are appended.

Quinones in Electron Transport. Edited by G. E. W. WOLSTENHOLME and CECILIA M. O'CONNOR Little, Brown and Co., 34 Beacon Street, Boston 6, Mass., 1961 xii + 453 pp. 13.5 × 20.5 cm. Price $11.

Reports on biochemical studies related to the quinones, particularly ubiquinone (coenzyme Q), and their part in electron transport are compiled in this book. Nineteen papers were contributed and discussed at the May 1960 Ciba Foundation Symposium.

Pharmacology and Oral Therapeutics. 12th ed. By EDWARD C. DOBBS. The C. V. Mosby Co., 3207 Washington Blvd., St. Louis 3, Mo., 1961. 578 pp. 16 × 24 cm. Price $10.

Revision of this authoritative textbook assures consideration of those drugs official in U.S.P. XVI and N.F. XI, as well as the drugs evaluated in the latest editions of "New and Nonofficial Drugs" and "Accepted Dental Remedies." The book is excellent for dental students and practitioners, and includes useful information for pharmacists.

Comparative Animal Physiology. 2nd ed. By C. LADD PROSSER and FRANK A. BROWN, JR. W. B. Saunders Co., West Washington Square, Philadelphia 5, Pa., 1961. ix + 688 pp. 16.5 × 25.5 cm. Price $15.50.

Intended as a text for upper-class undergraduates and first-year graduate students and as a reference volume, this edition reflects the additional knowledge and current views developed since the 1950 edition. The authors consider the reactions of animals to specific variations in a series of environmental factors and then consider effector and coordinating mechanisms in general.

Biochemists' Handbook. Edited by CYRIL LONG. D. Van Nostrand Co., Inc., 120 Alexander St., Princeton, N. J., 1961. xxii + 1192 pp. 15.5 × 25 cm. Price $25.

Compiled chiefly for biochemists and others in related sciences, this encyclopedia-type handbook is divided into six sections. A revised and augmented edition of volume 8, part 1, in the series "Technique of Organic Chemistry." The first edition was reviewed in THIS JOURNAL, 42, 507(1953). The text should be extremely useful in the field of physical pharmacy. An index is appended.

Metabolic Pathways in Microorganisms. By VERNON H. CHELDELIN. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1961. ix + 91 pp. 12.5 × 18.5 cm.

A compilation of lectures on carbohydrate metabolism in microbial systems, emphasizing metabolic peculiarities of acetic acid bacteria.

Book Notices

Virus Meningo-Encephaltis. Edited by G. E. W. WOLSTENHOLME and MARGARET P. CAMERON. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1961. viii + 120 pp. 12.5 × 18.5 cm.

A compilation of 13 papers and discussions on subjects related to meningo-encephalitis which were presented at a study group in September 1960. References and a subject index are appended.

Quinones in Electron Transport. Edited by G. E. W. WOLSTENHOLME and CECILIA M. O'CONNOR Little, Brown and Co., 34 Beacon Street, Boston 6, Mass., 1961 xii + 453 pp. 13.5 × 20.5 cm. Price $11.

Reports on biochemical studies related to the quinones, particularly ubiquinone (coenzyme Q), and their part in electron transport are compiled in this book. Nineteen papers were contributed and discussed at the May 1960 Ciba Foundation Symposium.

Pharmacology and Oral Therapeutics. 12th ed. By EDWARD C. DOBBS. The C. V. Mosby Co., 3207 Washington Blvd., St. Louis 3, Mo., 1961. 578 pp. 16 × 24 cm. Price $10.

Revision of this authoritative textbook assures consideration of those drugs official in U.S.P. XVI and N.F. XI, as well as the drugs evaluated in the latest editions of "New and Nonofficial Drugs" and "Accepted Dental Remedies." The book is excellent for dental students and practitioners, and includes useful information for pharmacists.

Comparative Animal Physiology. 2nd ed. By C. LADD PROSSER and FRANK A. BROWN, JR. W. B. Saunders Co., West Washington Square, Philadelphia 5, Pa., 1961. ix + 688 pp. 16.5 × 25.5 cm. Price $15.50.

Intended as a text for upper-class undergraduates and first-year graduate students and as a reference volume, this edition reflects the additional knowledge and current views developed since the 1950 edition. The authors consider the reactions of animals to specific variations in a series of environmental factors and then consider effector and coordinating mechanisms in general.

Biochemists' Handbook. Edited by CYRIL LONG. D. Van Nostrand Co., Inc., 120 Alexander St., Princeton, N. J., 1961. xxii + 1192 pp. 15.5 × 25 cm. Price $25.

Compiled chiefly for biochemists and others in related sciences, this encyclopedia-type handbook is divided into six sections. Section 1 includes selected topics in physical and organic chemistry, with tabulated data. Section 2 discusses enzyme kinetics and describes about 300 enzymes. Metabolic pathways are treated in Section 3. Data on the chemical composition of animal tissues and plants are given in Sections 4 and 5, respectively. Section 6 gives information on some physiological and nutritional topics. The general index requires 64 pages.

Physical Chemistry of Macromolecules. By CHARLES TANFORD. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1961. xiv + 710 pp. 15 × 23 cm. Price $18.

Areas of physical chemistry in this book are taken up in the order: Molecular structure, with emphasis on X-ray diffraction; Statistics of linear polymers; Thermodynamics; Light scattering; Transport processes and viscosity; Electrostatic free energy and polyelectrolytes; Multiple equilibria; and Kinetics of macromolecular reactions. Fundamental theories are given and then modified or extended to apply to molecules of high molecular weight. Author and subject indexes are appended

Pharmacy Examination Review Book. Vol. 1. Medical Examination Publishing Co. Inc., P. O. Box 36, Fresh Meadows, Flushing 65, N. Y., 1960. 179 pp. 13.5 × 21.5 cm. Paperbound.

The purpose of this book is to reveal those areas of pharmaceutical knowledge that require further study by the individual preparing for examinations. It includes about 1,000 multiple choice questions (and answers) in sections on pharmacy, pharmacology, microbiology and public health, chemistry, biochemistry, and physiology.

Progress in Drug Research. Vol. 2. Edited by ERNST JUCKER. Interscience Publishers, Inc., 250 Fifth Ave., New York 1, N. Y., 1960, 636 pp. 16.5 × 24 cm. Price $22.50

The development of a reference work in the field of drug research is continued with the issuance of volume 2 in this series. The publication of volume 1 was noted in THIS JOURNAL, 49, 62(1960). Other volumes will appear annually. Extensive review articles cover nine subjects in volume 2. The articles are printed in the languages of the contributors. In this volume five articles are in English and four are in German. Indexes are not appended, but each article has a detailed table of contents.

Investigation of Rates and Mechanisms of Reactions. Part 1. 2nd ed. Edited by ARNOLD WEISSBERGER. Interscience Publishers, Inc., 250 Fifth Ave., New York 1, N. Y., 1961. xii + 713 pp. 15.5 × 22.5 cm. Price $23.50.

A revised and augmented edition of volume 8, part 1, in the series "Technique of Organic Chemistry." The first edition was reviewed in THIS JOURNAL, 42, 507(1953). The text should be extremely useful in the field of physical pharmacy. An index is appended.

Metabolic Pathways in Microorganisms. By VERNON H. CHELDELIN. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1961. ix + 91 pp. 12.5 × 18.5 cm.

A compilation of lectures on carbohydrate metabolism in microbial systems, emphasizing metabolic peculiarities of acetic acid bacteria.

Review Article

Structure-Activity Relationships of Drugs Affecting the Lungs

By DOMINGO M. AVIADO

THE LUNGS can respond to drugs in four different ways: (*a*) there are sensory nerve endings in the lung parenchyma which can be stimulated chemically to influence respiration, (*b*) the smooth muscles of the bronchioles can be contracted or relaxed by drugs and therefore alter the resistance to flow of air during respiration, (*c*) the smooth muscles of the pulmonary vessels can be constricted or dilated by drugs and therefore alter the resistance and pressure of blood flowing in the pulmonary circulation, and (*d*) the total amount of pulmonary blood flow can be reduced or increased by a primary action of drugs on the heart and systemic vessels. This paper will review each of these four types of actions with special emphasis on the relationships of chemical structure to physiological activity as observed on various structures of the lungs.

It should be stated at the outset that no drug has its action limited to only one structure in the lungs. For example, one sympathomimetic amine, like epinephrine, can influence bronchiolar muscle tone, pulmonary vascular tone, and pulmonary blood flow. Another sympathomimetic amine, such as methoxamine, can influence only pulmonary blood flow, but not directly the bronchiolar and pulmonary vascular smooth muscles; however, the consequences of a primary systemic pressor action include reflex increase in vagal tone which can include bronchoconstriction. These examples serve to demonstrate the differences in extent of action of drugs belonging to the sympathomimetic class, and this is true also for xanthines and antihistaminics which will be discussed below. An attempt will be made to explain such differences on the basis of chemical structure. As new compounds are developed, it is possible that some of them may prove clinically useful as selective respiratory stimulants, bronchodilators, and pulmonary vasodilators.

REFLEXES FROM THE LUNGS

Nature of Drug Action.—The respiratory effects of chemical stimulation of receptors in the lungs have been reviewed (1, 2). These receptors are supplied by the vagal innervation of the lungs and, when stimulated, would cause temporary apnea followed by tachypnea. These receptors that influence respiration are believed to be normally functioning as stretch receptors in the lung parenchyma (Hering-Breuer reflex) and baroreceptors in the pulmonary vessels (Bezold-Jarisch reflex). It has not been possible to show any direct response to the latter receptors because isolation from other vagal receptors innervating surrounding structures is difficult.

Received from the Department of Pharmacology, Schools of Medicine, University of Pennsylvania, Philadelphia 4.

The experiments discussed herein were supported by the U. S. Army Medical Branch and Development Command, Department of the Army, under Contract No. DA-49-193-MD-2093.

Adapted from a paper presented at the Gordon Research Conference on Medicinal Chemistry, Colby Junior College, New London, N. H., July 31 to August 4, 1961.

Active Compounds.—The following compounds have been shown to increase the activity of the pulmonary stretch receptors: inhalation of ether, trichlorethylene, and chloroform (3); intravenous injection of veratrum alkaloids (4–6), 5-hydroxytryptamine (7), amidines (8), aconitine (9), strychnine (10), and antihistaminic compounds (11). The following compounds have been shown to elicit the reflex from the lungs, but action potential studies are still lacking: nicotine (12), lobeline (13), tributyrin (14), capsaicin (15, 16), andromedotoxin (17), benzofurans (18), and aminoethylisothiuronium (19).

The variety of compounds that elicit a respiratory reflex from the lungs makes it difficult to specify a common pharmacological action to explain the response. It is very probable that the receptors are stimulated in one of three ways: (*a*) direct action of the compound on the sensory nerve ending; (*b*) direct action of the compound on the vessels which will in turn stimulate the baroreceptors; and (*c*) direct action of the compound on the bronchiolar smooth muscle which will in turn influence the sensitivity of the stretch receptors. Although actions (*b*) and (*c*) will be discussed below, it should be stated here that such actions have not been investigated for most of the compounds that elicit the respiratory reflex.

Antihistaminic Compounds.—This group deserves some special attention because it has been adequately studied from several standpoints. Winder and Thomas (20) reported that diphenhydramine caused apnea followed by tachypnea when injected intravenously in the anesthetized dog. Because the effects were eliminated by vagotomy, they postulated that the respiratory effect was due to a central augmentation by the drug of normal vagal proprioceptive impulses from the lungs. Catheterization of the cardiopulmonary circulation showed that this antihistaminic drug was acting not centrally, but peripherally, on receptors in the lungs (21). Takasaki, *et al.* (22), reconfirmed the reflex nature of the response in other animal species (cat and rabbit). Jones (23) showed in such species that the respiratory reflex could not be explained entirely by pulmonary stretch receptors but suggested other receptors in the lungs which have not yet been identified. Unlike most other compounds, the antihistaminics do not stimulate cardiac receptors responsible for bradycardia and hypotension.

Possible Clinical Use.—In the anesthetized animal, the reflex induced by antihistaminic compounds consists of an initial apnea followed by prolonged tachypnea. If the latter response were confirmed in man, it would be possible to develop a new type of respiratory stimulant. Most clinically useful stimulants act centrally and therefore have other undesirable effects (convulsions), so that a stimulant acting exclusively by reflexes would be expected to be free of such central actions.

Structure-Activity Relationships.—Another special feature of the antihistaminic group is that 27 compounds have been tested for reflex respiratory action (21). The results allow the following generalizations in structure-activity relationships: (*a*) Almost all of the antihistaminic compounds tested have a basic ethylamine structure. (*b*) The nature of substitution of the amine partly determines the ability of the compound to elicit the reflex. The most active compounds have either two methyl or two ethyl substituents. (*c*) The nature of aromatic substituents at the β-carbon atom also influences the activity of the compound. The active and inactive substituents are summarized in Fig. 1.

BRONCHODILATATION

Active Compounds.—Hawkins (24) has compiled a series of tables which summarize the effects of several types of compounds on the bronchiolar smooth muscles. It is apparent from such tables that several groups of compounds can be depended upon to relax bronchiolar smooth muscles, particularly after spasm induced by histamine. The groups are as follows: sympathomimetic amines, parasympathetic blocking drugs, local anesthetics, antihistaminics, and a miscellaneous group of compounds with musculotropic action.

Sympathomimetic Amines.—This group has been used widely in the treatment of bronchial asthma. The major limitation in the clinical use is the accompanying effects on the cardiovascular system. These side effects have been systematically compared in anesthetized dogs (25), and the pattern of action for each of six bronchodilators are as follows: (*a*) Isoproterenol injected directly into the common carotid, vertebral, superior mesenteric, and external iliac arteries causes vasodilatation. This action is the major cause for the systemic arterial hypotension. It masks the accompanying cardiac stimulation which can be detected as increases in myocardial force of contraction and in pulmonary blood flow. (*b*) Methoxyphenamine and (*c*) isoprophenamine cause systemic vasodilatation similar to that of isoproterenol, but much larger doses are required. The accompanying effect on the heart is a depression of myocardial force of contraction. (*d*) Epinephrine causes vasoconstriction when injected into

Fig. 2.—Comparison of chemical structure and side effects of sympathomimetic bronchodilators.

the various systemic arteries. The systemic hypertensive response following its intravenous injection is due both to vasoconstriction and to stimulation of myocardial force of contraction. (*e*) Ephedrine causes vasoconstriction in the various systemic arterial beds and stimulation or depression of myocardial force. (*f*) Pseudoephedrine is a weaker constrictor than ephedrine for the common carotid, external iliac, and superior mesenteric arteries. Unlike ephedrine, pseudoephedrine causes vasodilatation in the area supplied by the vertebral artery. The stimulation and depression of myocardial contraction for both ephedrine and pseudoephedrine are equal in intensity.

Structure-Activity Relationships.—A comparison of the chemical structure of bronchodilator amines has failed to make a distinction between active and inactive substituents (Fig. 2). The 3,4-dihydroxy substitutions common to both epinephrine and isoproterenol are lacking in ephedrine and pseudoephedrine; methoxyphenamine has a 2-methoxy group whereas isoprophenamine contains a 2-chloro substituent in the phenyl ring. The attachment of an hydroxyl or a methyl radical in the ethyl chain is not a normal feature of all bronchodilators. The only common feature is a substitution in the amine and this is true for other sympathomimetic amines that have been proven effective in experimental animals (24). The need for new bronchodilators appears largely to be for a more selective one with minimal activity on the cardiovascular system; the structure-activity relationships for bronchodilatation should be correlated with those for cardiovascular actions discussed below.

PULMONARY VASODILATATION

Types of Vasodilators.—The literature on the effects of drugs on the pulmonary vessels has been reviewed recently (26). The vasodilators that have been used clinically to reduce pulmonary hypertension include aminophylline, isoproterenol, and tolazoline. Although each of these three agents is able to dilate the pulmonary vessels, they also dilate the peripheral vessels, and stimulate the heart. The latter action is accompanied usually by an increase in cardiac output or pulmonary blood flow so that the net result of the drug may even be a rise in pulmonary arterial pressure. Derivatives of aminophylline have been examined and these will be discussed next.

Structure-Activity Relationships of Xanthines.—Forty derivatives of aminophylline (theophylline ethylenediamine) were tested in anesthetized dogs to compare the vascular action in the lungs and the extremities (27). All compounds tested revealed either dilatation for both, or constriction for both, but never opposite effects (Fig. 3).

Theophylline (1,3-dimethylxanthine) gave essentially the same results as those described for aminophylline (theophylline ethylenediamine); i.e., pulmonary and femoral vasodilatation. Caffeine (1,3,7-trimethylxanthine) was slightly more powerful than aminophylline in dilating the pulmonary vessels but weaker in dilating the femoral vessels. Theobromine (3,7-dimethylxanthine) was half as active as theophylline in dilating the vessels of the lungs and legs. The following generalizations apply to the correlation of chemical structure of the other xanthines tested for their vascular effect: (*a*) unsubstituted xanthine is a weak dilator (less than one-half the potency of theophylline) for the lung and limb vessels; (*b*) replacement of the oxygen linked to the carbon atoms at positions 2 and/or 6 with sulfur does not affect the dilator action; (*c*) lengthening the carbon chain attached to the nitrogen at position 3 does not alter the dilator effect characteristic of caffeine, theobromine, and theophylline; (*d*) lengthening the carbon chain attached to the nitrogen at position 1 beyond one carbon converts the dilator action of theophylline and caffeine to constriction; (*e*) lengthening the carbon chain at No. 7 nitrogen position beyond the methyl substituent converts the dilator action of theobromine to vasoconstriction; however, if there is an hydroxyl or chlorine attached to the ethyl substituent, the dilator action is restored; (*f*) an additional substitution at No. 8 carbon position either maintains or reverses the dilator action of theophylline or caffeine. Lengthening the carbon chain beyond a methyl group converts the compound to a vasoconstrictor. However, the benzyl and the *p*-aminobenzyl substituted compounds retain their vasodilator effects. Hydroxyl or amino substitution of the methyl carbon results in a vasoconstrictor, as is the carbamyl substituted methylamino compound. An aliphatic or aromatic ether group, and the nitro and sulfhydryl analogs, also give rise to vasoconstrictors. The 4-methylpiperazinyl analog is a vasodilator, whereas the amino substituted compound is a vasoconstrictor.

Patterns of Responses of Sympathomimetic Amines.—Eighty amines have been tested in the anesthetized dog for effects on pulmonary vascular tone and pulmonary blood flow (28). The results of 22 of them which are commercially available are summarized in Fig. 4. It can be

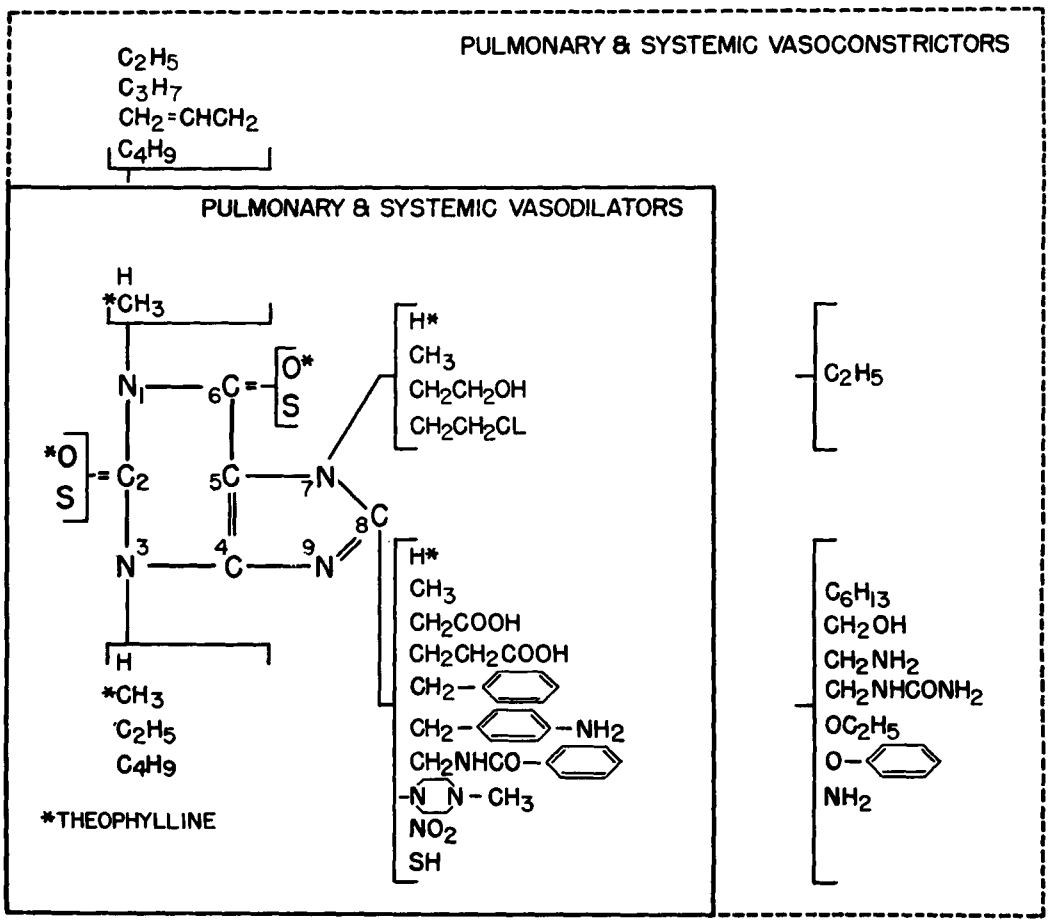

Fig. 3.—Chemical structures of xanthines which cause nonselective vasodilatation or vasoconstriction. Reprinted from reference 27 with the permission of the publishers.

noted that the effects on vessel tone or flow can be grouped into increase, decrease, or variable effect so that there are nine possible combinations of actions. Among the pulmonary vasodilators, the diethoxyl derivative of methoxamine (compounds 45–50) can consistently cause a fall in pulmonary blood pressure because the pulmonary blood flow is reduced. The reduction in flow appears to be related to the substitutions in the 2 and 5 positions of the phenyl ring.

PULMONARY BLOOD FLOW

In the above discussion of sympathomimetic dilators for the lung vessels it was stated that hemodynamically, a reduction in pulmonary arterial pressure is more likely to occur if the drug reduces pulmonary blood flow or cardiac output. An exception to this would be a relative failure of the left ventricle so that the reduction in output would mean a rise in left atrial pressure, pulmonary venous pressure, and even pulmonary arterial pressure. It is for this reason that the sympathomimetic amines were tested in an attempt to find a pulmonary vasodilator with no reduction of pulmonary blood flow, but with less conspicuous increase in pulmonary blood flow than with isoproterenol and mephentermine. Seven derivatives of mephentermine were tested and the results are reported below.

Methods.—Dogs under morphine (2 mg./Kg., s.c.) and chloralose (70 mg./Kg., i.v.) anesthesia were used. The following procedures were routinely performed in all animals: (*a*) cannulation of the trachea to allow the use of a Starling Ideal pump, (*b*) cannulation of a femoral vein for drug injection, (*c*) catheterization of a carotid artery for recording of aortic blood pressure by a Statham transducer, and (*d*) opening of the chest in the left fifth intercostal space to allow measurements of pressure in the pulmonary artery from a catheter tied into the artery of the left upper lobe. The additional procedures performed in each of two groups of dogs consisted of the following: (*e*) measurement of

Fig. 4.—Chemical structure of sympathomimetic amines and their effect on pulmonary circulation.

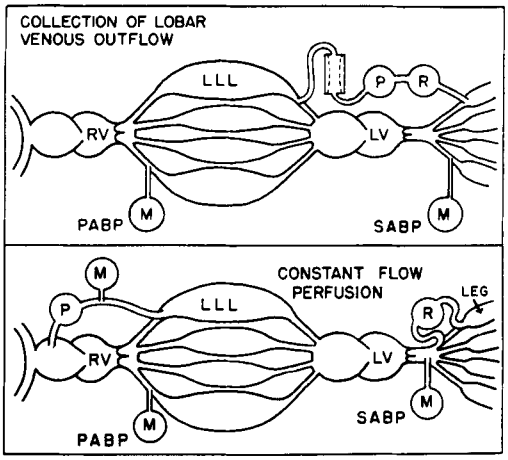
pulmonary venous outflow (28) and force of myocardial contraction by means of a strain gauge arch sutured to the surface of the right ventricle (29), (*f*) inflow perfusion of the left lower lobe (28) combined with measurement of femoral arterial blood flow by insertion of a Shipley-Wilson recording rotameter. All these methods are depicted in Fig. 5 and are briefly described with the results obtained with them. Manuronate (10 mg./Kg., i.v.) was routinely used as the anticoagulant. Aqueous solutions of the compounds were prepared as concentrations such that the total volume of injection did not exceed 0.1 ml. for intra-arterial injection, and 1.0 ml. for intravenous injection.

Results.—The effects of mephentermine and its seven derivatives are summarized in Table I. Each compound was tested on at least three dogs and the comparative activity is expressed in relation to that of mephentermine with an activity ratio of 1.0. The relative potency of the derivative is expressed as either (*a*) the effect of an equivalent dose or (*b*) the dose that elicits an equivalent effect. Thus, the activity ratio of 0.5 signifies that an equivalent dose of the derivative produces half the effect of mephentermine, or twice the dose of the derivative produces an effect equivalent to mephentermine.

Pulmonary Vasodilatation.—The local action of a drug on the lung vessels was investigated by perfusing the left lower lobe at a constant flow with mixed venous blood from the dog's own right atrium (Fig. 5, top). Mephentermine (1 mg./Kg.) injected directly into the perfused pulmonary artery causes an immediate reduction in perfusion pressure. The 4-methoxy derivative

(compound 1364) induces a similar reduction in perfusion pressure when injected in a dose of 1 mg./Kg., indicating that this derivative causes pulmonary vasodilatation. Figure 6 depicts this response and includes the failure of 0.5 mg./Kg. of mephentermine to induce pulmonary vasodilatation. It is on this basis that the potency of the 4-methoxy derivative is expressed as 2.0.

All the other derivatives of mephentermine are weak pulmonary vasodilators (potency of 0.2) with one exception. The nitro derivative (compound 979) instead causes a rise in perfusion pressure, which means that this compound constricts the pulmonary vessels.



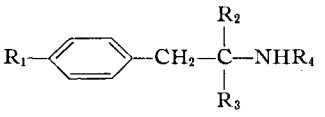


Fig. 5.—*Top.*—Collection of lobar venous outflow in a closed collapsible rubber reservoir, emptied by a Dale-Schuster pump (*P*), measured by a Shipley-Wilson rotameter (*R*), and returned to the animal's own femoral artery. Pulmonary arterial blood pressure (PABP) and aortic blood pressures (SABP) are measured by Statham transducers (*M*) recording on a Sanborn Poly Viso. *Bottom.*—Constant inflow perfusion of left lower lobe with mixed venous blood derived from the animal's own right atrium. Femoral arterial blood is shunted through a Shipley-Wilson rotameter (*R*). Perfusion pressure, arterial pressure of intact lobes, and aortic pressure are registered by Statham transducers (*M*).

Femoral Vasodilatation.—The same group of dogs that were subjected to lung perfusion were also utilized for the investigation of the femoral vascular bed by insertion of a rotameter for measuring arterial blood flow (Fig. 5). It can be noted in Fig. 6, *A* and *C*, that mephentermine and its 4-methoxy derivative, in a dose of 0.1 mg./Kg. injected directly into the femoral artery, cause an immediate increase in femoral blood flow. The responses as femoral vasodilatation induced by both compounds are equivalent in intensity (potency for both expressed as 1.0). The six other derivatives are uniformly able to dilate the femoral vascular bed, although most of them are weaker than mephentermine.

Pulmonary Venous Outflow.—Because of the various objections to the indirect methods of measuring cardiac output, it was decided to measure pulmonary venous outflow by a direct and unequivocal method (Fig. 5). A glass cannula was inserted into the vein of the left lower lobe. All the effluent blood was collected in a collapsible rubber reservoir at the same horizontal level as the cannula. The blood was instantaneously returned by means of a Dale-Schuster pump to the animal's own left atrium or femoral vein. The pump was set to empty the reservoir continuously so that pressure between the lobar vein and the reservoir was never allowed to increase. A Shipley-Wilson rotameter was inserted into the outflow side of the pump to obtain a graphic recording of the rate of blood flowing from the pulmonary vein. Although the pulmonary venous outflow measured by this method represents only one lobe, it is felt that it can be regarded as a reasonable criterion of flow in all lobes and of cardiac output.

The intravenous injection of mephentermine

TABLE I.—DERIVATIVES OF MEPHENTERMINE[a] AND THEIR PULMONARY VASCULAR EFFECTS BASED ON ACTIVITY OF MEPHENTERMINE EXPRESSED AS 1.0

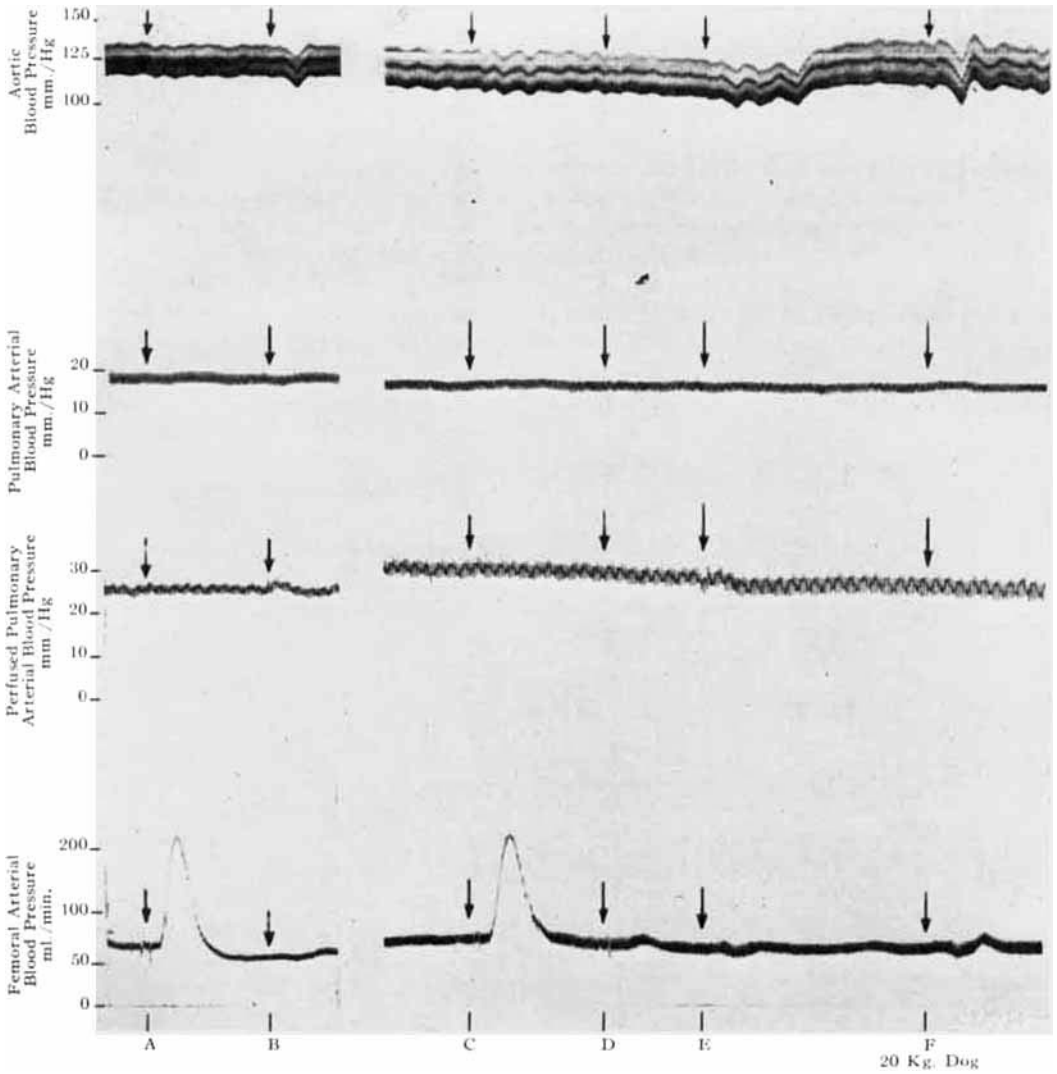

Fig. 6.—Comparative effects of mephentermine and 4-methoxy derivative. *A*, Mephentermine 0.1 mg./Kg. into femoral artery; *B*, mephentermine 0.5 mg./Kg. into perfused pulmonary artery (elapsed time between *B* and *C*, 20 min.); *C*, 4-methoxy derivative 0.1 mg./Kg. into femoral artery; *D*, saline 0.2 ml. into femoral artery; *E*, 4-methoxy derivative 0.5 mg./Kg. into perfused pulmonary artery; *F*, 4-methoxy derivative 1.0 mg./Kg. intravenously.

(1 mg./Kg.) causes an increase in pulmonary venous outflow (Figs. 7, *B*, and 8, C). The corresponding effect of the 4-methoxyderivative is a less intense increase in pulmonary venous outflow, with an activity ratio of 0.3 (Figs. 7, *A*, and 8, *A*). The other derivatives have variable effects on pulmonary venous outflow, either an increase or a decrease, and both may even appear in the same dog after repeated injections of the same compound. This variability is related to the biphasic action on the heart muscle which is described in the following paragraph.

Force of Myocardial Contraction.—The known stimulant action on the myocardium for mephentermine can be demonstrated by means of the Walton strain gauge. An intravenous injection (1 mg./Kg.) causes an increase in force of myocardial contraction, and this occurs simultaneously with the increase in pulmonary venous outflow (Figs. 7, *B*, and 8, *C*). An equivalent amount of the 4-methoxy derivative causes either an equally intense or less intense stimulation. After repeated injection of this compound, the stimulation may be converted to a temporary depression (Fig. 8, *D*). The variable effect on myocardial depression is related to the less intense increase in pulmonary venous outflow. The other derivatives have variable effects on myocardial force.

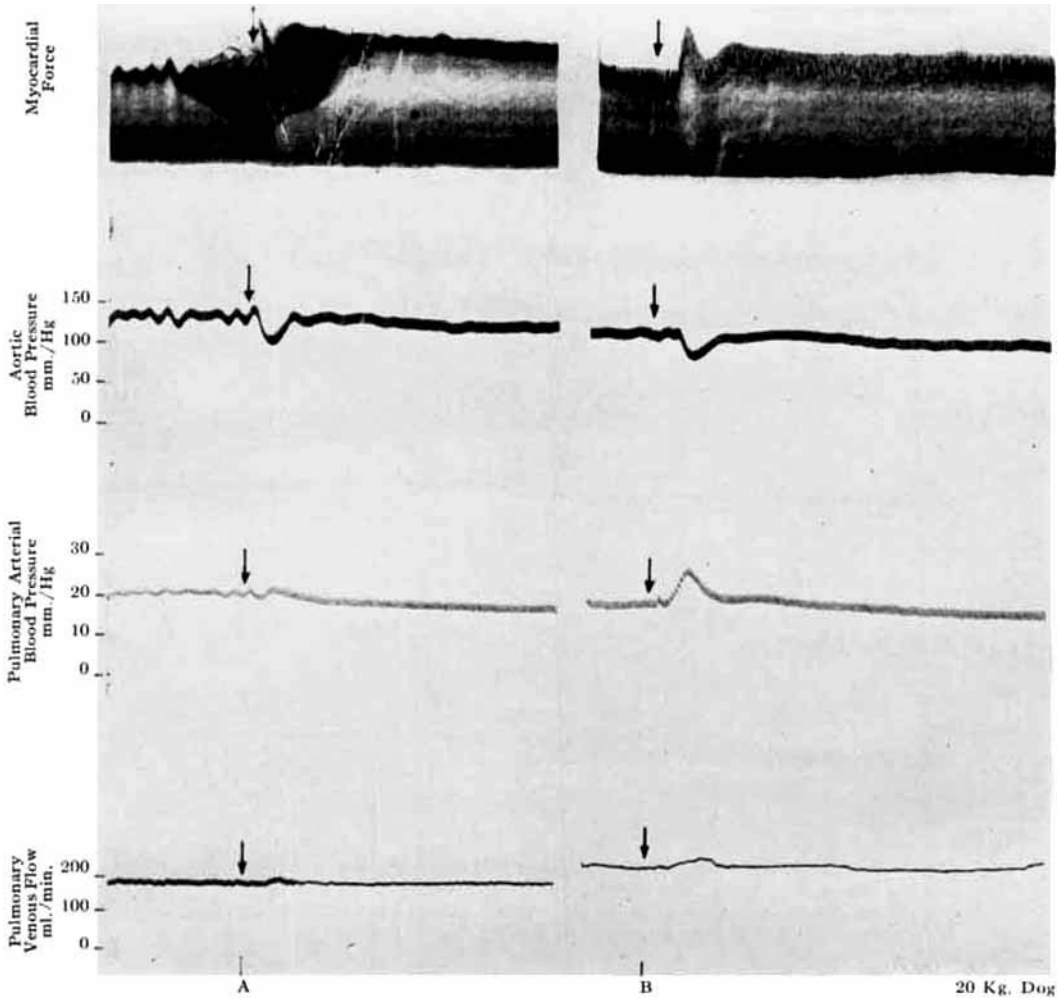

Fig. 7.—Comparative effects of mephentermine and 4-methoxy derivative on myocardial force, aortic blood pressure, pulmonary arterial blood pressure, and pulmonary venous outflow. *A*, 4-Methoxy derivative 1 mg./Kg. intravenously; *B*, mephentermine 1 mg./Kg. intravenously.

Pulmonary Blood Pressure.—The most usual response of pulmonary arterial blood pressure following the intravenous injection of 4-methoxy derivative is a fall. This fall most probably is related to the vasodilatation demonstrable in the perfused lung, which appears to be more important than the increase in pulmonary blood flow. In some instances the pulmonary arterial pressure is unchanged, and this can be explained by both increased flow and vasodilatation occurring to equalize each other. The pulmonary arterial pressure responses of mephentermine and the six derivatives (other than 4-methoxy) are variable, and are related to the effects on pulmonary blood flow and pulmonary vasomotor tone reported above.

Aortic Blood Pressure.—The aortic pressor response of mephentermine can be elicited by the intravenous injection of 1 mg./Kg. This has been explained by cardiac stimulation which has been documented by reports of various investigators (29–34). The pressor response is converted to a depressor response after the injection of the 4-methoxy derivative (Fig. 7) and this indicates that the systemic vasodilator action of mephentermine becomes of primary importance. The basic mechanism for this predominance induced by the 4-methoxy derivative is not known but may be an indication of cross-tachyphylaxis between the two compounds.

The behavior of aortic blood pressure following the intravenous injection of 4-methoxy derivative (1 mg./Kg.) is variable even in a dog receiving this compound for the first time. In a group of 6 dogs, a fall was encountered in 3, a rise in 1, and no change in 2. The fall can be explained by the

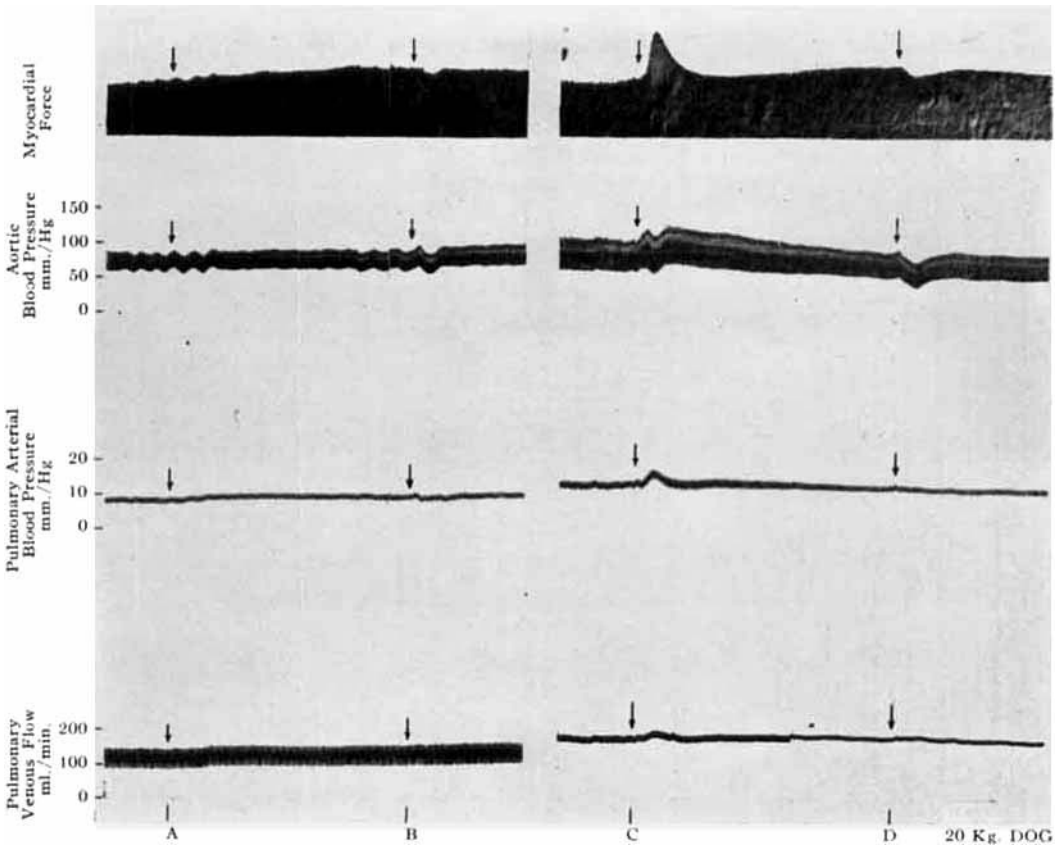

Fig. 8.—Comparative effects of mephentermine and 4-methoxy derivative on myocardial force, aortic blood pressure, pulmonary arterial blood pressure, and pulmonary venous outflow. *A*, 4-Methoxy derivative 1 mg./Kg. intravenously; *B*, 4-methoxy derivative 1 mg./Kg. intravenously; *C*, mephentermine 1 mg./Kg. intravenously; *D*, 4-methoxy derivative 2 mg./Kg. intravenously.

systemic vasodilatation, but final proof must await studies on systemic vascular beds other than the femoral.

Correlation of Chemical Structure to Pulmonary Vascular Action.—The effects of seven derivatives of mephentermine suggest the following generalizations. (*a*) The addition of a 4-methoxy radical in the phenyl ring to mephentermine causes an exaggeration of pulmonary vasodilator action but a reduction in the ability to increase pulmonary blood flow. The addition of a 4-amino radical does not reduce the pulmonary vasodilator action but reduces the systemic dilator action. (*b*) The substitution of a nitro radical converts the compound into a pulmonary vasodilator, the activity which is reduced by conversion of the methyl substituent in the terminal nitrogen to a longer aliphatic chain. A similar reduction in activity can be induced by substituting both methyl radicals in the α-carbon to two carbinol groups. All of these alterations reduce the vasodilator potency not only for the femoral vessels but also for the pulmonary vessels. (*c*) The ability to stimulate myocardial force is a feature common to all the derivatives tested, although this action is not a consistent one since depression may be encountered.

CONCLUDING REMARKS

The structure-activity relationships of antihistaminics, xanthines, and sympathomimetic amines have been reviewed. These drugs are able to (*a*) influence respiration by activation of pulmonary vagal receptors, (*b*) relax bronchiolar tone, (*c*) dilate pulmonary vessels, and (*d*) either decrease or increase pulmonary blood flow. The major shortcoming of active agents is their lack of selectivity for a specified structure in the lungs. They usually affect two or more reactive areas in the lungs and usually influence the heart and the systemic vessels.

Complexation of Organic Acids and Bases with Their Salts in Aqueous Solution

By MICHAEL R. VALINOTI and SANFORD BOLTON

The solubilization of certain organic acids in aqueous solutions of their salts has been attributed to a complexation between the acid and anion species. In the present investigation solubility studies were used in an effort to ascertain the factors influencing such complexation and to determine the nature of the complexes formed. Benzoic acid, salicylic acid, *p*-hydroxy-, 2,4-dihydroxy-, 2,5-dihydroxy-, 2,6-dihydroxy-, and 3,4-dihydroxybenzoic acids, phenylacetic acid, adipic acid, barbituric acid, barbital, phenobarbital, and saccharin showed substantial increases in solubility in the presence of their sodium salts. Studies with atropine and procaine in solutions of their salts showed that similar complexes occurred in these systems. In some cases insoluble complexes were formed at high salt concentrations. Addition of hydroxyl groups to benzoic acid favors complexation. Quantitative evaluation of equilibrium constants could not be determined because of a concurrent salting out effect.

THE APPARENT increase in solubility of various organic acids in aqueous solutions of their alkali or alkaline earth metal salts has been attributed to the formation of an acid-anion complex (1–6). Ross and Morrison (1) have described solubility curves for various mandelic acid-metal mandelate systems and have noted the formation of complexes of acid-salt ratios of 1:1, 2:1, and 3:1. They proposed the following formula as the most favorable representation of the complex species

where n can be either 1, 2, or 3. Hoitsema (2) investigated the salicylic acid-sodium salicylate and hippuric acid-potassium hippurate systems

and isolated, in each case, 1:1 "double salt" complexes. Marshall and Cameron (3) noted the appearance of, and characterized, an insoluble complex in the succinic acid-potassium succinate system. Kolthoff and Bosch (4), in studies designed to determine the activity coefficient of benzoic acid in solutions of various salts, observed an increase in the solubility of benzoic acid in the presence of up to 1 *M* sodium benzoate. Higuchi and co-workers (5) have noted an insoluble benzoic acid-ammonium benzoate complex; and Ongley (6) has listed, without interpretation, the increase in solubility of benzoic, salicylic, and 2,6-dihydroxybenzoic acids in 1 *M* solutions of their salts.

It was the purpose of the present investigation to attempt to elucidate the prerequisite factors and the nature of the binding forces involved in this type of complex. Solubility studies with a number of model compounds were used to determine the extent of complexation. Benzoic acid, phenylacetic acid, and a group of hydroxybenzoic acids were selected to determine the effect of some structural features of aromatic acids on the degree of complexation. Systems containing suitable monocarboxylic, straight chain acids proved to be too difficult to analyze because of the formation of colloidal soap solutions by their salts. Therefore, the adipic acid-sodium adipate system was investigated as an example of complex formation by nonaromatic carboxylic acids. Since no similar studies involving noncarboxylic acids have been reported in the literature, saccharin, barbituric acid, barbital, and phenobarbital complexes were also investigated. Likewise, because of the absence of published work of an analogous nature concerning bases and their salts, atropine and procaine complexes are reported here.

EXPERIMENTAL

Reagents.—All chemicals used were of the highest purity commercially available. The purity of the acids and bases was checked by (*a*) melting point, (*b*) solubility analysis, and (*c*) titration with standard acid or base. Those compounds failing to meet these criteria were recrystallized, usually from hot water. The melting points of the acids and bases used are listed in Table I. Solutions of salts that were not readily available were prepared either directly by adding an equivalent of sodium hydroxide to the acid or by preparing solutions from pure salt which was obtained by evaporation of the above solutions in a flash evaporator. With the exception of disodium adipate, monosodium salts were used as complexing agents for all acids. Atropine sulfate and procaine hydrochloride, both U.S.P. grade, were used as complexing agents for the bases.

Procedure.—A solubility method, similar to that employed by Higuchi and Lach (7), was used to follow the course of complexation. In all cases, a constant excess of the solid acid or base was added to varying concentrations of the salt solution. To determine the solubilizing effect of salt beyond its saturation point, calculated amounts of salt were added to the saturated solution. Because the small changes in volume resulting from the solubilization of the excess salt during complex formation could not be determined accurately, values plotted beyond the salt saturation point are, of necessity, approximations.

The mixtures, in duplicate, were placed in stoppered glass vials and rotated in a water bath at 30 ± 0.1° for at least 3 hours. In the base systems the shaking time was kept to a minimum to minimize hydrolytic decomposition.

In general, a 5-ml. sample of filtrate was withdrawn by means of a pipet fitted with a piece of rubber tubing plugged with cotton. The majority of the sodium salts were very soluble in water and, consequently, their solutions became very viscous as the saturation point was approached. This condition and the presence of large amounts of solid acid, complex, or salt in the system made withdrawal of accurate aliquots unfeasible in some instances. As a consequence, the solubility analyses were carried

TABLE I.—SOLUBILITY CHARACTERISTICS AND INTERACTIONS OF SOME ORGANIC ACIDS AND BASES WITH THEIR SALTS

Compound	M.P., °C.	Solubility Compound, Mole/L. × 10^2	Solubility Salt, Mole/L.	Apparent K_1, L./Mole	Insoluble[a] Complex

out to a point of salt concentration beyond which the results were believed to be inaccurate.

The clear aliquot was titrated potentiometrically with standard sodium hydroxide or hydrochloric acid, unless the titration was readily amenable to the use of phenolphthalein. Barbital and phenobarbital, which were titrated potentiometrically, required the prior addition of ethanol to the aqueous solutions in order to yield a clearly discernible end point. For a number of compounds, in concentrated salt solutions, the end point could not be clearly detected. In these cases, to eliminate most of the salt, the aqueous aliquot was first extracted with ether (chloroform was used in the case of atropine), the organic solvent evaporated, and the residual acid or base titrated as before. Preliminary determination of known concentrations of the acids and bases in concentrated solutions of their salts substantiated the accuracy of the above method.

The acid:salt ratios of the insoluble complexes were determined by analyzing the precipitates in the appropriate containers for acid content.

RESULTS

Benzoic and Monohydroxybenzoic Acids.—Figure 1 illustrates the results obtained for benzoic, salicylic, and *p*-hydroxybenzoic acids. The benzoic acid curve, up to 1 *M* sodium benzoate, parallels the previously reported data of Kolthoff and Bosch (4) whose study was made at 25°. No insoluble complex is formed in this system; the plateau region at high salt concentration indicates that the solution, in this range, is saturated with respect to salt. Salicylic acid shows a significantly greater complexing tendency than benzoic acid. The decrease in acid solubility, observed at low salt concentrations, is probably a salting out effect, a result also observed by Hoitsema (2). The termination of the sharply ascending curve is caused by the appearance of an insoluble complex containing acid and salt in a 1:1 ratio. Further addition of salt results in depletion of acid in solution as more complex is precipitated (7). *p*-Hydroxybenzoic acid, like benzoic acid, shows no initial decrease in solubility. A 1:1 complex precipitated along the first plateau region on this curve. The shape of the terminal portion of the curve and the analysis of the solid phase in that region strongly suggest the formation of a new insoluble species containing acid and salt in a ratio of 1:2.

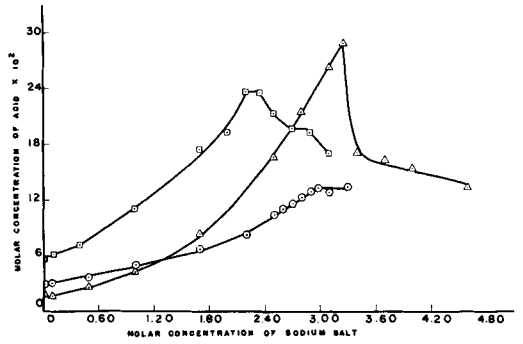

Fig. 1.—Apparent solubilization of benzoic ⊙, salicylic △, and *p*-hydroxybenzoic ▣ acids by their sodium salts in water at 30°.

Dihydroxybenzoic Acids.—Figures 2 and 3 show the results of the dihydroxybenzoic acid interactions studied. Among these acids, only the 2,6-dihydroxy derivative shows an initial decrease in solubility. This acid and 2,4-dihydroxybenzoic acid form soluble complexes only. Analysis of these curves according to a method suggested by Higuchi and Lach (7) indicated formation of 1:1 complexes. In both the 3,4-dihydroxy and 2,5-dihydroxybenzoic acids, precipitation of a 1:1 complex occurs after an initial increase in the apparent solubility of the acid.

Phenylacetic and Adipic Acids.—Figure 4 shows the interaction of phenylacetic and adipic acids with their respective sodium salts. In the phenylacetic acid system, a salting out effect is apparent at low salt concentrations, as evidenced by the appearance in the solubility curve of an initial flattened portion followed by an abrupt rise. Adipic acid forms an insoluble complex with its sodium salt. Analysis of the precipitate on the descending portion of the curve was indicative of an insoluble species containing acid to salt in a 2:1 ratio. At the terminal segment of the curve, the solution is saturated with salt and the solid phase consists of insoluble complex plus salt.

Noncarboxylic Acids.—Figure 5 shows the results obtained for saccharin. A pronounced initial decrease in acid solubility is noted, followed by solubilization up to the salt saturation point. Further addition of salt along the plateau region failed to precipitate a complex species.

Figure 6 illustrates the varied behavior of barbituric acid and its derivatives. The barbituric acid-barbiturate complex is the least soluble of all

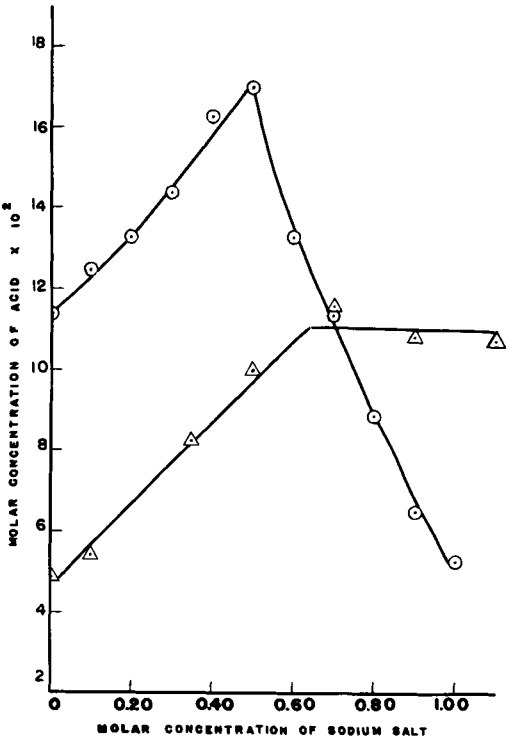

Fig. 2.—Apparent solubilization of 2,4-dihydroxybenzoic △ and 3,4-dihydroxybenzoic ⊙ acids by their sodium salts in water at 30°.

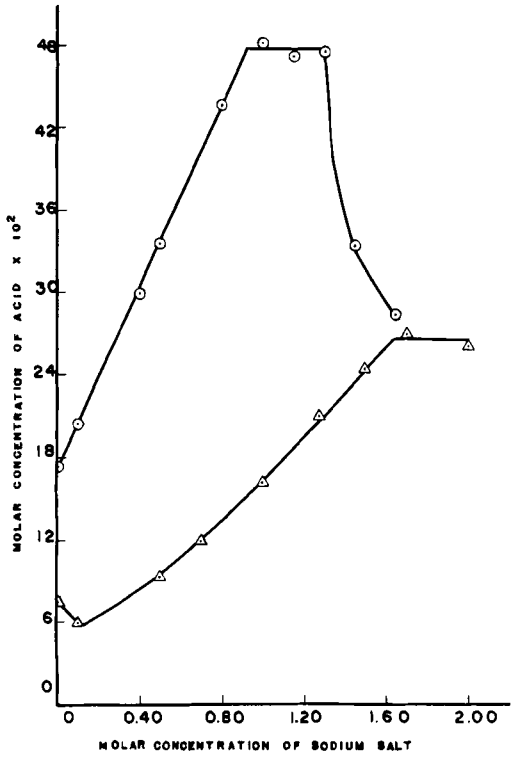

Fig. 3.—Apparent solubilization of 2,5-dihydroxybenzoic ⊙ and 2,6-dihydroxybenzoic △ acids by their sodium salts in water at 30°.

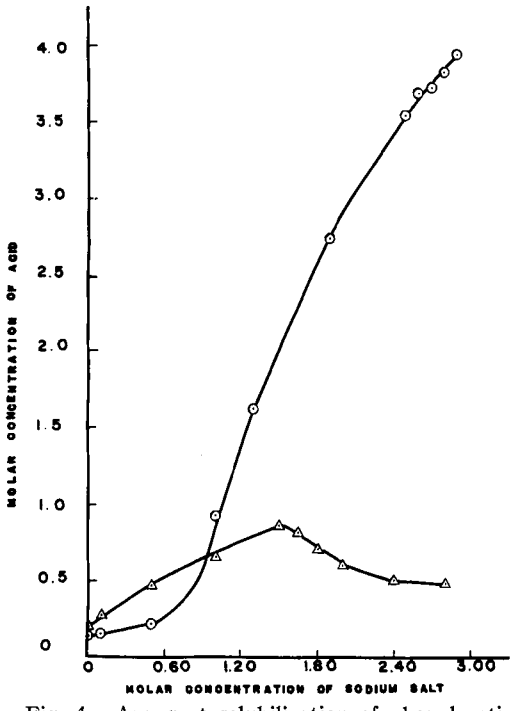

Fig. 4.—Apparent solubilization of phenylacetic ⊙ and adipic △ acids by their sodium salts in water at 30°.

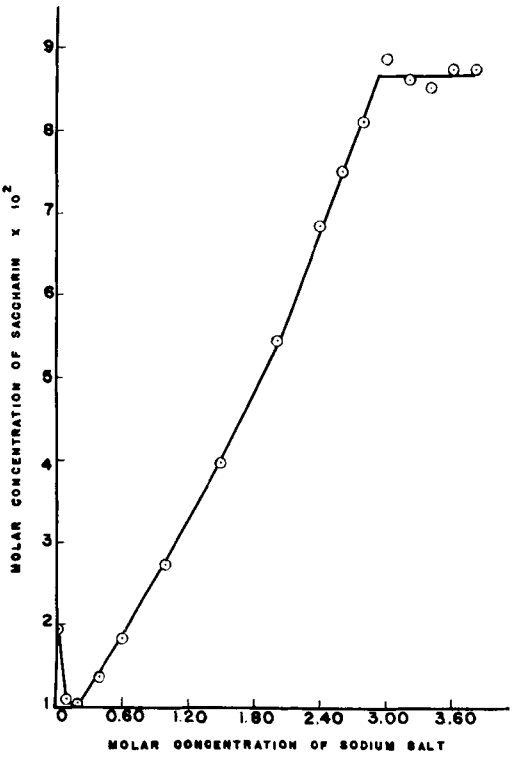

Fig. 5.—Apparent solubilization of saccharin by sodium saccharin in water at 30°.

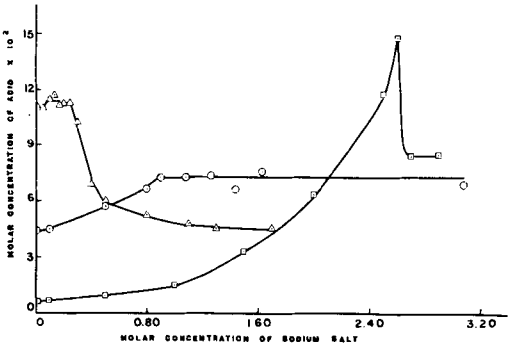

Fig. 6.—Apparent solubilization of barbituric acid △, barbital ⊙, and phenobarbital ◻ by their sodium salts in water at 30°.

complexes noted in this study. After an initial decrease, a small increase in acid solubility is observed, followed by the appearance of a 1:1 complex. Again, along the terminal portion of the curve, the system is saturated with salt and is invariant. Barbital is solubilized up to the salt saturation point, and no insoluble complex is formed. In the case of phenobarbital, the relatively small increase in solubility at low salt concentrations may indicate a salting out effect, somewhat masked by complex formation (similar to the phenylacetic acid system). With increasing salt concentration, however, solubilization increases rapidly. The insoluble complex which appeared at high salt concentration corresponded closely to an acid:salt ratio of 1:4.

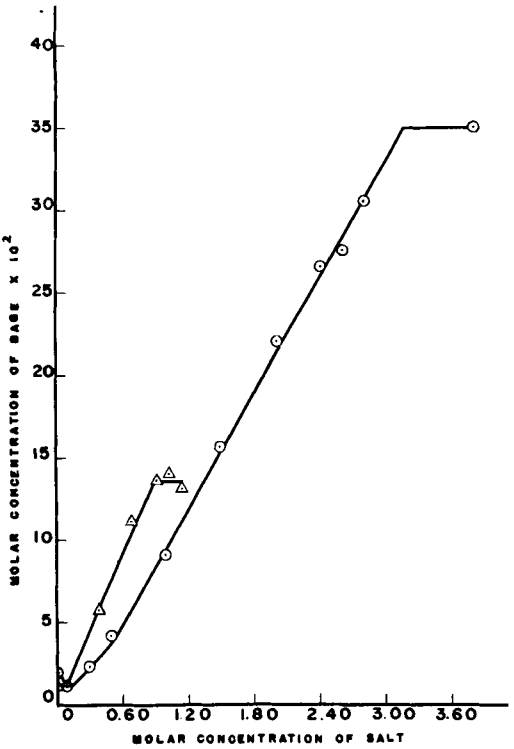

Fig. 7.—Apparent solubilization of atropine by atropine sulfate △ and procaine by procaine hydrochloride ⊙ in water at 30°.

Bases.—The complexation of atropine and procaine with their salts is shown in Fig. 7. The curves are similar in nature to those observed in the acid systems. In both of these cases no insoluble complex appears. In the procaine system, the observed increase in solubility of both the base and salt species due to complex formation indicated formation of a 1:1 complex (7).

DISCUSSION

The fact that complex formation in these systems is accompanied by an inseparable salting out effect renders accurate evaluation of stability constants impossible. Nevertheless, constants were approximated for 1:1 complexes, neglecting salting out effects. These constants were calculated, according to a previously reported method (7), from the initial portions of the curves where 1:1 complexation could be considered to be the predominant equilibrium. Although this approach, admittedly, yields only rough approximations, the results appeared to give a reasonable indication of the extent of complex formation (Table I). In any case the constants, thus calculated, give low values since salting out effects tend to obscure complexation effects.

The K_1 value for barbituric acid was approximated from the final invariant portion of the curve. In this region, the solution is saturated with both complex and salt. The solubility of the complex may be estimated from the initial rise in the solubility curve, and the solubility of the salt is known. The concentration of free acid in these solutions may be calculated as follows

(free acid) = (total acid in solution) − (complex)

and

$$K_1 = \frac{(\text{complex})}{(\text{free acid})\,(\text{free salt})}$$

Since physical properties, such as melting point and solubility, are measures of intermolecular forces and may give insights into complexation forces, these data are included in Table I.

In the series of benzoic acid and its hydroxy derivatives, there appears to be little or no correlation of complexing activity with the indicated physical properties. This fact suggests that the interaction is the result of an interplay of many factors. The solubility of the complexes formed also shows no obvious relation to any single property of these acids. The fact that the addition of hydroxy groups to the benzoic acid nucleus results in an increase in the degree of complexation suggests that binding may occur through hydrogen bonds as well as through the metal atom as previously suggested (1). It is of interest to note that the 2-substituted hydroxy acids showed the strongest complexation in all cases.

The limited, comparable data reported by Ross and Morrison (1) for mandelic acid indicates that at low salt concentrations this acid complexes more strongly with its sodium salt than does phenylacetic acid with its salt. The introduction of a hydroxyl group in mandelic acid may again be offered as an explanation of this difference.

Significant complexation occurred in the nonaromatic acid and the base systems; but the degree of binding, as well as the solubility of the complexes, again appeared to be nonselective.

The variety of complex systems tested indicates that interaction between organic acids or bases and their salts is a widespread phenomenon. There does not appear to be any overall structural requirements although, in a given class of compounds, certain structural variations are probably influential. Despite a wide range of melting points and solubilities of the acids, bases, and their salts, these factors alone do not seem to provide a basis for correlation with complexing activity.

Stabilization of Epinephrine against Sulfite Attack

By SIDNEY RIEGELMAN and ELIEZER Z. FISCHER†

Sulfite and bisulfite ions are known to attack the optically active side chain of epinephrine in the absence of oxygen by an S_N2 mechanism. Evidence is presented whereby chelation of the catechol nucleus with boric acid results in marked stabilization of epinephrine from this type of degradation. The effects of variation of the boric acid and hydrogen ion concentration are investigated. The equilibrium reaction of boric acid and epinephrine are reported in detail and the stability constant for the chelate is evaluated.

In 1958 Schroeter and Higuchi (1, 2, 3) reported on a reaction of epinephrine with bisulfite in an oxygen-free atmosphere. The mechanism of this reaction appears to involve nucleophilic attack of sulfite at the partially positive carbon of the epinephrine side chain to yield a carbon-sulfur bond. There is a loss of optical activity simultaneous to epinephrine and bisulfite loss; the result is a zwitterionic sulfonate

(Eq. 1)

The latter compound had been prepared by Tomino (4) and by Schroeter (5), although the former worker proposes that the sulfonate group is attached at the β-carbon atom.

Studies of the kinetics of the reaction by Higuchi and Schroeter definitely confirm the reaction to be a second-order reaction, dependent on both the concentration of the epinephrine and of the bisulfite. Epinephrine analogs and model compounds were examined by these workers (2) who pointed to the general nature of this type of nucleophilic attack on *p*-substituted benzyl alcohol derivatives. *Meta*-substituted derivatives did not react. The results led to the suggestion that the *p*-quinoid structure of the benzyl alcohol derivatives is the reactive form.

Based on this background information, the present authors postulated that chelate formation between boric acid and the catechol grouping of epinephrine might affect the overall rate of sulfite attack on the compound. Chelate formation of boric acid with polyhydroxy compounds is well known (6, 7). Boric acid chelates of catechol derivatives were first studied by Boeseken and Mijs (8) whose main interest was directed toward preparation of the optically active forms of the chelates. Recently Näsänen (9) has studied the chelate formation of catechol-3,5-disulfonic acid with boric acid by a potentiometric method. The titration of dilute mixed solutions of boric and catechol disulfonic acids with sodium hydroxide solution revealed the formation of only a one-to-one chelate. Since boric acid was found to stabilize epinephrine against sulfite attack, it was deemed important to determine the stability constant for the formation of boro-epinephrine chelate in order to elucidate the quantitative aspects of the stabilization. The results of the degradation and chelate formation studies are the basis of this report.

EXPERIMENTAL

Kinetic Studies.—Epinephrine solutions were prepared at varying concentrations in phosphate or boric acid buffers at varying pH. The pH was determined at 25°. These solutions were filled into hard-glass ampuls, flushed with nitrogen, degassed in a vacuum and once again filled with nitrogen, and then sealed. Identical solutions were prepared containing sodium bisulfite. As mentioned earlier, the reaction of epinephrine with bisulfite had been shown to be a bimolecular reaction with simultaneous loss of optical activity and sulfite. In order to accelerate the rate of reaction, a swamping excess of sodium bisulfite was used in the reaction system converting the system to a pseudo first-order reaction. Thus it was possible to make the observations on samples equilibrated in a constant temperature bath at 25°. Individual ampuls were removed periodically and the optical activity of the solution at 25° was determined on a Rudolph research polarimeter using filtered sodium light (589 mμ) and a 2.0-dm. microtube. The chemical activity of the epinephrine was verified in a number of the solutions by isolation of the triacetyl derivative according to the method reported by Higuchi, Sokoloski, and Schroeter (10). The bisulfite concentration of the ampuls was also determined by iodometric titration.

Chelate Formation Studies.—Solutions of epinephrine, phenylephrine, and boric acid were prepared

using exact equivalents of hydrochloric acid to prepare the salts from the free bases. Sodium chloride was added to adjust the ionic strength of the solutions. The solutions were transferred to a four-necked flask and degassed with nitrogen purified with a vanadous sulfate solution to remove residual traces of oxygen (11). The potentiometric measurements were made using the Beckman standard combination electrode (No. 39142) and the Beckman model G pH meter. Standard sodium hydroxide solution was delivered from a 5-ml. microburet.

Chelate formation was studied spectrophotometrically using 0.4% epinephrine solutions in the presence of an excess of boric acid. The solutions were adjusted to varying pH's by the addition of 10 *N* sodium hydroxide. The pH's of the solutions were measured as noted above. The ultraviolet absorption spectrum was recorded using a Cary model 11 spectrophotometer.

RESULTS AND DISCUSSION

Typical degradative attack of sulfite on epinephrine in the absence of boric acid is shown in Fig. 1. In these solutions, the concentration of epinephrine was held at 0.082 *M* and the concentration of sodium bisulfite was 0.96 *M*. It is evident from Fig. 1 that the reaction follows first-order kinetics under these conditions. The amount of sulfite consumed was completely accounted for by the simultaneous loss in epinephrine, as measured chemically, or by the change in specific rotation of the solutions. It is noted that in the absence of a complexing agent the rate of sulfite attack increases with decrease in hydrogen-ion concentration. This is in agreement with the observations of Higuchi and Schroeter (2) at elevated temperatures and different concentration conditions.

When identical solutions in respect to epinephrine and sulfite concentrations are prepared containing 0.318 *M* boric acid adjusted to the same pH, an interesting effect takes place relative to the rate of sulfite attack. Figure 2 presents the data for the deterioration of epinephrine at the same pH values as shown in Fig. 1. In the presence of boric acid, the rate of sulfite attack is reduced as the hydrogen ion concentration decreases. The half-life for epinephrine under the reaction conditions at pH 6.0 in the absence of boric acid was 195 hours, while in the presence of boric acid the half-life was found to be 267 hours. At pH 7.5, however, the half-life of epinephrine was found to be 74 hours in the absence, and 1,270 hours in the presence of boric acid. It might be postulated that epinephrine is increasingly chelated by the boric acid molecules as the pH is made more alkaline, and that the chelated epinephrine is far less susceptible to sulfite attack than free epinephrine. This is analogous to the findings of Higuchi and Lachman in their studies on the effect of complexation of benzocaine with caffeine (12). In that latter study it was concluded that the complexed form of the drug does not undergo any perceptible cleavage at the ester linkage of the benzocaine. In order to ascertain more facts relative to the stability of the boro-epinephrine chelate to sulfite attack, it was necessary to determine the stability constant for the reaction.

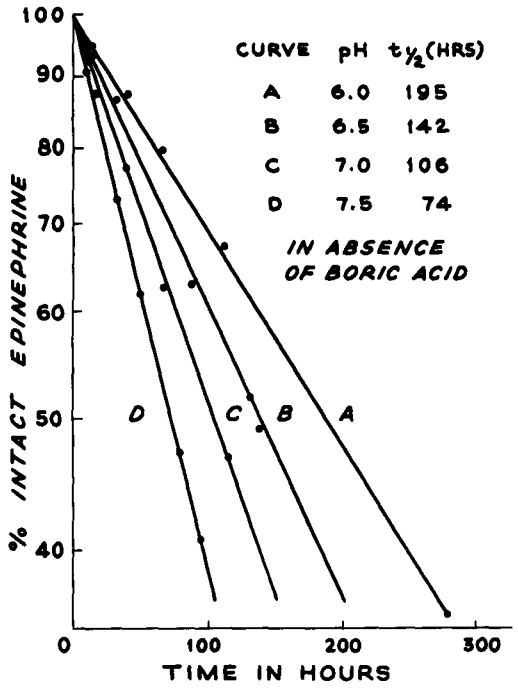

Fig. 1.—The per cent epinephrine remaining in a 1.5% (0.082 *M*) solution containing 10% (0.96 *M*) sodium bisulfite. Solutions were stored at 25° in sealed ampuls in a nitrogen atmosphere in the absence of oxygen. The solutions contained no boric acid.

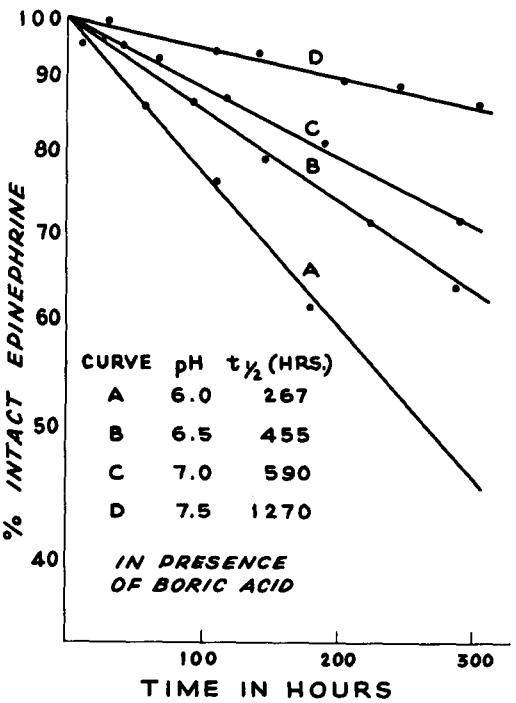

Fig. 2.—The per cent epinephrine remaining in a 1.5% (0.082 *M*) solution containing 10% (0.96 *M*) sodium bisulfite and 2.0% (0.318 *M*) boric acid. The solutions were stored at 25° in sealed ampuls in a nitrogen atmosphere in the absence of oxygen.

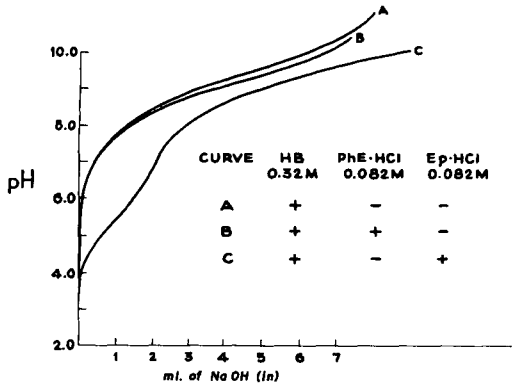

Fig. 3.—Titration of 0.318 *M* boric acid alone (*A*), in the presence of 0.082 *M* phenylephrine hydrochloride (*B*), and in the presence of 0.082 *M* epinephrine hydrochloride (*C*).

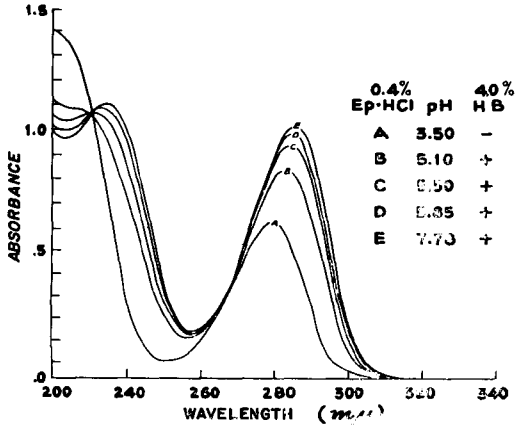

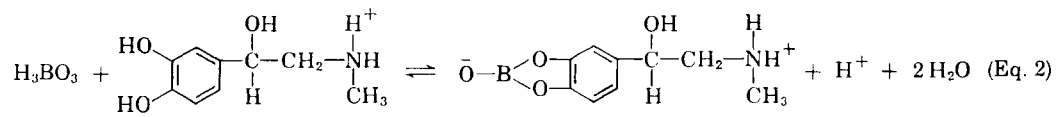

Fig. 4.—Ultraviolet absorption spectra of 0.022 *M* epinephrine alone and in the presence of 4% (0.65 *M*) boric acid at various hydrogen ion concentrations, path length 0.1 mm.

Figure 3 presents the titration curves of 0.32 *M* boric acid alone (*A*), in the presence of 0.082 *M* phenylephrine hydrochloride (*B*), and in the presence of 0.082 *M* epinephrine hydrochloride (*C*). Phenylephrine, of course, differs from epinephrine in that it is a *m*-cresol amine while epinephrine is a catechol amine derivative. Thus epinephrine is able to form a chelate through its dihydroxy structure and the absence of any chelate formation with phenylephrine indicates that the site of binding does not involve the side chain. Curve *B* is slightly shifted relative to the pure boric acid titration curve (*A*) due to the simultaneous neutralization of the first acid function of phenylephrine hydrochloride. Similar titration data for the 1:1 ratio of boric acid to epinephrine have been reported by Riegelman, *et al.* (13). These data may be represented by the reaction

(Eq. 2)

The equilibrium constant for the reaction represented by Eq. 2 may be represented as follows

$$K = \frac{[H^+][EpB^-]}{[Ep][Hb]} \qquad \text{(Eq. 3)}$$

where [HB], [Ep], and [EpB^-] represent the equilibrium concentrations of the boric acid, epinephrine, and boro-epinephrine chelate, respectively. Activity coefficients are ignored. In analogy to the results of Näsänen (9) who found only the 1:1 chelate, one might expect only a 1:1 chelate under the present conditions where the concentration of boric acid is equal to or exceeds the concentration of the epinephrine. This is also verified by the reaction of only one mole of base per mole of epinephrine added and the existence of an isosbestic in the absorption spectral curves (Fig. 4).

The stability constant for the reaction can best be calculated in the pH region where base is not consumed by the excess of boric acid present. Under these conditions the amount of base consumed is equal to the amount of chelate formed, and each of the equilibrium concentrations represented in Eq. 3 are thereby easily calculated from simple stoichiometric relationships. The data in Table I list the results from the calculations at two different ratios of boric acid to epinephrine. Since the ionic strength of the two systems differ, the difference in the calculated stability constants may be due to ionic strength effect or to other experimental considerations. Näsänen found a pK of 4.0 for catechol disulfonic acid with relatively large ionic strength effects.

Figure 4 presents the ultraviolet absorption spectra of epinephrine 0.022 *M* in the presence of 0.65 *M* boric acid at varying hydrogen ion concentrations. Since the extinction coefficient of boro-epinephrine chelate is not known with certainty, a modification of the method of Rosenblatt (14) must be used to calculate the stability constant from the absorption data. Equation 3 may be rewritten as

$$K' = [HB]K = \frac{[H^+][EpB^-]}{[Ep]} \qquad \text{(Eq. 4)}$$

since under the condition of the spectrophotometric analysis, [HB] $\sim$ constant. Substituting the appropriate extinction coefficients, we have

$$\frac{1}{K'} = \frac{1}{[HB]K} = \frac{\epsilon_{(EpB^-)} - \epsilon_n}{\epsilon_n - \epsilon_{(Ep)}} \frac{1}{[H^+]_n} \qquad \text{(Eq. 5)}$$

where ϵ_{Ep} = specific extinction coefficient of Ep; $\epsilon_{(EpB^-)}$ = specific extinction coefficient of EpB^-, and ϵ_n = specific extinction coefficient of a mixture of each component at the hydrogen ion concentration, $[H^+]_n$, or

$$-[H^+]_n\,\epsilon_n\left(\frac{1}{K'}\right) + [H^+]_n\left(\frac{\epsilon_{Ep}}{K'}\right) + \epsilon_{(EpB^-)} = \epsilon_n \qquad \text{(Eq. 6)}$$

This is a linear equation of four terms and three

unknowns since $[H^+]_n$ and ϵ_n are measurable quantities. This may be solved by use of a third-order determinant, or

$$[HB]K = K' = \frac{\begin{vmatrix} [H^+]_1\ \epsilon_1 & [H^+]_1\ 1 \\ [H^+]_2\ \epsilon_2 & [H^+]_2\ 1 \\ [H^+]_3\ \epsilon_3 & [H^+]_3\ 1 \end{vmatrix}}{\begin{vmatrix} \epsilon_1 & [H^+]_1\ 1 \\ \epsilon_2 & [H^+]_2\ 1 \\ \epsilon_3 & [H^+]_3\ 1 \end{vmatrix}}$$

The results from the analysis at two wavelengths are given in Table II. The calculated stability constants from the spectrophotometric studies compare surprisingly well with those determined by the titration method.

TABLE I.—CALCULATION OF THE STABILITY CONSTANT FOR THE BORO-EPINEPHRINE CHELATE FROM THE TITRATION DATA

Composition	pH	pK
Ep = 0.082*M* HB = 0.082*M*	4.66	4.65

TABLE II.—CALCULATION OF STABILITY CONSTANT FOR THE BORO-EPINEPHRINE CHELATE FROM U. V. SPECTROPHOTOMETRIC DATA

Composition	pH	A_{285} mμ	A_{240} mμ
Ep = 0.022 *M* HB = 0.648 *M*	5.10	0.835	0.725
	5.50	0.932	0.880
	5.83	0.950	0.960
	$pK_{285\ m\mu}$ = 4.66		
	$pK_{240\ m\mu}$ = 4.71		
[HB] equil. was assumed to be 0.625 *M*			

Closer examination of the sulfite attack on epinephrine in the presence of boric acid may now be made. The stability constant calculated above indicates that the reaction illustrated by Eq. 2 is predominantly shifted to the left at low pH. The ratio of the boric acid to the epinephrine and the hydrogen ion concentration both affect the concentration of free epinephrine in the system. Since there is a practical limit to the concentration to which we can increase the concentration of boric acid, the most important variable in the reaction is the hydrogen ion concentration. As the hydrogen ion concentration is decreased, the boro-epinephrine chelate concentration is increased, and the preparation is thereby stabilized to sulfite attack.

At pH's above 6.0 and at relatively high concentrations of boric acid, it becomes increasingly difficult to estimate the concentration of free epinephrine directly from Eq. 3. This is due to the fact that boric acid forms autocomplexes in the concentration ranges utilized which, in turn, affect the apparent dissociation constant of the boric acid (15, 16). In the pH range where the sulfite attack was studied, a portion of the base was utilized to titrate boric acid and polyboric acids.

The amount of free and chelated epinephrine can be evaluated by an alternative approach. Using the same ratio of boric acid to epinephrine as utilized in the deterioration studies (3.9/1), a series of solutions were made at 0.022 *M* epinephrine and 0.084 *M* boric acid and adjusted to the exact pH values used in the deterioration studies. The ultraviolet absorption spectra of the solutions were examined in a 0.1-mm. path length. Since two isosbestics were observed, solutions contained only two absorbing species. The spectrum of a solution of epinephrine hydrochloride in the absence of boric acid and a mixture of boric acid and epinephrine at pH 9.0 was also recorded. By analysis of the system at two wavelengths, the concentration of free epinephrine was determined for each solution. The data are recorded in Table III. Column 2 lists the fraction of free epinephrine as determined spectrophotometrically. In analogy to the approach of Higuchi and Lachman, the overall rate of reaction of epinephrine with sulfite is dependent on the reaction rate for the free and chelated epinephrine, or

$$k_{obs} = k_f F_f + k_c F_c \qquad \text{(Eq. 8)}$$

where the subscripts f and c stand for the free and chelated epinephrine, respectively, and F = the fraction of each form. If we assume that the rate of degradation of the chelated epinephrine is extremely small compared with the free, and substituting reciprocal half-lives for the respective rate constants we have, $F_f = (t_{1/2})_f/(t_{1/2})_{obs}$.

TABLE III.—COMPARISON OF CALCULATED AND EXPERIMENTAL ESTIMATION OF FREE EPINEPHRINE CONCENTRATION

pH	Calculated Free Epinephrine	Observed Free Epinephrine
6.0	0.45	0.45
6.5	0.22	0.315
7.0	0.069	0.15
7.5	0.031	0.058

Column 3, Table III lists the calculated fraction free from the data given in Figs. 1 and 2. It should be recalled that the solutions used in the degradation studies included 0.96 *M* sodium bisulfite, which produced an ionic strength far different from that used in the spectrophotometric evaluations. In addition, the latter measurements utilized solutions of identical ratio but diluted 3.75-fold in order to measure their absorbancies. While the deviation in columns 2 and 3 may be due to the changes in experimental conditions, an assumption that $k_c \leq 0.05\ k_f$ can approximate the values observed.

Effect of Boric Acid and Bisulfite on the Rate of Oxidation of Epinephrine

By SIDNEY RIEGELMAN and ELIEZER Z. FISCHER†

An investigation of epinephrine and sulfite oxidation in the presence and absence of light was undertaken to determine what effect complexation may have on the rate of oxidation of epinephrine under controlled conditions. The initial oxidative step is shown to be the oxidation of the sulfite ion. At a critical sulfite ion concentration, adrenochrome commences to form; however, the residual sulfite apparently reacts with the adrenochrome, resulting in a colorless adrenochrome sulfonate. It continues to form until all the sulfite is consumed, whereupon the solution deteriorates with visible discoloration. In the dark, epinephrine will remain stable to oxidation until light catalyzed, even after the destruction of all the sulfite and the formation of the adrenochrome sulfonate.

IT HAS BEEN reported recently by the authors (1) that boric acid stabilizes epinephrine against sulfite attack in an oxygen-free atmosphere. Epinephrine reacts with boric acid forming a boro-epinephrine chelate in accordance with the reaction given previously (1). The stability constant for the reaction was found to be 2×10^{-5}; however, use of an excess of boric acid and neutral or slightly alkaline pH conditions converts the vast majority of the epinephrine into the chelate form. The chelate form was found to be stable to sulfite attack. Since these conditions maintain stability of the epinephrine in the package until opened, it remains to investigate the effect of these additives on the stability of the epinephrine under oxidative attack.

The oxidation of epinephrine has been studied by many workers and has recently been reviewed by Heacock (2). At intermediate pH, epinephrine in aqueous buffered solution is oxidized to red substances; the speed of the reaction and the nature of the final products are dependent on the catalysts and buffers employed. In general, oxygen uptake begins only after a considerable induction period. Trace metals, particularly copper, manganese, and nickel, have been shown to initiate the reaction, possibly by the formation of an autoöxidizable epinephrine-metal chelate (3–5). Once the reaction is initiated, adrenochrome becomes a significant factor in the overall reaction rate (6, 7). Iron and copper chelating agents such as EDTA have been shown to increase the rate of oxidation, and other chelating agents also have been shown to increase the oxidation rate (8, 9). The catalytic action of adrenochrome has been postulated as being due to a chelated form of the compound (6). Trautner and Messer (10) reported on the effect of boric acid on the oxygen uptake of epinephrine and reported a stabilizing effect on epinephrine in alkaline solution.

Reducing agents such as sodium bisulfite (11), ascorbic acid, cysteine, and other reducing and

chelating agents (12) have been shown to inhibit the oxidation of epinephrine by molecular oxygen. Among these agents, sodium bisulfite appears to be the most commonly used antioxidant.

The oxidation of sulfite ions by oxygen has been shown to be a chain reaction, very sensitive to both positive and negative catalysts. One of the classical papers on this subject is the work of Fuller and Chryst in 1941 (13). These workers found that extreme precautions had to be taken to prevent metal contamination of their system. Double distilled water stored in hard-glass bottles was found to introduce spurious results after storage for longer than 3 hours. The rate of oxidation was affected by the rate of stirring and an adequate rate of oxygen absorption could not be maintained in solutions containing more than 0.015 *M* sulfite. The rate of cupric ion catalysis was found to be 10^9-fold the uncatalyzed rate under their conditions. Mannitol acted as a negative catalyst. The rate of oxidation is dependent primarily on the sulfite ion concentration, and bisulfite was much less easily oxidized. Later workers have confirmed the basic facts of the studies of Fuller. A detailed mechanism for the autoxidation of sulfite ions has been proposed by Abel (14, 15).

EXPERIMENTAL

Materials and Solution Preparation.—No special purification of distilled water, glassware, or of the reagent grade chemicals was undertaken. A single source of each chemical was used throughout. Efforts were taken to standardize the procedures used in the preparation of the solution to avoid the accidental incorporation of chance contaminants. Therefore, it is possible that the solutions were reproducible in respect to contamination and reflect best commercial manufacturing techniques.

Oxidative Method A.—Solutions containing 0.082 *M* epinephrine hydrochloride and varying amounts of sodium bisulfite and boric acid were adjusted to pH 6.5. A 25-ml. quantity of solution was placed in 200-ml. multiple-dose vials and attached to a reciprocating shaking device in a constant temperature bath at 25°. The solutions were open to air and exposed to light during the day from overhead fluorescent light, from a distance of approximately 10 feet. Samples were taken at the time of appearance of the visible red coloration of the solutions and at appropriate intervals thereafter. The solutions were examined for their absorbance at 440, 480, 550, and 600 mμ.

Oxidative Method B.—A fluorescent desk lamp containing two 20-inch fluorescent G. E. daylight tubes was inverted so that the light was reflected upward. Two polymethacrylate plates were separately spaced above the lights to allow air circulation. Glass beakers were thereby placed 2.5 inches from the light source. A Weston photometer was used to select that portion of the fluorescent tube which yielded uniform light intensity. Approximately the middle two-thirds was used.

Solutions containing sodium bisulfite and epinephrine, with or without boric acid, were studied alone and in combination. Air was bubbled through a coarse sintered-glass gas dispersion tube after water saturation and in a manner that the gas flow was essentially equal in all tubes. The rate of gas flow was as rapid as possible without dispelling a portion of the contents from the containers. In several determinations, the solutions were also stirred at 1750 r.p.m. by a two-bladed propeller. Certain solutions were covered with aluminum foil to exclude light, yet allowing other conditions of the experiment to remain unchanged.

The solutions were assayed for their sulfite content by iodometric titration and for their epinephrine deterioration products by spectrophotometric methods.

RESULTS AND DISCUSSION

Figure 1 illustrates a typical determination utilizing oxidative method B. These solutions contained 0.1% sodium bisulfite and were adjusted to pH with standard sodium hydroxide. Since the conditions for the reaction were not as ideal as used by Fuller, the curves were not exactly duplicated on repetition. However, the variation was of a minor qualitative nature. Curve A illustrates the rate of oxidation observed with the sodium bisulfite solutions buffered to pH 7.0 with boric acid and sodium hydroxide. The half-life of the reaction was observed to be 8 to 9 minutes in a series of five duplicate determinations. Curve B illustrates the results in the absence of boric

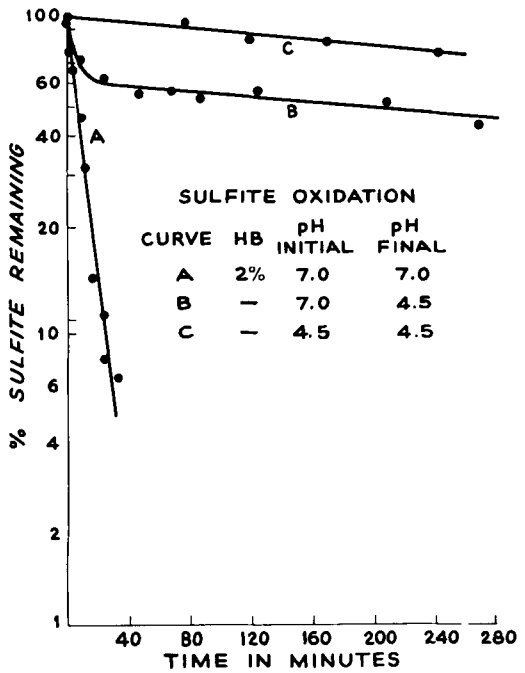

Fig. 1.—Oxidation of 0.1% sodium bisulfite solution at various initial hydrogen ion concentrations in the presence and absence of boric acid (HB). Data were obtained by oxidative method B.

acid buffer. Under these conditions, the oxidation of sulfite to sulfate ion increases the acidity of the solution. At pH 4.5, virtually all the sulfite ion vanishes and the oxidation rate is dependent on the remaining bisulfite ion concentration. This is verified by the data represented in curve C where the initial pH is adjusted to 4.5 and the rate of oxidation follows the linear portion of curve B.

As is well recognized, the first visible product of the oxidation of epinephrine is the formation of the red adrenochrome, which has a broad absorption maximum at 480 mμ. The onset and relative rate of oxidation can, therefore, be detected spectrophotometrically. The effect of sulfite and boric acid concentration on the rate of oxidation of epinephrine (method A) buffered at pH 6.5 is shown in Fig. 2. Two groups of curves are presented, all containing 1.5% (0.082 *M*) epinephrine. A comparison of the 0.2% to the 0.4% sodium bisulfite series indicates that the induction period is not doubled by a doubling of the concentration of the bisulfite. A solution containing 2.0% boric acid and 0.2% bisulfite has an induction period of 51 hours *vs.* 68 hours at the 0.4% level. An increase in concentration of boric acid at a fixed pH of 6.5 appears to accelerate the rate of oxidation of the bisulfite and therefore influences the length of the induction period. This may be due to trace impurities contained in the boric acid. Within experimental error, the slopes of the curves are identical, indicating that the rate of oxidation of the epinephrine is constant after the exhaustion of the antioxidant. An increase in concentration of boric acid will increase proportionately the concentration of the boro-epinephrine chelate, as is apparent from the reaction given by Eq. 1. This chelate does not influence the oxidative process under the present experimental conditions, possibly due to the presence of trace metals which form a much stronger chelate.

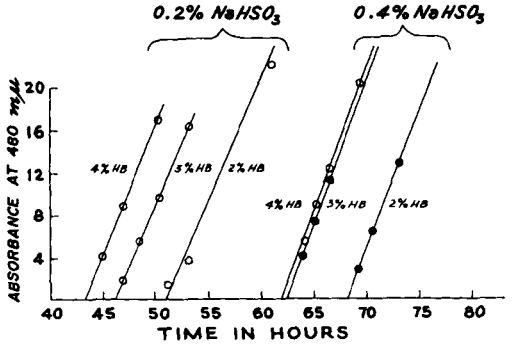

Fig. 2.—Oxidative studies on 1.5% epinephrine solutions at pH 6.5 by oxidative method A.

In the course of the assay of epinephrine solutions exposed to oxygen in the presence of bisulfite and boric acid buffer, a secondary ultraviolet absorption peak was observed at 350 mμ, increasing in intensity just prior to the development of the visible adrenochrome discoloration. In a recent study, van Espen (16), reported the formation of an adrenochrome bisulfite addition product, and presented detailed evidence indicating that this product is an adrenochrome sulfonate with the sulfonate group attached at position 4 or 7. The absorption spectrum of the

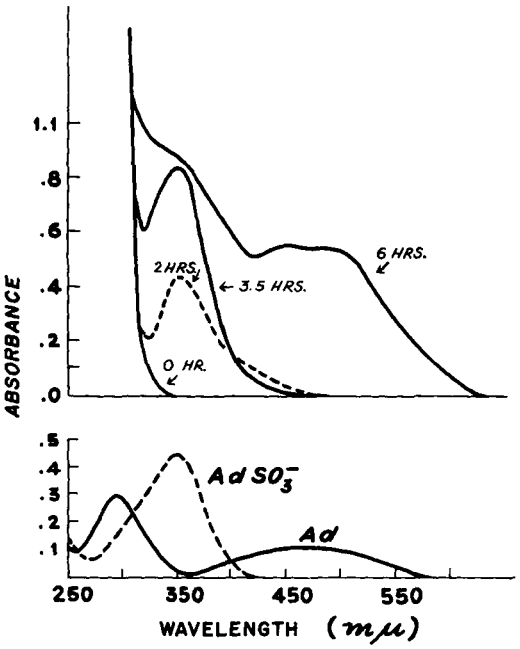

Fig. 3.—Upper curves: absorption spectra of epinephrine-bisulfite-boric acid solution at various intervals during the oxidation by method B. The curves were obtained from solution in a 3.0-mm. path length. Lower curves: absorption spectra of adrenochrome sulfonate ($AdSO_3^-$) and adrenochrome (Ad), redrawn from van Espen (16). Concentration = 2.8×10^{-5} *M*/L.; 1.0-cm. path length.

isolated compound was reported, and is redrawn in Fig. 3. The upper curves of Fig. 3 indicate the typical results obtained in spectrophotometric analysis of the epinephrine solutions. Prior to the exposure to oxygen by method B, the undiluted solution shows very strong absorption below 315 mμ due to the high concentration of epinephrine. Figure 3 includes the absorption curves for the same solution after 2, 3.5, and 6 hours. At the earlier periods, the solution contains bisulfite ions and is colorless to the eye; however, the absorption peak at 350 mμ indicates the presence of an oxidative product of epinephrine, probably the adrenochrome sulfonate, reported by van Espen. The 6-hour curves illustrates the results obtained after the oxidative reaction has exhausted all of the antioxidant. The curve indicates the presence of the adrenochrome sulfonate peak at 350 mμ, a considerable portion of adrenochrome since there is a peak with a maximum at approximately 480 mμ, and also the presence of higher oxidation products due to the secondary maximum at approximately 435 mμ.

Figure 4 presents a detailed experiment conducted by oxidative method B, utilizing a 1.5% epinephrine solution buffered at pH 7.0 including 2% boric acid and 1.0% sodium bisulfite. The rate of oxidation of the sulfite was followed iodometrically and the results are reported as the curve drawn through the closed circles. Under the conditions, the rate of oxidation is first order in respect to the bisulfite concentration. Even though the experimental conditions duplicated those used in the data presented in Fig. 1, the half-life for the initial portion of the reac-

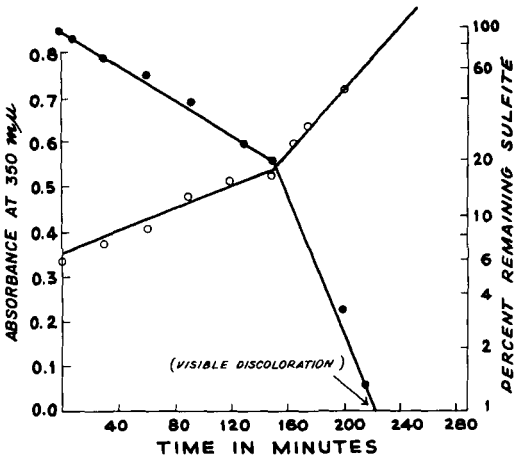

Fig. 4.—Illustrating the rate of oxidation of sulfite ions in the presence of 1.5% epinephrine and 2.0% boric acid at pH 7.0 (closed circles), and the rate of formation of adrenochrome sulfonate as measured by the absorbance at 350 mμ (open circles).

tion is approximately 65 minutes, while the identical solution in the absence of epinephrine possessed a half-life of 8 to 9 minutes. Catechol derivatives are known to be strong chelating agents (17, 18) for cupric and many other metallic ions, and it might be proposed that the epinephrine is a stabilizing agent for the sulfite by chelation of the trace metals.

It was interesting to note the marked change in rate of oxidation of the sulfite near the end of the reaction, even though the pH of the solution remained essentially constant. This second curve was duplicated repeatedly and could be followed to the last traces of sulfite in the solution. The half-life for the second reaction was roughly approximated to be 16 minutes. In a number of the experiments, the second portion was nonlinear. Simultaneous with the analysis of the sulfite content of the solutions, samples were examined spectrophotometrically at 350 mμ to obtain a more definitive understanding of the rate of appearance of the postulated adrenochrome sulfonate compound. The results are reported in Fig. 4 (open circles), and give a clear indication of the events taking place. Apparently there is a small progressive oxidation of a small number of the epinephrine molecules to adrenochrome sulfonate throughout the early part of the reaction, even though the sulfite is present in the solution. When the concentration of the bisulfite falls to approximately 20% of the original value, the rate of appearance of the adrenochrome sulfonate increases rapidly and the sulfite ions are withdrawn from the solution by two processes: (*a*) oxidation of sulfite, and (*b*) reaction with adrenochrome with the formation of adrenochrome sulfonate. The data of van Espen allows one to estimate the molar extinction coefficient of the adrenochrome bisulfite to be approximately 15,000. The increased rate of disappearance of sulfite in the second portion of the reaction cannot be accounted for completely on the basis of reaction with the adrenochrome. Therefore, an increase in the direct oxidative reaction must be presumed.

It must be emphasized that all of the oxidative studies of epinephrine reported above have been conducted under direct (method B) and diffuse (method A) exposure to fluorescent light. When identical solutions were run in the dark by either method, the rate of oxidation of the sulfite was represented by a constant rate of oxidation similar to the first portion of the bisulfite curve in Fig. 4. However, when all of the bisulfite is oxidized, epinephrine in the solution does not immediately oxidize. A long induction period follows which may be continued for days. Immediately after exposure to light, these solutions commence to oxidize and turn red.

It seems apparent, therefore, that some component in the solution is photochemically active in initiating the reaction. Since the 2-hour and 3.5-hour curves of Fig. 3 indicate the presence of an absorbing compound, believed to be adrenochrome sulfonate, it is postulated that this compound is the photochemically active molecule which catalyzes the initial stage in the epinephrine deterioration in the presence of sodium bisulfite. When the last traces of sodium bisulfite disappear, adrenochrome is no longer transformed to the colorless, but photochemically active sulfonate. Since adrenochrome absorbs in the visible, it can be postulated that higher light intensity in this region favors the catalysis via the adrenochrome.

Mechanism of Phenobarbital Degradation

By FREDERICK TISHLER, JOSEPH E. SINSHEIMER, and JERE E. GOYAN

Previous studies on the degradation of barbiturates have indicated that the products of hydrolysis of the ionic and nonionic forms might be different. During the course of a study on the analysis of phenobarbital it was discovered that one of the postulated products (phenylethylacetylurea) could be determined in the presence of phenobarbital. Experiments were therefore undertaken to follow the breakdown of phenobarbital and the ureide at different pH values. The pseudo first-order rate constants for phenobarbital and the ureide were then determined. Analysis of equilibria phenomena and series first-order reaction kinetics show that the fraction decomposing by the ureide path is dependent on the concentration of the ionic form as previously postulated.

PREVIOUS WORK on the degradation of barbiturates (1) led to the postulate that the mechanism of hydrolysis of the ionized and nonionized forms was different, leading to distinguishable intermediates[1] (Fig. 1). This postulate could be tested by determining the concentration of these intermediates as a function of varying concentrations of the ionic and nonionic forms. Unfortunately, the determination of these intermediates is difficult for most of the barbiturate series. During a study on the analysis of phenobarbital (2) it was found that both phenobarbital and the ureide (G) can be determined spectrophotometrically in the presence of the decomposition products of phenobarbital. This, therefore, makes it possible to test the postulated mechanism.

EXPERIMENTAL

Reagents and Apparatus.—Phenobarbital, U.S.P. grade was recrystallized from dilute ethanol, m.p. 176–178°. Phenylethylacetylurea was prepared by thermal degradation of a 5% aqueous solution of phenobarbital and isolation of the precipitate. The ureide was recrystallized from dilute ethanol, m.p. 147–149° (3–5).

Ammonia buffer solutions (0.2, 0.4, 0.6, and 0.8 total molarity NH_3 and NH_4^+) at pH values of 8.0, 8.5, 9.0, and 0.8 *M* at a pH of 8.2, 8.7, and 9.5 were used. The total ionic strength was adjusted to 1.0 with potassium chloride in each case. A Beckman model DU spectrophotometer and a Beckman zeromatic pH meter were used.

Assays.—The concentration of phenobarbital was followed by determining the change in absorbance at 241 mμ in the following manner: a 10-ml. sample was diluted to 100 ml. with ammonia buffer (pH 10.0) and two 10-ml. aliquots of this were taken. One of these was diluted to 100 ml. with the same ammonia buffer while the second sample was diluted with 10 ml. of 1.0 *N* hydrochloric acid and sufficient buffer to make 100 ml. (Final pH = 1.5.) This absorbance difference is now used to obtain the phenobarbital concentration free of interference by the breakdown products (2).

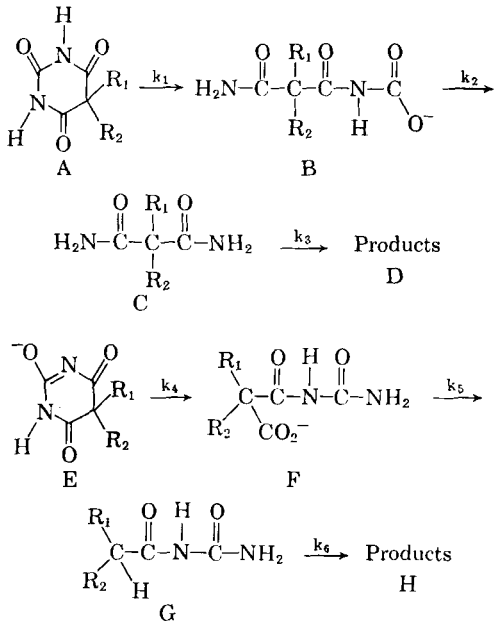

Fig. 1.—Degradation pathways of the nonionic and ionic species.

The concentration of phenylethylacetylurea during the degradation of phenobarbital was followed by measuring the absorbance of a 5-ml. sample at 245 and 260 mμ after the addition of 10 ml. of 1.0 *N* hydrochloric acid and dilution to 100 ml. with the pH 10.0 ammonia buffer. The use of simultaneous equations (after correction for the absorbance of phenobarbital) then made possible the determination of the ureide in the presence of diamide, or other interfering degradation products, all of which have approximately the same molar absorptivities at 245 and 260 mμ.

Concentration of Phenobarbital and Phenylethylacetylurea as a Function of Time.—Samples of phenobarbital (0.1% w/v final concentration) and

Received April 28, 1961, from the University of Michigan, College of Pharmacy, Ann Arbor.
Accepted for publication June 22, 1961.
Abstracted in part from a thesis by Frederick Tishler to be presented to the University of Michigan Graduate School in partial fulfillment of the requirements for the Ph.D. degree.
Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.
The authors wish to thank Dr. Lee Worrell whose early interest in the analysis of barbiturates made this study possible.

[1] A different mechanism has been proposed by Hasegawa, *et al.* (7). Their mechanism, however, does not allow for the production of the diamide which has been isolated as a hydrolysis product (3, 8).

phenylethylacetylurea (0.01% w/v final concentration) were made up at different pH values using various concentrations of ammonium chloride for each pH value. (See Table I.) The samples were sealed in ampuls and kept in a constant temperature water bath at 60 ± 0.1°.

The reactions followed a pseudo first-order course since the log of the absorbance plotted *vs.* time was a straight line (Figs. 2 and 3). Table I gives the pseudo first-order rate constants for the different samples as determined by the method of least squares.

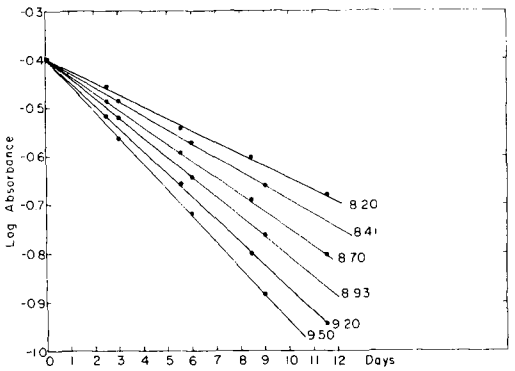

Fig. 2.—Degradation of phenobarbital at 60°. All at 0.8 *M*, numbers on individual lines are pH values.

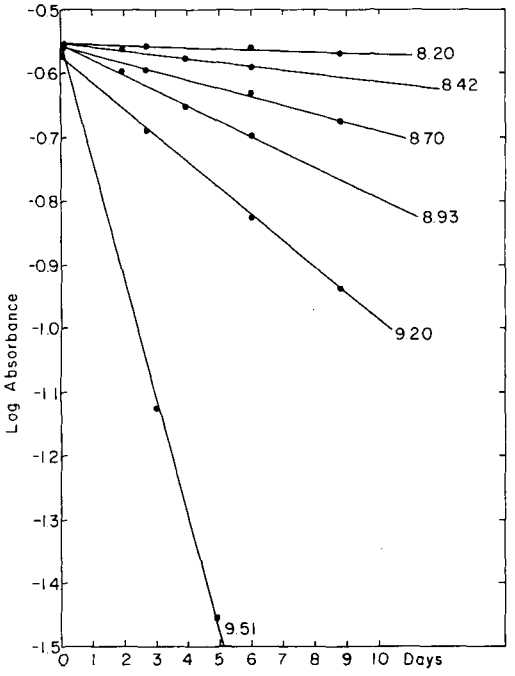

Fig. 3.—Degradation of phenylethylacetylurea at 60°. All at 0.8 *M*, numbers on individual lines are pH values.

DISCUSSION

In order to verify the similarity between the hydrolytic breakdown of phenobarbital and other barbiturates previously studied, a plot of the pseudo first-order rate constants *vs.* ammonium ion concentration was made (Fig. 4). These curves show a marked similarity to the curves obtained in previous work (1).

TABLE I.—FIRST-ORDER RATE CONSTANTS FOR THE DEGRADATION OF PHENOBARBITAL AND PHENYLETHYLACETYLUREA AT 60°

	Phenobarbital

0.1896	8.20	4.13×10^{-2}	...
0.3792	8.20	4.52×10^{-2}	...
0.5687	8.20	5.10×10^{-2}	...
0.7583	8.20	5.66×10^{-2}	4.03×10^{-3}
0.7030	8.42	6.70×10^{-2}	1.63×10^{-2}
0.1704	8.70	5.38×10^{-2}	...
0.3408	8.70	6.13×10^{-2}	...
0.5112	8.70	7.01×10^{-2}	...
0.6815	8.70	7.99×10^{-2}	3.10×10^{-2}
0.5569	8.93	9.29×10^{-2}	5.55×10^{-2}
0.1291	9.20	6.98×10^{-2}	...
0.2581	9.20	8.27×10^{-2}	...
0.3872	9.20	9.59×10^{-2}	...
0.5163	9.20	1.11×10^{-1}	9.55×10^{-2}
0.2922	9.51	1.23×10^{-1}	4.24×10^{-1}

The concentration of the ureide as a function of time may be predicted in the following manner (from Fig. 1)

$$E \xrightarrow{k_4} F \xrightarrow{k_5} G \xrightarrow{k_6} H$$

$$\frac{dE}{dt} = -k_4 [E], \quad \frac{dF}{dt} = -k_5 [F] + k_4 [E]$$

$$\frac{dG}{dt} = -k_6 [G] + k_5 [F]$$

Since species (F), the malonuric acid, is a very unstable compound (3, 5), it was assumed that $k_5 \gg k_4$ and the steady state approximation

$$-k_5 [F] + k_4 [E] = 0$$

or

$$[F] = \frac{k_4}{k_5} [E]$$

was made.

$$\therefore \frac{dG}{dt} = -k_6 [G] + k_4 [E]$$

This equation is solved in the usual manner (6) to obtain

$$[G]_T = \frac{E^0 k_4}{k_6 - k_4} [e^{-k_4 t} - e^{-k_6 t}] \quad \text{(Eq. 1)}$$

where E^0 is the original concentration of E.

If it is assumed that all of the barbiturate decomposes by the ureide path, E^0 becomes the original phenobarbital concentration, k_4 the pseudo first-order rate constant for the degradation of phenobarbital, and k_6 the pseudo first-order rate constant for the degradation of the ureide. The fraction of the total degradation going by the ureide path can then be defined as

$$f = \frac{[G]_M}{[G]_T} \quad \text{(Eq. 2)}$$

where $[G]_M$ is the measured concentration of ureide

TABLE II.—ANALYSIS OF FRACTION BY UREIDE PATH

pH	8.20		8.42		8.70		8.93		9.20		9.50

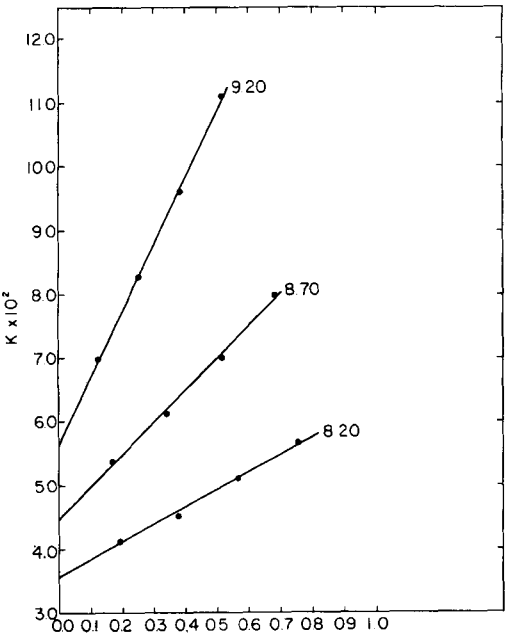

Fig. 4.—Pseudo first-order rate constants plotted *vs.* ammonium ion concentration at 60°. Numbers on individual lines are pH values.

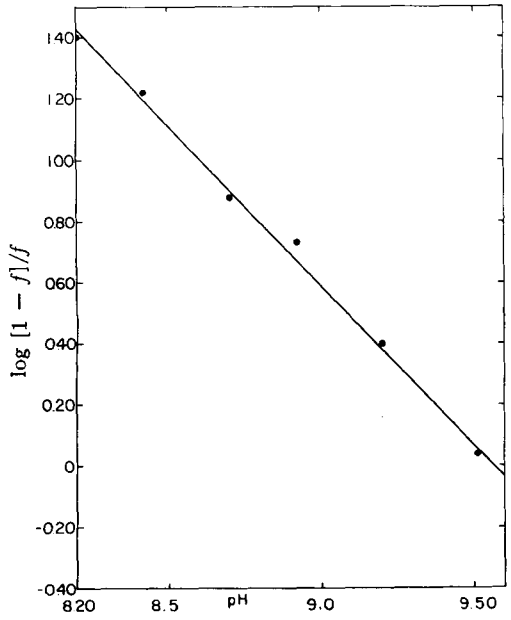

Fig. 5.—The effect of pH on fraction (f) degrading by ureide pathway.

at some given time and $[G]_T$ is the "theoretical" concentration computed by Eq. 1.

The assumption that the ureide pathway is taken by the ionized form of phenobarbital may now be formulated as follows: equilibrium requires

$$K_A = \frac{[E]\,[H^+]}{[A]} \qquad \text{(Eq. 3)}$$

where $[H^+]$ is the hydronium ion concentration of the solution

$$R_1 = k_1\,[A] \qquad \text{(Eq. 4)}$$

$$R_2 = k_4\,[E] \qquad \text{(Eq. 5)}$$

where R_1 and R_2 are the rates of degradation of the two forms, then

$$f = \frac{R_2}{R_1 + R_2} = \frac{k_4\,[E]}{k_1\,[A] + k_4\,[E]} = \frac{k_4\,[K_A]}{k_1[H^+] + k_4[K_A]} \qquad \text{(Eq. 6)}$$

and

$$1/f = 1 + \frac{k_1}{k_4\,K_A}\,[H^+] = 1 + \alpha\,[H^+] \qquad \text{(Eq. 7)}$$

or

$$\log\left[\frac{1-f}{f}\right] = \log\alpha - \text{pH} \qquad \text{(Eq. 8)}$$

Equation 8 therefore predicts that if the proposed mechanism is correct, a plot of log $[1 - f]/f$ *vs.* pH should be a straight line with a slope of -1. The experimental results are summarized in Table II and Fig. 5. The least squares slope of the line in Fig. 5 is -1.035. Thus, it appears that the proposed mechanism fits the experimental facts.

SUMMARY

1. The degradation of phenobarbital and phenylethylacetylurea have been followed concurrently in solution.

2. The results of these studies have been used to corroborate previous hypotheses about the degradation mechanism of barbiturates.

Studies on *Vinca major* (*Apocynaceae*) II

Phytochemical Investigation

By N. R. FARNSWORTH, H. H. S. FONG, R. N. BLOMSTER†, and F. J. DRAUS‡

Vinca major L. (*Apocynaceae*), commonly known as "Pervenche Grande" or the "Greater Periwinkle," has been mentioned frequently as a folk remedy. This plant, collected in Yugoslavia, has been subjected to a phytochemical screening and found to contain alkaloids, saponins, unsaturated sterols, organic acids, and phenols. Tannins, flavanols, and cardiac glycosides were not detected by the micromethods used. The results of a proximate analysis are also reported together with a method for the chromatographic separation of the total alkaloids. Paper partition and thin layer chromatographic data of the separated fractions are presented to indicate the complex character of the total alkaloids of this plant. An aqueous extract of the leaves and stems, as well as the total alkaloids, were shown to have no leukopenic activity in rats.

VINCA MAJOR[1] has been used for centuries as a folk remedy in the treatment of diabetes (2), as an abortifacient (2, 3), vulnerary, and in the treatment of menorrhagia (2). The plant has a wide distribution, having been introduced to the United States (4), England, Portugal, Spain, Malta, and Algeria (1). It is reported indigenous to France, Italy, Switzerland, Sicily, Madeira, Canary Islands, Crete, Rhodes, Chios, and the south and east coasts of the Black Sea (1). There is a great deal of current interest in the plants of the genus *Vinca*, not only because they are members of the alkaloid-rich *Apocynaceae*, but because of the recent isolation of the antileukemic alkaloid vincaleukoblastine from a related plant, *Catharanthus roseus* (L.) G. Don (*Vinca rosea* L.) (5).

To date, nine crystalline alkaloids have been isolated from *V. major* (Table I). They include reserpinine (6), vincamajoridine (akuammine) (7), vincamajoreine (8), vincamajine (9), perivincine (10), pubescine, vinine, and an alkaloid with m.p. 194–195° (11), as well as an alkaloid thought to be serpinine (6). Djerassi, *et al.* (12), have suggested that serpinine is identical with tetraphyllicine. In addition to these alkaloids, ursolic acid (13), dambonitol (14), and robinoside (15) have been isolated, and *o*-pyrocatechuic acid has been found to be present in acid hydrolysates of this plant (16).

TABLE I.—ALKALOIDS FROM *Vinca major* L.

No.	Name	Formula
1	Reserpinine	$C_{22}H_{26}N_2O_4$
2	Vincamajoridine	$C_{22}H_{26}N_2O_4$
3	Vincamajoreine	$C_{21}H_{26-28}N_2O_2$
4	Vincamajine	$C_{22}H_{26}N_2O_3$
5	Perivincine	$C_{22}H_{28}N_2O_4$
6	Pubescine	$C_{20}H_{26}N_2O_4$
7	Vinine	$C_{19}H_{26}N_2O_4$
8	Alkaloid m.p. 194–195°	
9	Serpinine (?) m.p. 316°	

The total alkaloids of *V. major* have been found to be ganglioplegics as well as spasmolytics, but only exert a transient hypotensive effect (17). Reserpinine (18) and perivincine (10) have been reported to produce only a transient hypotensive action in animals but vinine exerts a pronounced and prolonged blood pressure depression (11).

In this communication we wish to report the results of a phytochemical study of the leaves and stems of *V. major* and the effects of extracts of this plant on the leukocyte counts of rats.

EXPERIMENTAL

Phytochemical Screening.—The plant material used in this investigation was collected in Yugoslavia during the summer of 1957 and consisted of the dried leaves and stems.[2] The air-dried material was ground to a coarse powder and screened for alkaloids, saponins, flavanols, tannins, unsaturated sterols, organic acids, and phenols by the micromethod of Wall, *et al.* (19). In addition, cardiac glycosides were tested for by the method of Krider, *et al.* (20). The results of these tests are listed in Table II. There is some conflict of these results with those obtained by Wall, *et al.* (21), who used *V. major* leaves and twigs collected in Athens, Georgia, during 1951 and recorded negative alkaloid, organic acid, and phenol tests for this plant. The

negative alkaloid test by these workers can be explained on the basis of their extracts being too dilute. Their current revised alkaloid testing procedure has been modified so that instead of 1 ml. being equivalent to 0.2 Gm. of dry plant sample, it is now equivalent to 4.0 Gm. (22). The positive hemolysis test for saponins is due to the ursolic acid content of the leaves.

Proximate Analysis.—A proximate analysis of the air-dried leaves and stems of *V. major* was conducted according to standard U.S.P. and A.O.A.C. methods (23–30). The results are shown in Table III and represent averages for four determinations expressed in terms of the air-dried material.

Alkaloid Isolation and Fractionation.—The method used for the isolation of total alkaloids and separation into crude fractions I, II, and III has been previously reported (10). Figures 1 and 2 represent schematic outlines of this work.

Chromatographic Separation of Alkaloid Fractions.—*Fraction I.*—Three grams of fraction I (petroleum ether-insoluble) crude alkaloids was dissolved in 10 ml. of methanol with the aid of gentle heat. Fisher adsorption alumina, 10 Gm. (80–200 mesh, pH 9.95), which had been previously heated at 200° for 4 hours, was added to the solution of alkaloids and the mixture stirred on a water bath until the methanol was removed. A glass column (36 × 3/4 in.) was tightly packed with 230 Gm. of alumina, activated as described, and the alkaloid-adsorbed alumina added to the column in the same manner. A small pledget of glass wool was added to prevent disruption of the adsorbent on addition of the eluent. Elution of the alkaloids was effected by means of the following series of gradient eluents: benzene, benzene-methanol (99.5:0.5), benzene-methanol (99:1), benzene-methanol (98:2), benzene-methanol (95:5), benzene-methanol (90:10), benzene-methanol (50:50), and methanol.

Fractions were collected utilizing an automatic fraction collector equipped with a 20-ml. siphon.[3] Each fifth fraction was tested for alkaloids in the usual manner with Mayer's reagent. By observing the density of precipitation with this reagent it was possible to follow the relative concentration of alkaloids throughout the separation. Consecutive fractions were pooled according to the results of this estimation, evaporated to dryness, and weighed. When negative fractions could not be found for cut-off points, the low point between any two peaks was selected. The results of the separation of fraction I crude alkaloids are shown in Table IV.

TABLE IV.—CHROMATOGRAPHY OF FRACTION I (3 GM.)

Fraction No.	Volume, ml.	Eluent	Weight, Gm.	Test for Alkaloids

I-F	1,500	Benzene-methanol (90:10)	0.119	+
I-G	2,000	Benzene-methanol (50:50)	0.132	+
I-H	3,600	Methanol	0.245	+

Fraction II.—This fraction (benzene-petroleum ether-soluble) of alkaloids was treated in the same manner as fraction I except that 4 Gm. of crude alkaloids was dissolved in 10 ml. of chloroform and mixed with 10 Gm. of alumina prior to application on a 230-Gm. column of alumina, as previously described. The same series of gradient eluents was used (Table V).

Fraction III.—Four grams of fraction III (benzene-insoluble) crude alkaloids was extracted with five successive 20-ml. portions of methanol by trituration in a mortar, followed by filtration. The nonalkaloidal residue weighed 1 Gm. The methanol filtrates containing 3 Gm. of crude alkaloids were mixed with 23 Gm. of alumina and dried as previously described. This mixture was then placed on top of a packed column containing 200 Gm. of alumina and the same series of eluents added. The results are summarized in Table VI.

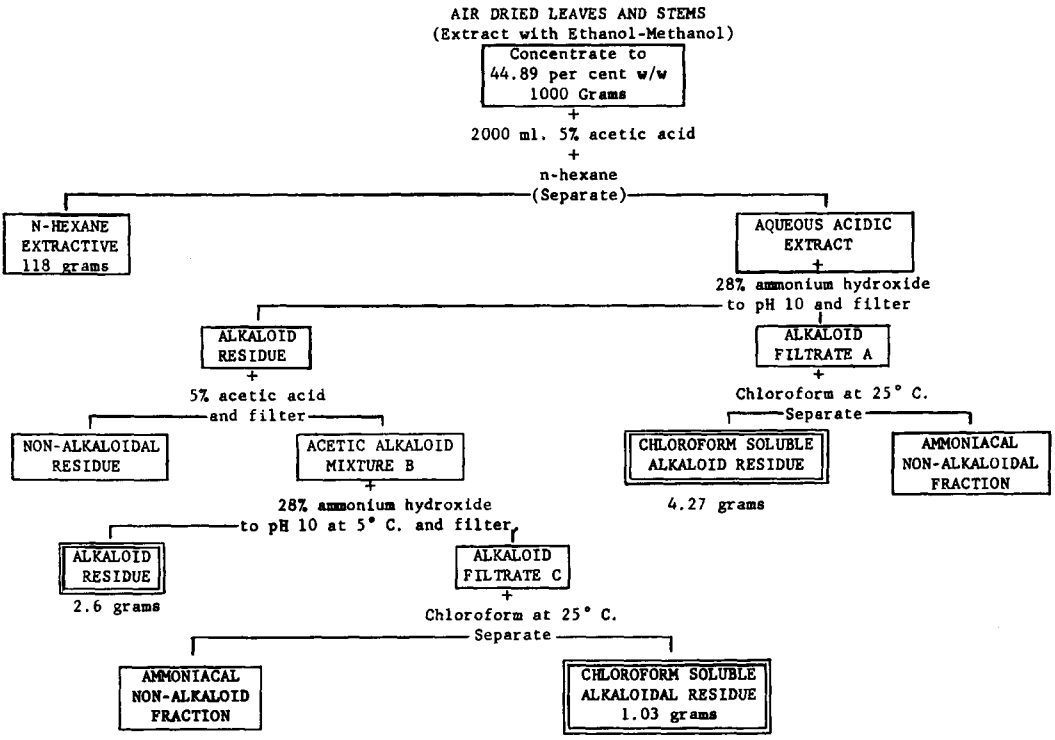

Fig. 1.—Flowsheet for the removal of the total crude alkaloids from the leaves and stems of *Vinca major*.

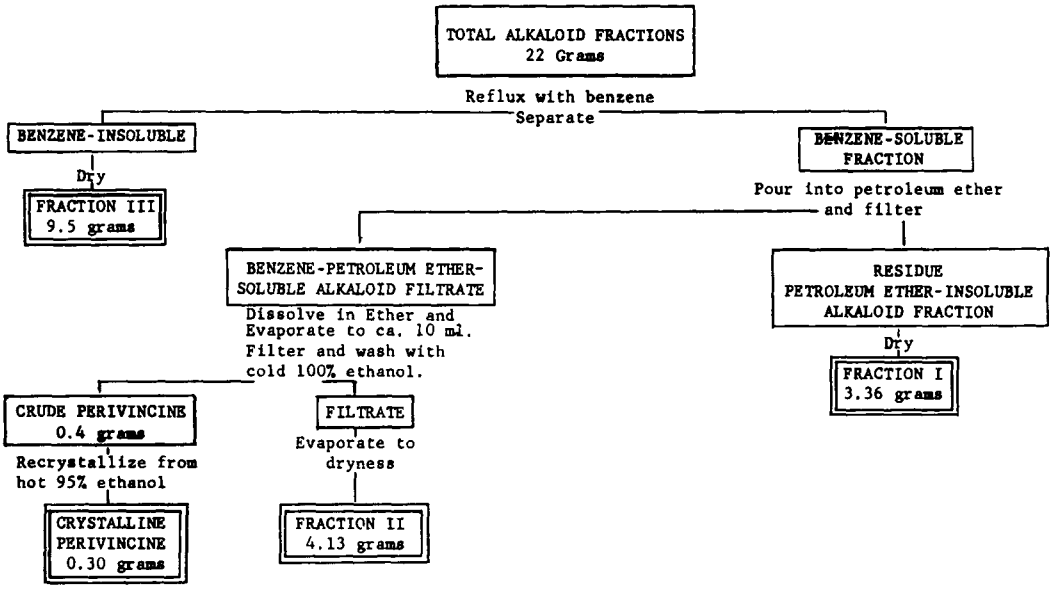

Fig. 2.—Flowsheet for the preliminary fractionation of the total crude alkaloids from the leaves and stems of *Vinca major*.

Alkaloid Composition of Separated Fractions.—The alkaloid composition of the separated fractions was determined by paper as well as by thin-layer chromatography. It was possible to determine alkaloid spill-over in this manner by the comparison of R_f values as well as by the color and intensity of the alkaloid spots, as viewed under ultraviolet illumination, and by the use of Dragendorff's reagent.

Paper Partition Chromatography.—The most efficient paper chromatographic method for the separation of *Vinca* alkaloids was found to be that of Korzun, *et al.* (31), with the modification of pH adjustment of the formamide with formic acid to

either pH 5.2 or pH 8.0. Samples of commercial formamide were found to vary in pH from 10.1 to 11.7 which led to variation in results. Solutions of the alkaloid fractions were prepared in either methanol or chloroform at 1% (w/v) concentrations and 50 λ of each applied. An equilibration period of 4 hours was found necessary in order to obtain reproducible results. The completed chromatograms were dried at 90–95° for one-half hour and then observed under long and short wave ultraviolet light. Fluorescent areas were outlined and the colors noted. After spraying with a modified Dragendorff reagent (32), the R_f values were calculated. In some instances areas giving a positive Dragendorff reaction were not distinct and appeared to run together. In these instances, the more sensitive fluorescent areas which had been marked, aided in the differentiation of distinct areas for R_f calculation. The results of chromatographing all of the alkaloid fractions in a system utilizing formamide adjusted to pH 8.0 are listed in Table VII. The R_f values tabulated represent averages of duplicate samples of each fraction.

[a] Each R_f represents the average from two chromatograms. Letters following each R_f refer to fluorescent color under long wave ultraviolet light: o = orange, b = blue, bb = brilliant blue, p = pink, y = yellow, g = green, oy = orange-yellow.

Thin-Layer Chromatography.—A rapid and relatively simple method for detecting the alkaloids in each fraction was thin-layer chromatography. Plates were prepared using silica gel G and the

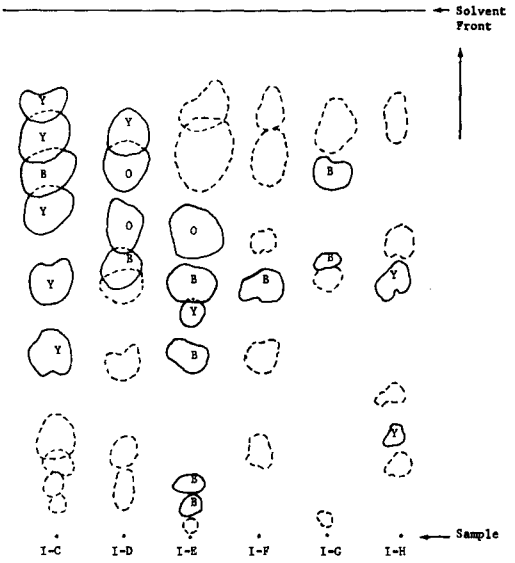

Fig. 3.—Thin-layer chromatogram of fraction I alkaloids using silica gel G adsorbent and chloroform-methanol (95:5) as eluent. Key: (under long wave U.V. light) B = blue, O = orange, Y = yellow fluorescence.

Desaga[4] apparatus. The adsorbent was mixed by slowly adding 40 ml. of distilled water, with stirring, to 30 Gm. of silica gel G. An additional 20 ml. of distilled water was then added, mixed thoroughly, and poured into the spreading applicator and applied to 200 × 200-mm. glass plates in the usual manner. The glass plates were then placed in a preheated oven at 105° for 30 minutes, allowed to cool to room temperature, and then spotted with the various alkaloid fractions. Solutions of the alkaloid fractions were prepared at 10% (w/v) concentrations in either methanol or chloroform. Ten-lambda increments were spotted on the prepared plates, allowed to air-dry, and then the plates were placed into equilibrated glass chambers lined with filter paper. Several eluents were used, with chloroform-methanol (95:5) giving the best separations. Normal development time was found to be about 1 hour. The results of the chromatographic separations using this method are shown in Figs. 3–5. Interpretation of the chromatograms was accomplished as previously described. The relative concentration of alkaloids, as indicated by the intensity of fluorescence under ultraviolet illumination, has been shown in the figures as follows: (*a*) spots of definite color and intensity are circled with a solid line enclosing a letter indicating the fluorescent color, (*b*) spots which could definitely be determined but were of low intensity so that colors could not be assigned to them are circled with broken lines.

Interpretation of Chromatograms.—The results of both the paper partition and the thin-layer methods of chromatography were compared to chromatograms of the following alkaloids:[5] reserpinine, yohimbine, α-yohimbine, lochnerine, vincamine, sarpagine, serpentine, vincamajoridine, ajmaline, ajmalicine, vincamajine, perivincine, reserpiline, tetrahydroalstonine, reserpine, deserpidine, and rescinnamine. The presence of serpentine, vincamine, sarpagine, and tetrahydroalstonine is strongly suspected from these results and work is now in progress to evaluate all of the alkaloid spots against a large number of reference alkaloids from the *Apocynaceae*. Although there is little doubt from our data that perhaps 40 or more distinct alkaloids are present in this plant, more work must be conducted to determine the extent of alkaloid spill-over from one fraction to another.

Screening of Extracts for Leukopenic Activity.—Noble, *et al.* (5), were the first to report on the leukopenic activity of *Vinca rosea* in experimental animals. Their study resulted in the isolation of vincaleukoblastine, the alkaloid responsible for the major portion of the leukopenic activity of crude extracts of *V. rosea*. Vincaleukoblastine is now available as an aid in the treatment of Hodgkin's disease and choriocarcinoma in humans.[6] Although these workers indicated that extracts of *V. major* as well as *V. minor* did not affect the blood picture of rats in their studies, it seemed advisable to confirm these results with studies using *V. major* from Yugoslavia, especially since Noble, *et al.* (5), reported that *V. rosea* plants grown as annuals in England possessed only about one-fourth of the leukopenic activity of plants grown as perennials in the West Indies. For testing purposes, two extracts were prepared; extract A was essentially an aqueous concentrate, containing all of the alkaloids of the plant in addition to other water-soluble materials, while extract B was a propylene glycol solution of total alkaloids as free bases.

Preparation of Extract A.—A Soxhlet extraction apparatus was packed with 380 Gm. of powdered air-dried leaves and stems and continuously extracted with methanol until free from alkaloids. The methanol extract was cooled to room temperature, filtered, and concentrated *in vacuo* at 40° to *ca.* 500 ml., mixed with 500 ml. of distilled water, shaken with Celite filter aid, and filtered. The filtrate was again concentrated *in vacuo* to 225 ml. which, after filtration, resulted in an alcohol-free aqueous extract containing the equivalent of 1.7 Gm. of air-dried plant material in each 1 ml.

Preparation of Extract B.—A portion of extract A was treated with 28% ammonium hydroxide solution to pH 10 with constant stirring. The precipitated alkaloids were removed by several extractions with chloroform. The combined chloroform extracts were dried over sodium sulfate, filtered, and evaporated to dryness *in vacuo*. The alkaloid residue was dissolved in propylene glycol to make a solution containing 0.155 Gm. in each 1 ml.

Leukocyte Counting.—Doses of 8.25 ml./Kg. of extract A and 0.82 ml./Kg. of extract B were selected after toxicity tests indicated that these doses were the highest that could be tolerated with 100% survival of all animals injected. Both total and differential leukocyte counts were performed in the usual manner utilizing blood from the tail of male albino rats.[7] All counts were made on consecutive

days and at approximately the same time each day. The rats were fed a normal diet *ad libitum*. The rats were divided into four groups of six animals each. In addition to daily blood counts, rat weight was tabulated since, according to Noble, *et al.* (5), leukopenia due to extracts of *V. rosea* was always accompanied by a drop in weight one to two days after i.p. injection. After 7 consecutive days of control normal blood counts from all animals, single i.p. injections were given. Group 1 received 8.25 ml./Kg. of extract A and group 2 received 8.25 ml. of distilled water as a control. Group 3 received 0.82 ml./Kg. of extract B, and group 4 received 0.82 ml./Kg. of propylene glycol as a control. Daily blood counts and weight recordings were continued for at least 6 days. The results as shown in Figs. 6 and 7 indicate that extract A and extract B do not depress the leukocyte counts under these experimental conditions. Differential counts in all groups remained within normal limits when compared to the control animals. These results are consistent with those reported by Noble, *et al.* (5), for their extracts of *V. major*.

DISCUSSION

This investigation has pointed out the complex nature of the total alkaloids of *V. major*. Through an interpretation of our chromatographic data, which will be reported at a later date, we can show the presence of at least 40 alkaloids in this plant. Although this is a rather large number it is not unusual since a related plant, *V. rosea*, has yielded at least 21 well described alkaloids at the time of this writing, in addition to four more which appear, from available data, to be additions to this list. *V. lancea* (*Catharanthus lanceus*) total alkaloids appear to include at least 70 separate alkaloids which we have been able to detect in some preliminary work by two-dimensional thin-layer chromatography. Although we have proposed that tetrahydroalstonine and sarpagine are present in the *V. major* alkaloids, it will be interesting, after additional work, to confirm this since these two alkaloids have not been reported to date as being present in any of the *Vinca* species which have been investigated, although they do appear in the *Catharanthus* group. Interestingly enough, of the 21 alkaloids isolated to date from species of *Catharanthus*, only vincamajoridine (akuammine) has been reported to be present in any of the *Vinca* species.

It has become evident to us during this investigation that thin-layer chromatography will prove to be an invaluable tool in phytochemistry and especially in chemotaxonomic studies. The method is simple, rapid, and accurate for the tentative identification of substances which are chromatographed on the same plate with known reference compounds.

The chromatographic separation of alkaloid fractions from *V. major* on a pilot scale has indicated that reasonable separation of alkaloids has been accomplished and that by inspection of paper and

thin-layer chromatograms, we can group certain eluates prior to attempting crystallizations from them.

SUMMARY

1. A phytochemical screening of the leaves and stems of *Vinca major* L. collected in Yugoslavia has shown the presence of alkaloids, saponins, unsaturated sterols, organic acids, and phenols. Tannins, flavanols, and cardiac glycosides were not detected.

2. A proximate analysis of the plant material is reported.

3. Methods for the separation of total alkaloids as well as their fractionation by gradient elution chromatography on alumina and detec-

tion by paper partition and thin-layer chromatography are described.

4. Screening of an aqueous extract as well as the total alkaloids of *V. major* in rats for possible leukopenic activity has confirmed a previous report of the absence of such activity.

Stability of Antibacterial Preservatives in Parenteral Solutions I

Factors Influencing the Loss of Antimicrobial Agents from Solutions in Rubber-Stoppered Containers

By L. LACHMAN, S. WEINSTEIN, G. HOPKINS†, S. SLACK, P. EISMAN, and J. COOPER

Losses of preservative due to degradation and absorption in rubber-closed multiple-dose vials were investigated. The preservatives evaluated were benzyl alcohol, phenylethyl alcohol, *p*-chloro-β-phenylethyl alcohol, chlorobutanol, and methylparaben. The elastomer closures used in this study were intended to be representative of those most commonly employed for pharmaceuticals and were natural, neoprene, and butyl rubbers. The temperature dependency of the degradation and diffusion processes were studied. An attempt was made to correlate preservative loss and microbiological activity.

RUBBER CLOSURES are used extensively by pharmaceutical manufacturers to seal vials containing injectable solutions. It is well known that rubber may react with, absorb, or even dissolve substances in contact with it. Thus, incompatibilities between elastomer closures and injectable solutions occur frequently, thereby presenting many problems. One such very important problem is the interaction between rubber closures and bacteriostatic agents present in the solutions. These agents are added to multiple-dose parenteral preparations to insure bacteriostasis for the life of the product. Loss of preservative from solution by interaction with rubber closures could result in bacterial contamination of the injectable preparation if bacteria were accidently introduced.

The 1953 edition of the British Pharmacopoeia (1) recognizes the tendency of rubber to absorb preservatives from injectable solutions. It therefore directs that closures for parenteral solutions should be boiled in several changes of distilled

Stability of Antibacterial Preservatives in Parenteral Solutions I

Factors Influencing the Loss of Antimicrobial Agents from Solutions in Rubber-Stoppered Containers

By L. LACHMAN, S. WEINSTEIN, G. HOPKINS†, S. SLACK, P. EISMAN, and J. COOPER

Losses of preservative due to degradation and absorption in rubber-closed multiple-dose vials were investigated. The preservatives evaluated were benzyl alcohol, phenylethyl alcohol, *p*-chloro-β-phenylethyl alcohol, chlorobutanol, and methylparaben. The elastomer closures used in this study were intended to be representative of those most commonly employed for pharmaceuticals and were natural, neoprene, and butyl rubbers. The temperature dependency of the degradation and diffusion processes were studied. An attempt was made to correlate preservative loss and microbiological activity.

RUBBER CLOSURES are used extensively by pharmaceutical manufacturers to seal vials containing injectable solutions. It is well known that rubber may react with, absorb, or even dissolve substances in contact with it. Thus, incompatibilities between elastomer closures and injectable solutions occur frequently, thereby presenting many problems. One such very important problem is the interaction between rubber closures and bacteriostatic agents present in the solutions. These agents are added to multiple-dose parenteral preparations to insure bacteriostasis for the life of the product. Loss of preservative from solution by interaction with rubber closures could result in bacterial contamination of the injectable preparation if bacteria were accidently introduced.

The 1953 edition of the British Pharmacopoeia (1) recognizes the tendency of rubber to absorb preservatives from injectable solutions. It therefore directs that closures for parenteral solutions should be boiled in several changes of distilled

Received April 28, 1961, from the Research Department, Ciba Pharmaceutical Products, Summit, N. J.

water and then either boiled under a reflux condenser for 30 minutes, or stored for not less than 48 hours in a solution containing the same bacteriostat in the same concentration as in the injectable solution, or preferably in twice this concentration. However, the British Pharmacopoeia adds the further precaution that in prolonged storage, rubber so treated is still likely to absorb preservative from the injectable solution.

As early as 1923, Masucci and Moffat (2) reported on the substantial loss of cresol or phenol from rubber-capped vials of solutions stored at room temperature. The loss of preservative was explained as due to the vaporization of cresol or phenol through the rubber caps. In 1937 McGuire and Falk (3), studying certain biological products, found that 0.5% phenol was reduced to 0.3% after 237 days at 37°, while controls with glass-stoppered containers underwent no diminution of preservative content.

Within recent years, the influence of vial stoppers on the preservative content of parenteral products has received considerable attention. Wiener (4) studied the effect of various composition rubber closures on the bacteriostatic action of thiomersolate and observed great variability as to their interference with antibacterial properties. Berry (5) has shown that rubber caps could reduce the strength of a 0.1% chlorocresol solution by as much as 75% under normal conditions of storage. Wing (6–8) and Nielsen (9) studied the absorption of phenol and chlorocresol by elastomer caps. Wing (8) also investigated the effects of varying the chemical composition of the rubber mix on the absorption of these preservatives. Royce and Sykes (10) determined the loss of phenol, cresol, benzyl alcohol, chlorocresol, chlorobutanol, and phenylmercuric nitrate from rubber-closed multiple-dose containers. Of these preservatives, phenol and benzyl alcohol were the least affected and phenylmercuric nitrate the most affected. These investigators also evaluated the methods recommended in the British Pharmacopoeia for the pretreatment of rubber closures and found that they were not adequate to equilibrate the rubber with the preservative in solution. Wiener (4) also found this to be true in the case of thiomersolate.

It is evident from these studies that a considerable amount of work has been done relating the effects of rubber closures on preservative agents. In most instances, however, the investigators did not define the compositions of the rubber closures used. It must therefore be realized, when considering these data, that another composition closure might not produce the same effects. Siddell (11) reviewed the problems as they relate to chemical uniformity of vial stoppers. He attributed the existence of these problems to inadequate quality standards and poor control of methods of manufacture. Since 1954, attempts have been made in the United States and England to develop standards which would control the composition and properties of rubber closures. The lack of success in this endeavor is evident in the U.S.P. XVI, whose only specification for rubber closures is that "containers and closures shall not physically or chemically interfere with the preparations in any manner to alter the strength, quality, or purity beyond the official requirements."

In most of the previous work, little consideration was given to the possible degradation of preservative in solution. Generally, only the absorption or diffusion characteristics were evaluated. This study evaluates several preservatives with three commonly used rubber closures for (*a*) preservative degradation in solution, (*b*) loss of preservative due to absorption or diffusion into and through the closure, (*c*) influence of chemical structure on diffusion characteristics, (*d*) temperature dependency of the degradative and diffusion processes, (*e*) relationship of preservative loss to microbiological activity, and (*f*) changes in the physical properties of the rubber in contact with the preservative solutions.

EXPERIMENTAL

Materials.—0.275 *M* Citric acid-sodium phosphate buffer of pH 4.0. *p*-Chloro-*β*-phenylethyl alcohol, Ciba, b.p. 80–83° at 1.07 mm. Phenylethyl alcohol, Eastman Organic Chemicals. Benzyl alcohol, reagent grade, Fisher Scientific Co. Methylparaben U.S.P. Chlorobutanol, anhydrous, U.S.P. Elastomer closures: V-32-natural crepe, neoprene polymer, and butyl polymer, West Co. U.S.P. type I, 10-ml. amber ampuls and vials, Kimble Glass Co. Three piece aluminum caps for vials, West Co., No. 13-30.

Equipment.—Beckman spectrophotometer model DU. Beckman spectrophotometer model DK-2. Shore type A hardness tester. Beckman pH meter model G.

Preparation of Closures and Vials. The stoppers used in this study were immersed in a 1.0% solution of tetrasodium pyrophosphate and heated at 90° for 15 minutes under constant agitation. They were removed from the solution and washed 10 times with distilled water and then five times with filtered water for injection. The stoppers were dried at 40° for 48 hours before use.

The ampuls and vials were washed, placed into special pans, and covered. These pans of ampuls and vials were sterilized at 180° for 2 hours.

Preparation of Ampuls and Vials of Preservative Solution.—Solutions containing (*a*) 0.3% *p*-chloro-*β*-phenylethyl alcohol, (*b*) 0.5% phenylethyl alcohol.

(*c*) 1.0% benzyl alcohol, (*d*) 0.2% methylparaben, and (*e*) 0.5% anhydrous chlorobutanol, on a weight to volume basis, were prepared with water for injection buffered to pH 4.0. The preservative solutions were then passed through medium porosity sintered-glass filters. Each preservative solution was filled into 10-ml. amber ampuls and vials. The ampuls were closed by customary pull sealing techniques under an oxygen-gas flame. The vials of each preservative were stoppered with three different composition closures. The stoppered vials were then sealed with three-piece aluminum caps at a constant sealing head pressure of 60 p.s.i. with a Westcapper. Samples of buffer solution in ampuls and vials were filled and sealed similarly. The buffer and preservative solutions in ampuls and vials were placed into constant temperature ovens regulated at 25, 40, 50, and 60, ±1.5°. Half of the vials were stored upright and half inverted. The constant temperature equipment employed has been described in a previous publication (12). At designated time intervals, samples were withdrawn and tested for residual preservative content, microbiological activity, pH, and physical changes. In addition, physical tests were performed on the closures to determine whether or not changes had taken place as to hardness, shape, and color. As a control, buffer solutions in ampuls and vials were run concurrently.

Loss of Preservative Upon Sterilization.—Samples of each of the five preservative solutions in vials stoppered with natural, neoprene, or butyl rubber and in ampuls were autoclaved at 115°, 10 p.s.i., for 30 minutes. Assay for residual preservative content was then performed.

Apparent Distribution of Preservative Between Buffer Solution and Rubber.—Ten-millimeter aliquots consisting of (*a*) *p*-chloro-β-phenylethyl alcohol, (*b*) phenylethyl alcohol, and (*c*) chlorobutanol were filled into 20-ml. amber ampuls. The ampuls containing each preservative were separated into three groups. In one group, 5 Gm. of natural rubber stoppers (cut in half) were placed into each ampul; into each ampul of the second group cut neoprene polymer stoppers were added. No stoppers were added to the ampuls of the third group. The ampuls were pull sealed and placed into constant temperature ovens regulated at 25 and 40 ±1.5°. At the end of 4 weeks' storage the ampuls were removed and the solution assayed for residual preservative. Apparent distribution coefficients were calculated as follows

$$K_T = \frac{10(C_A - C_B)}{C_B V} = \frac{C_R}{C_B}$$

where K_T = apparent distribution coefficient at temperature T, C_A = concentration of preservative in ampul solution after storage without closures (mg./ml.), C_B = concentration of preservative in ampul solution after storage with 5 Gm. of closures (mg./ml.), V = volume of 5 Gm. of rubber, $10(C_A - C_B)$ = concentration of preservative in rubber (mg.), and $[10(C_A - C_B)]/V = C_R$ = concentration of preservative in rubber calculated as mg./ml.

To avoid discrepancies in the distribution values due to degradation of preservative in solution, the concentration of preservative in the ampul solution without closures, after 4 weeks' storage at the above temperature conditions (C_A), was taken as the total preservative concentration for the calculation of K_T.

Analytical Methods. — *Chlorobutanol.* — The method employed is essentially that of Rehm and Mader (13) with minor changes. The undegraded chlorobutanol in solution was determined by pipetting a 3-ml. aliquot of solution into a suitable microsteam distillation apparatus. One drop of concentrated sulfuric acid was added and the sample steam distilled for 3 minutes. The condenser was washed down with warm distilled water and the rinsings added to the distillate to make a total volume of 50 ml. The remainder of the procedure was according to the method of Rehm and Mader in the absence of interfering substances: mg. chlorobutanol/ml. = A sample/A standard × 0.5 × dilution factor measured at the absorption maximum of 500 mμ.

p-Chloro-β-phenylethyl Alcohol.—Residual preservative was determined by pipetting 5 ml. of solution into a microsteam distillation apparatus. The sample was steam distilled and 40 ml. was collected. Then 50 ml. of methanol was added to the distillate and brought up to volume with distilled water in a 100-ml. volumetric flask. Absorbance was measured at 267.5 mμ where $A(1\%, 1\text{ cm.}) = 22$.

Phenylethyl Alcohol.—The concentration of preservative was determined by pipetting 3 ml. of solution into a microsteam distillation apparatus and the sample steam distilled to 30 ml. The distillate was brought up to 50 ml. in a volumetric flask with distilled water. Absorbance was measured at 257 mμ where the $A(1\%, 1\text{ cm.}) = 18$.

Benzyl Alcohol.—The method employed was similar to that used for phenylethyl alcohol, except that 1 ml. of solution was pipetted into a microsteam distillation apparatus and steam distilled to 25 ml. and absorbance was measured at 257 mμ where $A(1\%, 1\text{ cm.}) = 18$.

Methylparaben.—A 5-ml. aliquot was pipetted into a 100-ml. volumetric flask and brought up to volume with methanol. Five milliliters of this solution was transferred to another 100-ml. volumetric flask and brought up to volume with methanol. Absorbance was measured at 256 mμ where $A(1\%, 1\text{cm.}) = 1{,}115$.

Zinc Mercaptobenzothiazole.—This substance was leached from the rubber and detected by the presence of a sharp peak at 318 mμ in the ultraviolet spectra of the preservative solutions. The concentration of this material was measured at 318 mμ where the $A(1\%, 1\text{ cm.}) = 16.7$.

Chromatography of Degraded Samples.—Thin-layer chromatography, according to the method of Stahl (14), was performed on each of the preservatives after storage in vial solutions at a pH of 4.0 and at 60° for 12 weeks. The concentrations of preservative placed on the layered plates were (*a*) 60 γ *p*-chloro-β-phenylethyl alcohol, (*b*) 100 γ phenylethyl alcohol, (*c*) 200 γ benzyl alcohol, (*d*) 40 γ methylparaben, and (*e*) 100 γ chlorobutanol. Silica gel G was used as the layer and the solvent system employed was benzene-acetone (1:1). The detecting reagent used for spraying the plates was composed of equal volumes of 1% aqueous solutions of ferric chloride and potassium ferrocyanide.

Measurement of Rubber Hardness.—A Shore type A-2 hardness tester was used. Measurements were made on the flange of the stoppers and readings were taken in triplicate and averaged.

Microbiological Tests.—*Bactericidal Activity of Preservatives.*—The phenol coefficient-type test employed involved the contamination of various concentrations (in pH 4 buffer) of the five preservatives under study with *S. aureus* and *E. coli*. The concentration of preservative necessary to destroy all the test organisms in less than 15 minutes, but not in 10 minutes, was determined by subculturing into fresh broth after contact periods of 5, 10, and 15 minutes.

Self-Sterilizing Properties of the Preservatives.—Solutions of the five preservatives, buffered to pH 4 and at the concentration noted earlier in this section, were evaluated as to the time required to destroy 50 and 95% of the following test organisms: *E. coli*, *S. aureus*, and the spores of *B. cereus* var. *mycoides*. Plate counts for the number of surviving organisms were performed after 1, 3, 5, 24, 48, 72, and 96 hours, and again after 7 days. In addition, at these time intervals, aliquots were tested for sterility by transferring to thioglycollate fluid medium.

Correlation of Chemical Assay to Microbiological Activity.—The microbiological assay method was investigated with only *p*-chloro-β-phenylethyl alcohol. It involved the development of a standard curve by using preservative concentrations in pH 4 buffer solution from 0.3 to 0.06% and diluting 1:7 with buffer solution before contamination. The solutions were contaminated by adding 1-ml. amounts of an 18-hour diluted culture (91% light transmission in a Bausch and Lomb Spectronic 20 colorimeter fitted with a No. 580 light filter) of *E. coli* to 14-ml. quantities of solution. At various time intervals, 1-ml. portions were removed and plated in trypticase soy agar for survivor count. Curves were plotted of per cent survivors *vs.* time for each concentration and the time required to produce 50% killing was obtained from the plots. A standard curve was then drawn of the time required to kill 50% of the organisms *vs.* concentration of preservative. Using the 50% killing time value of a degraded sample of preservative and placing it on the standard curve, an estimate of the residual concentration of preservative was obtained.

RESULTS AND DISCUSSION

The decrease in concentration of several bacteriological preservatives in aqueous buffered solutions stored in rubber-stoppered vials was investigated. These solutions were buffered to a pH of 4 in order to maintain a constant hydrogen ion concentration as well as to permit the study of chlorobutanol at a pH in which degradation in solution would be minimal.

The stoppers chosen for evaluation are representative of three rubber compositions commonly employed for multiple-dose vial closures. The composition and per cent rubber content of these stoppers are presented in Table I. Several of the physical properties of these closures are given in Table II.

Chemical and Physical Results.—An ascending thin-layer chromatographic technique was employed to distinguish decreases in preservative content in rubber-stoppered vial solutions which had been stored at 60° for 12 weeks. From the chromatogram in Fig. 1, it was estimated that in the case of chlorobutanol approximately a 90% reduction in concentration had occurred while for the other preservatives about a 50% reduction in concentration resulted. Consequently, additional studies were performed to ascertain the portion of preservative lost due to degradation in solution as well as the amount lost by reaction with the rubber stopper.

TABLE I.—CLOSURE COMPOSITION

Natural Rubber	Neoprene Rubber	Butyl Rubber
Natural crepe[a]	Neoprene polymer[b]	Butyl polymer[c]
Titanium dioxide	Sulfonated oil	Barium sulfate
Barium sulfate	Calcined clay	Calcined clay
Zinc oxide	Barium sulfate	Carbon black
Iron oxide	Zinc oxide	Titanium dioxide
Diphenylamine-acetone condensation product	Magnesium oxide	Stearic acid
	Iron oxide	Paraffin wax
Thiuram combined with aniline reaction product	Stearic acid	Sulfur
	Mineral oil	Thiazole-dithiocarbamate accelerator
	Imidazoline type accelerator	

[a] Rubber content, 50.4% of total composition. [b] Rubber content, 42.4% of total composition. [c] Rubber content, 36.9% of total composition.

TABLE II.—PHYSICAL CHARACTERISTICS OF THE RUBBER STOPPERS

Properties	Stopper Composition		
	Natural Rubber	Neoprene Rubber	Butyl Polymer
Specific gravity	1.600	1.490	1.609

Weight[b]	618 mg.	548 mg.	595 mg.

[a] Measured microscopically and value is average of five measurements of different stoppers. [b] Value is average of 10 stoppers.

Chlorobutanol.—Chlorobutanol has been used widely as a bacteriostatic agent in parenteral solutions. The results of a number of studies on the stability of chlorobutanol in solution have been reported (15–20). The majority of these reports (15, 17–20) are concerned with the instability of chlorobutanol solutions during autoclaving. Several investigators (18, 19) have found that decomposition is minimal at pH 5 or below. Recently, a comprehensive quantitative study of the degradation of chlorobutanol was performed by Nair and Lach (21) who evaluated the kinetics of the degradation over a pH range from 2 to 7.5. From pH 2 to 4 the decomposition was found to be pH independent and having a half-life of about 90 years at 25°. However, at pH 7.5, the half-life dropped sharply to slightly less than 3 months. Therefore, for pharmaceuticals containing chlorobutanol as the preservative, it appears desirable to buffer the solution to pH 4 or below in order to minimize the degradation reaction.

In this investigation, the influence of natural, neoprene, and butyl rubber stoppers on the concentration of chlorobutanol in vial solutions buffered at pH 4 was studied. The residual concentrations of chlorobutanol in ampul solutions found at different time intervals and at several elevated temperatures are shown in Fig. 2. It is evident from the plot that the degradation reaction is first order with respect to chlorobutanol concentration. Using the integrated Arrhenius equation, the heat of activation was calculated employing the rate constants at

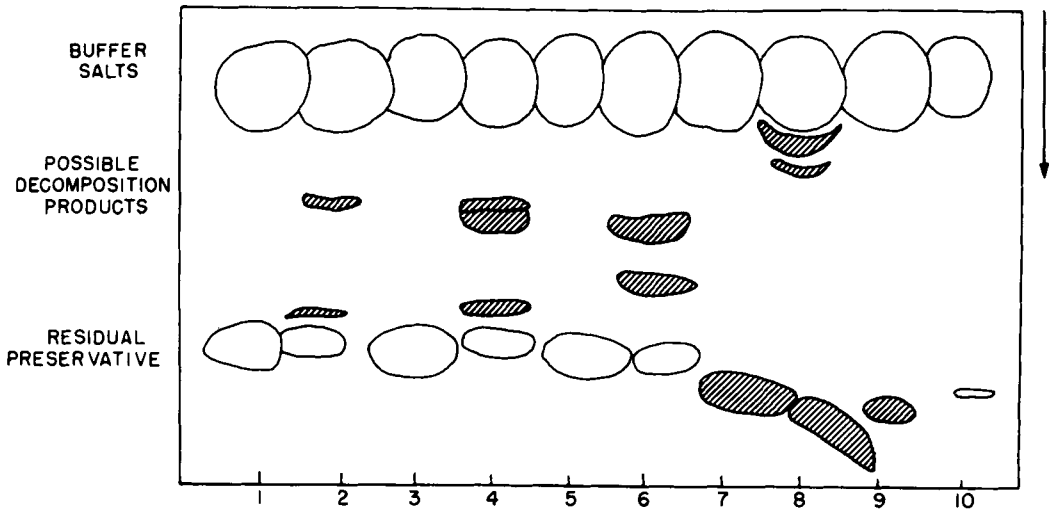

Fig. 1.—Thin-layer chromatograms of aged (60° for 12 weeks) and freshly prepared solutions of the five preservatives. 1, *p*-Chloro-β-phenylethyl alcohol standard solution; 2, *p*-chloro-β-phenylethyl alcohol after storage; 3, phenylethyl alcohol standard solution; 4, phenylethyl alcohol after storage; 5, benzyl alcohol standard solution; 6, benzyl alcohol after storage; 7, methylparaben standard solution; 8, methylparaben after storage; 9, chlorobutanol standard solution; 10, chlorobutanol after storage. ▨, Blue stain; □, white stain.

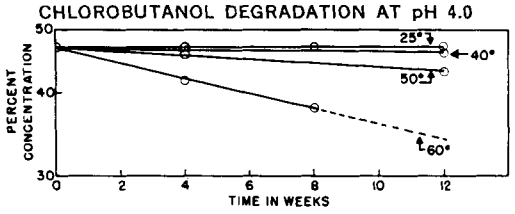

Fig. 2.—Plot of the logarithm of the per cent residual concentration of chlorobutanol against time at pH 4.0.

50 and 60°. A value of 27.6 Kcal. was obtained as the heat of activation for the degradation of chlorobutanol at pH 4. This is a reasonable value for a hydrolytic reaction of this nature and is in fair agreement with the value of 30.7 Kcal. obtained by Nair and Lach (21) for this reaction.

A comparison of chlorobutanol loss in vials stoppered with these different composition closures with that found for solutions in ampuls is presented in Table III. It is evident from these data that the closures have a marked deleterious effect on preservative concentration at all temperatures. This greater loss of preservative in the vial solutions can be attributed to (*a*) adsorption and absorption of preservative by the rubber, (*b*) possible diffusion of the preservative through the rubber and subsequent volatilization into the atmosphere, and (*c*) interaction of preservative with material extracted from the closure. Of these three factors, adsorption and absorption of the preservative by the closure is probably responsible for the greatest loss.

In Table IV are presented data indicating the per cent of chlorobutanol lost from solution due to the influence of the rubber stopper. These values were obtained by subtracting the per cent residual preservative found in the vial solutions from that found in the ampul solutions under the same storage conditions. From the data in this table and that in Table III, it is demonstrated that the major quantity of preservative lost due to rubber stopper effect takes place during the first 2 weeks of storage. Thereafter, very little if any, further loss occurs. This may be ascribed to the development of an apparent equilibrium state between the concentration in the solution and in the stopper.

It is interesting to note that the storage of vial solutions in an inverted position seems, for the most part, to cause a greater loss of preservative from solution than occurs in those vials stored in an upright position. Since it is not uncommon for vials to be on their side during storage in pharmacies, hospitals, or physicians' offices and thereby permitting the contents to come in contact with the rubber stopper, the losses of preservative in vials stored in the inverted position warrant serious consideration.

According to the 60° storage data in Table IV, it is evident that the preservative loss due to the rubber stopper decreases with the increase of preservative degradation as indicated by the ampul assays in Table III. This effect can be explained by the significant degradation of preservative in solution which, in turn, results in a reduction of the amount of available chlorobutanol to equilibrate between the solution and closure.

The data in Tables III and IV indicate that the neoprene rubber stopper is responsible for the greatest loss of chlorobutanol from solution. At 60°, after 12 weeks' storage, the vials in the inverted position show only an 8.5% residual concentration, whereas the ampuls under the same storage conditions contain 72.4%. These results are in agreement with the estimate of 10% residual preservative obtained from the thin-layer chromatogram. The other two stoppers, natural and butyl rubber, exert approximately the same effect on preservative loss with possibly the natural rubber stopper exerting a slightly lesser deleterious effect. This substantially

	12	14.9	29.8	42.6	63.8	25.6	25.6

greater effect caused by neoprene stoppers can essentially be explained by the physical properties of this rubber as compared with the other two. It is apparent from the data in Table II that neoprene rubber is of a more porous composition than either natural or butyl rubber. As a result of this greater porosity, chlorobutanol could diffuse into the closure with less impediment. The physical properties listed in Table II for the natural and butyl rubber stoppers indicate that the porosity of these two rubbers are approximately the same. Accordingly, if the chlorobutanol loss from solution is due essentially to absorption by the rubber, then the quantity absorbed should be approximately the same for both elastomers which, according to the data in Tables III and IV, proved to be the case.

Of particular interest are the results pertaining to the loss in preservative content from vial solutions at room temperature. Although the ampuls stored for 12 weeks at 25° show no loss of chlorobutanol content, the vial solutions stored in an inverted position undergo a loss ranging from 19 to 36%, depending upon the stopper used. These results are not surprising in the light of the report by Royce and Sykes (22) which indicated that a 0.5% aqueous solution of chlorobutanol was partitioned between rubber and water in the ratio of 85 to 15% after one month storage at room temperature. In their partition studies, these investigators used a ratio of 1 Gm. rubber to 3 ml. of solution.

During the study with chlorobutanol solution, it was found that zinc mercaptobenzothiazole, an accelerator used as part of the curing system in the butyl rubber stopper, was extracted by the solution, forming a fine colloidal precipitate in the vial solution. In addition, the portion of the closure in contact with the preservative solution became discolored and the solution developed a yellow color. Preliminary tests with other preservatives in solution showed similar results. As a result of the physical incompatibility of this rubber stopper with the various preservative solutions, it was eliminated from comprehensive evaluation with the other preservatives.

p-Chloro-β-phenylethyl Alcohol.—Hess and Speiser (23, 24) in their studies on the comparative efficiency of bactericidal compounds in buffer solutions, showed that *p*-chloro-β-phenylethyl alcohol exhibited promising potentialities as a new bactericidal agent. Studies performed in our laboratories have confirmed their findings, and additional data are presented in a later section of this paper.

In order to evaluate the stability of *p*-chloro-β-phenylethyl alcohol in vials stoppered with natural and neoprene rubber stoppers, a 0.3% solution buffered at pH 4 was employed. As controls, ampul solutions were used at each storage condition. According to the data given in Table V, the closures have a significant deleterious effect on preservative concentration at the several storage conditions. As in the case of the chlorobutanol solution, the neoprene closure causes a significantly greater loss of preservative content than does the natural rubber stopper.

The per cent *p*-chloro-β-phenylethyl alcohol lost due to the closure is summarized in Table VI. These values are representative of the per cent residual preservative in the vial subtracted from the

TABLE V.—INFLUENCE OF DIFFERENT COMPOSITION CLOSURES ON THE PER CENT RESIDUAL CONCENTRATION OF *p*-CHLORO-β-PHENYLETHYL ALCOHOL IN VIAL SOLUTIONS AFTER STORAGE

	12	17.1	20.6	34.4	44.8
60	2	13.8	17.3	24.1	34.6
	8	17.2	20.7	24.2	37.9
	12	20.7	27.6	37.9	44.8

per cent remaining in the ampuls at the particular condition and time of storage. Again, as in the chlorobutanol solution study, the largest loss of preservative content takes place during the first 2 weeks of storage, with subsequent loss being relatively small. However, the loss of preservative due to closure effect is substantially less in the case of this preservative as compared to that for chlorobutanol. This may be explained by the apparent distribution coefficient of the preservatives between solution and rubber, where chlorobutanol favors the rubber to a greater extent than does *p*-chloro-β-phenylethyl alcohol. This is discussed in greater detail in a subsequent section of this report.

It is interesting to note (Table VI) that for the vials stoppered with the neoprene rubber and stored in an inverted position, there is a substantially greater loss in preservative content than occurs in the vials stored upright. However, for vials stoppered with natural closures, the loss of preservative from solution in the inverted vials does not differ significantly from that lost in the upright vials.

Of major importance is the loss of preservative content which takes place when the vial solutions are stored at room temperature for 12 weeks. It can be seen from Table VI that vials stored in an inverted position lose between 24 to 34% preservative from solution, the larger quantity being from the vials stoppered with neoprene closures. Because of this substantial loss in preservative content, it would seem that this preservative as well as chlorobutanol should not be used in vial solutions unless prior closure-preservative studies are performed. The ampul solutions used as controls showed no loss in preservative content during the storage period.

Phenylethyl Alcohol, Benzyl Alcohol, and Methylparaben.—Preliminary studies of the type just described for chlorobutanol and *p*-chloro-β-phenylethyl alcohol have been performed for phenylethyl alcohol, benzyl alcohol, and methylparaben. The results obtained indicate that these preservatives are also absorbed by the closures. Comprehensive studies of these preservatives are under way and the results will be reported at a later date.

Influence of Autoclaving Conditions on Preservative Loss.—Vial solutions of the several preservatives buffered at pH 4 and stoppered with neoprene, natural, and butyl rubber closures were autoclaved at 115°, 10 p.s.i. for 30 minutes. The residual preservative content in these solutions was determined and the data are summarized in Table VII. It is apparent from these results that the vial solutions containing *p*-chloro-β-phenylethyl alcohol are most deleteriously affected with respect to residual preservative concentration. Of the closures tested, natural rubber is the least reactive. It should be noted that the only ampul solution undergoing loss in preservative content after autoclaving was chlorobutanol. A 5% loss in preservative content took place in the ampul solutions of chlorobutanol. Nair and Lach (21), in their kinetic studies of chlorobutanol degradation in solution, found that at pH 5 there occurred a 13% loss of chlorobutanol content upon autoclaving at 115°, 10 p.s.i. for 30 minutes.

TABLE VII.—EFFECT OF AUTOCLAVING AT 115°, 10 p.s.i. FOR 30 MINUTES ON THE PRESERVATIVE CONTENT IN VIAL SOLUTIONS STOPPERED WITH DIFFERENT COMPOSITION RUBBER CLOSURES

Preservative[a]	% Residual Preservative — Ampul Control	Natural Rubber	Neoprene Rubber	Butyl Rubber
p-Chloro-β-phenylethyl alcohol	100	91	88	88
Phenylethyl alcohol	100	100	96	98
Chlorobutanol	95	92	92	92
Benzyl alcohol	100	100	90	100
Methylparaben	100	100	100	100

[a] Preservative solutions were buffered to pH 4.0.

Since the half-life of the degradation reaction at pH 4 is about 2.2 times that at pH 5, the value of 5% degradation obtained in this study seems to be entirely in order.

Apparent Distribution of Preservative Between Rubber and Solution.—It has been reported by Wing (7) and Royce and Sykes (22) that the proportion of chlorocresol absorbed by rubber is much higher than that of phenol. This results in partition coefficients which are almost 20 times greater than for phenol with the same rubber. It would appear that the chlorine substituent on the cresol molecule greatly influences the diffusion of the preservative into the rubber.

In order to determine whether a similar situation existed for *p*-chloro-β-phenylethyl alcohol and phenylethyl alcohol, distribution studies were performed. The results obtained are summarized in Table VIII. These data indicate that the chlorinated compound distributes more strongly into the rubber than does the nonchlorinated analog. In addition, the neoprene rubber absorbs to a greater degree than does the natural rubber. The data show that the distribution values decrease with a rise in temperature, with the exception of neoprene rubber in contact with *p*-chloro-β-phenylethyl alcohol solution. In this case the 40° distribution value is greater than for the 25° value.

TABLE VIII.—APPARENT DISTRIBUTION OF PRESERVATIVES BETWEEN RUBBER AND BUFFER SOLUTION[a] AFTER 4 WEEKS STORAGE

$K_T = C_R/C_B$

Temperature, °C.	Phenylethyl Alcohol[b]		*p*-Chloro-β-phenylethyl alcohol[c]	
	Natural	Neoprene	Natural	Neoprene
25	1.72	4.23	6.05	16.4
40	1.39	4.13	5.70	21.8

[a] Solutions buffered to a pH of 4.0. [b] Ampul concentration at end of 4 weeks: 25° = 0.46%, 40° = 0.43%. [c] Ampul concentration at end of 4 weeks: 25° = 0.26%, 40° = 0.25%.

Of the closures investigated, the butyl polymer was the only one to exhibit significant physical incompatibilities. With each of the preservative solutions, zinc mercaptobenzothiazole was leached from the closure, forming a colloidal precipitate in the vial solutions. That portion of the closure in contact with the solution became discolored and the solutions developed a yellow color. Hardness testing of the three closures in contact with the preservative solutions at different temperature conditions showed no significant changes when compared to original values.

Results of Microbiological Tests.—In order to evaluate the comparative bactericidal activities of the five preservative solutions under study, a phenol coefficient type test was performed with *S. aureus* and *E. Coli.* The data obtained from this study are summarized in Table IX. It is evident from these results that *p*-chloro-β-phenylethyl alcohol is the most active of these preservatives. In comparison to its nonhalogenated analog, phenylethyl alcohol, it is approximately five times more active when tested with *S. aureus* and approximately three times more active when the test organism is *E. coli.* This superior activity of the halogenated molecule may be explained according to the theory of Hess and Speiser (24) who have postulated the existence of a lipid barrier at the cell surface of the organisms. Since the halogenated molecules distribute more readily into nonpolar solvents, it would be expected to penetrate the lipid barrier more rapidly than the nonhalogenated molecule and, hence, require a smaller concentration to achieve the same degree of activity. It is probably this same property which causes chlorinated preservatives to be absorbed by rubber closures to a greater extent than the nonhalogenated analogs.

TABLE IX.—RELATIVE BACTERICIDAL ACTIVITY OF PRESERVATIVES

Preservative[a]	Lowest Concentration, %, Required to Destroy All Test Organisms in 15 Minutes or Less, But Not in 10 Minutes	
	S. aureus	*E. coli*
p-Chloro-β-phenylethyl alcohol	0.10	0.15
Chlorobutanol	0.28	0.30
Phenylethyl alcohol	0.50	0.50
Benzyl alcohol	0.90	0.80
Methylparaben	0.25	0.25

[a] All preservative solutions were buffered to pH 4.0.

Studies of the self-sterilizing properties of the five preservatives were carried out at concentrations most commonly used for parenteral solutions. The results of this study are given in Table X. These data show that all the preservatives tested are very effective against *S aureus* and *E. coli.* However, against spores of *B. cereus*, benzyl alcohol seems to be the most effective preservative, with *p*-chloro-β-phenylethyl alcohol next in effectiveness. Of the five preservatives, phenylethyl alcohol is the least effective as a sporicidal agent.

Assays based on the chemical analysis of preservative in pharmaceutical solutions may, in certain instances, yield data of questionable significance. It is conceivable that a chemical breakdown of an effective preservative, as for example the loss of a chlorine substituent, may yield a product which *per se* possesses intrinsic antibacterial properties. Thus, an assay which is indicative of chemical breakdown or alteration of a preservative can be misleading, since the degraded product may exert demonstrable antimicrobial activity.

In view of these theoretical considerations, it was of interest to attempt the correlation of a chemical breakdown of *p*-chloro-β-phenylethyl alcohol in solution with a loss, if such should prove to be the case, of antibacterial activity as determined by microbiological methods. The method used for determining the latter activity involved the establishment of a standard curve obtained by plotting the ET_{50} (time required for freshly prepared standard solutions to destroy 50% of the test organisms) *vs.* the logarithm of preservative concentration. The best fitting straight line was computed by the method of least squares. Because of difficulties experienced thus far in reproducing the slope of the standard curve, the microbiological data with respect to the assay of chemically degraded solutions are not available at this time for interpretation. The results of this study, however, will be presented at a later date.

TABLE X.—SELF-STERILIZING PROPERTIES OF SELECTED PRESERVATIVES

Preservative	Time Required to Destroy the Following Percentages of Test Organisms,[a] hr. 50%			95%		
	E. coli.	*S. aureus*	Spores of *B. cereus*	*E. coli*	*S. aureus*	Spores of *B. cereus*
pH 4 Buffer solution	1–3	1–3	168	5–24	3–5	>168
p-Chloro-β-phenylethyl alcohol (0.3%)	<1	<1	5–24	<1	<1	48–72
Phenylethyl alcohol (0.5%)	<1	<1	48	<1	<1	<168
Benzyl alcohol (1.0%)	<1	<1	5	<1	<1	48–72
Methylparaben (0.2%)	<1	<1	24–48	<1	<1	<168
Chlorobutanol (0.5%)	<1	<1	24–48	<1	<1	>168

[a] Inoculum: *E. coli*, 700,000; *S. aureus*, 500,000; *B. cereus* spores, 50,000.

It is evident from this investigation that the choice of a rubber stopper for a particular vial solution requires considerable study to select one which exhibits optimal stability. Such a study should include the testing of the vial solutions stored in an upright as well as in an inverted position. In order to accomplish this most effectively, close cooperation must exist between the pharmaceutical and rubber stopper manufacturers.

Additional studies are under way to determine the effect of coated stoppers on preservative loss from solution and the influence of nonaqueous parenteral vehicles on closure properties.

SUMMARY

In this investigation an attempt was made to determine the contributing factors responsible for the loss of preservative from multiple-dose vial solutions. The preservatives evaluated were (*a*) chlorobutanol, (*b*) *p*-chloro-β-phenylethyl alcohol, (*c*) phenylethyl alcohol, (*d*) methylparaben, and (*e*) benzyl alcohol. Solutions of these preservatives in multiple-dose vials were stoppered with three commonly used rubber closures representing natural rubber, neoprene polymer, and butyl polymer. The results obtained are summarized as follows:

1. Preservative solutions in vials stoppered with rubber closures exhibited a substantially greater loss in preservative content than ampul solutions of the same preservative.

2. Vials stored in an inverted position demonstrated a greater loss in preservative content than those stored upright.

3. The natural rubber stoppers exerted the least deleterious effect on preservative content in solution.

4. The butyl rubber closure was found to be physically incompatible with the preservative solutions tested due to a leaching of an accelerator residue.

5. Vial solutions of chlorobutanol and *p*-chloro-β-phenylethyl alcohol stored in an inverted position at room temperature exhibited as much as 30% reduction in preservative content in less than 8 weeks. Since it is not unusual for vials to be stored in a manner whereby their contents are in direct contact with the rubber stopper, these results warrant serious consideration when formulating multiple-dose vial preparations.

6. Distribution studies on *p*-chloro-β-phenylethyl alcohol and phenylethyl alcohol have shown that the chlorinated compound is absorbed into the rubber to a substantially greater degree than the nonchlorinated analog.

7. Results obtained from studies on the comparative bactericidal activity of the preservative solutions have shown that *p*-chloro-β-phenylethyl alcohol was the most effective agent aginst *E. coli* and *S. aureus*.

8. An attempt was made to relate loss in preservative content with corresponding changes in antimicrobial activity.

Chick Embryo Technique for the Evaluation of Absorption of Radioactive Sodium Iodide from Ointment Bases

By JOHN S. RUGGIERO and DONALD M. SKAUEN

In view of the lack of agreement pertaining to the absorption of ingredients from ointment bases, an investigation was conducted to develop a procedure which would be suitable for this type of evaluation. A new method was developed which measures the percentage of absorption of radioactive sodium iodide by 11-day-old chick embryos. Penetration of the isotope was measured from the ointment base through the shell membrane and chorioallantoic membrane of the chick embryo to their thyroid glands.

EVER SINCE man first used a vehicle as a diluent for applying medication, a search has been conducted to find the "ideal ointment base" which could be used to give maximum release and penetration of the active ingredients. Unfortunately, much of the information that has been gathered in this field has led to confusion with many contradictory statements appearing in the literature. For example, Macht (1) states that lanolin and lard are unsatisfactory for absorption through the skin while Fayaud (2) claims that lanolin is best adapted for use as a base to be absorbed through the skin. According to Beeler (3), washable ointment bases permit the best penetration of medicaments, while Busse (4) claims that absorption through the skin depends exclusively on the nature of the substance which is incorporated and that the base makes little difference in the total absorption.

During the past half century many ingenious methods have been proposed to evaluate ointment bases according to their ability to release incorporated ingredients. In general, these methods may be classified either as *in vitro* or *in vivo* procedures. The *in vitro* methods (5–20) can contribute to our knowledge of the release of ingredients under certain specific conditions, but cannot be correlated with *in vivo* efficacy. On the other hand, although *in vivo* methods (21–36) are more applicable, they are usually limited by the unavailability of large numbers of experimental animals which are frequently needed to yield meaningful results.

Many of the aforementioned techniques have been superseded by radioisotopic procedures (37–48). These techniques offer a number of distinct advantages, especially since radioisotopes behave the same as their stable counterparts in chemical and biological processes. Also methods for their detection are so very sensitive, making it possible to test for minute quantities of the isotope.

Perhaps the major difficulty in attempting to develop a procedure for evaluating absorption lies in the fact that no animal possesses skin quite like that of man and, therefore, any correlations which have been made from experiments conducted *in vitro* or *in vivo* are necessarily limited. True, animal and human skin have many and important differences, however, experience indicates certain fields in which animal skin may be used to predict human skin reactions. Neuhauser (49), in seeking a form of keratin which would support the growth of dermatophytes, found a very good correlation between the physical similarities of human epidermis and the shell membrane of the avian egg. Hunter and Smith (50) have previously developed a technique that utilizes chick embryos for evaluating the release of antibiotics from various ointment bases through the shell membrane and chorioallantoic membrane. According to such a procedure, absorption would only be evaluated via the transepidermal route (51) since there are no appendages present to provide for transfollicular absorption. It is interesting to note, however, that even when absorption takes place through hair follicles and other appendages found in hairy animals, the absorbed ingredients must pass through at least one layer of epidermis, which is somewhat analogous to the thin tissue system of the chick embryo.

Radioactive isotopes were incorporated into ointment bases and chick embryos were employed as test animals in an attempt to develop a new technique for evaluating the efficiency of a base to release its active ingredients.

EXPERIMENTAL

The procedure that was developed utilizes radioactive sodium iodide (I^{131}), measuring the penetration of the isotope through the shell membrane and

Received June 17, 1960, from the Research Laboratories, University of Connecticut, School of Pharmacy, Storrs.
Accepted for publication June 16, 1961.
Presented to the Scientific Section, A.PH.A., Los Angeles meeting, April 1958.

chorioallantoic membrane to the thyroid gland of chick embryos (Fig. 1).

Following preliminary experiments indicating the degree of absorption of radioactive sodium iodide by chick embryos of various ages, it was decided that 11-day-old embryos which had been incubated with the isotope for 48 hours would be most suitable for use in evaluating the release of ingredients.

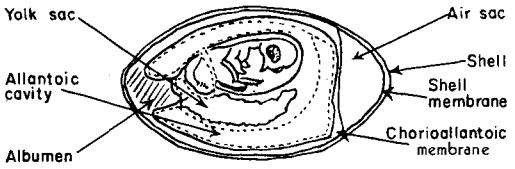

Fig. 1.—Schematic drawing of a chick embryo.

Preparation of the Ointment.—The ointment bases which were to be evaluated were prepared by carefully pipetting a calculated amount of radioisotope onto a known weight of ointment base that had been smeared onto a watch glass. After allowing this mixture to dry, the ointment was thoroughly mixed to insure uniform dispersion of the isotope.

Application of the Ointment.—Small glass rings were utilized in the application and standardization of the ointment in order to assure the fact that the ointment would come into contact with the same area of shell membrane in each embryo employed. These rings were cut from 10-mm. Pyrex tubing by a rotating carborundum wheel. The height of the rings was established by means of an adjustable stop which permitted little variation in height.

The rings were filled with ointment in much the same manner as one would fill an ointment jar. The rings were placed upon a piece of parchment paper and held firmly with a forcep while the ointment was added by means of a microspatula. It was possible to transfer the filled rings to the shell membrane of the embryos by first gently sliding the tip of a microspatula underneath the ring and then carefully pushing the ring from the spatula with the aid of a pair of forceps. Due to the delicate nature of the shell membrane, extra caution was employed when depositing the ring on the membrane so that trauma would not result and influence the degree of absorption.

The ointment was applied to the shell membrane by lowering the ring through a suitable opening which was made by piercing the shell at the air sac at a point where the shell membrane conveniently divides into two layers (Fig. 1). After application of the ointment, the opening in the air sac was sealed with Scotch Tape and the embryos were returned to an incubator at 37.5° where they were allowed to remain for 48 hours.

Determination of the Amount of Radioactivity Applied.—Usually three rings containing the ointment (more could be used depending on the total number of cases involved) were set aside from each batch of ointment used in order to ascertain the relative amount of radioactivity that was applied in each case. The amount of radioactivity in the rings, selected at random, was determined by dissolving the ointment in a suitable solvent, and then assaying various aliquots of the solutions. The result of averaging the radioactivity indicated in each of the samples was chosen to represent the relative amount of radioactivity applied in each case.

Determination of Amount of Radioactivity Absorbed by the Thyroid Glands.—After the radioactive ointment had remained in contact with the shell membrane for 48 hours, the eggs were removed from the incubator. The embryo was separated from the egg, taking care not to contaminate the embryo with any excess ointment that remained. The thyroid glands were viewed through a stereoscopic Bausch and Lomb microscope and removed with the aid of watchmaker's forceps. The glands were macerated with 10% sodium hydroxide solution, dried, and assayed for radioactivity.

Calculation of the Percentage of Absorption.—The percentage of radioactivity that was absorbed in each case was calculated by dividing the amount of radioactivity found in each thyroid by the amount of radioactivity that was applied. The percentage of absorption indicated by each of the embryos in the group was then averaged and reported as the percentage of absorption of radioactivity for a particular ointment base. A sample form showing all of the pertinent data is illustrated in Table I.

TABLE I.—EXAMPLE OF STANDARD FORM AND RESULTS OBTAINED FOR A TYPICAL OINTMENT BASE[a]

Embryo No.	C.p.m. in Thyroid above Background	Percentage of Applied Radioactivity in Thyroid
1	50.0	0.33
2	16.8	0.12
3	35.6	0.23
4	23.2	0.15
5	18.8	0.12

9	31.2	0.20
10	10.0	0.07
11	33.8	0.22
12	29.2	0.19
13	14.0	0.09
	0.176 ± 0.075 (mean % absorbed)	

[a] Amount applied, average of three standard rings, 15,360 c.p.m.; duration, 48 hours; base, Almay emulsion base (product of Almay, Inc.); background count, 22 c.p.m.

SUMMARY

A method is presented for determining the efficiency of ointment bases to release sodium iodide. The method utilizes the thin tissue system provided by the shell membrane and chorioallantoic membrane of 11-day-old chick embryos and the ability of the thyroid gland to absorb and concentrate radioactive sodium iodide. Such a system provides a rather simple, inexpensive, and rapid analysis of absorption.

Evaluation of the Absorption of Radioactive Sodium Iodide from Various Ointment Bases by Means of a Chick Embryo Technique

By JOHN S. RUGGIERO and DONALD M. SKAUEN

Forty-seven ointment bases were evaluated for their ability to release radioactive sodium iodide when evaluated by a chick embryo technique. In general, ointments of the hydrophilic type indicated better release of the isotope than did bases of the absorption or oleaginous type.

A PREVIOUS REPORT (1) illustrates the development of a chick embryo technique which permits the investigator to evaluate the ability of various ointment bases to release radioactive sodium iodide. This chick embryo technique is employed here to determine the release of radioactive sodium iodide from different ointment bases. Limited studies were also conducted to evaluate the effect of surface-active agents and of varying quantities of water on the degree of absorption that might take place from ointment bases.

Received June 17, 1960, from the Research Laboratories, University of Connecticut, School of Pharmacy, Storrs.
Accepted for publication June 16, 1961.
Presented to the Scientific Section, A.PH.A., Los Angeles meeting, April 1958.

EXPERIMENTAL

Various ointment bases were selected as representatives of the three major categories of ointment bases as listed by Robinson (2), namely; those which are oleaginous or water repellent; those which absorb water, but are greasy and nonwashable; and those which are water miscible or water soluble.

Petrolatum U.S.P. XV	O	14	0.061	0.030
White ointment U.S.P. XV	O	22	0.041	0.017
Hydrosorb plus 30% water	A	19	0.040	0.009
Wool fat U.S.P. XV	A	17	0.021	0.007
Hydrosorb plus 10% water	A	20	0.015	0.007

Absorption Bases.—Wool fat U.S.P. XV; hydrous wool fat U.S.P. XV; hydrophilic petrolatum U.S.P. XV; Aquaphor, product of Duke Laboratories; Hydrosorb, product of Abbott Laboratories; Hydrosorb plus 10% water; Hydrosorb plus 20% water; Hydrosorb plus 30% water; Hydrosorb plus 40% water; Polysorb, product of E. Fougera and Co., Inc.; hydrophilic Plastibase, product of E. R. Squibb and Sons; Qualatum, product of Almay, Inc.; Falba, product of Pfaltz and Bauer, Inc.; Amerchol CAB, product of American Cholesterol Products, Inc.; Singiser base No. 250 (3).

Hydrophilic Bases.—Rose water ointment U.S.P. XV; hydrophilic ointment U.S.P. XV; hydrophilic ointment U.S.P. XIV; polyethylene glycol ointment U.S.P. XV; hydrophilic ointment No. 1, contains all of the ingredients in hydrophilic ointment U.S.P. XV except that 0.5% Pluronic L64[1] was substituted for polyoxyl 40 stearate; hydrophilic ointment No. 2, as above with 1% Alrodyne 315;[2] hydrophilic ointment No. 3, as above with 1% Medialan LL33;[3] hydrophilic ointment No. 4, as above with 1% Deriphat 150A;[4] hydrophilic ointment No. 5, as above with 1% Deriphat XD160;[4] Velvachol, product of Texas Pharmacal Co.; Omnia cream, product of Dohme Chemicals, Inc.; Almay emulsion base, product of Almay, Inc.; Multibase, product of Ar-Ex Cosmetics, Inc.; Unibase, Product of Parke, Davis and Co.; Beeler's base (4); o/w emulsion base (5); vanishing cream (2); Carbowax compound 1500, product of Carbide and Carbon Chemicals Corp.; Robinson's polyethylene ointment (2).

For the most part, these bases were chosen because of the frequency with which they appear in dermatological preparations and also because of their availability. Some bases were chosen mainly on the basis of claims that have been made by various researchers (3–5).

Each ointment was prepared as described by Ruggiero and Skauen (1) and evaluated for its ability to promote penetration of radioactive sodium iodide through the shell membrane and chorioallantoic membrane to the thyroid glands of 11-day-old chick embryos. The percentage of

[1] Products of Wyandotte Chemicals Corp.
[2] Product of Alrose Chemical Co.
[3] Product of Antara Chemicals.
[4] Product of General Mills, Inc.

absorption that occurred in each case is reported in Table I.

Evaluation of the Effect of Water on Absorption.—The literature (6–8) reports some controversy with regard to the effect that water has in absorption from ointment bases. In order to check the efficiency of this new method in evaluating and distinguishing among bases according to their water content, a series of Hydrosorb bases was prepared, each of the bases containing different percentages of water by weight. The results of absorption from these bases is shown in Table II.

Evaluation of Surfactants in Hydrophilic Ointments.—Miller and Selle (9) report that wetting agents increase absorption by causing emulsification of sebum and making contact with the glandular and follicular cells of the skin. More recently, various researchers (10–12) have evaluated the release of medication from bases that contained various surface-active agents. In order to evaluate the efficiency of this new technique to distinguish among absorption from ointments that contain different surface-active agents, a series of hydrophilic ointments was prepared, each containing the basic formula for hydrophilic ointment U.S.P. XV except that the surface-active agent was changed in each case. The results of absorption from these bases is reported in Table III.

TABLE II.—PER CENT ABSORPTION OF RADIOACTIVITY FROM HYDROSORB CONTAINING VARIOUS AMOUNTS OF WATER

Base	No. of Embryos Used	Average % of Radioactivity in Thyroid
Hydrosorb	15	0.508
Hydrosorb plus 40% water	17	0.109
Hydrosorb plus 20% water	20	0.075
Hydrosorb plus 30% water	19	0.040
Hydrosorb plus 10% water	20	0.015

TABLE III.—EFFECT OF SURFACTANTS ON ABSORPTION FROM HYDROPHILIC OINTMENTS

Surf	No. of Embryos Used	Average % of Radioactivity in Thyroid
0.5% Pluronic L62 and 0.5% Pluronic L64	45	2.837
1% Medialan LL33	18	1.532
1% Sodium lauryl sulfate	13	1.138
1% Deriphat XD160	22	0.736
5% Myrj 52	27	0.485
1% Alrodyne 315	17	0.254
1% Deriphat 150A	20	0.229

SUMMARY AND CONCLUSIONS

Examination of Table I indicates that eight of the first 10 bases listed belong to the hydrophilic group, while no member of the hydrophilic group appears among the last ten bases. The mean percentage of absorption of radioactivity, calculated for all of the bases from each of the three ointment classes, indicates 0.969% absorption in the hydrophilic group and 0.294% and 0.248%, respectively, for the absorption and oleaginous groups. These figures indicate that absorption of sodium iodide was best from the hydrophilic group but that there was little difference between absorption from the oleaginous and absorption bases.

The ointment bases which contained polyethylene glycols showed low absorption percentages when compared to the other bases in the hydrophilic group, however, it should be noted that when these ointments were assayed, most of the chick embryos were dead before the thyroid glands were removed. Perhaps absorption had been so pronounced that death had come before the thyroids were able to concentrate more radioactive sodium iodide.

Singiser (3) has presented a series of bases that contain varying amounts of metallic soaps, liquid petrolatum, white petrolatum, and wool fat. Table I shows that of the Singiser bases which were evaluated, base No. 250, which contains 6% wool fat, is more capable of releasing radioactive sodium iodide than the other Singiser bases which were evaluated.

According to the results shown in Table II, the addition of water to Hydrosorb ointment base decreased the percentage of radioactive sodium iodide that was absorbed from the base itself. There does not seem to be any pattern established with regard to the degree of decrease and the amount of water added. This limited study indicates that the technique is capable of distinguishing among bases that contain varying percentages of water.

Results shown in Table III indicated that the chick embryo technique is capable of detecting differences in absorption of labeled sodium iodide from these ointments. The base which contains the 0.5% Pluronic L62 and 0.5% Pluronic L64 closely conforms to a formula prepared to contain the required hydrophilic-lipophilic balance for such a preparation.

Study of the Boric Acid-Glycerin Complex II

Formation of the Complex at Elevated Temperatures

By JOHN J. SCIARRA and ANTHONY J. MONTE BOVI

A study of the boric acid-glycerin complex was conducted at temperatures of 30, 40, 50, and 60° and the effect of increasing the concentration of glycerin upon the solubility of boric acid was studied. This may then be indicative of the degree of complex formation taking place between these two substances. Concentrations of glycerin varying from 0 to 100% were utilized. The results of these experiments show the relationship between (*a*) solubility of boric acid and (*b*) temperature and concentration of glycerin. A phase diagram was constructed at these temperatures showing the quantitative relationship among boric acid, water, and glycerin. From a plot of the log solubility of boric acid *versus* the reciprocal of absolute temperature, the heat of solution at various concentrations of glycerin was calculated. It was found that the degree of complex formation between boric acid and glycerin increased with an increase in temperature but showed little, if any, increase with an increase in glycerin concentration from 0 to about 40%. However, above this concentration of glycerin, the degree of complex formation, as indicated by the solubility, increased with an increase in concentration of glycerin.

THE FORMATION of a complex compound between boric acid and glycerin has been known and investigated by many workers. This complex has been detected by many methods, among them being changes in pH (1, 2) and in solubility (3). In most cases the addition of glycerin to boric acid will allow the formation of a complex compound which is soluble to a greater extent than boric acid alone. However, during the course of previous investigations it has been found that boric acid behaves quite differently in glycerin than in the presence of other substances capable of forming a complex compound, such as sorbitol (4), mannitol, fructose, and other similar substances. Some of the differences in behavior between the boric acid-glycerin complex and the boric acid-sorbitol complex have been indicated in a previous publication (5) where the complex formation between these substances was studied at 25°. The results of this investigation prompted further work at elevated temperatures.

An increase in temperature generally will increase the solubility of substances in water and other solvents. The solubility of substances which are favorably affected by an increase in in temperature will show a negative heat of solution. The heat of solution of a substance will vary depending upon the concentration of solute in solution. The partial molal or differential heat of solution is defined as $d(\Delta H)/dn_2$, where ΔH is the heat of solution of a mole of solute in a quantity of solution so large that the addition of the one additional mole of solute does not appreciably change the concentration of the solution (6).

A solubility study can be used to determine the heat of solution of boric acid in varying concentrations of glycerin. By determining the solubility of boric acid in the various glycerin solvents at several temperatures and plotting these results, according to the van't Hoff relationship

$$\frac{d \ln S}{dt} = \frac{\Delta H}{2.303\ RT}$$

which when integrated becomes

$$\log S = \frac{-\Delta H}{2.303\ RT}$$

one can calculate the heat of solution. In the van't Hoff equation, S is the molal solubility of boric acid in the glycerin solvent, ΔH is the heat of solution, R is the gas constant, and T is the absolute temperature. An error is introduced since ΔH is treated as a constant, an assumption which is not entirely true (7).

Boroglycerin glycerite N.F. has been used for many years as an antibacterial substance. This consists chiefly of a 50% (by weight) solution of boroglycerin ($C_3H_5BO_3$) in glycerin. Official directions specify that this product be kept in a dry container (8). This glycerite is also described as a soluble preparation of boric acid (9), however, in certain cases, the addition of water is followed by the precipitation of boric acid. This is due to the hydrolysis of the boroglycerin complex to form boric acid which precipitates when water is not present in sufficient concentration.

Received April 28, 1961, from the Department of Pharmaceutical Chemistry, St. John's University, College of Pharmacy, Jamaica 32, N. Y.
Accepted for publication June 20, 1961.
Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.

A comparison of this reaction with the reaction taking place between boric acid-sorbitol and water has previously been reported (5). However, to study this reaction more fully, the relationship between the amount of boric acid precipitated and the concentration of glycerin-water solutions was studied by combining various combinations of saturated solutions of boric acid in glycerin and in water at 25°.

EXPERIMENTAL

Saturated solutions of boric acid in solutions of glycerin and water were prepared in a manner previously reported (5). This method consisted of diluting glycerin U.S.P. containing 99%, by weight, of $C_3H_5(OH)_3$ with varying quantities of distilled water so that concentrations of glycerin were obtained from 0 to 100%, by weight, in increments of 10%. These solutions were then neutralized to phenolphthalein by the addition of a few drops of 1 *N* sodium hydroxide. An excess of finely divided, crystalline boric acid U.S.P. was added to about 100 ml. of glycerin solvent which had been placed into a 150-ml. glass solubility tube. The tube was placed into a constant temperature water bath at 30 ± 0.1° and stirred continuously for 24 hours (preliminary experiments showed that equilibrium had been attained during this period). After allowing the undissolved particles to settle to the bottom of the solubility tube, two 25-ml. portions of the clear, supernatant liquid were removed, placed into tared beakers, and quickly weighed. The amount of boric acid in each of these solutions was determined by assaying the solutions according to the U.S.P. assay for boric acid (10). The above procedure was repeated at temperatures of 40, 50, and 60°, all ±0.1°. Constant temperature was maintained through use of a Sargent full visibility, constant temperature water bath.

A different procedure was used to determine the amount of boric acid which would precipitate from saturated solutions of boric acid in both water and glycerin. A saturated solution of boric acid in water was prepared at 25° according to the official method (8), and assayed as above. A similar solution of boric acid was prepared in glycerin [over 99% by weight $C_3H_5(OH)_3$] and assayed. Various quantities of these solutions were added to a 150-ml. solubility tube in the quantities shown in Table I. Each tube contained a total weight of 100 Gm. These tubes were then tightly stoppered and placed into the constant temperature water bath at 25 ± 0.1° and allowed to stand without agitation. Maximum precipitation of boric acid was obtained at this time. Then two 25-ml. portions of the clear, supernatent liquid were removed and assayed as indicated above.

RESULTS

From the above results, the solubility of boric acid in the various glycerin-water solvents was calculated at elevated temperatures and expressed as weight per cent of boric acid as shown in Table II. In order to show the effect of temperature upon the solubility of boric acid Fig. 1 was constructed. Figure 2 relates the concentration of glycerin with the solubility of boric acid at the indicated temperatures.

The composition of each of the solutions was calculated on a weight per cent basis and the amount of each component present (boric acid-water-glycerin) is given in Table III. From this data, Fig. 3, which is a phase diagram of this multicomponent system, was constructed.

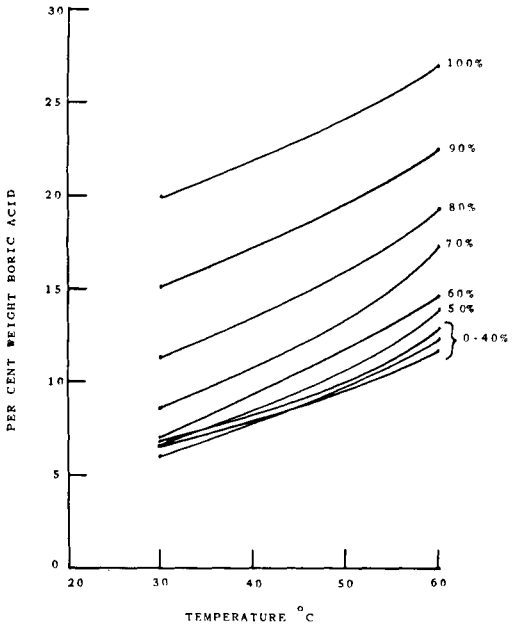

Fig. 1.—Effect of temperature upon the solubility of boric acid in glycerin.

Tables III and IV show the data necessary to plot Fig. 4 and calculate the heat of solution for each of the solvent systems studied. These also show the application of the van't Hoff equation to this system.

Table I shows the calculations involved in determining the amount of precipitation of boric acid taking place when saturated solutions of boric acid in both water and glycerin are combined.

These results are shown graphically in Fig. 5.

DISCUSSION

The degree of complex formation between boric acid and glycerin was found to increase with an increase in temperature as indicated by the corresponding increase in solubility of boric acid. The temperature effect also increased as the concentration of glycerin increased; that is, temperature had a greater effect at higher concentrations of glycerin. See Table V. This is shown in Fig. 1 where it can be noted that the curves representing from 0 to 40% are quite close to one another, in fact it is difficult to separate them. However, as one approaches

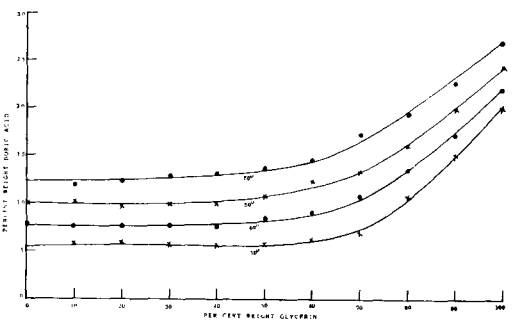

Fig. 2.—Isotherm curves showing solubility of boric acid in glycerin.

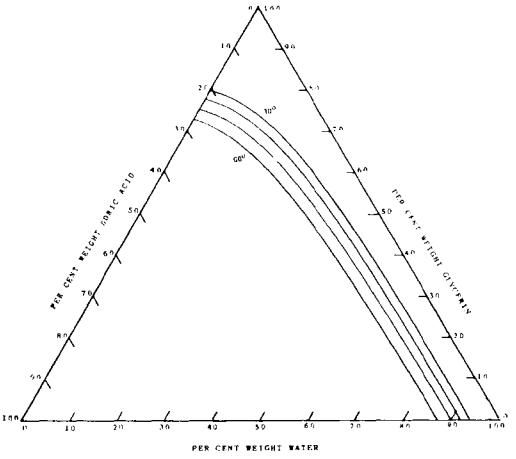

Fig. 3.—Phase diagram of boric acid-water-glycerin system.

50% and higher concentrations of glycerin, the curves are separated by a greater difference. The maximum temperature effect is obtained in going from a solvent containing 90% glycerin to one containing 100%. A similar relationship is found in Fig. 4 where the log solubility is plotted *vs.* reciprocal or absolute temperature. Since straight lines are produced in all cases, it may be assumed that the van't Hoff relationship is applicable to this system. Similar to Fig. 1, 0 to 40% glycerin concentrations show very little difference in solubility, as seen in Fig. 4. This difference becomes greater with increase in concentration of glycerin. In both Figs. 1 and 4 it can be seen that the temperature gradients going from 30 to 40°, 40 to 50°, and 50 to 60° seem to be about the same in all cases. This might be expected from results of prior reports. From Fig. 4, the slope can be determined from which the heat of solution can be calculated in each solvent. It is interesting to note that the slope of the lines for concentrations of glycerin from 30 to 60% are parallel, therefore they would have the same heat of solution. These results would indicate that very little, if any, complex formation takes place between boric acid and glycerin solutions in the range of 0 to 40%. This also seems to be independent of temperature.

A plot of the solubility of boric acid *vs.* concentration of glycerin, as shown in Fig. 2, also shows the

lack of complex formation between these two substances until 45 or 50% concentrations of glycerin are attained. Then the solubility increases sharply as 100% glycerin is approached. A comparison of these results with the results obtained in studying the boric acid sorbitol complex are quite interesting (4). As previously indicated, the boric acid-sorbitol complex is formed in ranges from 0 to 70% sorbitol. This indicates increased stability of the boric acid-sorbitol complex as compared to the boric acid-glycerin complex, especially at low concentrations.

Temperature increases will give a greater area of miscibility to the boric acid-water-glycerin system as seen in Fig. 3. These curves are separated from one another by an equal distance, indicating the temperature effect to be constant.

In order to determine the amount of boric acid which would precipitate from solutions of the boric acid in glycerin (essentially boric acid-glycerin complex), varying quantities of a saturated solution of boric acid in water (to ensure that the amount of boric acid precipitated from the glycerin did not redissolve in water) was added to the glycerin solution of boric acid. These results are depicted in Fig. 5 where essentially a bell shaped curve is obtained.

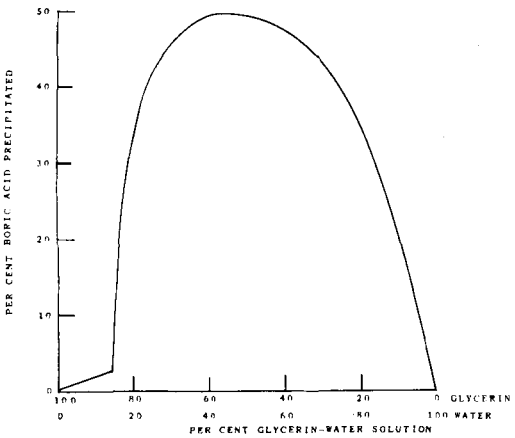

Fig. 5.—Precipitation of boric acid from glycerin-water solutions.

As expected, maximum precipitation of boric acid occurs about 45% water and 55% glycerin. About 15% water can be added without causing precipitation of boric acid. However, additional quantities of water will cause a large increase in the amount of precipitation. This observation would limit the use of boroglycerin glycerite when diluted with certain amounts of water.

SUMMARY AND CONCLUSIONS

1. A solubility study of the boric acid-water-glycerin system has been made at temperatures of 30, 40, 50, and 60°.

2. The degree of complex formation between boric acid and glycerin was found to increase with an increase in temperature.

3. Concentrations of glycerin from 0 to 40% had little effect, if any, upon the degree of complex formation as indicated by a solubility determination. This complex was found to increase as the concentration of glycerin was increased from 40 to 100%.

4. The heat of solution for each of the solvent systems was calculated through use of the van't Hoff relationship.

5. Maximum precipitation of boric acid from solutions of boric acid in glycerin was found to take place at a concentration of 45% water and 55% glycerin.

Infrared Method for the Determination of Ethanol and Acetone in Thimerosal Tincture N.F.

By FREDERIC A. GRONAU, DONALD E. BROADLICK, and JAMES E. HAMILTON

The distillation method for determining ethanol in thimerosal tincture N.F. is time consuming and involves special handling to prevent interference of the acetone in the preparation. A shorter method is described based on the extraction of the ethanol into carbon tetrachloride and the measurement of the infrared absorption at 11.37 μ. The relative freedom from the interference by other alcohols and acetone assures greater specificity than the distillation method. The acetone present in tincture thimerosal N.F. can also be determined using the same extracted solution by reading the absorption of the carbonyl band at 5.86 μ.

THE DETERMINATION of ethanol in thimerosal tincture N.F. as described in the National Formulary (1) is that of Thorpe and Holmes (2). It has the disadvantage of being time consuming. It is also possible that it may not give a true estimate of the amount of ethanol in the preparation due to incomplete recovery of the ethanol in the distillate. The method formerly used in this laboratory was a modification of that of Hoff and Macoun (3) using paraformaldehyde and sodium hydroxide to form a nonvolatile reaction product with the acetone before distilla-

tion. The ethanol content is then determined by measuring the specific gravity of the distillate. In an attempt to overcome these disadvantages, an infrared spectrophotometric method has been developed. It has proved to be faster, more accurate, and is specific for ethanol.

Souder and Deluca (4) reported the determination of chloroform in pharmaceuticals by infrared absorption measurement. This procedure has been adapted to the determination of ethanol in tincture thimerosal. The method involves extraction of the ethanol from the sample into carbon tetrachloride. The carbon tetrachloride is dried and the absorption measured at an ethanol band at 11.37 μ. Although not of primary concern, the acetone content of the sample can be determined on the same extracted solution by measuring the absorption of the carbonyl band at 5.86 μ.

EXPERIMENTAL

Band Selection.—The infrared spectra of the common pharmaceutical solvents used in external preparations—ethanol, acetone, methanol, and isopropanol—were obtained on a Beckman IR-5 recording spectrophotometer. The ethanol band at 11.37 μ was chosen for quantitative estimation for several reasons. This unique band does not seem to be associated with the hydroxyl portion of the molecule (5) which eliminates the interference of many compounds such as other alcohols. The band appears in a generally nonabsorptive region of the spectrum where the common solvents listed show little absorption (Fig. 1). The band also follows Beer's law in the concentration range expected to be found in the tincture thimerosal N.F., that is, $\pm 10\%$ of the theoretical amount. In this region of the spectrum, carbon tetrachloride shows very little absorption.

General Technique.—To a suitable glass-stoppered flask containing exactly 50 ml. of carbon tetrachloride, 1 ml. of the tincture is added. About 30 Gm. of anhydrous sodium sulfate is added to form a hydrate with the water in the sample, allowing more of the ethanol to be dissolved in the carbon tetrachloride. The mixture is shaken for 1 minute. Several anhydrous salts capable of binding the water were tried and sodium sulfate was found to be the most suitable. By removing water in this manner one may transfer 98%+ of the ethanol into the carbon tetrachloride. About 5 ml. of the extracted solution is removed and dried in a suitable flask with about 2 Gm. of anhydrous sodium sulfate. This is a precautionary measure to protect the sodium chloride cells. The absorption of this solution is then determined at 11.37 μ in 1.0-mm. sodium chloride cells against a blank of carbon tetrachloride. After correcting for any cell blank, the absorption is compared to that of a standard run in the same manner. A Beckman model IR-2 spectrophotometer with sodium chloride optics was used for all quantitative results reported here.

Standard Preparation.—Standards were prepared in two ways. The alcohol and acetone were removed from a sample of tincture thimerosal by evaporating under vacuum until the absorption maximum of ethanol at 11.37 μ and of acetone at 5.86 μ disappeared. This blank material was then reconstituted by adding it to exactly 50 ml. of absolute ethanol and 10 ml. of acetone in sufficient volume to make 100 ml. A mixture of water, ethanol, and acetone was prepared by diluting 50 ml. of absolute ethanol and 10 ml. of acetone to 100 ml. with water. The absorption of carbon tetrachloride extracts of these solutions was determined at both the ethanol band at 11.37 μ and at the acetone band at 5.86 μ and found to be identical. All results reported in this work are determined against the water-ethanol-acetone standard. It became apparent from the work done on the standards that acetone could be determined on the same solution by reading the carbonyl band at 5.86 μ. Although the tincture contains only one-fifth as much acetone as ethanol, the unusually strong absorption of the carbonyl band resulted in an absorption almost as great as that of ethanol.

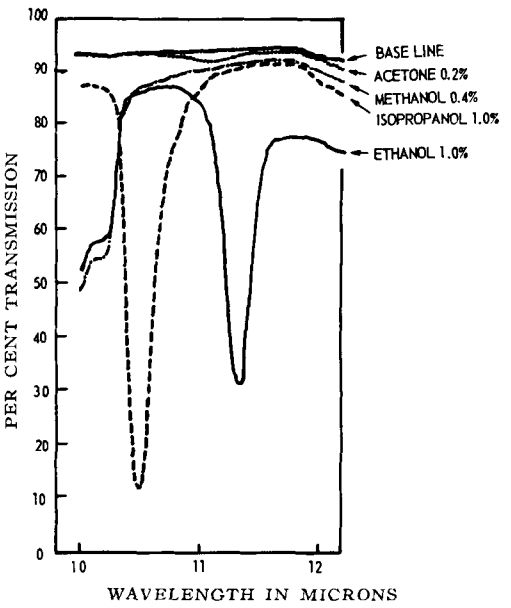

Fig. 1.—Infrared spectra of ethanol, methanol, acetone, and isopropanol in carbon tetrachloride.

Comparison of Methods.—Ten different production lots of the tincture were assayed using the general technique. These results are compared to those obtained by distillation (Table I). In the distillation procedure, 50 ml. of the tincture is diluted with 20 ml. of saturated sodium chloride solution in a liter boiling flask. A 7-Gm. quantity of paraformaldehyde and 5 ml. of a 50% solution of sodium hydroxide are added. This mixture is then distilled in a compact distilling apparatus using Friedichs condensers. About 50 ml. of distillate is collected and diluted to 100 ml. The specific gravity is measured on a Westphal balance and the per cent ethanol obtained from Standard Alcoholimetric Tables found in the U.S.P.

The per cent acetone found in the samples is included in Table I but the comparison to other methods is not made. It is noted that the infrared

TABLE I.—COMPARISON OF ETHANOL DETERMINATION BY INFRARED AND DISTILLATION

3 × S.D., %	1.25	2.70

method gives results which are closer to the theoretical amounts of ethanol in the product. An attempt was made to explain the higher results found by the infrared method. It had been felt that the distillation apparatus in use did not give complete recovery of the ethanol in the product. Using a system of added internal standard, the recovery efficiency of the distillation method for ethanol and the efficiency of the infrared method for both ethanol and acetone were measured.

Absolute ethanol was added to a previously assayed sample and the ethanol content was redetermined. By subtracting the original ethanol result from the total and comparing this figure to the amount of ethanol added, the efficiency of recovery was found. This study shows the distillation procedure used recovers only 96.7% of the ethanol while the infrared technique recovers 99.8%. This difference of 3.1% is consistent with that of 3.29% experienced in assaying the 10 samples by each method. The same technique was applied to the acetone which also shows a 99.8% efficiency.

Reproducibility of Method.—One sample was assayed in two groups of four aliquots each. These results are shown in Table II. The estimated standard deviation on these data was found to be 0.208 or about 0.4%. The reproducibility for these eight samples (3 × S.D.) was ±1.25%. The acetone standard deviation is 0.09 or about 0.9%. The reproducibility is ±2.7%.

SUMMARY

An infrared method is presented for the determination of ethanol in thimerosal tincture N.F. The method is less time consuming than distillation procedures and gives results which are closer to the theoretical amounts of ethanol in the product. The acetone in the product may also be determined in the same sample. Additional data are being collected on other hydroalcohol preparations and will be included in subsequent manuscripts.

Structural Studies on Terebinthone from *Schinus terebinthefolius*

By KRISHAN K. KAISTHA and LEMONT B. KIER

A new triterpene, terebinthone, has been isolated from the berries of *Schinus terebinthefolius* (Radd.). Analyses indicate the formula $C_{30}H_{46}O_3$. Spectral evidence indicates that the compound is a diketone with one group in the C-3 position and the second in a highly hindered position. Reduction and hydrogenation studies supported these findings. Ozonolysis produced acetaldehyde showing that the single double bond is in the side chain as an ethylidene group. The third oxygen of terebinthone is believed to be in a cyclic ether ring.

THE TREE *Schinus terebinthefolius* (Radd.), also known as the Brazilian pepper tree, belongs to the family *Anacardiaceae*. It is a small evergreen tree found in south and central Florida. During the winter months numerous clusters of small, bright red berries appear (1). These berries are said to exert a paralyzing effect on birds upon ingestion.

This study was initiated in an effort to evaluate the principle producing this action, to identify it as well as other major isolable products chemically, and to determine if there may be anything of therapeutic value. In the course of the study, the berries were initially defatted with hexane. From this solvent there was obtained a crystalline substance, which, though not possessing the aforementioned pharmacology, still was of considerable interest chemically. This compound is the subject of this first communication.

Analyses of this compound, provisionally named terebinthone, and several derivatives indicated that the molecular formula $C_{30}H_{46}O_3$ best fit the data. Further confirmation of this formula was found in the closeness of the Rast molecular weight to the theoretical value.

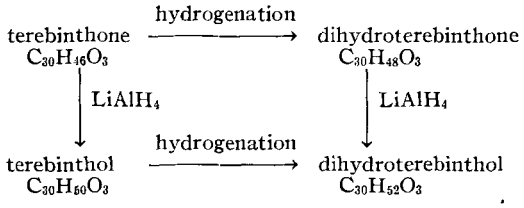
It was concluded that terebinthone was a triterpene from the finding of four C-methyl groups, gem dimethyl and terminal methyl group absorption in the infrared (1385 and 1365 cm.$^{-1}$) (2, 3), the close similarity in the infrared spectra of terebinthone and its derivatives with other triterpenes, color tests, and the molecular formula.

Perbenzoic acid titration (4) indicated the presence of one double bond. Infrared analysis showed two ketonic carbonyl group absorptions at 1708 and 1690 cm.$^{-1}$. The remaining oxygen function did not appear as a carbonyl or hydroxyl group in the infrared spectrum, but an absorption at 1095 cm.$^{-1}$ was observed in terebinthone and several other derivatives which has been assigned to the C—O—C group of a cyclic ether (5, 6).

The presence of two carbonyl groups and one double bond indicated that terebinthone is basically tetracyclic, and with the cyclic ether would be pentacyclic. This conclusion is in agreement with the molecular formula.

A closer examination of the carbonyl groups indicated that the peak at 1708 cm.$^{-1}$ could be ascribed to an isolated aliphatic or isolated six-membered ring ketone (3, 7). Terebinthone showed no absorption in the conjugated carbonyl region of the ultraviolet, confirming the fact that both keto groups are isolated. It was concluded that the 1708 cm.$^{-1}$ absorption peak was due to a 3-keto group from the fact that terebinthone gave a positive Zimmermann reaction (8) and an absorption maximum at 367 mμ for the mono-2,4-dinitrophenylhydrazone derivative. Reich (9) has shown that absorption in the 367–369 mμ region is due to the presence of this derivative of a 3-keto group.

The 1703–1690 cm.$^{-1}$ region is reported (2, 10) to be due to a saturated keto group in a hindered position. This is in agreement with the absorption of the second carbonyl group of terebinthone (1690 cm.$^{-1}$). The fact that this group was hindered was shown by the fact that only a mono-2,4-dinitrophenylhydrazone could be formed even under forcing conditions. This derivative still showed the 1690 cm.$^{-1}$ absorption.



Reduction of terebinthone with lithium aluminum hydride (11) gave a diol, terebinthol, $C_{30}H_{50}O_3$. This compound had only one acylable function, forming a mono-3,5-dinitrobenzoate, confirming the presence of a highly hindered keto group in terebinthone. The 1095 cm.$^{-1}$ absorption (cyclic ether) indicated that no change had occurred in the ether ring. Terebinthol gave a positive Liebermann-Burchard reaction (12) indicative of a 3-hydroxyl group.

Hydrogenation of terebinthone to dihydro-

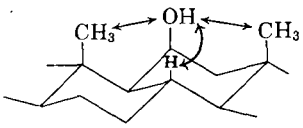
Received April 28, 1961, from the Department of Pharmaceutical Chemistry, College of Pharmacy, University of Florida, Gainesville.
Accepted for publication June 6, 1961.
Taken from a thesis by Krishan K. Kaistha submitted in partial fulfillment of the requirements for the degree of Ph.D.
Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.

terebinthone, $C_{30}H_{48}O_3$, with the measured consumption of hydrogen equivalent to one double bond, confirmed the presence of one reactive double bond in the molecule. Dihydroterebinthone gave a positive Zimmermann reaction and formed only a mono-oxime even under vigorous conditions (13). The 1095 cm.$^{-1}$ absorption was present indicating no cleavage of this ring.

Hydrogenation of terebinthol and lithium aluminum hydride reduction of dihydroterebinthone gave the same compound, dihydroterebinthol, $C_{30}H_{52}O_3$.

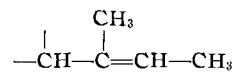
The compound retained the 1095 cm.$^{-1}$ absorption peak (cylic ether) in the infrared. A mono-tosylate was prepared which confirmed the fact that all four of these compounds contain a highly hindered oxygen function.

Zaffaroni (14) described a technique useful for partial characterization of steroids which consists of measurement of absorptions of concentrated sulfuric acid solutions from 200 to 500 mμ. The principal maxima for the four compounds above was at 304 mμ. Absorption between 280 and 296 mμ is associated with an α,β-unsaturated ketone (15). The fact that all four compounds exhibited the same maxima clearly indicates that no change has occurred in the positions of the oxygen functions and that the double bond, when present, does not exhibit any effect on any of these.



The Wolff-Kishner reduction (16) of dihydroterebinthone gave a major product with a molecular formula of $C_{30}H_{50}O_2$. The infrared analysis showed absorption at 1095 cm.$^{-1}$ (cyclic ether) and 1703 cm.$^{-1}$ which must be due to the same hindered carbonyl group previously discussed, since a successful Wolff-Kishner reduction depends upon the formation of a phenylhydrazone intermediate and no derivatives could be made of one carbonyl group. Furthermore, this compound, 3-desoxy-dihydroterebinthone gave no Zimmermann reaction, indicating that the 3-keto group had been reduced.

There can be no question that the hindrance of one oxygen function in these compounds is of the magnitude of the C-11 position in steroids or the C-7 and C-11 positions of tetracyclic triterpenes. In the latter case, the C-7 carbonyl group of lanostane-7,11-dione-3-yl acetate (I) has been reduced by the Wolff-Kishner method (17) to the 11-monoketone (II). Though this does not



(I) (II)

exclude the possibility of a C-7 keto group in terebinthone, or other possibilities as well, the evidence strongly suggests that the hindered keto group might well be in the C-11 position. If reduction of this keto group occurs to give an 11β-hydroxyl group, then this would account for the failure to form a derivative of this function. The 11β-hydroxyl group is practically unacylable (18) due to steric strain from two angular methyl groups and a hydrogen (III).

(III)

Ozonolysis (19) of terebinthone gave a volatile compound identified through its 2,4-dinitrophenylhydrazone as acetaldehyde. It appeared likely from this evidence that the double bond was located in the side chain as an ethylidene group. In an attempt to learn more of the environment of this unsaturation, terebinthone was treated with dry hydrogen chloride (20) to induce rearrangement if possible. The product, which could not be purified, was treated with ozone as before. The volatile product, identified through a derivative, was methyl ethyl ketone. From these reactions it is possible to conclude that the side chain must possess the arrangement (IV).

(IV)

In regard to the location of the cyclic ether function, no evidence is yet available though studies are continuing in this laboratory.

EXPERIMENTAL

All melting points were taken on the Kofler apparatus unless otherwise stated. Analyses were performed by the Weiler and Strauss Microanalytical Laboratory, Oxford, England, and Galbraith Laboratories, Knoxville, Tenn. Spectral work was done by the Department of Chemistry, University of Florida.

Plant Material.—The ripe berries of *Schinus terebinthefolius* (Radd.) were gathered during the winter months of 1959–1960 and 1960–1961 near St. Petersburg, Fla.[1] A voucher specimen of the plant is deposited in the herbarium of the University of Florida. The berries were air-dried for 3 days then minced in a meat grinder.

Isolation of Terebinthone.—Nine hundred grams of the minced berries was extracted with hexane in a Soxhlet extractor for 24 hours. The hexane was gently expelled under an air stream leaving a brown, viscous oil weighing 117 Gm. A crystalline deposit gradually formed in the oil and several crops were filtered from it. An average of 4 Gm. of crystalline material was obtained from several extractions or about 0.45% of the crude berries. The crude material was recrystallized several times from acetone and finally from alcohol to give fine needles, m.p. 178–179°, $[\alpha]_D^{22}$ −72.6° (chloroform). Chromatography of the material on a Celite column did not improve these values. The name terebinthone was provisionally assigned to this compound.

Anal.—Calcd. for $C_{30}H_{46}O_3$: C, 79.24; H, 10.20; mol. wt., 454; C-methyl, 13.3 (four). Found: C, 79.22; H, 10.22; mol. wt. (Rast), 445, 456; C-methyl, 12.7.

Infrared analysis indicated absorption at 1708 and 1690 cm.$^{-1}$ (two carbonyls), 1640 cm.$^{-1}$ (double bond), 1385 and 1365 cm.$^{-1}$ (gem dimethyl and angular methyl) and 1095 cm.$^{-1}$ (cyclic ether). Ultraviolet analysis indicated absorption at 213 mμ (E = 7272). The compound gave a positive Zimmermann test and a negative test with tetranitromethane. The material was insoluble in hot sodium hydroxide solution.

Terebinthone Mono-2,4-dinitrophenylhydrazone.—A solution of 60 mg. of terebinthone in 10 ml. of aldehyde-free alcohol was treated with 25 ml. of U. S. P. 2,4-dinitrophenylhydrazine solution and refluxed for 4 hours. The product was isolated in the usual way and recrystallized from ethanol-ethyl acetate to give orange needles, m.p. 221–223°.

Anal.—Calcd. for $C_{36}H_{50}N_4O_6$: C, 68.11; H, 7.94; N, 8.83. Found: C, 68.75; H, 7.57; N, 9.19.

Ultraviolet analysis indicated maximum absorption at 367 mμ (E = 1409). Infrared analysis showed absorption at 1690 cm.$^{-1}$ (carbonyl).

Perbenzoic Acid Titration of Terebinthone.—A 40-mg. sample of terebinthone was dissolved in purified chloroform at 5° and made up to exactly 10 ml. with the same solvent. Exactly 9 ml. of this solution was withdrawn and added to exactly 5 ml. of a solution of perbenzoic acid in benzene at 5°. The mixture was swirled and kept at 5° for 24 hours. A blank was prepared using 9 ml. of purified chloroform. At the end of 24 hours, a 2-ml. aliquot was added to a solution of 1 Gm. potassium iodide, 1 ml. acetic acid, and 20 ml. of water. The liberated iodine was titrated with 0.01 *N* sodium thiosulfate. The perbenzoic acid consumed was equivalent to 0.98 double bond. At the end of 48 hours, the acid consumption was equivalent to 1.1 double bonds.

Ozonolysis of Terebinthone.—A solution of 200 mg. of terebinthone in 25 ml. of carbon tetrachloride at 0° was treated with a stream of 3% ozonized oxygen for 30 minutes. Water was then added to the reaction mixture and the volatile constituents were then steam distilled into a solution containing 200 mg. of 2,4-dinitrophenylhydrazine, 14 ml. of 40% sulfuric acid, and 6 ml. of water. About half of the carbon tetrachloride was steam distilled to insure completeness of the distillation. The distillate mixture was shaken and the organic layer separated. The aqueous phase was then extracted with ether which was added to the carbon tetrachloride solution. The residue from this solution was recrystallized from ethanol to give needles, m.p. 143–145°. A mixed melting point with the corresponding acetaldehyde derivative gave no depression and the infrared spectra were identical.

Acid Treatment of Terebinthone.—A solution of 400 mg. of terebinthone in 30 ml. of distilled chloroform was treated with a slow stream of dry hydrogen chloride for 7 hours. The hydrogen chloride and the chloroform were then removed under vacuum leaving an oily residue which could not be crystallized. This residue was then treated with ozone as previously described. The 2,4-dinitrophenylhydrazone obtained, m.p. 104–106°, gave no depression in melting point when mixed with the corresponding derivative of methyl ethyl ketone.

Dihydroterebinthone.—A solution of 1 Gm. of terebinthone in 30 ml. of ethyl acetate was hydrogenated at 1 atmosphere using prereduced platinum oxide as a catalyst. The consumption of hydrogen was equivalent to 92% of the theoretical amount for one double bond. The product from evaporation of the ethyl acetate was recrystallized from methanol to give 940 mg. of needles, m.p. 152–153.5°, $[\alpha]_D^{22}$ −80.8° (chloroform).

Anal.—Calcd. for $C_{30}H_{48}O_3$: C, 78.89; H, 10.59. Found: C, 78.83; H, 10.78.

Infrared analysis indicated strong absorption at 1700 cm.$^{-1}$ (carbonyl). The compound gave a positive Zimmermann test.

Dihydroterebinthone Mono-oxime.—A solution of 225 mg. of dihydroterebinthone and 650 mg. of hydroxylamine hydrochloride in 25 ml. of dry pyridine was refluxed for 20 hours. The pyridine was removed under vacuum and the residue recrystallized from methanol-water to give microcrystals, m.p. 164–166°.

Anal.—Calcd. for $C_{30}H_{49}NO_3$: C, 76.38; H, 10.47; N, 2.97. Found: C, 76.20; H, 10.62; N, 3.26.

Infrared analysis indicated absorption at 1700 cm.$^{-1}$ (carbonyl).

Terebinthol.—A suspension of 400 mg. of lithium aluminum hydride in 30 ml. of dry, peroxide-free ether was stirred for 1 hour. To this was added dropwise a solution of 500 mg. of terebinthone in dry, peroxide-free ether. Stirring was continued for 24 hours. At the end of this time, 1 ml. of 10% sodium hydroxide solution was added dropwise, followed by 1.2 ml. of water, then stirring continued for another 18 hours. The reaction mixture was then treated with water and the ether phase separated. The residue from the ether was recrystallized from acetone-hexane to give prisms, m.p. 189.5–191.0°, $[\alpha]_D^{22}$ −49.1° (chloroform).

Anal.—Calcd. for $C_{30}H_{50}O_3$: C, 78.55; H, 10.99;

[1] The authors wish to thank Mr. Lloyd Remington and his students at Boca Ciega High School for gathering the material. We are also indebted to them for introducing to us the local folklore concerning this plant's action.

active hydrogen (two), 0.41. Found: C, 79.08; H, 10.59; active hydrogen, 0.39.

Infrared analysis indicated a strong absorption at 3400 cm.$^{-1}$ (hydroxyl) and 1035 cm.$^{-1}$ (C—O). There was no absorption in the carbonyl region. The compound gave positive Liebermann-Burchard and Salkowski tests but negative Tortelli-Jaffe and tetranitromethane tests.

Terebinthol Mono-3,5-dinitrobenzoate.—A solution of 100 mg. of terebinthol and 500 mg. of 3,5-dinitrobenzoyl chloride in 3 ml. of dry pyridine was heated for 1 hour on a steam bath then allowed to stand at room temperature for 5 hours. This solution was then added to 10 ml. of water and the precipitate filtered off and washed with 2% sodium carbonate and water. The crude material was chromatographed on an alumina-Celite (1:2) column. The lower of two bands, developed with benzene, was cut from the column and extracted with chloroform. The residue from the chloroform was recrystallized from methanol, m.p. 119–121°.

Anal.—Calcd. for $C_{37}H_{52}N_2O_8$: C, 68.07; H, 8.03; N, 4.29. Found: C, 68.59; H, 7.74; N, 4.58.

Infrared analysis indicated absorption at 3400 cm.$^{-1}$ (hydroxyl).

Dihydroterebinthol.—(*a*) *Hydrogenation of Terebinthol.*—A solution of 1.7 Gm. of terebinthol in ethyl acetate was hydrogenated as previously described. The residue from the ethyl acetate was chromatographed on alumina. One gram of product was eluted with ether and recrystallized from methanol to give rods, m.p. 159–161°, $[\alpha]_D^{22}$ −38.7° (chloroform).

Anal.—Calcd. for $C_{30}H_{52}O_3$: C, 78.20; H, 11.38; Found: C, 78.49; H, 11.27.

(*b*) *Reduction of Dihydroterebinthone.*—An ethereal solution of 350 mg. of dihydroterebinthone was reduced with lithium aluminum hydride as previously described. This product, m.p. 159–161°, gave no depression in melting point with the compound obtained by the hydrogenation of terebinthol. The infrared spectra were also identical.

Dihydroterebinthol Mono-tosylate.—A solution of 100 mg. of dihydroterebinthol and 600 mg. of *p*-toluenesulfonyl chloride in 5 ml. of pyridine was heated on a water bath for 4 hours. The solution was then cooled, diluted with aqueous acid, and extracted with ether. The ether solution was washed with 5% sodium carbonate, dried, and the residue recrystallized from methanol to give needles, m.p. 144–146°.

Anal.—Calcd. for $C_{37}H_{56}O_5S$: C, 72.54; H, 9.15; S, 5.23. Found: C, 72.24; H, 9.40; S, 4.99.

Infrared analysis indicated absorption at 3400 cm.$^{-1}$ (hydroxyl).

Wolff-Kishner Reduction of Dihydroterebinthone (3-Desoxy-dihydroterebinthone).—Two hundred milligrams of sodium in 50 ml. of distilled, dry diethylene glycol was heated to 180°, 2.4 ml. of anhydrous hydrazine was added, and refluxing continued for 5 minutes. The solution was then cooled to 140° and 1 Gm. of dihydroterebinthone added, followed by 5 ml. of diethylene glycol. Refluxing was resumed with intermittent shaking to dissolve the compound completely. Refluxing was continued for 22 hours at 180°, then some hydrazine was allowed to escape until the refluxing temperature rose to 210°. This temperature was maintained for another 22 hours. The reaction mixture was cooled, diluted with water, and extracted with benzene. The residue from the benzene weighed 50 mg. and could not be further purified.

The aqueous phase was acidified with 10% acetic acid and extracted with benzene. The residue from the benzene, weighing 200 mg., was recrystallized from ethanol-water to give crystals, m.p. 137–139°, $[\alpha]_D^{22}$ −37.8° (chloroform).

Anal.—Calcd. for $C_{30}H_{50}O_2$: C, 81.39; H, 11.38; mol. wt., 442. Found: C, 81.10; H, 11.33; mol. wt. (Rast), 444.

Infrared analysis showed a single carbonyl absorption (1703 cm.$^{-1}$) and cyclic ether (1095 cm.$^{-1}$). The compound gave no Zimmermann reaction.

Absorption Spectra in Sulfuric Acid.—The absorption spectra between 220 and 700 mμ of concentrated sulfuric acid solutions of terebinthone, terebinthol, dihydroterebinthone, and dihydroterebinthol were obtained after time intervals of 5, and 15 minutes, 2 and 24 hours. The principal maxima in each case was observed at 304 mμ. A secondary peak in the terebinthone solution at 258 mμ was observed to disappear with the passage of time.

Production of Cardiac Glycosides by Plant Tissue Cultures I

Nutritional Requirements in Tissue Cultures of *Digitalis lanata* and *Digitalis purpurea*

By E. JOHN STABA

The techniques employed and the agar medium suggested for the establishment of *Digitalis lanata* Ehrh. and *Digitalis purpurea* L. seed and root callus tissue are reported. Particular attention is devoted to the concentration effects of the auxins, 2,4-dichlorophenoxyacetic acid (2,4-D), 2-benzothiazoleoxyacetic acid (BTOA), and 1-naphthaleneacetic acid (NAA) contained in a growth medium suggested for the two *Digitalis* species.

THE GENERAL procedures employed to establish *in vitro* plant tissue cultures have been well documented and reported (1–3). However, the establishment of a defined medium for a specific plant to be grown as either normal or callus tissue is still determined empirically.

Nickell (4), Steward (5), and Bergmann (6) have shown that callus plant tissue cultures could be transferred to liquid submerged cultures and grown as single plant cells or small aggregates of plant cells. Many investigators have since speculated on the possible application of plant tissue cultures for producing economically useful plant constituents (4, 7).

The experimental evidence pertaining to the capability of an *in vitro* plant tissue culture to biosynthesize a desired plant constituent is inconclusive. *Datura* crown-gall tumors are known to contain high amounts of hyoscine (7); *Datura tatula* L. root tissue cultures are known to biosynthesize the alkaloids hyoscyamine and hyoscine (8); and, *Atropa belladonna* L. root and callus tissue cultures are known to biosynthesize the alkaloid atropine (9). However, callus tissue cultures of *Agave toumeyana* Trel. leaves do not contain the sapogenin hecogenin (10).

This publication represents the first one of a series that will attempt to determine whether or not tissue cultures of cardiac glycoside-containing plants can biosynthesize cardiac glycosides.

EXPERIMENTAL

The digitalis seeds used on medium A (see Table I) were obtained from the Saier Seed Co., Dimondale, Mich., and those seeds used on medium B were obtained from the medicinal plant laboratory and garden, University of Minnesota.[1] Roots were obtained from digitalis plants approximately 6 months old and growing in the drug plant greenhouse, University of Nebraska.

Sterilization of Seeds and Roots.—Digitalis seeds were sterilized in a 5.25% sodium hypochlorite solution (Purex Corp., Ltd., South Gate, Calif.) diluted 1:4 with sterile distilled water for approximately 10 minutes in vacuum. The seeds were then washed with sterile distilled water and transferred to sterile Petri dishes containing approximately 10 ml. of sterile distilled water. Two seeds were transferred aseptically to a nutrient medium after approximately 80% of the seeds had begun to germinate. This occurred on the fifth day for *D. lanata* Ehrh. seeds and on the third day for *D. purpurea* L. seeds.

Root sections were cut from digitalis plants grown in soil, washed in tap water, and sterilized in the above solution in vacuum for approximately 15 minutes. By aseptic procedures, the sterilized root sections were washed with distilled water, placed in Petri dishes containing a small amount of distilled water, and chopped with a scalpel into small root sections of about 2 cm. The root sections were then transferred aseptically to a nutrient medium.

Auxin Stock Solutions and Coconut Milk.—All auxins were prepared as 30% ethanol stock solutions. The auxins and coconut milk were autoclaved with the constituents of medium A or medium B. With the exception of 2-benzothiazoleoxyacetic Acid (BTOA),[2] all auxin stock solutions were used within 48 hours of their preparation.

Experiment One.—Medium A, with 0.7% agar, was prepared in the following four variations: (*a*) medium A; (*b*) medium A with 2,4-dichlorophenoxyacetic acid (2,4-D), 2 parts per million (p.p.m.); (*c*) medium A without enzyme-hydrolyzed casein hydrolysate (EHCH) but with 2,4-D, 2 p.p.m.; and (*d*) medium A without EHCH, coconut milk, or 2,4-D. The pH after autoclaving of media (*a*) and (*b*) was 4.1, and of media (*c*) and (*d*), 5.4. The low pH of media (*a*) and (*b*) was due to the presence of EHCH and caused the media to liquefy.

Received April 28, 1961, from the College of Pharmacy, University of Nebraska, Lincoln.
Accepted for publication July 18, 1961.
Supported in part by grant from the National Heart Institute (H-5308) and the University of Nebraska Research Council, Grants-in-Aid (Johnson Fund—1960).
Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.
The author is indebted to Mr. Sidney J. Stohs for technical assistance.

L-Asparagine	25.0		

[a] *Media* were prepared with inorganic chemicals of reagent grade, organic chemicals from either Nutritional Biochemical Corp., Cleveland, Ohio, or Calbiochem, Los Angeles, Calif., and distilled water, redistilled from glass. [b] Pfanstiehl Laboratories, Waukegan, Ill. [c] Dr. Toshio Murashige, University of Hawaii, formerly in the laboratory of Dr. Folke Skoog, University of Wisconsin. [d] Perma Green Iron 135, Refined Products Corp., Lyndhurst, N. J. [e] Eagle's vitamins solution, Hyland Laboratories, Los Angeles, Calif.

Murashige's mineral solution; Murashige's mineral solution, half-strength; and modified White's mineral solution were prepared with each of the above four variations.

Two sterile, germinated digitalis seeds were placed aseptically on 5 ml. of each medium contained in 17 mm. × 100 mm. sterile plastic test tubes.[3]

Experiment Two.—Medium B, with 0.7% agar, was prepared in the following three variations: (*a*) medium B without coconut milk; (*b*) medium B with coconut milk and EHCH, 0.2%; and (*c*) medium B with coconut milk and complex supplement.

To each of the above three media, auxins were added to yield the following p.p.m. concentrations: indoleacetic acid (IAA) 0.1 and 1; BTOA 2 and 6; 2,4-D 4 and 8; naphthaleneacetic acid (NAA) 6; BTOA 2 + IAA 0.1; BTOA 2 + 2,4-D 4; and IAA 0.1 + 2,4-D 4 + NAA 2. The following auxin concentrations also were used in medium (*a*): BTOA 2 + kinetin 0.5; and IAA 0.1 + kinetin 0.5.

The complex supplement was Seitz-filtered and, at all times, added aseptically to autoclaved and cooled medium B.

The above media were adjusted to pH 5.7 with ammonium hydroxide solution before Seitz-filtration or autoclaving.

Experiment Three.—Medium B was prepared in the following two variations: (*a*) medium B, and (*b*) medium B with complex supplement.

In each of the above two media, auxins were used in the p.p.m. concentrations shown in Table II and in the following auxin combinations: BTOA 1 + 2,4-D 5; BTOA 5 + 2,4-D 1; BTOA 5 + 2,4-D 5; BTOA 1 + NAA 1 + 2,4-D 5.

Approximately 15 ml. of each medium in experiment 2 and experiment 3 was added to autoclaved, 1-oz., plastic-capped, wide-mouth prescription bottles. Two sterile, germinated digitalis seeds were placed aseptically in each bottle. This procedure was repeated four times for each medium.

RESULTS AND DISCUSSION

Experiment One.—Germinated digitalis seeds were completely inhibited in growth if placed on medium A, or any of its variations containing

[a]Of 16 control Digitalis plants, one developed a small callus after 95 days of growth. [b]Of eight plants, one developed a callus on the 115th day.

EHCH. Although this substance is normally a good nutrient supplement for plant tissue cultures (11), it has affected tissue growth of Jerusalem artichoke tubers adversely in the absence of nitrate ions (12). Casein hydrolysate, in the absence of IAA and kinetin, also caused adverse growth effects in tobacco callus cells (13).

Germinated digitalis seeds grew normal-appearing roots and stems on medium A without EHCH, coconut milk, or 2,4-D. Root development was generally poor unless the medium contained IAA or NAA. One small callus appeared after approximately 45 days of growth on medium A without EHCH, but with 2,4-D, 2 p.p.m.

No significant influence on the growth of digitalis seeds by any of the three mineral solutions used was observed.

Experiment Two.—Medium B was prepared at a pH of 5.7 with EHCH in order to confirm that this substance was responsible for the inhibition of germinated digitalis seeds and not the high acidity of the medium. As previously observed in experiment 1, all germinated digitalis seeds in experiment 2 were also completely inhibited in growth on media containing EHCH.

Due to the adverse growth effects of EHCH, a chemically defined complex supplement (see Table I) was formulated to serve as the nitrogen and carbohydrate source. This supplement appeared to increase the vigor of digitalis seed growth, with the one exception of media containing IAA where it appeared to retard root development.

Small callus tissues were observed to form occasionally from sterile, germinated digitalis seeds or roots on media containing the auxins, 2,4-D, BTOA, or their combinations. Media containing NAA stimulated root production. Previous investigators have obtained questionable growth effects when digitalis was grown on a medium containing 2,4-D, 6 p.p.m., with NAA, 0.1 p.p.m. (1).

Experiment Three.—As the digitalis seeds consistently grew better on a medium with the complex supplement, the descriptions of growth given below and in Table II pertain only to media containing the complex supplement.

Digitalis seeds developed normal-appearing stems and leaves on media without auxins for about 65 days (Fig. 1, frame 1), with eventual drying and browning of the stem and leaves after about 115 days (Fig. 2, frame 2). Root systems in the control plants were poorly developed.

Effects of the Auxin, BTOA.—The stimulatory effects of BTOA on tissue growth of both carrot and Jerusalem artichoke tuber have been reported (11).

D. purpurea appeared slightly less sensitive (Fig. 1, frames 4, 5, 6) and more varied (Fig. 1, frame 2) in response to BTOA than *D. lanata* (Fig. 2, frames 4, 5, 6). The *D. purpurea* callus shown in Fig. 1, frame 2 is growing on medium B with BTOA, 5 p.p.m., and increased more than 6,000% when calculated as the wet weight over the original weight of the seed (0.1 mg.) in 95 days.

In both digitalis species callus appeared to form from the stem-root node, stem, or cotyledon tissue in contact with the medium.

Effects of the Auxin, 2,4-D.—All digitalis seeds on media containing 2,4-D formed very poor stems and roots (Fig. 2, frame 1) and eventually formed callus tissues.

Both digitalis species at the lower 2,4-D concentrations, developed excellent callus tissue within 25 to 35 days (Fig. 1, frames 7, 8, 9). The callus would generally develop from small nodules on either the roots, stems, or cotyledons (Fig. 2, frames 7, 8, 9). Root-like nodules were observed to form on some callus tissues of *D. lanata* (Fig. 2, center of frames 8, 9).

Effects of the Auxin, NAA.—*D. purpurea* seeds at the lower NAA concentrations generally produced good stem growth and a short, thick root system (Fig. 1, frame 3). At the higher NAA concentrations, the seeds developed practically no stems and were transformed into small callus tissues containing small rootlets (Fig. 1, frames 10, 11, 12).

D. lanata seeds at the lower NAA concentrations generally produced good stem growth, a short, thick root system, and occasionally callus tissue. At the higher NAA concentrations all the *D. lanata* seeds developed a rapidly growing callus containing an abundance of root nodules and root hairs (Fig. 2, frames 10, 11, 12). In contrast to the growth rate of *D. purpurea* tissue, the growth of *D. lanata* tissue on higher NAA concentrations was rapid.

Effects of Combinations of the Auxins, BTOA, 2,4-D, and NAA.—Digitalis seeds formed callus tissue on all auxin combinations containing 2,4-D. However, if the 2,4-D concentration was 5 p.p.m. or greater, the callus growth was generally less vigorous. Combinations of BTOA, 1 or 5 p.p.m., with 2,4-D, 1 p.p.m., resulted in very good callus growth formation for both digitalis species (Figs. 1 and 2, frames 13, 14, 15).

Digitalis Root Callus Formation.—The incidence of contamination in bottles containing digitalis roots of plant origin was about 50%. Callus tissue did occasionally form on medium B containing either BTOA, 2,4-D, NAA, or their combinations. *D. lanata* root callus formation is shown on medium B containing NAA, 10 p.p.m. (Fig. 2, frame 3).

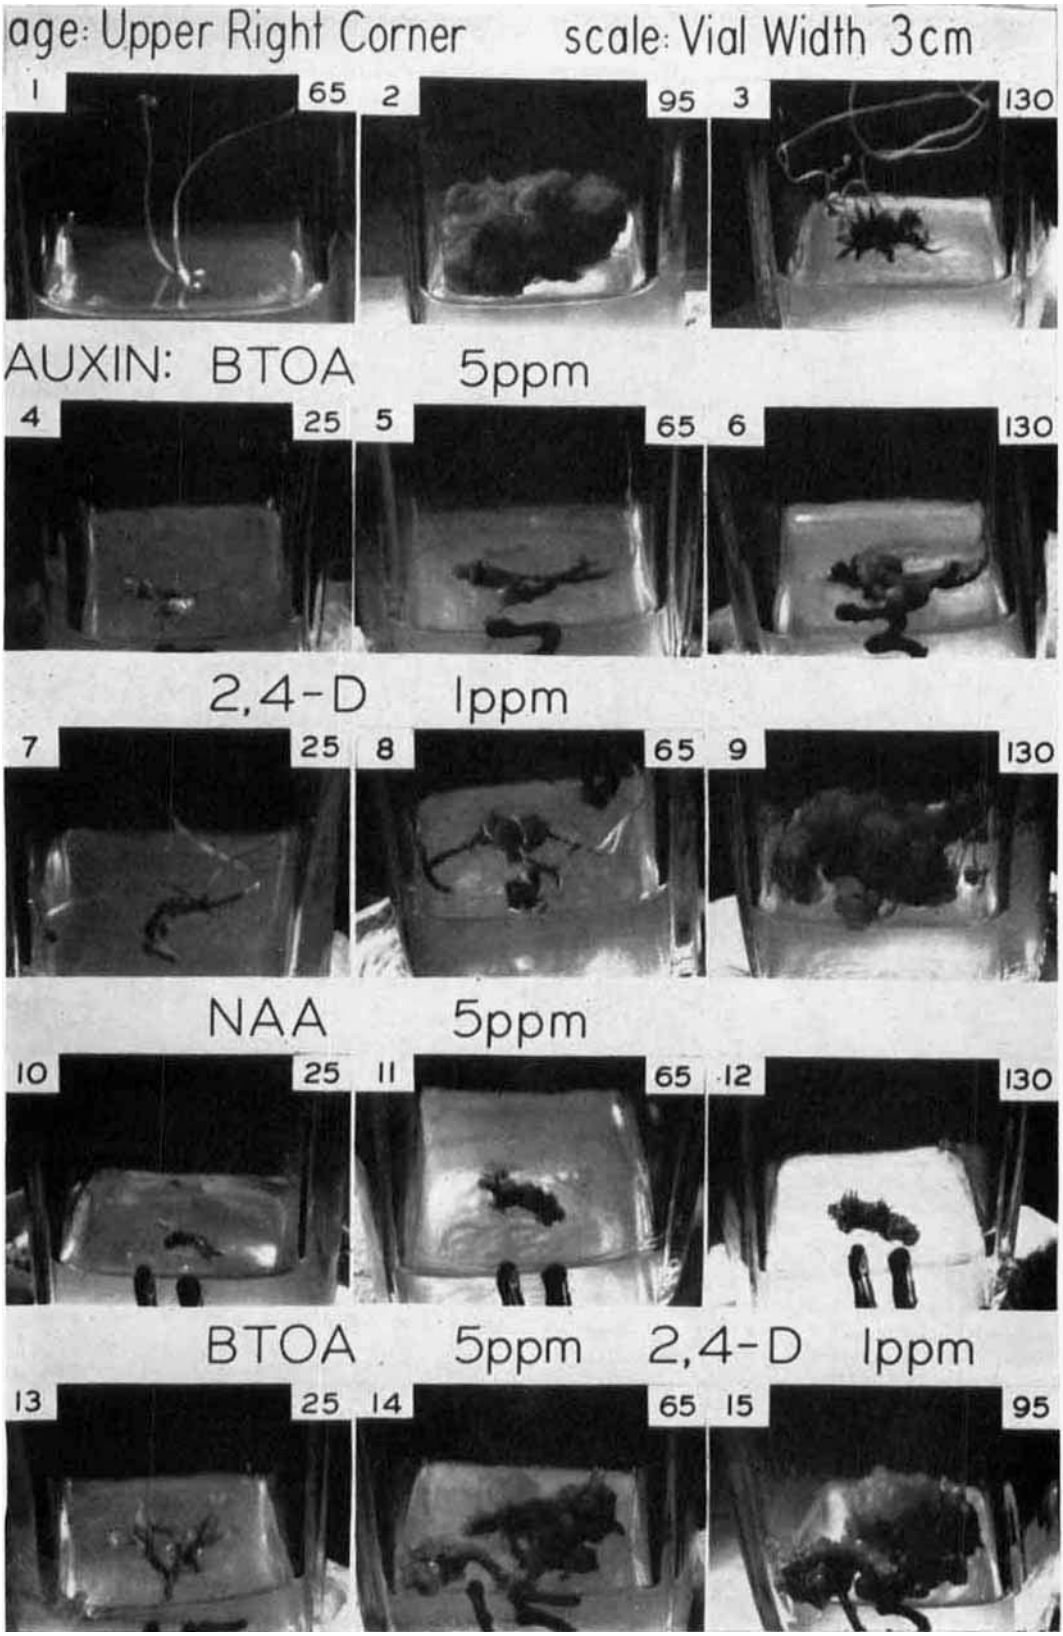

Fig. 1.—*Digitalis purpurea* L.

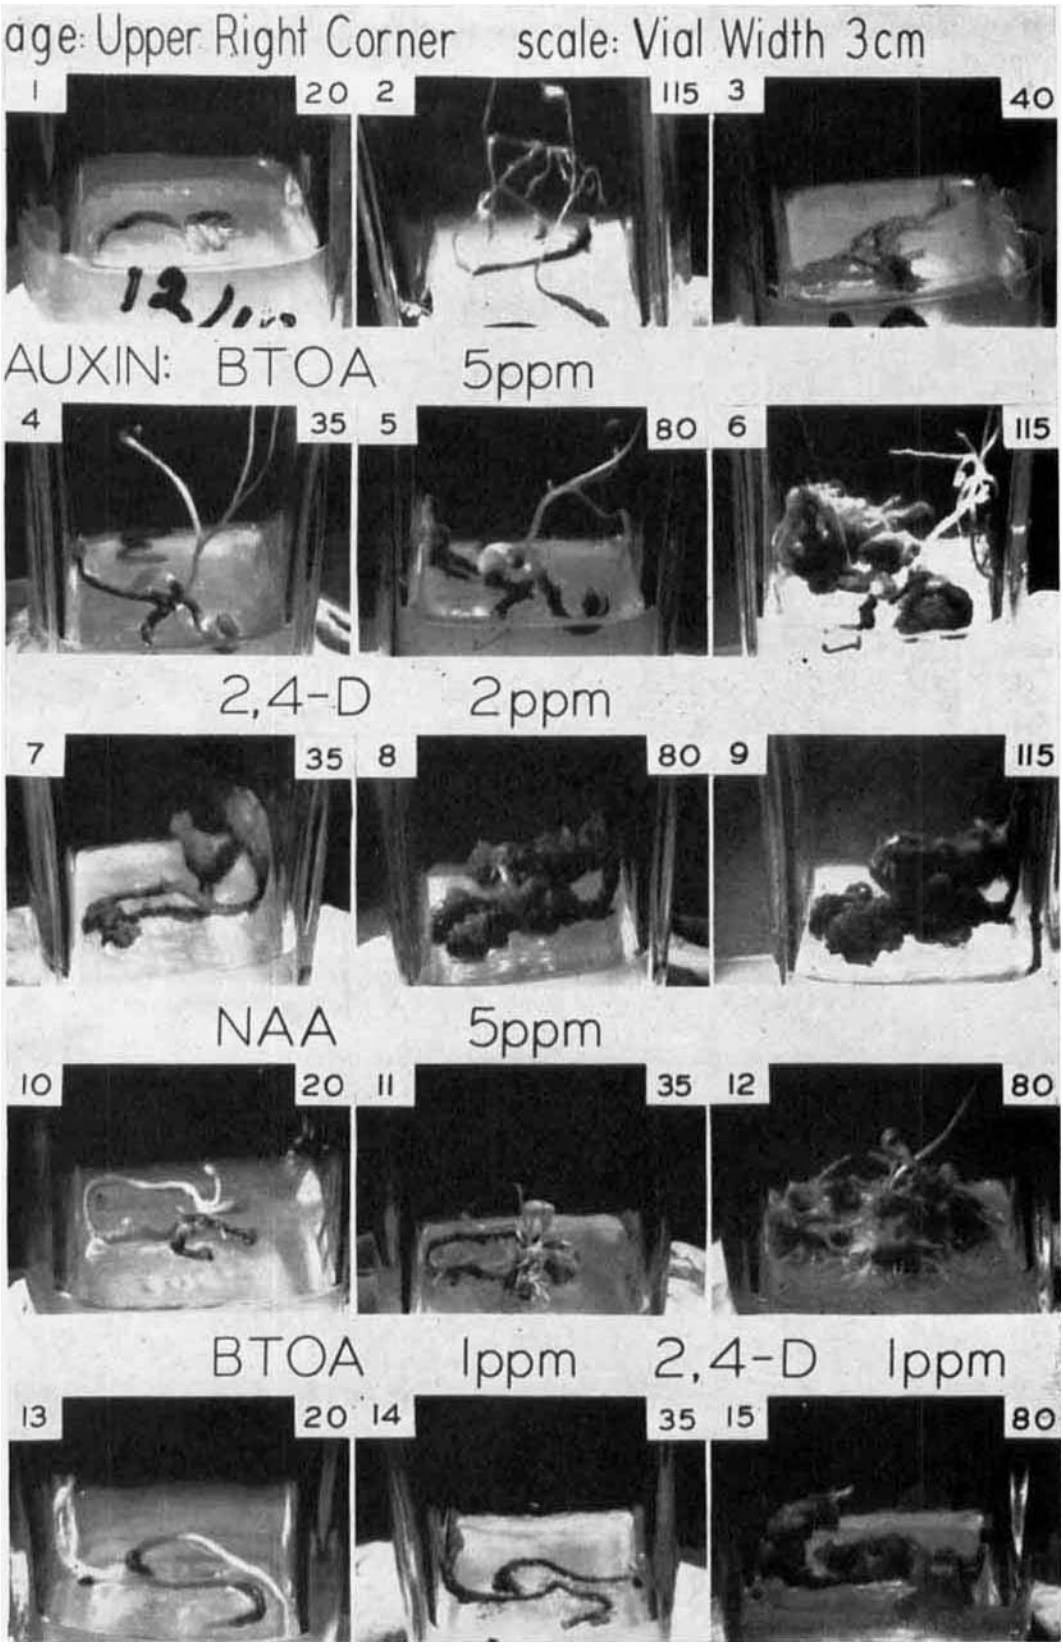

Fig. 2.—*Digitalis lanata* Ehrh.

SUMMARY AND CONCLUSIONS

1. On the media defined, enzyme-hydrolyzed casein will inhibit the growth of germinated digitalis seeds.

2. On medium B with complex supplement, the auxins BTOA, 5 p.p.m.; 2,4-D, 2 p.p.m.; NAA, 5 p.p.m.; or appropriate auxin combinations, BTOA, 1 to 5 p.p.m., with 2,4-D, 1 to 2 p.p.m., will cause digitalis seeds or roots to form callus tissues.

Radioisotopic Method of Evaluating Dispersed Systems I

Emulsions

By JAMES B. APPINO†, JOHN E. CHRISTIAN, and GILBERT S. BANKER

Liquid petrolatum emulsions were prepared by a standard method and evaluated by a new radioisotopic method. The radioisotopic method required less time and was more sensitive than previously used methods. A radioisotopic creaming rate was determined for each emulsion and can be used to compare microscopically identical emulsions and/or production samples of an emulsion to a previously determined standard. The method is applicable to w/o or o/w emulsions.

THE PRECISE evaluation of emulsions has presented problems to pharmaceutical and other scientists for many years. In an attempt to appraise and control emulsion appearance, uniformity of dosage, and stability, the following emulsion properties have been evaluated: particle size, particle size distribution, viscosity, and creaming rate (1–3). The evaluation of these factors gives some insight into the question, "How long can the product remain pharmaceutically elegant on the pharmacist's shelf?" but may leave the question of uniformity either wholly or partially unanswered.

This study is concerned primarily with an evaluation of the creaming rate and/or phase uniformity of emulsions in less time than is now required by the conventional visual (4) or microscopic (5) methods, or the more tedious though perhaps more accurate chemical or analytical methods (6). Radioisotopes, because of their sensitivity of detection (7), were utilized as tools in evaluating these properties.

Received April 28, 1961, from Purdue University, School of Pharmacy, Lafayette, Ind.

Accepted for publication June 12, 1961.

Presented to the Scientific Section, A. PH. A., Chicago meeting, April 1961.

† Present address: Armour Pharmaceutical Co., Kankakee, Ill.

EXPERIMENTAL

Preparation of Emulsion Samples.—The compositions of the emulsions evaluated in this study are given in Table I. The standard method of manufacture of all emulsion samples involved heating the liquid petrolatum and emulsifiers to 55° and the water and preservatives to 60°. The water phase was then added to the oils with constant agitation and the emulsion mixed until the temperature dropped to 38°. All emulsions were prepared in 1-L. quantities and allowed to deaerate for 24 hours before use.

Approximately 1 mc.[1] of sodium iodide (I^{131})[2] or iodobenzene (I^{131}) (8) per 100 ml. of emulsion was

[1] Gave 8,000–12,000 c.p.m. in end counting and 5,000–8,000 c.p.m. in side counting apparatus. Apparatus described later in text.

[2] Weight of sodium iodide is insignificant.

SUMMARY AND CONCLUSIONS

1. On the media defined, enzyme-hydrolyzed casein will inhibit the growth of germinated digitalis seeds.

2. On medium B with complex supplement, the auxins BTOA, 5 p.p.m.; 2,4-D, 2 p.p.m.; NAA, 5 p.p.m.; or appropriate auxin combinations, BTOA, 1 to 5 p.p.m., with 2,4-D, 1 to 2 p.p.m., will cause digitalis seeds or roots to form callus tissues.

[a] Emulsion 1: 1A, NaI^{131} added to finished emulsion; 1A', replication of 1A. Emulsion 2: 2A, NaI^{131} added to finished emulsion; 2B, $C_6H_5I^{131}$ added to finished emulsion. Emulsion 3: 3A, NaI^{131} added to finished emulsion; 3B, $C_6H_5I^{131}$ added to finished emulsion; 3C, $C_6H_5I^{131}$ added before emulsification.

used to label the emulsions studied. These labels were chosen on the basis of their selective solubilities in the water and oil phases, respectively, and insolubility in the other components of the emulsions. One of the following methods was used to prepare any single emulsion sample: (*a*) NaI^{131} was added to the water phase of the finished emulsion, (*b*) iodobenzene (I^{131}) was either added to the oil before emulsification, or (*c*) incorporated in 2 ml. of liquid petrolatum, 0.5 ml. of Span 20,[3] and 0.5 ml. of Tween 20[3] and added to the finished emulsion.

To facilitate detection of any visual changes in phase uniformity of the emulsions, 5–10 drops of a 1% amaranth solution was added to 120 ml. of an unlabeled control sample and to 120 ml. of a labeled control sample of each emulsion.

Evaluation of Emulsion Samples.—Approximately 120 ml. of each emulsion was placed in a separate 18 mm. i.d., constant bore Pyrex cell, 44 cm. in length. Gentle suction was then applied with a water aspirator for approximately 3 minutes to remove any air remaining in the emulsion. The cells were filled to within 3 mm. of the top and one cell was then placed in the counting apparatus and counted. Three other cells containing unlabeled, uncolored; unlabeled, colored; and labeled, colored emulsions, respectively, were stored as controls.

Two counting apparatuses were constructed to determine the ratioactivity in the labeled emulsions (Fig. 1). The first apparatus, number 1, was designed to detect activity through the side of the cell and the second apparatus, number 2, through the ends of the cell. Initially, the side counting method appeared to be the logical method to use in evaluating the emulsions; but due to its insensitivity when the water phase was labeled, the end counting method proved to be superior.

In the end counting apparatus the cells were sealed with Saran[4] wrap and paraffin. The Saran wrap was placed over the end of the cell and paraffin poured around the outer edge to seal it (no paraffin was used at the upper end of the cell). Two Geiger-Müller tubes, type D-33,[5] were used to detect the activity in the cell. The upper tube was placed against a 1/8 inch thick lead plate that had a 1/4 inch diameter hole drilled through it. The lower tube was placed through a plywood platform drilled just to accommodate the tube with the end window against another lead plate which had a 1/4 inch diameter hole drilled through it for collimation.

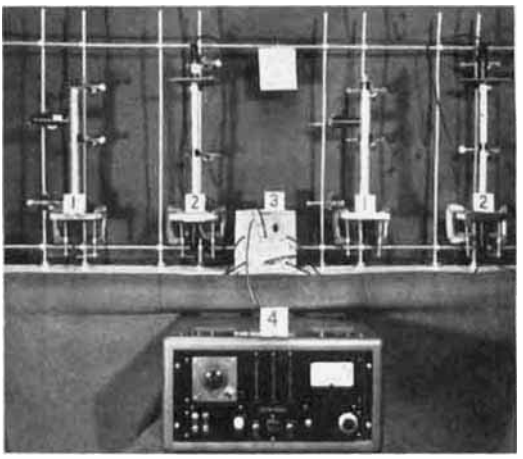

Fig. 1.—Multiple counting apparatus. 1, Side counting apparatus; 2, end counting apparatus; 3, control panel; 4, scaler.

The cell was placed on a 1.5 × 2.5 inch piece of hard rubber to aid in sealing the bottom. The rubber had a 15 mm. diameter hole cut in it and the cell was positioned above this hole. The plywood platform was supported by a support ring attached to a permanent table mounted ring stand. Each Geiger-Müller tube was held in a fixed position by a ring stand clamp.

The cables from six Geiger-Müller tubes were connected to a central control panel (number 3, Fig. 1). The scaler, model 200-S[6] (number 4, Fig. 1), was also connected to this panel and by turning the panel switch from 1 through 6, each of the Geiger-Müller tubes could be put into operation without manually changing any connections.

Viscosity and Particle Size Determination.—A direct microscopic evaluation (9) of the globule diameters was made using a standard microscope equipped with a 10× eyepiece and 43× objective. The eyepiece contained a micrometer with a 5 mm. horizontal scale divided into 100 divisions. A 50% aqueous solution of propylene gylcol was used to dilute one drop of the emulsion three to fivefold to facilitate microscopic examination (10). One drop of the diluted emulsion was placed on a microscope slide, a cover slip placed over it, and then allowed to stand 15 minutes before examination. A sample size of 100 particles was found to be more than statistically adequate using the method of Harris, Horvitz, and Moon (11), with a maximum confidence interval of one unit, a 99% confidence coefficient, and a 95% probability.

The emulsions used in this study were thought to exhibit Newtonian properties (12). This supposition was verified using a Ferranti-Shirley cone-plate viscometer.[7] A Brookfield-Synchro-lectric, model RVF viscometer[8] was thus used in subsequent viscosity determinations using spindle No. 1 at 20 r.p.m. The viscometer was allowed to operate 10 minutes in the emulsion before a reading was taken.

3B Hourly	0.9626	0.9546	0.9961	0.1382	..	None
3C	0.9542	0.9536	0.9974	0.1506	1	1
3C Hourly	0.9441	0.9023	0.9910	0.2957	..	None

[a] r_1 = Zero order, r_2 = first order, r_3 = log-log. [b] Rate of change of ratio with respect to time, based on log-log plot. [c] Last day significantly different from all other days (Newman-Keuls test). [d] Day phase separation first observed in control emulsions. [e] No distinct phase separation, only a change in color intensity of the controls.

Statistics.—An analysis of variance (13) was used to identify significant differences in phase uniformity of the emulsion samples with time and a Newman-Keuls test (14) was employed to determine the days over which significant changes occurred. The method of least squares (13) was used in the graphical presentations of the data and correlation coefficients (13) were calculated for zero-order, first-order, and log-log expressions to determine the best form of expression of the data.

RESULTS

Radiation Effects.—When the particle size and viscosity data of the various emulsions were statistically analyzed, it was found that the addition of NaI^{131} or $C_6H_5I^{131}$ to the finished emulsion, in the manner described and in the amounts used, had no effect on the emulsion system.

Radioisotopic Evaluation.—The radioisotopic data were recorded as a ratio of counts per minute (c.p.m.) at the top of the cell to c.p.m. at the bottom of the cell. By using this ratio, a form of comparison counting was achieved and corrections for background, efficiency, absorption, and decay were unnecessary. This left only coincidence corrections to be applied to the data. The length of each count was the time calculated to give 1% error or less in counting, usually 5 minutes. The emulsions were counted three times a day at 6-hour intervals until the ratio no longer decreased. The data were then statistically analyzed and plotted. The plots of emulsions 1A, 2A, and 3A are given in Fig. 2. These are typical graphs for emulsions with the water phase labeled. The graphs for the emulsions with the oil phase labeled were of the same type except the slopes were positive.

Two cells of an identical emulsion (1A and 1A′) were used to determine if reproducible results could be achieved on different apparatus. After the counting was completed, an analysis of variance was conducted to determine if day to day differences did exist and a Newman-Keuls test (14) was run to determine which days differed significantly. In both emulsions there were significant day to day differences, but the Newman-Keuls test indicated no significant differences after the first day.

To determine the rate of change of the ratio with respect to time (radioisotopic creaming rate)[9] the

[9] The radioisotopic creaming rate is the rate of phase separation or creaming of labeled emulsions (ratio *vs.* time).

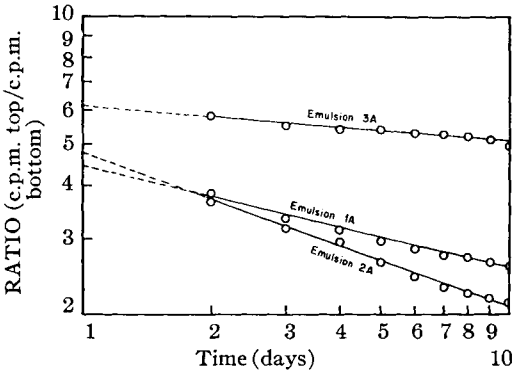

Fig. 2.—Typical log-log creaming curves.

method of least squares (13) was used; and to determine the best linear correlation, the correlation coefficients were calculated. The results of these tests are in Table II. The best linear correlation for emulsions 1A and 1A′, as for the remainder of the emulsions studied, was the log-log correlation. Thus, the mathematical expression was $\ln Y = \ln a + b \ln X$, where Y is the ratio of c.p.m. at the top of the cell to c.p.m. at the bottom of the cell, a is the Y intercept, b is the radioisotopic creaming rate (slope of the line), and X is the time. The general equation would therefore be $Y = aX^b$. From the radioisotopic creaming rates and the day to day variances, it can be seen that the two apparatuses did duplicate the results. The uncolored labeled and uncolored unlabeled controls of emulsion 1 showed no visible signs of phase separation. However, the colored controls showed a change in color intensity on the 10th day (Table II).

Emulsion 2, containing 0.5% electrolyte (sodium iodide), produced a system with more rapid phase separation. The results of this study are shown in Table II as 2A and 2B. The analyses of variance of both emulsions indicated significant day to day changes in the ratio. The Newman-Keuls test (Table II) indicated that emulsion 2B changed for a longer period of time than emulsion 2A. The radioisotopic creaming rates also indicated that emulsion 2, with 0.5% electrolyte, creamed more rapidly than emulsion 1, even though emulsion 2 had 5% more emulsifier. A change in color intensity of the dyed NaI^{131}-labeled control and the unlabeled control emulsions was observed on the 4th day, al-

though no change was observed in the uncolored samples. However, the same basic emulsion labeled with $C_6H_5I^{131}$ started to cream rapidly on the 6th day. This indicated the $C_6H_5I^{131}$ might be causing an acceleration of the creaming rate. To verify this assumption, unlabeled iodobenzene was added to emulsion 2 and again a rapid phase separation was observed.

Emulsion 3 was prepared to verify further the end counting method using NaI^{131} and to find a procedure for incorporating $C_6H_5I^{131}$ without accelerating the rate of creaming (Table I). Because of the rapid phase separation during the first 48 hours, observed in emulsions 1 and 2, emulsion 3 was counted every 2 hours for the first 12 hours, and every 2 hours from the 24th to 36th hour. After the 36th hour they were counted three times a day at 6-hour intervals. The analysis of variance of all three emulsions indicated a significant day to day change in ratio and the Newman-Keuls test showed the first day to be the only one significantly different from all others. In emulsions 3A and 3B there were no visual changes in the labeled or unlabeled controls. However, the labeled colored control of emulsion 3C indicated creaming had started on the first day. The radioisotopic creaming rates (Table II) of emulsions 3A and 3B were very similar, but that of emulsion 3C was greatly increased. From these results it was concluded that the $C_6H_5I^{131}$ added to the oil before emulsification increased the creaming rate, but when added with liquid petrolatum and the emulsifiers to the finished emulsion, had no effect on the emulsion system.

Emulsion 3A-hourly, 3B-hourly, and 3C-hourly are the results of the first 36 hours of counting of emulsions 3A, 3B, and 3C, respectively. As can be seen from Table II, the best linear correlation was again log-log. This indicated the same type of change in the ratios (log-log) from hour to hour or day to day. From these results it is apparent that if two emulsions that cream in a relatively short time are to be compared, an hour to hour isotopic analysis would be preferred.

DISCUSSION

The advantages of the radioisotopic method of evaluation are (*a*) sampling is simplified and subsequent chemical assays are not necessary, (*b*) there is a continuous indication of uniformity and if phase separation occurs, it is readily detected, (*c*) the isotope method approaches the problem of emulsion stability from the most important standpoint of dispersion uniformity, and (*d*) very small amounts of label can be used and thus not affect the emulsion system.

In this study a gamma emitter (I^{131}) was used as the label because it could be readily synthesized into water-soluble or oil-soluble compounds. However, if a beta emitter such as P^{32} were used to label the water phase, it is felt that the sensitivity would be increased due to the greater absorption of the beta particles as the emulsion tended to cream.

Although the end counting method was superior to the side counting method, it is felt that a combination of the two might be advantageous. To use the two methods in the most expedient manner, a precision turn table, that would hold a desired number of cells could be constructed with a Geiger-Müller tube mounted above and another below it. Then as the table turned it would lock a cell into position accurately between the two Geiger-Müller tubes. To side count the cell, another apparatus could be constructed that would slowly move a third Geiger-Müller tube and scan the cell. Thus with only three Geiger-Müller tubes, a scaler, a rate meter, and automatic recorder for the side scanning, a number of emulsions could be evaluated in a short period of time.

The radioisotopic method of evaluating emulsions appears to be applicable to other dispersed systems. By the use of the end counting method, suspensions could be evaluated for rate of sedimentation. The absorption of the label by the solid particles should increase the sensitivity of the apparatus. The radioisotopic method appears to have industrial application in comparing visually and microscopically statistically identical emulsions in a short period of time. Also, once a radioisotopic creaming rate has been determined for a given emulsion system, production samples can be withdrawn, labeled, and rapidly compared to the predetermined standard rate.

CONCLUSIONS

1. A radioisotopic method has been developed for determining the phase uniformity of emulsions and for detecting and expressing ratios of creaming of emulsions that is applicable to w/o and o/w emulsions with either phase being labeled.

2. The radioactivity added to the emulsions had no effect on the particle size or viscosity of the emulsions.

3. For the emulsion system studied, much less time was required for the radioisotopic evaluation than for visual or microscopic evaluations, and great sensitivity was evidenced by the detection of phase separation before it became visible.

Kinetics and Mechanism of the Salicyl Alcohol-Bisulfite Reaction

By LOUIS C. SCHROETER

Reaction between bisulfite or sulfite ion and salicyl alcohol appears to follow second-order kinetics over a wide (4.0–9.5) pH range. Results suggest two parallel S_N2 mechanisms involving uncharged salicyl alcohol with bisulfite or sulfite ion. The empirical heat of activation for the reaction was found to be 24 Kcal. mole^{-1}. The reaction shows a "normal" frequency factor of 4×10^{11} L. mole^{-1} sec.$^{-1}$ characteristic of many ion-neutral molecule reactions. Entropy of activation was calculated as −7.1 e.u. with a standard state of moles per L.

SALICYL ALCOHOL reacts with bisulfite to yield *o*-hydroxyphenylmethane sulfonate (1); however, the scope of the reaction is not limited to salicyl alcohol as the substrate. The reaction has proved useful for the synthesis of various *ortho*- or *para*-hydroxybenzylsulfonates and, with modifications, for the preparation of similar alkoxybenzylsulfonates (2). Kinetics and mechanism of the salicyl-bisulfite reaction are of interest not only as a model for this unique reaction but also for comparison with results obtained in a study of the reaction of epinephrine with bisulfite (3). The kinetics and mechanism of epinephrine reaction with bisulfite have been studied in some detail. Two distinct mechanisms have been uncovered: an S_N1 reaction which predominates at pH values below 4 and an S_N2 reaction which predominates at pH values over 5. The catecholamine, epinephrine, differs from salicyl alcohol in that it contains an asymmetric secondary alcohol function and exists as a charged ion over the pH range 3–7.

EXPERIMENTAL

Materials and Apparatus.—Salicyl alcohol, Eastman WL, was recrystallized twice from water, m.p. 87°. All other chemicals were of reagent grade. A Beckman GS pH meter, a Cary model 11 recording spectrophotometer, and a Perkin-Elmer model 221 spectrophotometer were used.

Kinetic Studies.—Reactant solutions were prepared to contain equimolar (0.03) concentrations of salicyl alcohol and bisulfite or sulfite in 0.30 *M* buffers. Ionic strength of the solutions was adjusted to predetermined values by addition of appropriate amounts of sodium chloride. Solutions were flushed with nitrogen and filled into hard glass ampuls. Ampuls were sealed under nitrogen, then stored in a thermostat in which the temperature variation was less than 0.1°. Sampling was performed by removing ampuls from the thermostat and quickly chilling in an ice-water mixture. Prior to analysis, ampuls were equilibrated briefly at 25°. Available bisulfite was determined by iodometric titration.

Received March 17, 1961, from the Research Laboratories, The Upjohn Co., Kalamazoo, Mich.
Accepted for publication June 16, 1961.

Product Isolation.—Reaction between equimolar (0.25) concentrations of salicyl alcohol and bisulfite or sulfite ion was carried out at pH 5 and 8 using previously described procedure (2).

Product Isolated from pH 5 (Bisulfite Ion) Reaction in 67% Yield.

Anal.—Calcd. for $C_7H_7NaO_4S$: C, 40.00; H, 3.36; S, 15.26. Found: C, 40.10; H, 3.48; S, 15.41. Infrared spectrum showed the following bands: —OH, 3,180 cm.$^{-1}$; salt, 2,760, 2,620 cm.$^{-1}$; C=C, 1,615, 1,600, 1,515 cm.$^{-1}$; $-SO_3^-$, 1,380, 1,180, 1,155 cm.$^{-1}$; C—O, 1,225, 1,100, 1,040 cm.$^{-1}$; aromatic substitution, 870, 795, 750 cm.$^{-1}$. Ultraviolet spectrum in ethanol: ϵ 213 = 7,250; ϵ 274 = 2,100.

Anal.—Calcd. for $C_7H_7NaO_4S$: C, 40.00; H, 3.36; S, 15.26. Found: C, 39.67; H, 3.36; S, 15.19. Infrared and ultraviolet spectra identical with pH 5 product.

RESULTS AND DISCUSSION

Second-order characteristics of the reaction between equimolar amounts of reactants are shown in Fig. 1 in which reciprocal bisulfite or sulfite concentration is plotted against time. The reaction appears to follow second-order kinetics over a wide range of hydrogen ion concentration. This would seem to indicate that both singly and doubly charged ions of sulfurous acid can participate in the reaction with the uncharged salicyl alcohol. Below pH 9, salicyl alcohol, pKa 9.9 (4), exists mainly as a neutral molecule. The apparent second ionization constant of sulfurous acid, Ka'_2 4.5×10^{-7} (determined in a nitrogen atmosphere at 65° in solution of ionic strength equal to unity), fixes the ratio of bisulfite to sulfite ion for any hydrogen ion concentration: bisulfite ion predominates at pH 4 with very little sulfite ion present while the converse is true at pH 8.5. This treatment does not consider further possible species such as pyrosulfite which can exist in equilibrium with bisulfite (5).

The pH profile of the reaction is shown in Fig. 2 in which the logarithm of the observed second-order rate constant, k, is plotted as a function of pH. The rate constant shows little variation with respect to hydrogen ion concentration between pH 4 and 5.5. The specific rate constant, k_1, at pH 4.5 and 65° under experimental conditions where bisulfite ion is the main species, was found to be 8.9×10^{-5} L. mole^{-1} sec.$^{-1}$. The relative concentration of

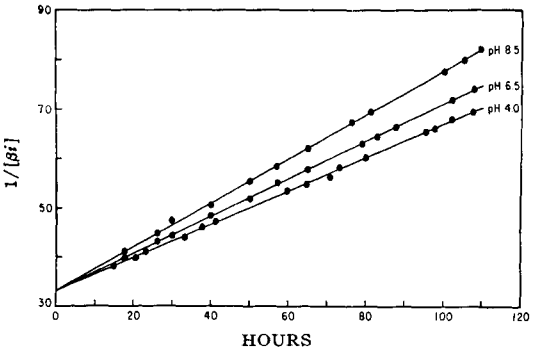

Fig. 1.—Typical second-order plots in which reciprocal bisulfite-sulfite concentration $[\beta i]$ is plotted as a function of time. Equimolar (0.03) solution of recatants in 0.30 M buffer with total ionic strength of 1.0 reacted under nitrogen at 65°. The specific rate constant at pH 4 is 0.32 L. mole^{-1} hr.$^{-1}$ while at pH 8.5 it is 0.45 L. mole^{-1} hr.$^{-1}$.

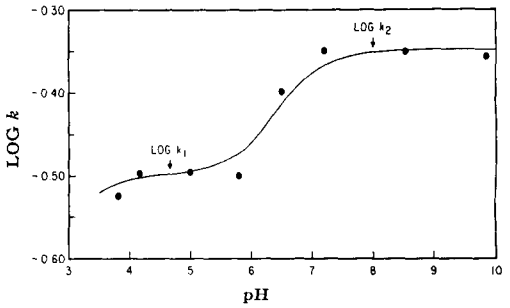

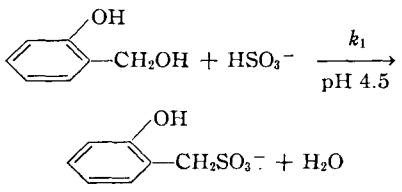

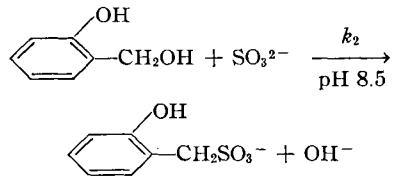

Fig. 2.—Logarithm of second-order rate constants (L. mole^{-1} hr.$^{-1}$) obtained by reacting equimolar (0.03) reactants in various 0.30 M buffers under nitrogen at 65°. Ionic strength of solutions adjusted to 1.0. Theoretical values indicated by solid line calculated from Eq. 5. Experimentally determined values indicated by solid circles. Log $k_1 = -0.50$; log $k_2 = -0.35$.

sulfite species and the observed rate constant increases with pH at pH values above 6 (sulfurous acid pKa'$_2$ 6.35, 65°, μ 1.0). When the added thio compound is totally present as sulfite species (pH > 8), the observed rate constant shows no further pH dependence. The specific rate constant, k_2, at pH 8.5 and 65° under experimental conditions where sulfite ion is the main species, was found to be 1.25×10^{-4} L.$^{-1}$ mole^{-1} sec.$^{-1}$. The results suggest parallel Sn2 reactions which lead to identical hydroxybenzylsulfonates

(A) 

$$\frac{-d(SA)}{dt} = \frac{-d(HSO_3^-)}{dt} = k_1 (SA) (HSO_3^-) \qquad \text{(Eq. 1)}$$

where (SA) = salicyl alcohol concentration.

(B) 

$$\frac{-d(SA)}{dt} = \frac{-d(SO_3^{2-})}{dt} = k_2 (SA) (SO_3^{2-}) \qquad \text{(Eq. 2)}$$

The overall rate expression is the sum of Eqs. 1 and 2

$$\frac{-d(SA)}{dt} = k_1 (SA) (HSO_3^-) + k_2 (SA) (SO_3^{2-}) \qquad \text{(Eq. 3)}$$

Equation 3 may be formulated in terms of added thio compound, St, by introduction of the relationship

$$St = (HSO_3^-) + (SO_3^{2-}) \qquad \text{(Eq. 4)}$$

along with the apparent second ionization constant of sulfurous acid, Ka'$_2$ 4.5×10^{-7}, determined under experimental conditions (65°, μ 1.0):

$$\frac{-d(SA)}{dt} = \frac{-d(St)}{dt} = k_1 (SA) (St) + (SA) (St) \frac{(k_2 - k_1)}{\left[\frac{(H^+)}{Ka_2} + 1\right]} \qquad \text{(Eq. 5)}$$

The theoretical pH profile obtained with Eq. 5 is shown in Fig. 2 as a solid line. The approximate validity of the expression is apparent from the fit of experimentally determined points to the theoretical line.

Mechanism (A) indicates that the bisulfite reaction would proceed with no change in hydrogen ion concentration while mechanism (B) shows the formation of one mole of hydroxide ion for each mole of product. Both reactions were found to give the identical product in good yield and, under conditions corresponding to A, the pH was found to remain nearly constant (pH 5 ± 0.5) while under conditions corresponding to B, stoichiometric production of hydroxide ion was observed, as shown in Table I.

TABLE I.—HYDROXIDE ION PRODUCTION IN THE SALICYL ALCOHOL-SULFITE ION REACTION AT PH 8 UNDER REFLUX CONDITIONS[a]

Minutes	[Sulfite], meq.	[Salicyl Alcohol], mmole	Total OH$^-$ Production,[b] meq.
0	50	50	0
35	33.4	32	16.5
90	22.2	21	27.6
120	19.4	20	30.5
150	16.7	17	43.2
210	13.1	12	37.0
390	8.1	8	42.0

[a] Initial solution composition: 0.05 moles salicyl alcohol, 0.05 moles sodium sulfite in 200 ml. of distilled water. This was reacted in a nitrogen atmosphere under reflux conditions with pH maintained at 8. [b] Determined by continuous titration with hydrochloric acid to maintain pH of reaction mixture at 8.

The effect of ionic strength on the rate constant of the reaction is shown in Fig. 3. Increasing the ionic strength results in a slight decrease in the specific rate constant. In dilute solutions ($\sim 10^{-3}$ M) Debye-Hückel theory (6) leads to an equation of the following form

$$\ln k \simeq \ln k_0 + K\sqrt{\mu}\,(Z \text{ salicyl})\,(Z\ HSO_3^-) \quad \text{(Eq. 6)}$$

which predicts no effect due to ionic strength, μ, inasmuch as the product of the charges, Z, of the reactants equals zero (salicyl alcohol is an uncharged molecule). It should be noted that the experimental ionic strengths are greater than this by several orders of magnitude and as such are not amenable to Debye-Hückel treatment. The changes in the activity coefficient of salicyl alcohol and in the apparent ionization constants of sulfurous acid at higher ionic strengths undoubtedly contribute to the observed slight decrease in the specific rate constant. Equations have been developed to extend Eq. 6 to higher ionic strengths by including a first power ionic strength term (7), but the coefficients cannot be predicted with certainty.

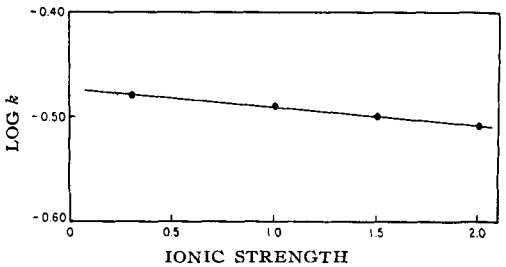

Fig. 3.—Logarithm of second-order rate constant, k_1, (L. mole^{-1} hr.$^{-1}$) as a function of ionic strength. Equimolar (0.03) solution of reactants in 0.30 M acetate, pH 4.9 buffer maintained at 65° under nitrogen atmosphere.

The empirical activation energy, *Ea*, obtained from Fig. 4 is 24 Kcal. mole^{-1}. This corresponds to conditions of mechanism (*A*) where bisulfite ion and neutral salicyl alcohol are reactants. Reaction between epinephrine and bisulfite or sulfite ion exhibits a similar (24 Kcal. mole^{-1}) experimental heat of activation (3) and the analogous Sn2 alkyl halide hydrolytic reactions show similar (23 Kcal. mole^{-1}) activation energies (8). The Arrhenius frequency factor was calculated for the salicyl alcohol-bisulfite reaction using 24 Kcal. mole^{-1} as the empirical activation energy with rate constants obtained at various temperatures. The average value for the frequency factor was found to be 4×10^{11} L. mole^{-1} sec.$^{-1}$; frequency factors for many ion-neutral molecule reactions appear to be of the order 10^{11} L.

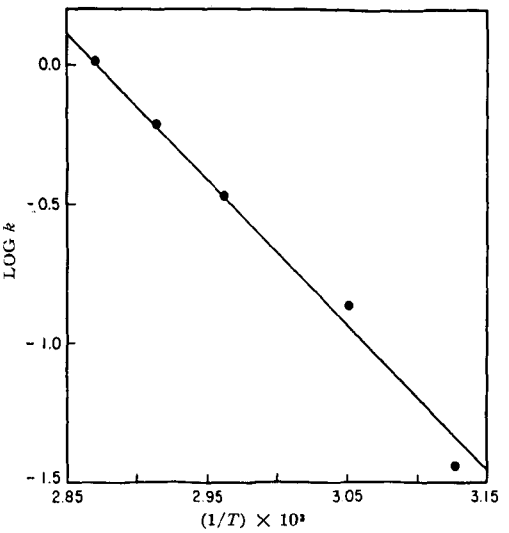

Fig. 4.—Logarithm of second-order rate constant, k_1, (L. mole^{-1} hr.$^{-1}$) as a function of reciprocal absolute temperature. Equimolar (0.03) solution of reactants in 0.30 M acetate, pH 4.9 buffers with total ionic strength of 1.0 reacted under nitrogen atmosphere.

mole^{-1} sec.$^{-1}$ (9) as predicted by collision theory (10). Entropy value for the reaction calculated with the Eyring equation (8)

$$k = \frac{RT}{Nh}\, e^{-\Delta Ha/RT}\, e^{\Delta Sa/R} \quad \text{(Eq. 7)}$$

gave an average value of −7.1 e.u. with a standard state of moles per L. Evaluation of the exponential term, $e^{\Delta Sa/R}$, using the experimental $\Delta Sa = -7.1$ e.u. gave the value of 2.8×10^{-2}; this value appears to be in proper order of magnitude (10^{-2}) for reactions which obey simple collision theory (8).

Studies on the Mechanism of Action of Phenolic Disinfectants I

Release of Radioactivity from Carbon^{14}-Labeled *Escherichia coli*

By JOSEPH JUDIS

The ability of a number of phenolic disinfectants to cause leakage of cell contents of *Escherichia coli* was studied by exposing cells of the latter that had been labeled by incubating with C^{14} glutamate. Release of cell contents, as indicated by release of radioactivity, was found to be caused by phenol, *p*-chloro-*m*-xylenol, *p*-chloro-*m*-cresol, *p*-chloro-*o*-cresol, 2,4-dichlorophenol, 2,4,6-trichlorophenol, and 2,4-dichloro-*m*-xylenol. Similar effects were caused by ethanol, mercuric chloride, acriflavine, and merthiolate. Tween 80 was found to protect *E. coli* from the lethal effects of *p*-chloro-*m*-xylenol and to prevent, in part, leakage of cell contents caused by the latter. Release of radioactivity was directly related to concentration of *p*-chloro-*m*-xylenol and pH had no marked effects.

SINCE THE DISCOVERY of phenol in 1834 and its introduction to antiseptic surgery by Lister in 1867 (1), both phenol and many of its derivatives have become firmly established as germicidal agents. Much of the work with the phenolic disinfectants has centered on practical considerations, such as antimicrobial spectrum, applications, formulations, and the like (2–6). Relatively little work has been done on cytological and biochemical sites of action of these agents. Phenol has long been recognized as a protein precipitant and denaturant and it has been assumed that the latter properties are related to antimicrobial action, especially when applied to vital structures and enzymes of microorganisms (3, 7). More recent work by Gale and Taylor (8), Beckett, Patki, and Robinson (9–11), and others (12–14), but most recently by Joswick and Gerhardt (15) have indicated that the phenolics may exert their lethal activity by damaging the cell membrane or mechanisms which control permeability of the cell membrane. The experiments described below are an attempt to study the ability of various phenol derivatives to cause leakage of cell contents from *Escherichia coli* labeled by incubation with carbon^{14}-tagged glutamate.

METHODS AND MATERIALS

Materials.—All chemicals were of reagent grade and biochemicals were obtained either from the California Corporation for Biochemical Research or Nutritional Biochemicals Corporation. Labeled glutamate (3,4-C^{14}) was obtained from the California Corporation for Biochemical Research and had a specific activity of 2.3 mc. per mmole. The phenol derivatives were a gift from the Ottawa Chemical Company, Toledo, Ohio.

Labeling of Bacteria.—*Escherichia coli* ATCC 11229 was used throughout and was maintained on nutrient agar. Cells for labeling or manometric work were obtained in the synthetic medium (C) of Roberts, *et al.* (16), and had the following composition: ammonium chloride, 2.0 Gm.; disodium phosphate dodecahydrate, 6.0 Gm.; potassium dihydrogen phosphate, 3.0 Gm.; sodium chloride, 3.0 Gm.; magnesium chloride, 0.01 Gm.; sodium sulfate, 0.026 Gm.; glucose, 5.0 Gm.; distilled water, 1 L. The glucose was sterilized separately as a 50% w/v solution and added aseptically at the time of inoculation. The pH of the medium was 6.75. The organism was carried through several transfers on the synthetic medium and a 1% inoculum was used for culture flasks. The latter consisted of 200 ml. of medium in 500-ml. Erlenmeyer flasks and were incubated at 37° on a Burrell wrist action shaker for 24 hours, after which they were harvested by centrifugation. The cells from a single flask were washed once with distilled water and suspended in one-hundredth the original culture volume in saline. The cell suspension was placed in an ice bath, 0.25 ml. of labeled glutamate solution was added (equal to about 230,000 c.p.m.) and allowed to stand for 60 minutes. The cells were then centrifuged, washed three times with cold saline, and suspended in enough saline to give a cell concentration of about 15 to 30 $\times$ 10^9 cells/ml. Generally, about 15 to 20% of the label was taken up by the cells and resulted in an activity of between 100 to 500 c.p.m./10^9 cells. According to the data of Roberts, *et al.* (16), labeling of *E. coli* under these conditions with glutamate results in the disappearance of free glutamic acid and the incorporation of the label of the latter into other, nondiffusable compounds.

Manometric Procedures.—Oxygen uptake was measured in a Warburg respirometer, using the usual techniques (17).

Measurement of Release of Radioactivity.—The reaction mixtures contained, in a final volume of 3.0 ml., about 10 to 20 $\times$ 10^9 cells, phosphate buffer (0.02 *M*, pH 7.2 unless otherwise indicated), phenolic germicide dissolved in 25% v/v ethanol in a maximum volume of 0.5 ml. per reaction mixture,

Received April 28, 1961, from the College of Pharmacy, University of Toledo, Toledo 6, Ohio.
Accepted for publication June 27, 1961.
This work was supported in part by a grant from the University of Toledo Research Foundation.
Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.

and enough saline to bring to volume. When less than 0.5 ml. of germicide solution was used, the difference was made up with 25% v/v ethanol to keep the concentration of the latter constant in the reaction mixtures since ethanol itself caused a release of radioactivity in low concentrations (see below). Enough sodium chloride was added to the phosphate buffers to make them isotonic with saline.

The labeled cells were incubated in the reaction mixtures at room temperature (22 ± 2°) for 10 minutes and removed by centrifugation. The supernatants were plated in 1-ml. quantities on $1^1/_4$ inch aluminum planchets to which 1 to 2 drops of 1% aerosol were added, and allowed to air dry. In cases where the radioactivity of cells was determined, suspensions were transferred to $1^1/_4$ inch aluminum planchets to which had been affixed a disk of lens paper with 1:3 collodion in acetone. Self absorption was corrected for by plating various volumes and calculating correction factors. All assays of radioactivity were carried out in a Nuclear Chicago thin-window gas flow counter and the 0.9 errors were calculated for the values obtained.

Survival in the Presence of Germicides.—The reaction mixtures and cell concentrations were essentially the same as in the experiments involving release of radioactivity and after incubation at 22° for 25 minutes, the viable count at the end of that time was determined by the standard pour plate procedures using nutrient agar as the culture medium.

RESULTS AND DISCUSSION

Of the known antimicrobial agents, the quaternary ammonium compounds and the polypeptide antibiotics are best established as exerting their lethal action by causing damage to the cell membrane (2, 18, 19). Some observations have been made on the ability of phenols to cause release of cellular contents from bacteria (see previously cited references) and the results obtained below would tend to strengthen the view that phenols possess the power to cause leakage from cells.

In Table I, the effects obtained with phenol are shown. At a concentration of phenol which is lethal to *E. coli* in the cell concentration used, the total radioactivity is not released into the supernatant. It also appears that radioactivity is caused to be released by a concentration of phenol which is only slightly bactericidal. Release of radioactivity increases with increase in concentration of phenol. This direct relationship between concentration and leakage has been reported for phenolic compounds (15, 20–22).

TABLE I.—RELEASE OF RADIOACTIVITY FROM LABELED *Escherichia coli* IN THE PRESENCE OF PHENOL[a]

Concentration of Phenol, mg./ml.	Radioactivity Released, c.p.m./ml.	Survival, %
0	99.2 ± 8	100
3.3	137.8 ± 9.2	76
6.25	490 ± 16.5	...
12.5	591 ± 18.2	0

[a] The cell concentration was 2 × 10^9 cells/ml. of reaction mixture and had an activity of 550 c.p.m./10^9 cells.

TABLE II.—RELEASE OF RADIOACTIVITY FROM *Escherichia coli* IN THE PRESENCE OF *p*-CHLORO-*m*-XYLENOL

Concentration of PCMX, mcg./ml.	Radioactivity Released c.p.m./ml.	Radioactivity Remaining in Cells, c.p.m.	Survival, %
0[a]	150 ± 9.8	1460 ± 37.2	100
66.7	270 ± 12.5	1145 ± 33	...
166.7	431 ± 15.7	710 ± 26.3	32.6
250	591 ± 18.2	676 ± 25.8	...
333.3	685 ± 19.5	702 ± 26.1	0.1

[a] This reaction mixture contained a final concentration of 4.2% ethanol as did all the others containing PCMX for purpose of keeping the PCMX in solution. The cell concentration was 5.2 × 10^9 cells/ml. of reaction mixture and had an activity of 164 c.p.m./10^9 cells.

TABLE III.—EFFECT OF ETHANOL ON THE RELEASE OF RADIOACTIVITY FROM *Escherichia coli*[a]

Concentration of Ethanol, % by Volume	Radioactivity Released, c.p.m./ml.	Survival, %
0	53.9 ± 6.4	100
2.1	131.5 ± 9	...
4.2	251.1 ± 12.2	100
8.33	300.3 ± 13.2	100
12.5	325.5 ± 13.7	58
25.0	392.7 ± 15	0.011

[a] The cell concentration was 4.6 × 10^9 cells per ml. of reaction mixture and had an activity of 252 c.p.m./10^9 cells.

TABLE IV.—EFFECT OF pH ON SURVIVAL AND RELEASE OF RADIOACTIVITY FROM *Escherichia coli* IN THE PRESENCE OF *p*-CHLORO-*m*-XYLENOL

pH	Concentration of PCMX, mcg./ml.	Radioactivity Released, c.p.m./ml.	Survival, %
4.6	0[a]	391 ± 14.9	100
	333.3	1463 ± 28.3	0.1
7.2	0	349 ± 14.1	100
	333.3	1238 ± 26.1	0.19
8.6	0	605 ± 18.4	100
	333.3	1163 ± 25.2	0.02

[a] All reaction mixtures contained a final concentration of 4.2% ethanol. The cell concentration was 4.6 × 10^9/ml. of reaction mixture and had an activity of 471 c.p.m./10^9 cells.

p-Chloro-*m*-xylenol, a halogenated phenol which is a much more potent germicide than phenol, gave similar results (Table II) but was active in much lower concentrations than phenol, both for release of radioactivity and killing.

Because most of the phenol derivatives have a low water solubility, it was convenient to dissolve them in 25% v/v ethanol, resulting in the presence of a certain concentration of ethanol in the reaction mixtures (4.2%). A control was always included which contained the same concentration of ethanol as was present in the reaction mixtures containing phenolics dissolved in ethanol, and these controls always showed greater release of radioactivity than was obtained by incubating labeled cells in the complete absence of ethanol. It seemed of interest to determine whether ethanol itself was capable of causing release of labeled compounds, and in Table III it can be seen that concentrations of ethanol which are not at all lethal do affect the permeability

TABLE V.—RELEASE OF RADIOACTIVITY FROM *Escherichia coli* IN THE PRESENCE OF VARIOUS PHENOLIC DISINFECTANTS[a]

Addition	Concentration, mcg./ml.	Radioactivity Released, c.p.m./ml.	Survival, %
Nothing	...	96 ± 7.9	100
4.2% Ethanol control	...	432 ± 15.6	100
p-Chloro-*m*-xylenol	166.7		32.6
	333.3	1205.6 ± 25.7	0.1
p-Chloro-*m*-cresol	333.3	911.6 ± 22.5	85
	666.7	1174.4 ± 25.4	0.24
p-Chloro-*o*-cresol	333.3	665.6 ± 19.2	44
	666.7	949 ± 22.9	0.17

2,4,6-Trichlorophenol	333.3	709 ± 19.9	68.5
2,4-Dichloro-*m*-xylenol	41.7	745 ± 20.3	60
	83.4		2.72
Phenol	12,500	1149 ± 25.1	0

[a] The cell concentration was 3.8 × 10^9 cells/ml. of reaction mixture and had an activity of 520 c.p.m./10^9 cells.

of the cell membrane of *E. coli*, and this leakage is undoubtedly involved in the bactericidal action of ethanol.

pH has been considered to be a factor affecting the germicidal activity of phenolics, but the general conclusion must be that predictions as to effects are difficult to make and the interaction of a specific germicide, the environment, and the test organism must be individually evaluated (5). For example, with *sec*-amyltricresol, the antibacterial action against *Micrococcus pyogenes* var. *aureus* decreased with increasing pH but increased with increasing pH in the case of *E. coli* (23). The results shown in Table IV indicate that whether one measures release of radioactivity or per cent survival after a given time interval of exposure, pH does not have marked effects on the activity of *p*-chloro-*m*-xylenol under the conditions used.

A number of other phenol derivatives were examined for their ability to cause release of radioactivity from *E. coli*, and the latter effect seems to be caused generally by phenolic germicides, as can be seen in Table V. It is interesting to note that the concentration which causes approximately the same amount of killing also results in the release of about the same proportion of the radioactivity of the cells. The ability to cause release of radioactivity from labeled cells is a property of other antimicrobial substances, as is indicated in Table VI where results with acriflavine, merthiolate, and mercuric chloride are shown.

It has been demonstrated that certain surface-active agents interfere with the antibacterial activity of phenolics (5, 24), especially Tween 80, and it seemed interesting to determine whether Tween 80 under the experimental conditions used above would be capable of preventing the lethal effects of *p*-chloro-*m*-xylenol and also inhibit the release of radioactivity from *E. coli*. Table VII gives typical results. Tween 80, under the experimental conditions, is capable of preventing the lethal effects of *p*-chloro-*m*-xylenol and also inhibited to a large degree, but not completely, the release of radioactivity from the cells. It is interesting to note that while Tween 80 has high surface activity itself, it does not cause release of radioactivity from or significant killing of *E. coli* in a concentration of 1%. Apparently the mode of action of the phenolic germicides involves something beyond simple surface activity. Table VIII shows the ability of Tween 80 to protect *E. coli* from the inhibition of glucose oxidation caused by *p*-chloro-*m*-xylenol. This protective effect seems to be exerted at all three of the pH's at which it was determined.

It should be pointed out that the experiments reported above represent a survey of the ability of phenolic germicides to affect the integrity of the cell membrane of *E. coli* as measured by release of radioactivity from labeled cells, and it is believed that the data presented in addition to those of other workers,

TABLE VI.—RELEASE OF RADIOACTIVITY FROM *Escherichia coli* IN THE PRESENCE OF SEVERAL ANTIMICROBIAL SUBSTANCES

Additions[a]	Concentration, mcg./ml.	Radioactivity Released, c.p.m./ml.
Nothing	...	53.9 ± 6.4
4.2% Ethanol control	...	251.1 ± 12.2
p-Chloro-*m*-xylenol	333.3	554 ± 17.7
Acriflavine	2000	560.3 ± 17.4
Merthiolate	1000	502.7 ± 16.8
Mercuric chloride	1000	768 ± 20.7

[a] The mixture containing *p*-chloro-*m*-xylenol contained a final concentration of ethanol of 4.2% and those of the other substances contained no ethanol. The cell concentration was 4.6 × 10^9 cells per ml. of reaction mixture and had an activity of 252 c.p.m./10^9 cells.

TABLE VII.—EFFECT OF TWEEN 80 ON THE RELEASE OF RADIOACTIVITY FROM *Escherichia coli* IN THE PRESENCE OF *p*-CHLORO-*m*-XYLENOL

Additions[a]	Radioactivity Released, c.p.m./ml.	Survival, %
None	76 ± 7.1	100
4.2% Ethanol control	349 ± 14.1	100
p-Chloro-*m*-xylenol (333.3 mcg./ml.)	1237.5 ± 26.1	0.19
p-Chloro-*m*-xylenol (333.3 mcg./ml.) and Tween 80 (1%)	739 ± 20.2	78
Tween 80 (1%)	88.7 ± 7.6	...
Tween 80 (1%) and 4.2% ethanol	390 ± 14.8	53

[a] The reaction mixtures containing *p*-chloro-*m*-xylenol contained 4.2% ethanol. The cell concentration was 4.6 × 10^9 cells/ml. of reaction mixture and had an activity of 471 c.p.m./10^9 cells.

TABLE VIII.—EFFECT OF pH AND TWEEN 80 ON THE INHIBITION OF GLUCOSE OXIDATION BY *Escherichia coli* IN THE PRESENCE OF *p*-CHLORO-*m*-XYLENOL[a]

Concentration of *p*-Chloro-*m*-xylenol, mcg./ml.	Q_{O_2}					
	pH 4.3		pH 7.2		pH 8.6	
	Tween 80		Tween 80		Tween 80	
	Absent	Present	Absent	Present	Absent	Present
0	39	45	46.7	46.1	59.8	52.5
83.3	42	43.5			55.9	64.5
166.7	0	40.6	38.9	54.5	9.1	52.5
333.3	0	18.0	19.5	24.7	0	37.5
500	0	...	0	...	0	...
666.7	0	0	0	2.6	0	5.3
833.3	0	0	0	2.6	0	4.5

[a] The flasks contained 140 μM of glucose, phosphate buffer in a final concentration of 0.034 M and of the indicated pH, and 8.5 mg. dry weight of cells in a final volume of 3.0 ml. plus 0.2 ml. of 10% potassium hydroxide in the center well. Tween 80, where used, had a final concentration of 1% and the *p*-chloro-*m*-xylenol was dissolved in 25% ethanol and added in an amount to give the indicated final concentrations. All flasks had a final concentration of 4.2% ethanol (which did not affect oxygen uptake). Temperature was 30°.

do strengthen the hypothesis that the cell membrane is a likely site of action of these germicides. The data also indicate that "leakage" of radioactive cell contents can occur in cell suspensions without a detectable drop in viable count. It would therefore seem that this type of damage to the cell membrane can be tolerated and repaired to a certain degree but, beyond that point, damage is irreparable and death of the cell ensues. The question has been raised as to which comes first, leakage or death (25), and the data would seem to indicate that leakage precedes death. An interpretation of the structural basis for the release of radioactivity from labeled *E. coli* cells must include several possibilities: (*a*) change in permeability of the osmotic barrier of the cell membrane with escape of normal cytoplasmic constituents; (*b*) "uncoupling" of cytoplasmic constituents with subsequent release from the cell; (*c*) a combination of the above. Differentiation of these effects will require experiments involving treatment of labeled cells with substances known to affect the cell membrane without causing uncoupling of cytoplasmic constituents. If phenolics cause release of additional radioactivity from cells so treated, it should be attributable to uncoupling of cytoplasmic constituents. An approach to this type of experiment has been reported by Beckett, Patki, and Robinson (26) and should be extended.

Much of the evidence for the mechanism of action of phenolic germicides indicates that their effect is due to physical damage of the cell membrane. If that is true, and their action is thus relatively nonspecific biochemically, there should be some explanation as to why some strains and species of bacteria are so resistant, relatively. Some possibilities are: (*a*) Resistant strains are incapable of binding the germicide chemically and thus are not damaged since lethal concentrations in the medium would normally be much too low to cause damage to proteins without some sort of concentration, such as at the cell surface or due to absorption within the cell. The inability to bind antibiotics has been observed in bacteria which are resistant to these antibiotics (21). (*b*) The chemical nature of the cell membrane is different in resistant strains so that the chemical site of damage is modified to be resistant. Resistance to quaternary ammonium compounds has been shown to be due to the presence of a high concentration of lipids in the organism which is far above the concentration usually found in sensitive organisms (27, 28). (*c*) Development of mechanisms for detoxication and/or degradation of the phenolic germicide.

It seems unlikely that resistance to phenolic germicides would be due to development of alternate metabolic pathways, since much of the data in the literature would suggest that higher concentrations of germicide are needed for enzyme inhibition than for killing (29–32) and would lead one to the conclusion that inhibition of metabolism is probably not the lethal mechanism. The data in Tables II and VIII seem to agree with this general conclusion, in that a concentration of *p*-chloro-*m*-xylenol of 333.3 mcg./ml. reduced the viable count by 99.9% but inhibited oxidation of glucose to somewhat less than half of normal.

SUMMARY

It has been shown that phenolic disinfectants are capable of causing a release of radioactivity from *E. coli* cells labeled by incubation with carbon^{14}-labeled glutamate. This release of radioactivity is related to concentration of the phenolic compound, occurs with concentrations of the latter not necessarily lethal, and is not markedly affected by pH in the case of *p*-chloro-*m*-xylenol. A number of other phenolic disinfectants, such as *p*-chloro-*m*-cresol, *p*-chloro-*o*-cresol, 2,4-dichlorophenol, 2,4,6-trichlorophenol, 2,4-dichloro-*m*-xylenol, and phenol caused a similar release of radioactivity. Tween 80 at a concentration of 1% can prevent, in part, the release of radioactivity caused by *p*-chloro-*m*-xylenol and protect *E. coli* from otherwise lethal concentrations of the latter. Other substances found to be capable of causing release of radioactivity were ethanol, mercuric chloride, merthiolate, and acriflavine.

Rheological Properties of Corn Oil Emulsions with Methylcellulose

By B. B. SHETH, DUNCAN E. McVEAN, and ALBERT M. MATTOCKS

Flow properties of a series of emulsions containing methylcellulose 1,500 cps. in eight concentrations and corn oil in 10 concentrations were measured. Known equations for non-Newtonian flow were not satisfactory for these systems, and a new equation, called the "viscoelastic flow equation" was derived and fitted to the data. The equation is $\eta_a = Ae^{-\alpha S} + Be^{-\beta S} + \eta_\infty$, where η_a is apparent viscosity, S is shear rate, η_∞ is ultimate viscosity, and the other terms are constants. From this expression limiting viscosity, η_0 could be obtained as A + B + η_∞. Values of η_0 were then fitted to fluidity plots to obtain intrinsic viscosities. These values agree with Taylor's equation only where the dispersion medium had high viscosity.

ALTHOUGH emulsions may be regarded as suspensions of spherical particles, their rheological properties are more complex than those of suspensions of solid particles. The equation of Einstein governing the viscosity of suspensions, may be expressed as

$$\eta_r = 1 + kC_v \qquad \text{(Eq. 1)}$$

where η_r is relative viscosity at low rates of shear, C_v is concentration by volume of suspended particles, and k is the Einstein constant or intrinsic viscosity, equal to 2.5 for spherical particles. This was modified for emulsions by Taylor (1), who took into account the flow induced in the suspended droplets. From hydrodynamic considerations Taylor derived the following

$$\eta_r = 1 + kC_v\left[\frac{\eta_1 + 0.4\eta_2}{\eta_1 + \eta_2}\right] \qquad \text{(Eq. 2)}$$

where η_1 is the limiting viscosity of the oil in the droplet, $\eta_{0\,(oil)}$, and η_2 is that of the solvent, $\eta_{0(solv.)}$. In a later work, Taylor (2) pointed out that deformation of fluid particles might occur during shear to form ellipsoids, and Oldroyd (3) showed that interfacial tension at the particle surface may retard flow within the particle. Other complexities which have been noted are the formation of adsorbed films with viscosities different from that of the medium or the droplet (3, 5).

In spite of these complicating factors, Nawab and Mason (6) found good agreement with Taylor's equation with one set of carefully prepared dilute emulsions, though most series did not agree, as has been the common result of other workers. In a most interesting fashion, Mason and Bartok (4) exhibited flow patterns and particle deformation of droplets in suspension with a rheometer which allowed the particles to be photographed in shear.

One of the difficulties encountered in the testing of the basic equations of Einstein and Taylor has

Rheological Properties of Corn Oil Emulsions with Methylcellulose

By B. B. SHETH, DUNCAN E. McVEAN, and ALBERT M. MATTOCKS

Flow properties of a series of emulsions containing methylcellulose 1,500 cps. in eight concentrations and corn oil in 10 concentrations were measured. Known equations for non-Newtonian flow were not satisfactory for these systems, and a new equation, called the "viscoelastic flow equation" was derived and fitted to the data. The equation is $\eta_a = Ae^{-\alpha S} + Be^{-\beta S} + \eta_\infty$, where η_a is apparent viscosity, S is shear rate, η_∞ is ultimate viscosity, and the other terms are constants. From this expression limiting viscosity, η_0 could be obtained as A + B + η_∞. Values of η_0 were then fitted to fluidity plots to obtain intrinsic viscosities. These values agree with Taylor's equation only where the dispersion medium had high viscosity.

ALTHOUGH emulsions may be regarded as suspensions of spherical particles, their rheological properties are more complex than those of suspensions of solid particles. The equation of Einstein governing the viscosity of suspensions, may be expressed as

$$\eta_r = 1 + kC_v \qquad \text{(Eq. 1)}$$

where η_r is relative viscosity at low rates of shear, C_v is concentration by volume of suspended particles, and k is the Einstein constant or intrinsic viscosity, equal to 2.5 for spherical particles. This was modified for emulsions by Taylor (1), who took into account the flow induced in the suspended droplets. From hydrodynamic considerations Taylor derived the following

$$\eta_r = 1 + kC_v\left[\frac{\eta_1 + 0.4\eta_2}{\eta_1 + \eta_2}\right] \qquad \text{(Eq. 2)}$$

where η_1 is the limiting viscosity of the oil in the droplet, $\eta_{0\,(oil)}$, and η_2 is that of the solvent, $\eta_{0(solv.)}$. In a later work, Taylor (2) pointed out that deformation of fluid particles might occur during shear to form ellipsoids, and Oldroyd (3) showed that interfacial tension at the particle surface may retard flow within the particle. Other complexities which have been noted are the formation of adsorbed films with viscosities different from that of the medium or the droplet (3, 5).

In spite of these complicating factors, Nawab and Mason (6) found good agreement with Taylor's equation with one set of carefully prepared dilute emulsions, though most series did not agree, as has been the common result of other workers. In a most interesting fashion, Mason and Bartok (4) exhibited flow patterns and particle deformation of droplets in suspension with a rheometer which allowed the particles to be photographed in shear.

One of the difficulties encountered in the testing of the basic equations of Einstein and Taylor has

been the limitation that Eq. 1 is applicable only to infinitely dilute suspensions, and various modified equations have been used to extrapolate flow data of suspensions of finite concentrations and thus obtain values representing Einstein conditions. The Einstein equation, modified to allow for hydrodynamic interactions occurring at finite concentration may be expressed as

$$\eta_r = 1 + 2.5\ C_v + k_1 C_v^2 + \ldots \quad \text{(Eq. 3)}$$

Some workers have applied this equation directly as a polynomial, others have utilized a curve of η_{sp}/C_v *vs.* C_v, where $\eta_{sp} = \eta_r - 1$, and extrapolated to $C_v = 0$ to obtain

$$\lim_{C_v \to 0} \eta_{sp}/C_v$$

as the Einstein constant. Other relationships, such as logarithmic functions, have been used with limited success. Recently, Ford (7) noted that if relative fluidity, ϕ_r, were used, plots of ϕ_r *vs.* C_v were usually linear up to rather high concentrations, as had been observed much earlier by Bingham (8), and that the fluidity relationship was a more suitable method for evaluating the Einstein constant. The equation was expressed as

$$\phi_r = 1 - 2.5C_v + \ldots \quad \text{(Eq. 4)}$$

which is the reciprocal of the Einstein equation in the form

$$\eta_r = 1 + 2.5C_v + 6.25C_v^2 + \ldots \quad \text{(Eq. 5)}$$

The report by Ford has thus supplied a more reliable method for testing the basic flow equations with suspensions of finite concentration.

Pharmaceutical emulsions are usually non-Newtonian in nature, since they generally contain thickening agents such as natural gums and synthetic cellulose deratives which are, themselves, non-Newtonian. This fact makes it more difficult to apply the basic equations governing flow to such emulsions because the apparent viscosity measured will be variable, depending on the rate of shear of measurement. The difficulty may be overcome, however, if flow equations which will accurately predict the limiting viscosity, η_0, or viscosity at infinitely low shear rate, are available. Since the sedimentation of particles in emulsions is thought to occur at extremely low shear rates and since the flow characteristics at low shear rates show promise of furnishing a means for evaluating interfacial tension (6) and occurrence of aggregation (4), the objective of obtaining suitable flow equations is of importance.

An equation for describing non-Newtonian flow may be evaluated by three criteria: (*a*) its agreement with observed data, (*b*) its accuracy in furnishing correct values of η_0, and (*c*) its theoretical foundation.

Few theoretical equations have been derived for non-Newtonian flow, the exceptions being that of Ree and Eyring (9) involving an inverse hyperbolic sine which is difficult to evaluate, and that of Williamson (10) which was used empirically for some time before being derived theoretically (11).

The equation of Williamson has been shown to fit a wide variety of non-Newtonian flow curves (12–14), but it was also noted that the asymptote to the curve was unrealistic, and a new equation, called the "structure equation," was utilized which gave more accurate values of the asymptote at high shear rates (14, 15). Unfortunately, the structure equation could not be fitted to most flow curves without the assumption of a fixed yield value which often does not agree with the observed data. The concept of a yield value representing a nonyielding condition which suddenly disrupts at a fixed stress is also not in agreement with the recent findings of McVean (16), who measured the strain of gels to find them more aptly described by a viscoelastic equation

$$F = Ae^{-\alpha t} + Be^{-\beta t} \quad \text{(Eq. 6)}$$

where F is stress, A, α, B, β, are constants, and t is time at constant strain. A non-Newtonian flow equation utilizing this viscoelastic concept of yield value which has been devised and used in these laboratories is as follows

$$\eta_a = F/S = Ae^{-\alpha S} + Be^{-\beta S} + \eta_\infty \quad \text{(Eq. 7)}$$

where η_a is the apparent viscosity at a given shear, S, and η_∞ is the ultimate high shear viscosity. This equation has been found to fit a variety of experimental flow curves quite accurately without the assumption of a fixed yield value. Equations of this type have been used for viscoelastic bodies, being represented by models containing two Maxwell elements in parallel (17). It might be expected that more or fewer exponential terms may be required for a given system, since the number will depend on the breadth of distribution of relaxation times of the non-Newtonian components.

The work reported in this paper illustrates the application of Eq. 7, called the "viscoelastic flow equation," to a series of emulsions.

EXPERIMENTAL

Preparation of Emulsions.—A sol was prepared by adding methylcellulose 1,500 cps., with stirring, to about one-half the calculated amount of water, previously heated to 70°. A preservative consisting of 0.1% of a mixture of three parts methylparaben

and one part propylparaben was dissolved in the hot water before incorporation of the methylcellulose. The mixture was made up to volume with cold water and stirred with chilling until its temperature was 0–5°; it was then stored in a refrigerator for at least 2 days before being used. The concentration of methylcellulose was accurately determined by drying a weighed sample of the final sol.

A basic corn oil emulsion was prepared with 60% corn oil (η = 0.4449), 5% of a mixture of three parts of Span 80 and one part of Tween 80, and 35% water. The emulsion was homogenized in a Manton-Gaulin homogenizer (model 15M8BA) at 3000 lb./in.^{2}. Droplet size of the dispersed phase was found to be quite uniform, 90% of the particles being in the range of 0.5–3 μ, and the size varied little with variation in homogenization pressure or with dilution with varying amounts of methylcellulose sol or water. Emulsions containing varying concentrations of oil and methylcellulose were obtained by dilution of the basic emulsion with water and methylcellulose sol, so that only one lot of basic emulsion and sol were used throughout the study. The final emulsions were stirred gently to remove air and allowed to stand at room temperature for 3 days before measurement.

Measurement of Flow Properties.—The emulsions were placed in an automatic recording viscometer with rotating cup and fixed bob (18). Shear rates were varied from 129 to 2,500 sec.$^{-1}$, and from the recorded curves data points representing 19 equally spaced intervals of shear were recorded for computation.

Computation of Flow Constants.—From the shear-stress data, values of η_a were calculated and plotted *vs.* S on 12 × 18 inch graph paper. These were placed on an X-Y recorder and fitted to the viscoelastic flow equation by means of an analog computer. Values of the constants were read directly from the computer.

Results.—Since the original stress-shear data are quite extensive and would require excess space, they are not reproduced in this paper. They are available, however, in the original thesis (18). The constants of the viscoelastic flow equation are presented in Table I. The constants of the equation were used to compute limiting viscosities, η_0, by the following relationship

$$\eta_0 = \lim_{S \to 0} \eta_a = A + B + \eta_\infty$$

These, in turn, were used to calculate values of ϕ_r, which were plotted *vs.* C_v to obtain slopes comparable to Einstein's constant. Constants of the viscoelastic flow equation and values of ϕ_r are presented in Table I, and slopes, or intrinsic viscosities, are given in Table II, along with values calculated from Taylor's equation. A typical curve fitted on the computer is shown in Fig. 1, a typical fluidity plot is given in Fig. 2, and the relationship between values of k and η_2 are presented in Fig. 3.

DISCUSSION

It was found that the viscoelastic flow equation fitted all the flow curves of this series of emulsions quite well. The fitting of five constants, however,

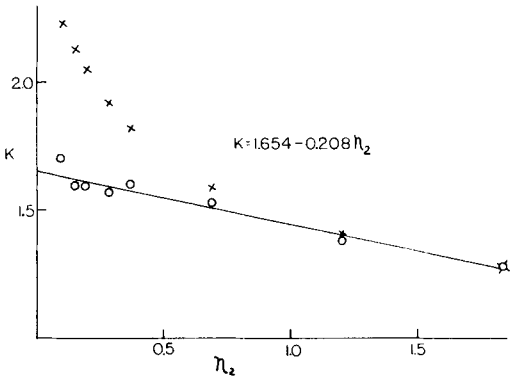

Fig. 3.—Relationship between k and η_2. Circles represent experimental points, X's are values calculated from Taylor's equation. The least squares equation for the line is given.

allows errors in one to be corrected for by errors in another, so that a given constant might not vary in a regular fashion with increases in concentration of emulsion. Nevertheless, the complete equation describes the flow curve quite accurately and the combined constants, such as η_0, do vary in an orderly manner. One might question whether a single value of α and β would suffice for a complete series involving a given suspending agent, since most of the non-Newtonian character might be ascribed to this component. This was attempted, using an approximate average value for α and β, but the errors were increased considerably by this procedure, while approximately the same values of intrinsic viscosity were obtained. It is obvious that accuracy of evaluation of the constants can be improved by extending the range of shear of the measurements.

Values of ϕ_r were invariably linear with respect to C_v, which supports the concept of Ford that fluidities are the terms of choice in evaluating intrinsic viscosity. These findings also favor the use of the viscoelastic flow equation for obtaining low shear viscosities.

From Fig. 3 it is seen that a linear relationship appears to exist between intrinsic viscosity and viscosity of the suspending medium. This is not in agreement with Taylor's equation which predicts nonlinearity throughout the range of η_2. The discrepancy could not be attributed to the formation of a hydrated sheath to give the particle a hydrodynamic volume above the apparent volume, since in such case the constants would be greater than 2.5. Neither could this be attributed to an apparently consistent decrease in viscosity of one of the components, since such a prediction would still call for the nonlinear portion described by Taylor's equation. Doublet formation or aggregation would yield high values for k. Thus, by elimination, the failure to agree with Taylor's equation at low values of η_2 is perhaps best explained by slippage of an adsorbed layer at the surface of the particles, as suggested by Oldroyd (3). It does seem reasonable that the degree of slippage might decrease with increase in η_2, since the layer involved would most likely be of a modified stratum of the medium itself.

These results indicate that the viscoelastic flow equation is of value in describing non-Newtonian flow data. It has the advantage of fitting the observed flow curves quite well without requiring a rigid yield value. It seems likely to have wide applicability by modification of the number of exponential terms, and extrapolated values of limiting viscosity appear to be useful in investigating basic relationships.

Preparation and Evaluation of Thiamine N-Cyclohexylsulfamate Hydrochloride

By JAMES A. CAMPBELL

The presently available salts of thiamine are known to have a characteristic bitter taste. The N-cyclohexylsulfamic acid salt of thiamine hydrochloride was prepared and was found to have a taste which was greatly improved over that of the presently available salts of thiamine. After characterization, the salt was placed under short term accelerated aging conditions. The data obtained appears to indicate that the salt possesses good stability.

THE THIAMINE MOLECULE contains two basic nitrogen atoms, the quaternary nitrogen of the thiazole ring and the nitrogen of the primary amino group attached to the pyrimidine ring. Two types of thiamine salts are, therefore, possible. The first type involves only the nitrogen of the thiazole ring which is a more strongly basic center than the primary amino function (1). The second type of salt results when further salt formation occurs at the primary amino group. An example of the former would be thiamine mononitrate, whereas an example of the latter would be thiamine chloride hydrochloride.

Thiamine chloride hydrochloride and thiamine mononitrate appear to be the salts of choice in pharmaceutical dosage forms at the present time. The mononitrate is reported to be preferred in dry dosage forms because of greater stability in the dry state (1).

Various salts of thiamine have been reported. Okumura and Sakurai (2, 3), with the aid of ion exchange resins, prepared the following salts: nitrate·HNO_3; acid sulfate; iodide·HI; bromide·HBr; thiocyanate·HCNS; chloride; bromide; iodide; and thiocyanate. Water-soluble disulfonates of thiamine have also been reported by the same authors (4).

Thiamine salicylate (5) was prepared in Germany a number of years ago and was reported to be useful in the treatment of rheumatic and arthritic disease.

Several phosphoric acid derivatives of thiamine are quite well known. These include thiamine phosphoric acid ester chloride, thiamine phosphoric acid ester phosphate salt, thiamine phosphoric acid salt, thiamine triphosphoric acid ester, thiamine triphosphoric acid salt, and others (6).

Although many thiamine derivatives have been described, nothing has been reported concerning the improvement of the bitter taste which is characteristic of thiamine. The primary objective in preparing thiamine N-cyclohexylsulfamate hydrochloride was to obtain a salt of thiamine with improved taste and with stability at least as good as that of the presently available salts of thiamine.

Silver nitrate was reacted with N-cyclohexylsulfamic acid to form insoluble silver N-cyclohexylsulfamate. The silver N-cyclohexylsulfamate was reacted with thiamine chloride hydrochloride to produce thiamine N-cyclohexylsulfamate hydrochloride, leaving behind the insoluble silver chloride. The reactions are illustrated by the equations.

Accepted for publication June 27, 1961.
Presented to the Scientific Section, A. PH. A., Chicago meeting, April 1961.

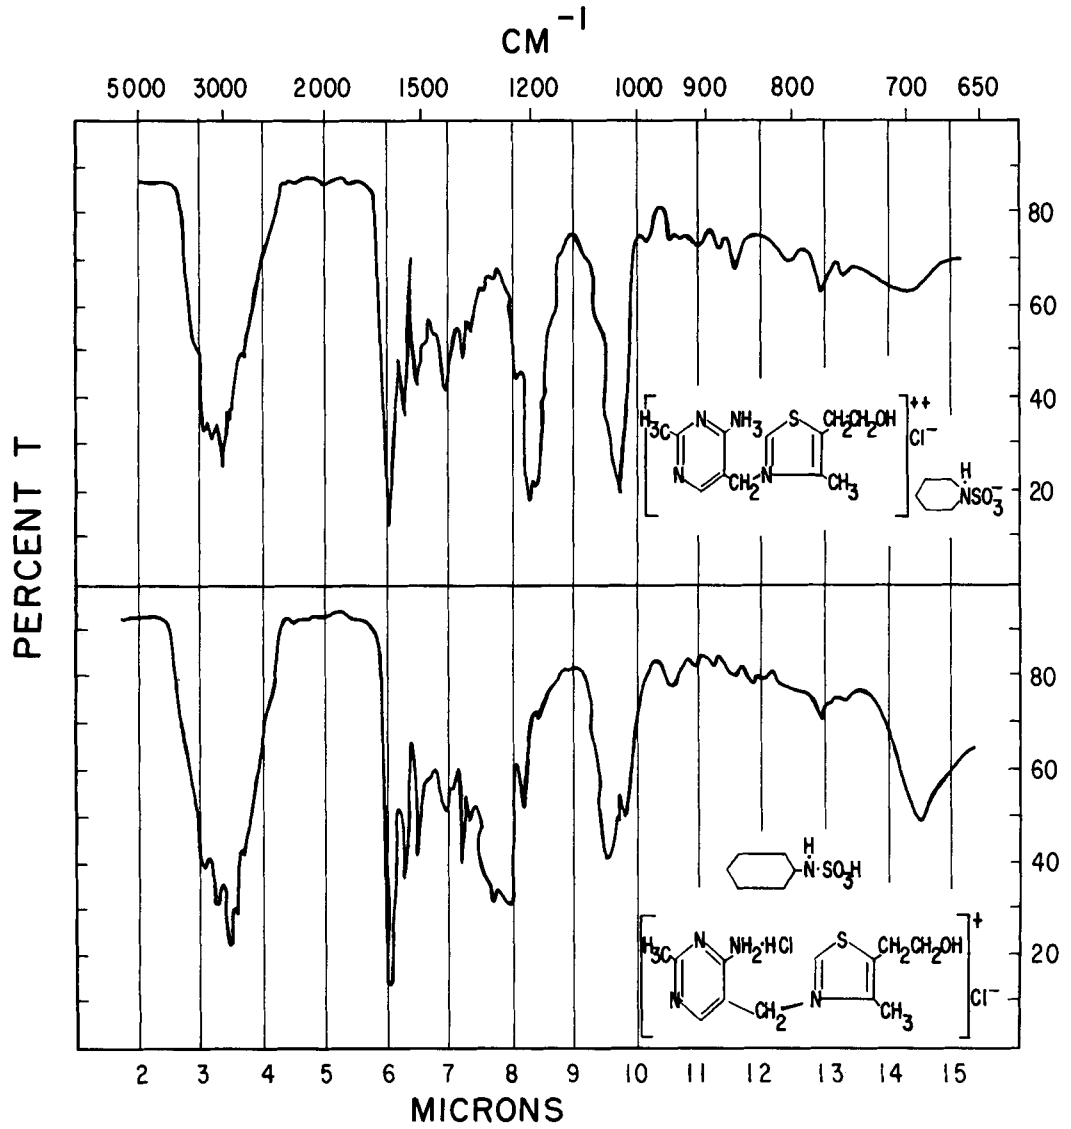

Fig. 1.—Infrared spectra. Above: thiamine N-cyclohexylsulfamate hydrochloride; below: equimolar mixture of thiamine hydrochloride and N-cyclohexylsulfamic acid.

EXPERIMENTAL

Preparation.—A solution consisting of 5 Gm. of silver nitrate in 3 ml. of water was added, with stirring, to a solution consisting of 5.25 Gm. of N-cyclohexylsulfamic acid in 50 ml. of water. The silver N-cyclohexylsulfamate which precipitated was collected on a filter, washed with water, and dried in an oven at 50°.

A 5-Gm. portion of thiamine chloride hydrochloride was dissolved in 10 ml. of water and to this was added 5 Gm. of the silver N-cyclohexylsulfamate. The suspension was stirred at 50° for 30 minutes and was then cooled and filtered. The filtrate was evaporated to dryness under reduced pressure. The solid residue was dissolved in warm methanol; and after cooling, ether was added to the solution to precipitate the final product as a white granular substance having a sweet taste and being freely soluble in water. The salt turned pink at 160° and decomposed between 185 and 190°.

Infrared Spectra.—A potassium bromide pellet was made containing an equimolar mixture of thiamine chloride hydrochloride and N-cyclohexylsulfamic acid. An equivalent concentration of the thiamine N-cyclohexylsulfamate hydrochloride was also incorporated into a potassium bromide pellet and the infrared spectra of both were obtained. The spectra, as shown in Fig. 1, are considerably different. Certain absorption peaks appeared in the spectrum of the compound that were absent in the spectrum of the mixture. These peaks can be observed at 805, 875, 1040, 1170–1220, and 1280–1320 cm.$^{-1}$. Likewise, certain absorption peaks appeared in the spectrum of the mixture that were absent in the spectrum of the compound. These peaks can be observed at 695, 833, 945, and 1065 cm.$^{-1}$.

Anal.—Calcd. for $C_{18}H_{30}ClN_5O_4S_2$: N (total), 14.60; N (basic), 5.83; HCl, 7.60; mol. wt., 480.05. Found: N (total, Kjeldahl), 14.58; N (basic), 6.09; HCl, 7.74.

Stability Studies.—An accelerated aging program was designed and carried out to determine the stability of the compound when combined in multiple vitamin preparations.

Solution Stability.—Three solutions of the following content were prepared

Substance	mg./ml.
Thiamine N-cyclohexylsulfamate HCl	10
Riboflavin-5-phosphate sodium	2
Nicotinamide	50
Panthenol (*dl*)	10
Pyridoxine HCl	5
Ascorbic acid	25
Chlorobutanol	0.6
Water *q.s.*	

Three solutions were prepared identical to that above except that thiamine mononitrate was substituted for the thiamine N-cyclohexylsulfamate hydrochloride in the same concentration.

One solution of each type was adjusted to pH 5 using sodium hydroxide, one solution of each type was adjusted to pH 4 using hydrochloric acid, and one solution of each type was adjusted to pH 3 using hydrochloric acid. Each of the final solutions was assayed for thiamine content and each was subdivided into three portions. The solutions were placed in amber glass bottles and a portion of each solution was stored at each of the following temperatures: 25, 40, and 50°. The solutions were assayed for thiamine content at the end of 3 months. The thiochrome method of assay was used in all assays and the assay results are shown in Table I.

Tablet Stability.—The thiamine N-cyclohexylsulfamate hydrochloride was incorporated into multiple vitamin tablets containing the following vitamins

Vitamins	Amount
Thiamine N-cyclohexylsulfamate HCl	10.0 mg.
Niacinamide	20.0 mg.
Riboflavin	2.5 mg.
Pyridoxine HCl	1.0 mg.
Sodium ascorbate	62.0 mg.
Vitamin B_{12}	1.0 mcg.
Vitamin A	5000.0 units
Vitamin D	500.0 units
Excipients *q.s.*	

The tablets were stored in tightly closed bottles for a period of three months at 25, 40, and 50°. The thiochrome method of assay was performed for thiamine content at zero, 1 month, and 3 month time intervals. The results are shown in Table II.

SUMMARY AND CONCLUSIONS

1. The N-cyclohexylsulfamic acid salt of thiamine was prepared and characterized.

2. The salt was found to have a pleasant taste which was judged to be superior to that of thiamine hydrochloride or thiamine mononitrate.

3. When combined with other vitamins in typical multiple vitamin preparations and subjected to accelerated aging, the salt has demonstrated a stability that compares favorably with that of thiamine mononitrate. It also appears that the optimum pH for the salt in aqueous solution is 3 or below.

Synthesis of 2-Thiophene Derivatives

By FRED C. ROGERS† and W. LEWIS NOBLES

The objective of this present study is the synthesis of certain new 2-thiophene derivatives to be evaluated as potential antispasmodic, analgesic, or local anesthetic agents. The first part of this study concerns the synthesis of β-aminoketones (Mannich bases). The second segment concerns the synthesis of γ-amino secondary alcohols by chemical reduction of the corresponding β-aminoketones. The third portion describes the synthesis of a series of γ-amino tertiary alcohols by application of the Grignard reaction to the corresponding Mannich bases. The last section of the study involves the preparation of γ-aminoalkyl esters from the corresponding tertiary alcohols.

THE INTEREST in compounds containing thiophene rings as biologically active agents stems primarily from the similar physical and chemical properties of benzene and thiophene. The concept of preparing thiophene analogs of biologically active compounds has stimulated workers in medicinal chemistry to the point that by now it appears that at least one thiophene analog has been prepared for every important therapeutic group containing a benzene nucleus.

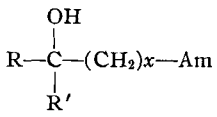
The physical and chemical characteristics of thiophene and benzene, as well as some of the biological activities of compounds of this type, can be reasonably well correlated by the application of the concept of isosterism as introduced by Langmuir (1) in 1919 and subsequently developed by Erlenmeyer (2) and others (3, 4). In the case of thiophene, the lower resonance energy and the presence of a hetero atom in the ring, along with the fact that a dipole moment exists, would logically lead one to postulate that thiophene compounds would be more easily degraded and detoxified in the human body. It is generally accepted from experimental evidence, however, that thiophene compounds are more toxic than their benzene analogs. There are important exceptions, however, and it is this realization that inspires further investigations in this field of endeavor.

The preparation of β-aminoketones requires the use of the Mannich reaction (5), which consists of the condensation of formaldehyde with ammonia, or a primary or secondary amine and a compound containing at least one active hydrogen atom. The amine is generally used in the form of its hydrochloride salt. An example of the reaction follows

$$C_6H_5COCH_3 + CH_2O + R_2NH.HCl \rightarrow C_6H_5COCH_2CH_2NR_2 \cdot HCl + H_2O$$

Mannich and Lammering (6) prepared a series of β-aminoketones and found that β-N-piperidinoethyl phenyl ketone, prepared from acetophenone, piperidine hydrochloride, and paraformaldehyde, possessed local anesthetic activity. Levvy and Nisbet (7) prepared a series of β-aminoketones from 2-acetylthiophene and found that 2-thienyl-β-piperidinoethyl ketone hydrochloride and the β-dimethylaminoethyl analog possessed local anesthetic activity, though considerably less than cocaine.

The work was extended by Denton and coworkers (8) who prepraed 22 β-aminoketones and evaluated them pharmacologically. In subsequent work by these investigators in which 23 additional β-aminoketones were prepared (9), it was concluded that, in general, a decrease in activity results from: (*a*) increasing the complexity of the amino group, and (*b*) the introduction of more complex aromatic radicals than the phenyl group.



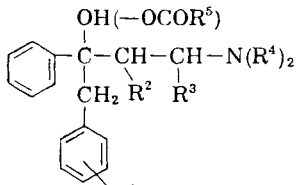
Mannich bases from benzalacetone were prepared by Burckhalter and Johnson (10) as vinylogs of β-aminopropiophenones in an attempt to enhance their analgetic activity. While these compounds were devoid of analgetic activity, they did possess *in vitro* action against bacteria. Denton and co-workers (11) reported the preparation of a secondary alcohol, 3-(1-piperidyl)-1,2-diphenyl-1-propanol hydrochloride, and found that it ranked higher in antispasmodic activity than did the seven tertiary alcohols with which it was compared.

Mannich (12) was not able to obtain *m*-aminophenyl β-piperidinoethyl ketone monohydrochloride by chemical reduction of the nitro base; Wright and Freifelder (13) were able to obtain this compound, however, by catalytic reduction of the ketone monohydrochloride in aqueous solution with 5% palladium on activated charcoal.

Nobles (14) reported the preparation of 3-dimethylamino-1-phenyl-1-propanol hydrochloride by the reduction of the corresponding amino ketone with sodium borohydride.

Received April 28, 1961, from the Graduate School, University of Mississippi, University.
Accepted for publication June 30, 1961.
Abstracted in part from a thesis presented to the Graduate School of the University of Mississippi by Fred C. Rogers, in partial fulfillment of the requirements of the degree of Master of Science, August 1960.
† Present address: E. I. du Pont de Nemours and Co., Inc., Camden, S. C.

Denton and co-workers (15–19) have prepared more than 100 γ-amino tertiary alcohols, a majority of which have exhibited physiological activity. The general structure of the γ-amino-alcohols prepared by these workers is represented as follows



Cunningham and co-workers (20) prepared 3-(N - piperidyl) - 1 phenyl - 1 - cyclohexy - 1 - propanol hydrochloride[1] and related compounds. These compounds were found to be potent antispasmodics.

Adamson (21) found that the intermediates for the preparation of compounds with antihistaminic properties may be obtained by treating tertiary aminoethyl ketones or their salts with 2-pyridyllithium and hydrolyzing the organo-lithium compound formed. One of the compounds mentioned was a 2-thiophene derivative: 3-dimethylamino-1-(2-thienyl)-1-propanol.

Pohland and Sullivan (22) demonstrated the formation of tertiary alcohols from the reaction of a β-aminoketone with a Grignard reagent and hydrolysis of the addition product to form 4-dimethylamino - 1,2 - diphenyl - 3 - methyl - 2-butanol and its hydrochloride salt and related compounds.

Pohland and Sullivan (22) were interested in the preparation of 4-dialkylamino-1,2-diphenyl-2-butanols and their esters. The general structure of these compounds may be represented as

Preliminary pharmacological evaluation of *dl*-4 - dimethylamino - 1,2 - diphenyl - 3 - methyl - 2-propionyl oxybutane hydrochloride indicated that the α-isomer possessed a high order of analgesic activity in animals and was found to be an effective analgesic in human beings (23).

DISCUSSION

The preparation of three β-aminoketones, 3-dimethylamino - 2 - methyl - 1 - (2 - thienyl) - 1 - propanone hydrochloride and the 3-piperidyl and 3-morpholinyl analogs, was accomplished by the reaction of 2-propionylthiophene and paraformaldehyde with the appropriate secondary amine hydrochloride. The starting compound, 2-propionylthiophene, was prepared by following the method of Kosak and Hartough (24) for the preparation of 2-acetylthiophene.

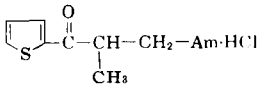
A different procedure was followed in the synthesis of each of the three β-aminoketones rather than following one general procedure. 3-Dimethylamino-2-methyl-1-(2-thienyl)-1-propanone had previously been prepared by Blicke and Burckhalter (25). Harradence and Lions (26) described a procedure for the production of Mannich bases using morpholine hydrochloride. This method was followed in the synthesis of 4-morpholinyl-3-methyl-1-(2-thienyl)-1-propanone hydrochloride. The method of Levvy and Nisbet (7) was utilized for the synthesis of the 4-piperidyl analog.

As a result of the relatively low yield (33%) of 4-piperidyl-3-methyl-1-(2-thienyl)-1-propanone hydrochloride obtained by following the method outlined by Levvy and Nisbet, the present authors found it necessary to prepare an additional quantity of this Mannich base salt. The method of Maxwell (27) was followed for this second preparation and a yield of 49% was obtained. Levvy and Nisbet (7) stated that a 1 molar quantity of paraformaldehyde is used in the initial reaction mixture and the mixture is refluxed for 15 minutes. A second mole of paraformaldehyde is added and refluxing is continued for an additional 15 minutes. Maxwell (27) uses a 1.5 molar equivalent of paraformaldehyde, which is placed in the reaction mixture at the onset of the reaction, and the reaction mixture is refluxed for 3 hours.

Table I indicates pertinent data with respect to the Mannich bases utilized in this study.

The preparation of the three γ-amino secondary alcohols, 3-dimethylamino-2-methyl-1-(2-thienyl)-1-propanol hydrochloride and the 3-piperidyl and 3-morpholinyl analogs, was patterned after the method of Chaikin and Brown (28) as modified by Nobles (14).

The secondary alcohols were obtained by reduction of the corresponding Mannich bases with sodium borohydride. Sodium borohydride is reported (29) to react quite vigorously with aldehydes and ketones at temperatures as low as −40° in methyl alcohol solution, but a quite gentle reaction is obtained at room temperature in an aqueous solution. A moderately vigorous, but easily controllable reaction was obtained at 20–30° when the ketone in methyl alcohol solution was reacted with a 50% methyl alcohol solution of sodium borohydride.



Data with respect to these alcohols are listed in Table II.

The preparation of γ-amino tertiary alcohols involves the reaction of a β-aminoketone with a Grignard reagent. Three different Grignard reagents were utilized in the preparation of this series of compounds: benzylmagnesium chloride, methylmagnesium bromide, and ethylmagnesium bromide. Only the first of the three Grignard reagents was prepared in this laboratory. The remaining two reagents were obtained commercially. The procedure of Gilman and Catlin (30) was followed for the preparation of benzylmagnesium chloride.

The synthesis of 4-dimethylamino-3-methyl-1-phenyl-2-(2-thienyl)-2-butanol hydrochloride and

[1] Marketed as Artane hydrochloride by Lederle Laboratories.

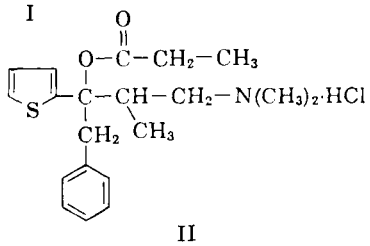
[a] Hydrochloride salt is extremely hygroscopic until washed free of impurities.

the 4-piperidyl and 4-morpholinyl analogs were carried out by following the procedure of Pohland and Sullivan (31). An attempted synthesis of 4-morpholinyl-3-methyl-1,2-diphenyl-butanol hydrochloride was conducted by following the procedure of Denton and his associates (11). The main difference in this method and the method of Pohland and Sullivan is the method of decomposing the addition complex. Denton's method advocates the use of hydrochloric acid to effect the decomposition. The probable reason for the failure of the present authors to obtain the γ-morpholinyl tertiary alcohol is that, after the addition complex was decomposed with dilute hydrochloric acid, the reaction mixture was allowed to stand overnight. The presence of the mineral acid in the reaction mixture for an extended time was undoubtedly sufficient to cause dehydration of the tertiary alcohol. The reaction product gave a positive test for unsaturation when treated with bromide in carbon tetrachloride and aqueous potassium permanganate. This portion of the work will be modified correspondingly in subsequent work.



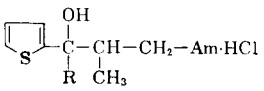
The tertiary alcohols are listed in Table III.

The attempted synthesis of γ-aminoalkyl esters was patterned after the work of Pohland and Sullivan (22, 23, 31). These workers prepared a compound, α - *d* - 4 - dimethylamino - 1,2 - diphenyl - 3 - methyl-2-propionyloxybutane hydrochloride (I).[2] This drug is reported to be an effective analgesic which is comparable to codeine in analgetic activity and is nontoxic and nonaddicting.

Various procedures for the esterification of tertiary alcohols were utilized by the present authors in the attempted synthesis of 4-dimethylamino-3-methyl-1-phenyl-2-propionyloxy-2-(2-thienyl)-butane hydrochloride (II) and the γ-morpholinyl and γ-piperidyl analogs.

I

II



Each attempt met with failure. An examination of the infrared spectrum of each of the reaction products did not reveal the presence of the characteristic alkyl ester absorption in the region of 1735-1750 cm.$^{-1}$ and, in most cases, no absorption peaks of any consequence could be observed from 1650-2000 cm.$^{-1}$.

The reason for the failure to obtain the γ-amino esters is not absolutely clear, although Campaigne and Diedrich (32) stated that their inability to obtain esters of secondary alcohols, derived from 2-acylthiophenes, was due to the relative inactivity of the hydroxyl group. They claimed that this inactivity was due to hindrance of the α-carbon in 2-substituted thiophenes.

Some of the reaction products from the attempted esterifications were tested for unsaturation with bromine in carbon tetrachloride and dilute permanganate solution. The tests indicated that dehydration had occurred. The location of the unsaturation in the olefinic products has not been

[2] Commercially available from Eli Lilly and Co. as Darvon.

determined, but, by consideration of resonance stabilization, it would be possible to predict the principle product of the dehydration of III as being that represented by structure IV.

Both the dehydration in preference to esterification and the suggested structure, IV, are in accord with the modern theories of this facet of organic chemistry as suggested by Morrison and Boyd (33). This is true despite the success of Pohland and Sullivan (22) in obtaining the tertiary alcohol esters in the *d*-propoxyphene hydrochloride series.

EXPERIMENTAL

The Mannich bases were prepared according to the general methods already indicated in this paper, according to the well-known methods of the chemical literature.

3 - Dimethylamino - 2 - methyl - 1 - (2 - thienyl)-1 propanol Hydrochloride.—Following the general procedure of Chaikin and Brown (30) as employed by Nobles (14), 10.0 Gm. (0.043 mole) of 3-dimethylamino-2-methyl-1-(2-thienyl)-1-propanone hydrochloride was dissolved in a minimum amount of water and made basic with ice cold 20% sodium hydroxide. The basic mixture was then extracted with ether. The ether was removed by evaporation at the water aspirator, and the free base was dissolved in 50 ml. of methyl alcohol. Meanwhile, 1.615 Gm. (0.427 mole) of sodium borohydride in 100 ml. of 50% methyl alcohol, cooled to 20°, was prepared and placed in a 300-ml. round-bottom flask, equipped with a magnetic stirrer, reflux condenser, and dropping funnel. The flask containing the sodium borohydride solution was surrounded by a cooling bath, and the alcoholic solution of the aminoketone was added, dropwise, with stirring and cooling so as to maintain the temperature below 30°. After the addition was complete, the mixture was stirred for an additional 30 minutes. The flask was removed from the cooling bath and warmed to 40–50° so as to decompose the excess sodium borohydride. The solution was then concentrated *in vacuo* to remove the alcohol. The residue was ether extracted and dried overnight with anhydrous magnesium sulfate. The drying agent was removed by filtration. The ether extract was chilled by means of an ice-water bath and treated with anhydrous hydrogen chloride while being stirred with a magnetic stirrer. The hydrochloride salt was collected on a sintered-glass funnel and washed with ether. Recrystallization from ethyl alcohol-ethyl acetate yielded 4.8 Gm. (48%) of white crystals, m.p. 152–156°.

3 - Piperidyl - 2 - methyl - 1 - (2 - thienyl) - 1-propanol Hydrochloride.—Following the above described procedure, 2.8 Gm. (0.074 mole) of sodium borohydride in 150 ml. of 50% methyl alcohol and 17.3 Gm. (0.073 mole) of 3-piperidyl-2-methyl-1-(2-thienyl)-1-propanone in 100 ml. of methyl alcohol yielded 16.8 Gm. (83%) of white crystals, m.p. 150–185°. A small sample, after recrystallization from ethyl alcohol-ethyl acetate, melted at 199–200°.

3 - Morpholinyl - 2 - methyl - 1 - (2 - thienyl) - 1-propanol Hydrochloride.—By the method outlined previously, 1.37 Gm. (0.036 mole) of sodium borohydride in 75 ml. of 50% methyl alcohol and 8.7 Gm. (0.036 mole) of 3-morpholinyl-2-methyl-1-(2-thienyl)-1-propanone in 75 ml. of methyl alcohol yielded 6.7 Gm. (67%) of white crystals, m.p. 172–180°. A sample after recrystallization from ethyl alcohol-ethyl acetate, melted at 178–181°.

4 - Dimethylamino - 3 - methyl - 2 - (2 - thienyl)-2-butanol Hydrochloride.—The general method of Pohland and Sullivan (23) for the preparation of γ-amino tertiary alcohols was used for this preparation. In a dry 500-ml. three-neck flask fitted with a mercury-sealed stirrer, a dropping funnel, and a condenser provided at its upper end with a drying tube containing a mixture of calcium chloride and soda lime, was placed 0.214 mole of methylmagnesium bromide and 50 ml. of dry ether. 3-Dimethylamino-2-methyl-1-(2-thienyl)-1-propanone, 21.1 Gm. (0.107 mole) in 200 ml. of dry ether was

pipetted into the dropping funnel and added dropwise with stirring to the Grignard solution. After the addition was completed, the reaction mixture was refluxed with stirring for 1 hour and cooled to room temperature. The reaction mixture was decomposed by the dropwise addition of a saturated ammonium chloride solution. The ether solution was decanted from the granular solid and the solid material was washed with 100 ml. of ether. The combined ether solutions were dried overnight with anhydrous magnesium sulfate. The drying agent was removed by filtration, and the ether solution was treated with anhydrous hydrogen chloride. The hydrochloride salt formed as a sticky mass and adhered to the walls of the flask. The ether was quickly decanted from the sticky mass and 10 ml. of acetone was added to the mass. The flask was restoppered and allowed to stand for 1 hour. After the mass had solidified, it was collected on a sintered-glass funnel and washed with a small quantity of acetone yielding 15.3 Gm. (55%) of white crystals m.p. 160–167°. A sample, after recrystallization from ethyl alcohol, melted at 170–172°.

4 - Morpholinyl - 3 - methyl - 2 - (2 - thienyl)-2-butanol Hydrochloride.—Following the above described procedure, 0.15 mole of methylmagnesium bromide in 50 ml. of dry ether and 16.15 Gm. (0.068 mole) of 3-morpholinyl-2-methyl-1-(2-thienyl)-1-propanone in 150 ml. of dry ether yielded 13.4 Gm. (68%) of white crystals, m.p. 160–166°. A sample, after recrystallization from ethyl alcohol, melted at 167–172°.

1-Dimethylamino - 2-methyl-3-(2-thienyl)-3-pentanol Hydrochloride.—By the method outlined previously, 0.214 mole of ethylmagnesium bromide in 50 ml. of dry ether and 21.1 Gm. (0.107 mole) of 3-dimethylamino-2-methyl-1-(2-thienyl)-1-propanone in 200 ml. of dry ether yielded 14.0 Gm. (50%) of white crystals, m.p. 170–173°. A sample, after recrystallization from ethyl alcohol-acetone, melted at 174.5–175°.

1 - Morpholinyl - 2 - methyl - 3 - (2 - thienyl) - 3-pentanol Hydrochloride.—By the method outlined previously, 0.182 mole of ethylmagnesium bromide in 50 ml. of ether and 21.7 Gm. (0.091 mole) of 3-morpholinyl-2-methyl-1-(2-thienyl)-1-propanone in 150 ml. of dry ether yielded 15.3 Gm. (55%) of white crystals, m.p. 154–160°. A sample, after recrystallization from ethyl alcohol-acetone, melted at 163–165°.

4 - Dimethylamino - 3 - methyl - 1 - phenyl - 2-(2-thienyl)-2-butanol Hydrochloride.—By the previously described method of Gilman and Catlin (31), 0.152 mole of benzylmagnesium chloride was prepared in a 2-L. three-neck flask equipped with a mercury-sealed stirrer, a dropping funnel, and a condenser provided with a drying tube containing a mixture of calcium chloride and soda lime. Following the method of Pohland and Sullivan (23) for the preparation of the tertiary alcohol, the Grignard solution was stirred during the dropwise addition of a solution of 14.9 Gm. (0.76 mole) of 3-dimethylamino-2-methyl-1-(2-thienyl)-1-propanone in 200 ml. of dry ether. After the addition of the ketone was completed, the reaction mixture was refluxed for 1 hour and then allowed to cool to room temperature. The reaction mixture was decomposed by the dropwise addition of a saturated ammonium chloride solution. The ether was decanted from the granular solid, and the solid material was washed with 50–75 ml. of ether. The combined ether solutions were dried overnight with anhydrous magnesium sulfate. The drying agent was removed by filtration, and the ether solution was treated with anhydrous hydrogen chloride. The white precipitate was collected on a sintered-glass funnel yielding 14 Gm. (57%) of white crystals, m.p. 156–165°. A sample, after recrystallization from methyl alcohol-ethyl acetate (1:3 ratio) melted at 180–184°.

4 - Piperidyl - 3 methyl - 1 - phenyl - 2 - (2-thienyl)-2-butanol Hydrochloride.—By the method outlined above, 0.38 mole of benzylmagnesium chloride and 30.0 Gm. (0.126 mole) of 3-piperidyl-2-methyl-1-(2-thienyl)-1-propanone in 200 ml. of dry ether yielded 15 Gm. (32%) of white crystals, m.p. 120–170°. A sample, after recrystallization from methyl alcohol-ethyl acetate, melted at 169–177°.

Some Aspects of Inhaler Technology

By LLOYD KENNON and JOHN J. GULESICH

This communication presents the results of a physical-chemical study of the characteristics of the inhaler dosage form. Such a study has not been reported previously. Analysis of the observations made permit the following generalizations: inhalers may be classified as being either a surface type (provides zero-order release) or a solution type (provides first-order type of release); in inhaler development the rates of volatilization can be controlled or modified; vapor pressure equilibrium concepts play a minor role. These concepts are amplified and discussed with supporting data.

INFORMATION concerning inhaler technology is conspicuous by its absence in readily available sources. The U.S.P. XVI (p. 823), which contains only one inhaler monograph (propylhexedrine inhalant), describes this dosage form as follows: "Inhalants are drugs or combinations of drugs which, by virtue of their high vapor pressure, can be carried by an air current into the nasal passage where they exert their effect. The device making possible the administration of an inhalant is known as an inhaler."

Inhalers, like all pharmaceutical products, should be physically and chemically stable so that satisfactory shelf- and use-life is attained. However, inhalers present somewhat different problems in that the delivered doses are not easily standardized, unlike the cases involving tablets, capsules, or solutions. In fact, the precision with which inhaler doses can be made "uniform" is of a completely different order of magnitude from that attainable with the latter products.

The purpose of this paper is to show that inhaler technology and inhaler problems can be profitably examined by applying the principles of physical chemistry. It is possible by these means to obtain a clearer picture of the behavior, including the limitations, of inhaler dosage forms. Variables such as the shape and size of the inhaler body and pledget, the concentration and state of the pledget charge, and the variation in performance of both individual and groups of inhalers have been studied. No attempt will be made here to discuss all the medical and pharmaceutical aspects or the chemical reactivities which would have to be considered in the formulation of a complete inhaler. Such factors as the physical and chemical stability, solubility, mechanical integrity, or compatibility of the active ingredient with the inhaler body, pledget, solvent, or organoleptic agents will not be discussed.

The paper describes and discusses some of the data obtained during the development of an inhaler whose volatile ingredient was phlorone, 2,5-dimethyl-1,4-benzoquinone. The inhaler was to deliver at least 50 mcg. of phlorone per liter of air passing through it.

EXPERIMENTAL

Apparatus.—Figure 1 pictures the breathing apparatus used in the evaluation of the inhalers. In essence, the system is designed to pull a known amount of air through an inhaler and then through a quantity of liquid in which the active ingredient in the vapor dissolves and which can be analyzed. The device was set so that each cycle took 2 seconds and delivered 200 ml. of air. Because the size of the holes in the glass aerating head affected the quantity of air which would pass per cycle, the apparatus was calibrated with a Collins vitalometer.[1] This was done by inflating the vitalometer, then connecting it in the position at which the inhaler is put during testing, running the breathing apparatus, and noting the decrease in air volume of the vitalometer per breathing cycle.

Procedure.—The manipulations consisted of drawing air serially through the various inhaler formulations and then through 25 ml. of analytical reagent grade isopropanol contained in a 75-ml. test tube. The isopropanol solution was then analyzed on the Beckman DU spectrophotometer. A second tube of isopropanol in series showed that no phlorone was carried out as vapor from the first tube, so only one tube was needed. The pump or breathing apparatus was set so that 200 ml. of air was pumped per complete cycle, each cycle taking 2 seconds (the actual time of air flow then being 1 second, with the machine "exhaling" the other second). To put 1 L. of air through an inhaler then took, of course, five cycles or 10 seconds.

Analytical.—Many standard solutions of phlorone in analytical reagent grade isopropanol were made and run at 250 mμ on the Beckman DU instrument; the response was linear and reproducible to a very

high degree of precision. Solutions stored in the dark for various periods of time up to 8 days assayed the same as originally. The absorptivity or absorbancy index was found to be 139; $K = 139 =$ absorbance/(Gm./L.). Since 25 ml. was a convenient volume of isopropanol in which to collect phlorone vapors, the relationship became simply: micrograms/25 ml. = absorbance × 180. This assay procedure was found to be very satisfactory. When equal concentrations of camphor, menthol, or eucalyptol were added to the phlorone standard solutions, no interference was noted in the absorbance at 250 mμ.

RESULTS AND DISCUSSION

Initial Studies.—The first inhalers were made by dissolving the phlorone in ether, placing the appropriate number of pledgets in the solution, and then evaporating the ether. The ether evaporating process is unwieldy and results in uneven distribution of the phlorone on the surface of either the cotton or folded blotter pledgets. Table I presents some of the data taken on inhalers which contained 50 mg. of phlorone and 4 mg. of menthol made by this process. The long plastic body was used. The greater available surface area of the blotter provided somewhat higher doses than the cotton pledget.

To replace the ether evaporation procedure, phlorone was added to the pledgets in solution form. Two solvents of very low volatility were chosen for study: dibutyl phthalate and benzyl salicylate. A solubility study was done to determine the limits of concentration that could be used. The limits determined were: 50 mg./ml. in dibutyl phthalate and 85 mg./ml. in benzyl salicylate. The solutions made with the latter formed more easily.

A group of inhalers was made by putting 1 ml. of a 50 mg./ml. solution of phlorone in dibutyl phthalate on cotton and blotter pledgets encased in the long plastic body. Doses obtained from this group are given in Table II. Again it is seen that the greater exposed surface area of the blotter pledget provides the higher doses.

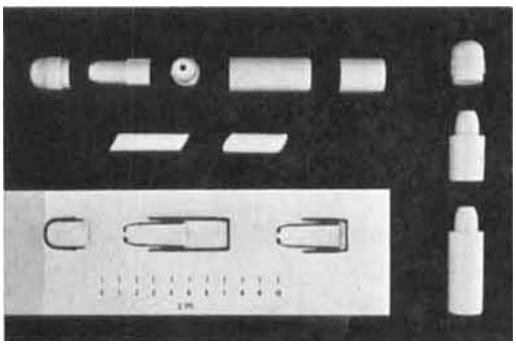

Fig. 2.—External and cut-away views of inhaler components.

On the basis of these data (Tables I and II) more inhaler groups were made in an attempt to decide which type of pledget and which inhaler type (surface or solution) would give better results. The following nine groups, all in long bodies, were then made: Surface: (*A*) evaporated ether method, 50 mg. charge, blotter pledget; (*B*) same method, long cotton pledget; (*C*) same method, short cotton pledget. Solution: (*D*) method: 1 ml. of warm 100 mg./ml. solution of phlorone in benzyl salicylate per pledget, blotter pledget; (*E*) method same, long cotton pledget; (*F*) method same, short cotton pledget; (*G*) method: 1 ml. of 50 mg./ml. solution of phlorone in dibutyl phthalate per pledget, blotter pledget; (*H*) same method, long cotton pledget; (*I*) same method, short cotton pledget.

The data obtained from these nine groups are given in Tables III and IV.

Taking an overview of the data of Table III, we may look at the averages as presented in Table IV.

Besides these data, trial runs with other Group A and B inhalers were made. Fifteen analyses (three inhalers breathed five times each at half-hour intervals) from each group showed that Group A gave an average dose of 78 mcg./L. of air; Group B gave 72 mcg./L. of air.

The data indicate that, all things considered (dose level, ease of making, solubility, etc.), the short cotton pledget charged with phlorone in benzyl salicylate appears to produce the best inhaler. We recognize that the "package" is an inherent part of the formula in an inhaler dosage form because the internal size and shape may govern the amount of drug put into the formula and the dosage obtained per "whiff."

Although inhalers made by the "evaporated ether" process were of less interest, some limited usage tests were made using inhalers of this type. The same four inhalers of Group A used to obtain the data of Table III were also used here. The time of breathing is also shown along with the dose data in Table V.

The data of Table V provide an insight into how well and with what variation some of the original inhalers perform.

Because of the possibility that more efficient utilization of the drug might result from its application closer to the nasal openings so that more of the inner nasal surfaces would be bathed with the vapors, some larger, aluminum inhaler bodies (identical to those of the obsolete Benzedrine inhaler) were tested. These bodies are somewhat thicker, and the nose-piece is of such size that it does not easily penetrate the nose as far as the nozzles shown in Fig. 2. It was found that the airflow characteristics of this inhaler body are such that the pledgets supply a dose lower than they do when encased in the plastic bodies. Even when four extra holes were drilled (No. 50 drill) in the sides of the air-inlet end in an attempt to permit more air to pass through, no increase in dosage was obtained. This indicates that resistance to air flow can be a rate-limiting factor. Table VI presents the data obtained.

Final Studies.—On the basis of the data collected on the preliminary inhalers, further work was done only on solution-type inhalers. Tables VII–IX present some of the data taken on inhalers containing 85 mg. of phlorone and 10, 20, or 30 mg. of camphor dissolved in 1 ml. of benzyl salicylate. The short size body and pledget was used. The camphor odor persisted throughout the trials. The data indicated also that the phlorone dosage is not affected by the presence of various amounts of camphor.

Although the data are given in quite a detailed manner, attempts to summarize the information result in too great a loss of clarity and completeness in the total picture.

Because rate processes should control inhaler function, it is interesting to note the effect of temperature on the rate of volatilization of phlorone. Several inhalers from the groups used to obtain the data of Tables VIII and IX were heated to 37°, then breathed. It can be seen that this increase in temperature increases the dose about 80% over that obtained at room temperature. Table X presents the data.

The data shown in Table XI resulted from study of the following solution-type inhaler formula: phlorone, 85.0 mg.; eucalyptol U.S.P., 0.03 ml.; and benzyl salicylate *q.s. ad.* 1.0 ml.

The phlorone and eucalyptol are dissolved in the benzyl salicylate, then 1 ml. of the solution is dropped onto the small cotton pledget which is then encased in the body of the inhaler. Some less extensive data on similar formulas (same except having 0.01 or 0.02 ml. of eucalpytol) were also collected but are not given here because they essentially duplicate the data following. The eucalyptol odor persisted throughout the trials.

The data of Table XI corroborate the concept that rate processes exert more weight than equilibrium does. For example, one of the continuous breathing series, dose numbers 122–150, shows that recovery times are essentially nonexistent.

In addition to the data already presented, this table also permits one (by examining the vertical columns) to see the variation in the performance of individual inhalers. Even though the ranges are fairly wide, the inhalers do perform quite consistently on the average. The following are the average doses given by the Table XI inhalers: No. 1, 85; No. 2, 90; No. 3, 83; No. 4, 91; No. 5, 84.

To check the effect of the state of the total charge the following was done: two groups of inhalers were made, each inhaler containing 42.5 mg. of phlorone and 0.015 ml. of eucalyptol. However, one group had the ingredients dissolved in 0.5 ml. of benzyl salicylate, the other in 1.0 ml. Each of the ten inhalers (short body, cotton pledget) was breathed six times with the following results: the "0.5-ml. group" averaged 64 mcg./L. of air, whereas the "1.0 ml. group" averaged 37. The conclusion is that in a solution type inhaler the concentration of drug is of much greater importance than the surface area over which it is spread. Again, this concentration dependence indicates that rate rather than equilibrium factors predominate.

We further investigated the effect of charge concentration on delivered dose. Phlorone-eucalyptol-benzyl salicylate inhalers were made having phlorone concentrations of 80, 70, 60, 50, and 40 mg./ml. in benzyl salicylate. Each short cotton inhaler pledget was charged with 1 ml. of solution. Figure 3 illustrates the results. It can be seen that

[a] Inhalers had doses taken from them at half-hour intervals; inhalers No. 15–18 were modified by drilling four holes (No. 50 drill) into side of inlet end.

the inhaler life and dosage level are predictable when such data are available.

The following was done to check the behavior of a surface type inhaler. Inhalers (blotter pledget, long body) were made by the evaporated ether method containing 10, 20, 30, 40, 50, 60, and 70 mg. of phlorone. Figure 4 illustrates the results. It can be seen that in this case the dosage does not fall off as quickly as with the solution type inhaler.

As a comparison to the above and to fortify still further the conclusions drawn from the data of Fig. 3, more inhalers were made containing 40, 50, 60, 70, and 80 mg. of phlorone dissolved in 1 ml. of benzyl salicylate. This time blotter pledgets in the large inhaler body were used. Figure 5 presents the data obtained. Again, just as in Fig. 3, the line goes through the origin.

The data of Figs. 3–5, beside contributing to the general picture, enable one to make a calculation of the useful life of the inhaler. It can be seen that the formula would deliver more than 400 doses of at least 50 mcg./L.

CONCLUSIONS AND COMMENTS

In general, it appears that inhalers may be classified as being one of two types. One kind may be called a "surface" type, i.e., the volatile material, *per se*, resides on the surfaces of the

[a] X indicates that the inhaler was breathed but not assayed.

pledget. This represents a conventional adsorption situation; it is easy to appreciate the fact that the more surface area the pledget has the greater the surface area of the material exposed to the airflow and the greater the opportunity for volatilization. Thus a larger or more loosely packed pledget will cause a larger dose to emanate from an inhaler than a smaller or tightly packed pledget. It is convenient to make this type of inhaler if the volatile material itself is a liquid. It should also be pointed out that the doses produced from a surface type inhaler stay relatively high while the pledget charge is being depleted according to a zero-order scheme. This is reasonable when one visualizes that the volatile material has formed a multimolecular (as distinguished from a monomolecular) layer on the pledget surfaces; thus, even though molecules are stripped off, the surface area and hence the dose remain essentially unchanged. However, as some areas of the pledget are denuded, the total exposed surface area of the volatile material decreases, and so does the dose.

The second inhaler type may be termed a "solution" type, i.e., the volatile material is dissolved in a suitable nonvolatile solvent, and this solution is placed on the pledget. The situation may be taken as an example of the operation of Raoult's and Henry's laws, i.e., the vapor pressure of the components are proportional in some way to their concentrations expressed as mole fractions. To keep the vapor pressure contribution of the solvent low in order to enhance the vapor pressure of the solute, a solvent of very low vapor pressure is used as the vehicle. In this inhaler type the exposed surface area of the material does not change as the inhaler is used; what does change is the concentration of the volatile material in the solvent. Thus the dose gradually decreases according to a first-order scheme as the drug concentration decreases. Of course, the nature of the pledget and the inhaler body

[a] X indicates that the inhaler was breathed but not assayed.

exert some effect here also, because if the airflow through the inhaler and the pledget type do not permit volatilization of the material, insignificant, low doses will result. The phlorone inhaler was of the solution type because the volatile drug is a solid, and solids do not lend themselves to easy pledget charging procedures. The inhaler was designed to deliver in excess of 50 mcg./L. of air passing through. The original doses (when the charge is a full 85 mg.) were about 90 mcg./L. of air; after the equivalent of over 400 doses are delivered and the amount of phlorone drops to 50 mg., the doses were about 52 mcg./L. of air.

If an inhaler were part solution and part surface in nature, one would expect the dosage drop-off line to be steeper than the type exemplified in Fig. 4, yet not as steep as those of Figs. 3 or 5.

Further amplification and clarification of the "surface" and "solution" type classification concept of inhalers might be achieved by considering the existing analogy to chromatographic systems. The surface-type inhaler corresponds to adsorption chromatography wherein the material is initially adsorbed on a carrier, then desorbed by a passing stream of liquid or gas, as the case may be. The solution-type inhaler corresponds to partition chromatography in which material in a solvent is supported by some medium and then partitioned between its original solvent and a passing stream of gas or liquid and thus removed.

Another conclusion which is implicit in the data but somewhat submerged concerns the relationship of the volatile active ingredient to the solvent. An increase in dose should result when the active ingredient is dissolved in solvents which cause it to deviate more positively from Raoult's law. Thus, the less the solute-solvent interaction and the greater the solute-solute interaction, the more pronounced will be the tendency toward volatilization of the solute. Using

relative solubility as a gauge of such interaction, one would expect greater doses of phlorone from dibutyl phthalate (in which it is less soluble) than from benzyl salicylate, at the same concentrations. This appears to be the case as comparable inhalers containing phlorone in dibutyl phthalate (50 mg./ml.) give doses of 86 mcg./L. (Table IV, group I), and in benzyl salicylate, 52 mcg./L. (Fig. 3).

Some comments on vapor pressure may be appropriate here. Although it might seem that the vapor pressure of the drug and additives would assume a position of primary importance, this does not appear to be the case. Vapor pressure values represent an equilibrium situation, whereas what is involved in the inhaler cases is a process controlled by factors affecting rates of volatilization. Now it is true of course that volatile materials usually have appreciable vapor pressures. However, it is not generally true that a compound with a vapor pressure value of, e.g., twice that of another compound will volatilize just twice as fast. Besides this fact, inhaler recovery times may be essentially zero, no equilibration time may be needed. Also, no dosage drops would be noted with the surface

[a] X indicates that the inhaler was breathed but not assayed.

type inhaler and no regular (i.e., linear with concentration) dosage drops would be noted with the "solution" type inhaler if the vapor pressure were the controlling factor.

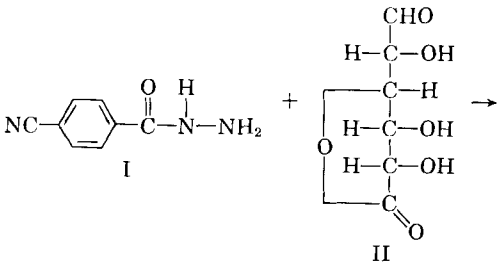
Unfortunately (from the standpoint of not having a more straightforward system to analyze), equilibrium and rate concepts are inextricably intertwined in the present situation. This easily leads to the basically incorrect tendency to try to predict kinetic data from thermodynamic values. However, because vaporization is relatively unencumbered with exotic entropy and orientation factors, rates of volatilization are often qualitatively proportional to the equilibrium properties of the materials involved. For example, equimolar quantities of the following compounds, allowed to evaporate at room temperature under the same conditions, will complete the evaporation process in this order: ether, acetone, chloroform, carbon tetrachloride, ethyl acetate, water. This order corresponds to both the materials' vapor pressures and boiling points. To further becloud the cause-and-effect relationship, the very magnitude of the numbers is such that the partial vapor pressure of the phlorone increases proportionately with the mole fraction. The concentration of benzyl salicylate is 5.15 moles/L. in the solutions, whereas the phlorone concentrations are 0.08–0.63 moles/L. Thus, the situation takes the form of plotting X and Y when the relationship is $Y = X/K + X$; when K is much larger than X, X and Y are essentially proportional to each other, i.e., if one doubles, so does the other; when K is much smaller than X, Y may be virtually a constant through a whole range of X values.

Hence, while vapor pressure concepts should not be neglected entirely in inhaler development, it is the rates of volatilization which must be controlled or modified.

Synthesis of Some New Hydrazone Derivatives

By LAWRENCE J. FISCHER and BERNARD ECANOW

The synthesis of D-glucuronolactone and D-mannuronolactone *p*-cyanobenzoyl hydrazones is reported. Also reported is a new melting point for *p*-cyanobenzoyl hydrazide. Infrared studies supporting evidence that the hydrazones exist in the uronolactone and not in the uronic acid form is reported.



NUMEROUS derivatives of hydrazine have been prepared by Domagk, *et al.* (1), and tested along with other known derivatives for antitubercular activity. Among those compounds was the hydrazide of *p*-cyanobenzoic acid. This compound was reported to have significant antitubercular activity. The method of preparation of this compound has not been reported to date and is published here.

The synthesis was first attempted by reacting *p*-cyanobenzoyl chloride with 85% hydrazine hydrate or hydrazine sulfate. This method proved unsuccessful. The ethyl ester of *p*-cyanobenzoic acid was prepared and then reacted with 85% hydrazine hydrate in dioxane. This method was successful providing yields of up to 84% of *p*-cyanobenzoic acid hydrazide. If the reaction was allowed to proceed longer than 2 hours, the yield was reduced considerably with formation of substances melting above 300°. The solvent used for recrystallization was distilled water which yielded white crystals which melted at 202-203° (corrected). The reported melting point of *p*-cyanobenzoic acid hydrazide is 191°(1). A new melting point substantiated by analysis is now reported.

Uronolactone hydrazones of *p*-cyanobenzoic acid were prepared from the hydrazide in an effort to decrease the inherent toxicity of hydrazine derivatives. Sah has prepared uronic acid and uronolactone hydrazones of isonicotinic acid. These compounds were reported to be less toxic than isonicotinic acid hydrazide with no apparent loss of antitubercular activity (2).

The method of preparation of D-glucuronolactone and D-mannuronolactone *p*-cyanobenzoyl hydrazones followed the method of Sah (3) for the preparation of D-mannuronolactone and D-mannuronic acid isonicotinyl hydrazones. D-Glucuronolactone *p*-cyanobenzoyl hydrazone (III) was prepared by warming a solution of D-glucuronolactone (II) and *p*-cyanobenzoyl hydrazide (I) in absolute ethanol. The volume of the solvent was reduced and white crystals of the hydrazone crystallized from the solution.

In a similar procedure to that used for the preparation of D-glucuronolactone *p*-cyanobenzoyl hydrazone, D-mannuronolactone (V) and *p*-cyanobenzoyl hydrazide (IV) were dissolved in absolute ethanol. The final concentration of the reaction

Abstracted from a thesis submitted to the graduate faculty of the Chicago Professional Colleges of the University of Illinois by Lawrence J. Fischer in partial fulfillment of the requirements for the degree of Master of Science.

TABLE I.—URONOLACTONE *p*-CYANOBENZOYL HYDRAZONES AND *p*-CYANOBENZOIC ACID HYDRAZIDE

	Formula	Yield, %	M. p., °C.	Carbon, % Calcd.	Carbon, % Found	Hydrogen, % Calcd.	Hydrogen, % Found	Nitrogen, % Calcd.	Nitrogen, % Found
D-Glucuronolactone *p*-cyanobenzoyl hydrazone	$C_{14}H_{13}N_3O_6H_2O$	7.0.2	127 (decompn.)	49.86	49.91	4.48	4.53	12.46	12.20
D-Mannuronolactone *p*-cyanobenzoyl hydrazone	$C_{14}H_{13}N_3O_6$	80.8	169 (decompn.)	52.66	52.78	4.10	4.28	13.17	13.28
p-Cyanobenzoic acid hydrazide	$C_8H_7N_3O$	83.9	202–203	...	...	...	...	26.1	26.0

mixture was 0.001 mole of the reactants in approximately 220 ml. of absolute ethanol due to the relative insolubility of D-mannuronolactone in absolute ethanol. The product obtained from this dilute reaction mixture melted at 190–192°. Upon analysis, the compound was found not to be the hydrazone but possibly a product of the reaction of two moles of *p*-cyanobenzoic acid hydrazide. Regardless of the exact nature of the product formed here, it was not possible to obtain the hydrazone under such dilute reaction conditions.

As an alternate method, distilled water was used as a solvent for the reaction and an identical procedure followed. The white crystalline product obtained was analyzed to be D-mannuronolactone *p*-cyanobenzoyl hydrazone (VI) (See Table I).

EXPERIMENTAL

Infrared Data.—Infrared spectra were obtained using a Beckman IR-4 infrared recording spectrophotometer. All of the compounds prepared exhibited the characteristic cyano band in the range 2240-2210 cm.$^{-1}$. The spectra of D-glucuronolactone *p*-cyanobenzoyl hydrazone and D-mannuronolactone *p*-cyanobenzoyl hydrazone were found to be identical. This would seem to indicate the two compounds have identical structures except for the position of the hydroxyl on C_5, which apparently does not influence the infrared spectra. The spectra of the hydrazones contain a strong band of 1780–1760 cm.$^{-1}$, which is indicative of a C=O stretching vibration of a gamma lactone reported as 1780–1760 cm.$^{-1}$ by Bellamy (4). Supporting evidence that the hydrazones exist in the uronolactone and not the uronic acid form is the absence of the carboxylic acid OH stretching vibrations, which usually occur as broad bands with a series of minor peaks over the range 3000–2500 cm.$^{-1}$ (5).

Preparation of Uronolactone *p*-Cyanobenzoyl Hydrazones Ethyl *p*-Cyanobenzoate.—*p*-Cyanobenzoyl chloride (0.09 mole) was placed in a 100-ml. beaker and 10 ml. of absolute ethanol added. The mixture was heated gently on a steam bath and the reaction proceeded as evidenced by the formation of hydrochloride gas.

Upon completion of the reaction after approximately 10 minutes of gentle heating, the reaction mixture was neutralized with a solution of sodium bicarbonate. Upon neutralization, crystals of ethyl *p*-cyanobenzoate formed and were filtered from the solution. The product was recrystallized from ethanol and water; yield, 81.6%, m.p. 53–54° (lit. 54°).

***p*-Cyanobenzoic Acid Hydrazide.**—Three grams (0.017 mole) of ethyl *p*-cyanobenzoate was placed in a 100-ml. round-bottomed flask equipped with a reflux condenser and 25 ml. of *p*-dioxane added. Five milliliters of 85% hydrazine hydrate was added and the mixture refluxed for 1.5 hours. The reaction mixture was allowed to cool to room temperature and the solvent evaporated under a jet of air in an evaporating dish. The resulting crystals were dried at room temperature and recrystallized from hot distilled water.

D-Glucuronolactone *p*-Cyanobenzoyl Hydrazone.—*p*-Cyanobenzoic acid hydrazide, 5.0 Gm. (0.031 mole) was dissolved in 50 ml. of hot absolute ethanol. D-Glucuronolactone (Eastman), 5.3 Gm. (0.031 mole), was dissolved separately in 50 ml. of hot absolute ethanol. The solutions were mixed and heated to 50–60° on a steam bath for 15 minutes.

After cooling to room temperature, the solution was concentrated under a jet of air to 25 ml. It was placed in a freezer and white crystals formed within 1 hour. The white crystals were filtered from the solution and recrystallized from absolute ethanol.

D-Mannuronolactone *p*-Cyanobenzoyl Hydrazone.—*p*-Cyanobenzoic acid hydrazide, 0.5 Gm. (0.0031 mole) was dissolved in 75 ml. of hot distilled water. D-Mannuronolactone (Kelco No. 2065), 0.53 Gm. (0.0031 mole), was dissolved separately in 5 ml. of hot distilled water. The solutions were mixed and heated between 50 and 60° on a steam bath for 15 minutes. The solution was allowed to cool to room temperature, filtered, and placed in a refrigerator.

The white crystals which formed overnight were filtered from the solution and washed with cold distilled water. The product was recrystallized from distilled water.

SUMMARY

1. Two new hydrazone derivatives were prepared: D-glucuronolactone and D-mannuronolactone *p*-cyanobenzoyl hydrazones.

2. A new melting point for *p*-cyanobenzoyl hydrazide is reported.

3. Infrared studies supporting evidence that the hydrazones exist in the uronolactone and not in the uronic acid form is reported.

Chemical Study of *Cestrum parqui*

By M. SILVA, P. MANCINELLI, and M. CHEUL

Solasonine and digitogenin were isolated and identified in the acid extract from *Cestrum parqui*.

THE BARK of *Cestrum parqui* L'Herit., a Chilean *Solanaceae*, is frequently used as an infusion for the treatment of common cold.

In connection with a systematic study on saponins of certain typical Chilean species (1–4), now under way in this laboratory, it appeared of interest to study *Cestrum parqui* in order to elucidate the presence or absence of alkaloids and sapogenins which have been reported repeatedly in current literature. Canham and Warren (5) have reported that *Cestrum parqui* contains two sapogenins, gitogenin and digitogenin. However, the authors failed to isolate any alkaloids. Mercier and Chevalier (6) had previously reported the presence of parquin. Several other investigators (7–10) had failed to isolate either parquin or any alkaloids.

This is a chemical study of the acetic acid extract of dried, pulverized, and benzene-defatted plant. This extract yielded a water-soluble fraction containing a saponin and a glycosidic alkaloid. The alkaloid was identified as solasonine. The saponin was hydrolyzed and its sapogenin identified as digitogenin. The benzene-soluble fraction yielded two products to be reported in a coming paper.

EXPERIMENTAL[1,2]

Isolation of Solasonine.—Stems and leaves of *Cestrum parqui* collected in April 1959 near Concepción, Chile, were dried at 80–90°. Nine kilos of the dried plant was ground and extracted in a Soxhlet extractor with benzene to exhaustion. The defatted plant material was dried at 80° and acid-soluble constituents were extracted with 5% acetic acid solution (11). This extract was then heated and precipitated with 5% ammonia solution. Subsequent filtering was extremely slow. The solid fraction was washed with diluted ammonia and dried at 90° to yield 184.5 Gm. The crude glycosidic alkaloid was partially purified by continuous extraction with ethanol.

The ethanol-soluble constituents were purified through repeated crystallization from ethanol-dioxane-water (4:4:2), yielding 31.5 mg. of solasonine; m.p. 260–264°. The infrared spectrum was identical to that of an authentic specimen.

Anal. (12).—Calcd. for $C_{45}H_{73}NO_{16}$: C, 61.1; H, 8.3; N, 1.6. Found: C, 61.2; H, 8.4; N, 1.6.

The melting point of the alkaloid was undepressed upon admixture with an authentic specimen, m.p. 264–266°.

Isolation of Digitogenin.—The alkaline filtrate from the precipitation of the alkaloid was concentrated and acidified with hydrochloric acid to render it approximately 2.5 *N*. The mixture was then refluxed for 9 hours and poured into water and ice. The precipitate was collected on a filter, washed with water, and dried to 90°; yield 195.3 Gm. The sapogenin was then extracted with petroleum benzin (b.p. 65–75°) in a Soxhlet extractor.

The extract was purified and recrystallized from ethanol to yield 8.55 Gm. of white needles, m.p. 264–267°. This product was chromatographed over 240 Gm. alumina Light H (13). Exhaustive elutions with benzene, chloroform, and ethanol yielded 31 fractions of 60 ml. each, which represented various degrees of purity of the same product. Paper chromatograms (14) of all eluted fractions indicated the presence of a single steroid. Fractions 8 to 18 were mixed to yield 355 mg. of digitogenin. This product was recrystallized from ethanol yielding white needles, m.p. 285–288°. This product did not show ultraviolet absorption and its infrared spectrum shows evidence indicating the presence of a steroid.

Anal.—Calcd. for $C_{27}H_{44}O_5$: C, 72.3; H, 9.9. Found: C, 72.0; H, 9.9.

Digitogenin acetate.—A solution of digitogenin (50 mg.) in pyridine (0.2 ml.) containing acetic anhydride (0.4 ml.) was boiled for 1 hour. The solid obtained by pouring the mixture into water was washed successively with 2 *N* hydrochloric acid, 5% sodium hydrogen carbonate solution, and water. Needles were obtained after recrystallization from ethanol; m.p. 233–235°.

Anal.—Calcd. for $C_{33}H_{50}O_8$: C, 69.0; H, 8.8. Found: C, 69.4; H, 9.1.

Comparison Study of Alkyl Boronic Acids with Boric Acid

By STEPHEN M. SLEIGHT and MURIEL C. VINCENT

The bacteriostatic activities of two alkyl boronic acids were compared with boric acid. Some primary irritation and chronic toxicity determinations of the compounds were also accomplished. The results indicated that nonyl boronic acid and dodecyl boronic acid possessed bacteriostatic activity superior to boric acid, and that very dilute concentrations of these compounds could be employed to achieve bacteriostasis. Toxicological testing showed the alkyl boronic acids employed to be only mildly irritating and apparently nontoxic when applied to animal skin.

PRELIMINARY REPORTS from the manufacturer indicated that some of the alkyl boronic acids possessed a considerable degree of antibacterial activity in quite dilute concentrations. Comparison studies with the activity of boric acid were necessary to determine their possible value as substitutes for boric acid in existing types of preparations. It was also necessary to ascertain within certain limitations the possibility of the development of toxic reactions from their use.

The compounds employed in this study were nonyl boronic acid [nonyl dihydroxy borane, $C_9H_{19}B(OH)_2$] and dodecyl boronic acid [dodecyl dihydroxy borane, $C_{12}H_{25}B(OH)_2$]. They are colorless liquids, having about the same consistency as glycerin. Both are completely miscible at room temperature with hexane, benzene, ethyl ether, and acetone. Nonyl boronic acid is slightly soluble in water (3% by weight) and very soluble in methanol (34% by weight). Dodecyl boronic acid is less than 1% soluble in water and 23% soluble in methanol. The surface tensions of the saturated aqueous solutions at 25° are 47.2 and 44.9 dynes/cm.^{2}, respectively, for nonyl and dodecyl boronic acids. They are much weaker acids than boric acid (1).

EXPERIMENTAL

Determination of the Bacteriostatic Activity of the Alkyl Boronic Acids.—Determination of the bacteriostatic activity of nonyl and dodecyl boronic acid was made by use of the standard serum-cup agar plate method. Dilutions of 1:1,000, 1:5,000, 1:25,000 and 1:50,000 were prepared for both compounds. Table I illustrates the bacteriostatic activity of the various dilutions of these compounds against *Micrococcus pyogenes* var. *aureus*, *Salmonella typhosa*, and *Bacillus subtilis*.

Since there must be a basis of comparison to the presently used boric acid, the same tests were made with boric acid itself. The dilutions and organisms employed were identical to those employed with the alkyl boronic acids. The results of these tests are also indicated in Table I. At the dilutions used with the alkyl boronic acids, boric acid exhibited no detectable bacteriostatic activity. To obtain more positive values, dilutions of boric acid more commonly in use were prepared. These results are also given in Table I.

TABLE I.—BACTERIOSTATIC ACTIVITY

Compound	Dilution	Organism: *Micrococcus pyogenes* var. *aureus*	Organism: *Salmonella typhosa*	Organism: *Bacillus subtilis*
Nonyl boronic acid	1:1,000	4[a]	4	4
	1:5,000	2	3	3
	1:25,000	2	3	2
	1:50,000	1	2	2
Dodecyl boronic acid	1:1,000	4	4	4
	1:5,000	3	4	4
	1:25,000	3	4	3
	1:50,000	2	2	2
Boric acid	1:1,000	0	0	0
	1:5,000	0	0	0
	1:25,000	0	0	0
	1:50,000	0	0	0
Boric acid	5%	2	1	1
	2%	1	0	0
	1%	0	0	0

[a] 4, Complete bacteriostasis (zone of inhibition 0.7 cm.); 3, bacteriostasis not complete (zone of inhibition 0.5–0.7 cm.); 2, small zone of inhibition (less than 0.5 cm.); 1, very slight activity (zone of inhibition less than 0.5 cm., bacterial overgrowth); 0, no zone of inhibition (bacterial overgrowth).

The data obtained from this phase of the study would seem to indicate that the alkyl boronic acids possess a degree of bacteriostatic activity considerably superior to that of boric acid. There is, however, some possibility that the greater zones of inhibition achieved with the alkyl boronic acids may have been due in part to the relatively low surface tensions of these compounds in aqueous solution, allowing greater diffusion of the solution being tested into the surrounding media.

Determination of the Toxicity of the Alkyl Boronic Acids.—A primary irritation study was first accomplished according to the procedure outlined by Draize (2) and co-workers. This procedure involved the application of the compounds being tested to the intact and abraded skin of albino rabbits. A given compound was applied so that there were three applications to intact skin and three to abraded skin. At the end of a 24-hour exposure the resulting reactions were evaluated for erythema and edema formation. Evaluations were also made after 72 hours to determine the duration and intensity of any resulting irritation.

Table II illustrates the results of the irritation study as well as the method used to score the results. Averages of the 24- and 72-hour scores for all dilutions were calculated. The combined average figure obtained by this method is usually referred to as the primary irritation index.

The results of this phase of the study indicated that although the alkyl boronic acids were several

Total possible edema score 4

Total possible score for primary irritation 8.

times more irritating than boric acid, they would still be classified as only mildly to moderately irritating to the skin.

A 20-day subacute toxicity determination was also performed with these compounds using the procedure outlined by Draize (3). The compounds and dilutions employed were the same as those used in the primary irritation study. In addition, a control was employed using normal saline solution. Quantities of 10 ml. per Kg. of body weight were applied daily to the clipped skins of albino rabbits. Each application covered approximately 10% of the body surface of the animal. The test animals were observed daily for visible symptoms of boron intoxication, and their body weights and food consumption were also checked daily. Weekly urine samples were collected and tested for boron content. The animals were also observed for a 2-week period following the last application for visible symptoms (4).

None of the animals died during the testing period. The two animals exposed to the lowest dilutions (1:1,000) of nonyl and dodecyl boronic acid and the control animal were sacrificed at the end of the observation period to be examined for pathological findings. Examination revealed no gross or microscopic evidence of boron poisoning in liver, kidney, or other tissues.

The results obtained by this study, while encouraging, should be extended to consider acute toxicity of these compounds by injection or oral ingestion.

SUMMARY

A comparison of the bacteriostatic activity, toxicity, and primary irritation of nonyl and dodecyl boronic acids with boric acid has been made.

The conclusions drawn from this study indicate that nonyl and dodecyl boronic acids possess bacteriostatic activity superior to the activity of the free form of boric acid. Very dilute concentrations of the alkyl boronic acids can be employed to achieve bacteriostasis.

Toxicological testing indicates that the alkyl boronic acids employed are only mildly irritating and apparently nontoxic when applied to rabbit skin. These results suggest that the compounds might be used as substitutes for ordinary boric acid in presently used topical preparations. *In vivo* testing of a more comprehensive nature is needed to establish the toxicity levels of these compounds by accidental ingestion or injection.

Presence of 6-Methoxybenzoxazolinone in Uninjured Corn Tissue

Sir:

Wahlroos and Virtanen (1) have reported the isolation of a glucoside from rye seedlings which, after enzymatic transformation to the aglucone, is capable of being converted to benzoxazolinone. Virtanen finds that aglucone formation occurs when the rye seedlings are crushed. He stated that benzoxazolinone and 6-methoxybenzoxazolinone are not originally present in the rye, wheat, or maize plants, but arise only after the plant tissue is injured (2). In a subsequent paper Wahlroos and Virtanen (3), who used maize seedlings, isolated the glucosidic precursor to 6-methoxybenzoxazolinone by placing the intact seedling in boiling water in order to destroy the glycosidase.

On the basis of the above reports, it appeared that 6-methoxybenzoxazolinone (resistance factor A, RFA) which had been isolated in these laboratories (4) would only arise when corn tissue was injured. The following experiments were conducted in order to prove or disprove the presence of 6-methoxybenzoxazolinone in uninjured corn tissue.

Six young, high-resistance corn plants, 12 inches high, were cut and immediately immersed in liquid air. The frozen plants were powdered readily on placing them between two boards and applying pressure. The powdered material was immediately added to 2,500 ml. of 95% ethanol. Six more plants were cut at the same time and were allowed to stand at room temperature for 8 hours after being cut into small pieces.

Virtanen and co-workers found it necessary to hydrolyze the glucoside precursor to 6-methoxybenzoxazolinone by boiling the tissue for 2 hours in 2 *N* hydrochloric acid to effect *in vitro* cleavage to the aglucone, since the glucoside does not hydrolyze in boiling water alone. Plant material from the liquid air treatment and that obtained by our usual procedure were dried separately at 40–45° and extracted with ether in Soxhlet extractors for 48 hours. The ether solutions were concentrated, and an amount equivalent to 1.5 Gm. of fresh plant material was chromatographed (5).

The absorption maxima (228 and 285 mμ) and the extinction coefficients of the material eluted from the columns with 80:20 ether-ethanol were superimposable. The maxima were identical with those of authentic 6-methoxybenzoxazolinone.

Since no enzymatic or *in vitro* hydrolysis of the glucoside could take place in the tissue treated with liquid air and ethanol, it must be concluded, contrary to Virtanen's reports, that 6-methoxybenzoxazolinone does exist in uninjured corn tissue.

Method of Preparation of Soluble Radiophosphate

Sir:

The radiopharmaceutical, sodium radiophosphate solution,[1] obtained from commercial sources by this laboratory, showed, on many occasions, a loss of activity on filtration through Whatman No. 1 filter paper or on transferring to a different container owing to surface adsorption, even at the recommended pH range from 5.0 to 6.0 (1). These adsorbable radiophosphate preparations exhibited a different tissue distribution from that of a soluble radiophosphate when injected intramuscularly into the rat (2). Inasmuch as the radiological and therapeutic efficacy of this radiopharmaceutical depends upon its ready diffusibility and ionizability in solution near pH 7.0 (3), a method for the conversion of the adsorbable preparations into soluble radiophosphate would appear to be desirable.

Radiophosphorus (P^{32}) is prepared from sulfur by an (n,p) reaction. Following oxidation of the elemental radiophosphorus to radiophosphate, two methods are in current use for the isolation of the radiophosphate: (*a*) distillation of the bulk of the sulfur in a nitrogen atmosphere at 500° (4) and (*b*) addition of an nonisotopic carrier to transfer the radioactivity as a metal phosphate, followed by removal of the metal ions with resin column (5). The former method of preparation is used at the Chalk River Plant of Atomic Energy of Canada Ltd., and in our experience yields a soluble phosphate; the latter method is employed by the Oak Ridge National Laboratory and may give preparations unsatisfactory for reasons stated above.[2]

It has been suggested that the precipitate formed on neutralization of the solution of the unsatisfactory preparations is organic in nature (6). However, we have calcined the precipitate at 500° and digested it with aqua regia and were still unable to effect solution at pH 7.0. We have found, however, that a soluble radiophosphate can always be prepared from the unsatisfactory preparations by passing a 0.1 *N* hydrochloric acid solution of the phosphate through a Dowex 50-X8, 100–200 mesh resin column (hydrogen form, 1 cm. × 15 cm.) at a flow rate of approximately 2 ml./min. After the effluent is evaporated to dryness on a water bath, the residue is present as phosphoric acid in trace amounts. It is taken up in isotonic saline and the solution filtered to give the soluble radiophosphate.

Extensive conditioning of the cation exchange resin is essential for the success of the above procedure; this can be done with alternate 1 *N* hydrochloric acid and 1 *N* sodium hydroxide washes, followed by exhaustive extraction with 95% ethanol to remove any organic impurities. In order to minimize radiation damage to the resin, the carrier-free radiophosphate solution is diluted to give an activity of approximately 1 mc. per ml. for passage through the column. The resin column is washed with 0.1 *N* hydrochloric acid after use and stored. The overall loss of radioactivity due to manipulation is negligible.

[1] These commercial preparations were marketed as sodium radiophosphate solution U.S.P. and presumably conformed to all the U.S.P. specifications and cautions.

[2] This statement should not be interpreted to be a criticism of the quality of the product since the Oak Ridge National Laboratory has specifically indicated that "the product is not pharmaceutically refined" on form X-375 accompanying each radioisotope shipment.

Unusual Dissolution Behavior Due to Film Formation

Sir:

We have recently studied the dissolution of salicylates in basic aqueous media employing a procedure described previously (1). Dissolution ordinarily takes place at a constant rate under the experimental conditions referred to, since surface area and concentration gradient across the diffusion layer remain essentially constant. Thus, a plot of amount of substance dissolved *vs.* time is linear as shown in the dissolution of acetylsalicylic acid (ASA) and aluminum acetylsalicylate (Al-ASA) in 0.1 *N* hydrochloric acid (1). While a similar linear relationship is obtained in the dissolution of ASA in basic aqueous media, the dissolution rate of Al-ASA does not remain constant but decreases with time until it becomes very low. This decrease in dissolution rate of Al-ASA is due to the formation of a basic, water-insoluble aluminum compound on the surface of the drug solids. Addition of EDTA to the dissolution medium prevents the formation of such a film by chelation of Al^{+++} and, consequently, the dissolution rate in this medium remains constant under the experimental conditions. The weight loss of an Al-ASA pellet after partial dissolution in a basic aqueous medium containing EDTA is consistent with the amount of salicylate found in solution. In the absence of EDTA, the weight loss of an Al-ASA pellet is less than the theoretical weight loss (as calculated on the basis of the amount of salicylate in solution), the added weight being due to the deposited layer of the basic aluminum compound. A more detailed discussion of this phenomenon, its mathematics, as well as a description of the effect of variables such as pH, type and capacity of buffer, and stirring rate will be included in a future publication.

Our observations may have biopharmaceutical implications as indicated by a consideration of the gastrointestinal absorption pattern and dissolution behavior of Al-ASA. Salicylate given in the form of this drug is much more slowly absorbed than when given as ASA and is, in fact, not fully available to humans under the experimental conditions of a study described in a previous report from this laboratory (1). Despite the slow and incomplete absorption of salicylate after Al-ASA administration, the absorption peak occurred at the same time as after ASA administration, instead of being delayed as would be expected. The slower absorption of salicylate from Al-ASA can be explained on the basis of the slower dissolution of this drug, as compared with ASA, but the relatively early absorption peak cannot. The latter is apparently due to the deposition of the described film on Al-ASA solids in the small intestine. Thus, drug dissolution and absorption occur at a maximum rate during the early post-ingestion period when Al-ASA is in an acidic environment where no film formation takes place.

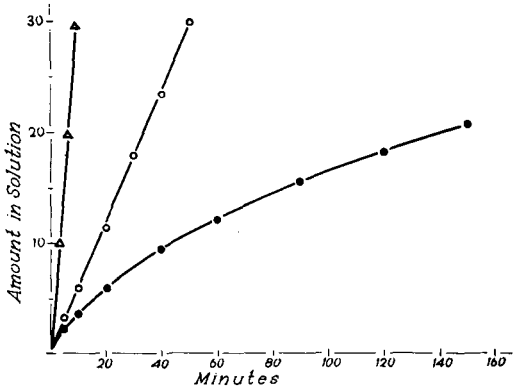

Fig. 1.—Dissolution of ASA and Al-ASA in 0.1 *M* Tris buffer of pH 8.0. △ ASA, ● Al-ASA, ○ Al-ASA with 1% EDTA added to dissolution medium. (Amount in solution expressed as mg. of salicylic acid.)

Film formation as a factor which may affect drug dissolution and absorption has, to our knowledge, not been described previously and is reported at this time in view of its biopharmaceutical implications.

Book Notices

Synthetic Methods of Organic Chemistry. Vol. 15. By W. THEILHEIMER. Interscience Publishers Inc., 250 Fifth Ave., New York 1, N. Y., 1961. xvi + 68 pp. 15 × 22.5 cm. Price $46.75.

New and improved methods of synthesis are recorded continuously in this series of books. This is the final volume of the third series and it includes a cumulative index to volumes 11–15. The body of the text carries all the reaction titles of volumes 11–15. Methods are given in abstract form. A valuable reference work.

Pharmakologie. 4th ed. By KNUD O. MØLLER. Benno Schwabe & Co., Verlag, Basel, Switzerland. Sole representatives in U. S. and Canada, Intercontinental Medical Book Corp., 381 Park Ave. South, New York 16, N. Y., 1961. 916 pp. 16.5 × 24 cm. Price $17.

Widely used in the Scandinavian and other European countries, this book (in German) has been revised to include many new drugs. A good index enhances its value as a reference textbook.

Rogers' Inorganic Pharmaceutical Chemistry. 7th ed. By TAITO O. SOINE and CHARLES O. WILSON. Lea & Febiger, Washington Square, Philadelphia 6, Pa., 1961. 704 pp. 15.5 × 23.5 cm. Price $10.

Inorganic chemicals used in medicine and pharmacy are covered extensively in this edition of the widely used textbook. Useful material from U.S.P. XVI and N.F. XI has been incorporated. A good textbook and reference volume.

Histopathologic Effects of Local Anesthetic Drugs and Related Substances. By PHILIP PIZZOLATO and WALTER MANNHEIMER. Charles C Thomas, 301–327 East Lawrence Ave., Springfield, Ill., 1961. vii + 100 pp. 15 × 22.5 cm. Price $5.50.

Drugs which may produce local injury as they penetrate skin, subcutaneous tissues, muscles, and nerves are discussed. Many photographs illustrate the brief text.

Basic Biochemistry. By M. W. NEIL. Medical Dept. J. B. Lippincott Co., East Washington Square, Philadelphia 5, Pa., 1961. xii + 360 pp. 14 × 21.5 cm. Price $6.75.

The immediate relevance of some of the current biochemical knowledge is stressed in this preclinical textbook, but it also includes material which indicates the potentiality and scope of biochemistry.

Some Recent Developments in the Chemistry of Phosphate Esters of Biological Interest. By H. GOBIND KHORANA. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1961. x + 141 pp. 15 × 22.5 cm. Price $5.25.

This book is based on lectures given in 1959 on some aspects of the chemistry of phosphate esters; particularly nucleotides and related compounds. Special emphasis was given to the recent (up to 1959) synthetic work.

Pharmacognosy. 4th ed. By EDWARD P. CLAUS. Lea & Febiger, Washington Square, Philadelphia 6, Pa., 1961. 565 pp. 17.5 × 25.5 cm. Price $12.50.

The editor has incorporated the latest available information into his biochemically classified, monograph arrangement of drugs. This revision includes U.S.P. XVI and N.F. XI material. A good index makes the book useful for reference as well as a teaching text.

Modern Pharmacology and Therapeutics. 2nd ed. By RUTH D. MUSSER and JOSEPH G. BIRD. The Macmillan Co., 60 Fifth Ave., New York 11, N. Y., 1961. xiv + 889 pp. 14 × 21 cm.

A textbook intended primarily for nurses, the second edition presents the principles of drug therapy and its practice. It includes most of the drugs that were new at the time of its revision. The text is clear and concise, and a good index is appended.

Problems of Pulmonary Circulation. Edited by A. V. S. DE REUCK and MAEVE O'CONNOR. Little, Brown and Co., 34 Beacon St., Boston, Mass., 1961. viii + 96 pp. 12 × 18.5 cm. Price $2.50.

Six reports and discussions related to the general title, which were given at the Ciba Foundation study group No. 8, are included in this pocket size booklet. The meeting was held November 1960. A subject index is appended.

The Pfizer Handbook of Microbial Metabolites. By MAX W. MILLER. The Blakiston Division, McGraw-Hill Book Co., 330 W. 42nd St., New York 36, N. Y., 1961. x +772 pp. 15 × 23 cm. Price $15.

Basic data on microbial metabolites are compiled in this book. Also included are current information and theories on biosynthetic routes to microbial metabolites. Three separate indexes list compounds (metabolites) by chemical name, by empirical formula, or by producing organism. Over 1,300 metabolites are listed; products of the *Streptomyces* predominating. The book is a new and useful reference source.

Pharmacy State Board Questions and Answers. Edited by RALPH J. MILL. Clark & Wilson Co., Box 3, General Post Office, Detroit 32, Mich., 1961. 21 × 28 cm. Paperbound.

A study guide and review.

Somatic Stability in the Newly Born. Edited by G. E. W. WOLSTENHOLME and MAEVE O'CONNOR. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1961. xii + 393 pp. 13.5 × 20 cm. Price $10.

A compilation of papers and discussions at the Ciba Symposium held January 1961. General author and subject indexes are appended.

A textbook intended primarily for nurses, the second edition presents the principles of drug therapy and its practice. It includes most of the drugs that were new at the time of its revision. The text is clear and concise, and a good index is appended.

Problems of Pulmonary Circulation. Edited by A. V. S. DE REUCK and MAEVE O'CONNOR. Little, Brown and Co., 34 Beacon St., Boston, Mass., 1961. viii + 96 pp. 12 × 18.5 cm. Price $2.50.

Six reports and discussions related to the general title, which were given at the Ciba Foundation study group No. 8, are included in this pocket size booklet. The meeting was held November 1960. A subject index is appended.

The Pfizer Handbook of Microbial Metabolites. By MAX W. MILLER. The Blakiston Division, McGraw-Hill Book Co., 330 W. 42nd St., New York 36, N. Y., 1961. x +772 pp. 15 × 23 cm. Price $15.

Basic data on microbial metabolites are compiled in this book. Also included are current information and theories on biosynthetic routes to microbial metabolites. Three separate indexes list compounds (metabolites) by chemical name, by empirical formula, or by producing organism. Over 1,300 metabolites are listed; products of the *Streptomyces* predominating. The book is a new and useful reference source.

Pharmacy State Board Questions and Answers. Edited by RALPH J. MILL. Clark & Wilson Co., Box 3, General Post Office, Detroit 32, Mich., 1961. 21 × 28 cm. Paperbound.

A study guide and review.

Somatic Stability in the Newly Born. Edited by G. E. W. WOLSTENHOLME and MAEVE O'CONNOR. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1961. xii + 393 pp. 13.5 × 20 cm. Price $10.

A compilation of papers and discussions at the Ciba Symposium held January 1961. General author and subject indexes are appended.

Book Notices

Synthetic Methods of Organic Chemistry. Vol. 15. By W. THEILHEIMER. Interscience Publishers Inc., 250 Fifth Ave., New York 1, N. Y., 1961. xvi + 68 pp. 15 × 22.5 cm. Price $46.75.

New and improved methods of synthesis are recorded continuously in this series of books. This is the final volume of the third series and it includes a cumulative index to volumes 11–15. The body of the text carries all the reaction titles of volumes 11–15. Methods are given in abstract form. A valuable reference work.

Pharmakologie. 4th ed. By KNUD O. MØLLER. Benno Schwabe & Co., Verlag, Basel, Switzerland. Sole representatives in U. S. and Canada, Intercontinental Medical Book Corp., 381 Park Ave. South, New York 16, N. Y., 1961. 916 pp. 16.5 × 24 cm. Price $17.

Widely used in the Scandinavian and other European countries, this book (in German) has been revised to include many new drugs. A good index enhances its value as a reference textbook.

Rogers' Inorganic Pharmaceutical Chemistry. 7th ed. By TAITO O. SOINE and CHARLES O. WILSON. Lea & Febiger, Washington Square, Philadelphia 6, Pa., 1961. 704 pp. 15.5 × 23.5 cm. Price $10.

Inorganic chemicals used in medicine and pharmacy are covered extensively in this edition of the widely used textbook. Useful material from U.S.P. XVI and N.F. XI has been incorporated. A good textbook and reference volume.

Histopathologic Effects of Local Anesthetic Drugs and Related Substances. By PHILIP PIZZOLATO and WALTER MANNHEIMER. Charles C Thomas, 301–327 East Lawrence Ave., Springfield, Ill., 1961. vii + 100 pp. 15 × 22.5 cm. Price $5.50.

Drugs which may produce local injury as they penetrate skin, subcutaneous tissues, muscles, and nerves are discussed. Many photographs illustrate the brief text.

Basic Biochemistry. By M. W. NEIL. Medical Dept. J. B. Lippincott Co., East Washington Square, Philadelphia 5, Pa., 1961. xii + 360 pp. 14 × 21.5 cm. Price $6.75.

The immediate relevance of some of the current biochemical knowledge is stressed in this preclinical textbook, but it also includes material which indicates the potentiality and scope of biochemistry.

Some Recent Developments in the Chemistry of Phosphate Esters of Biological Interest. By H. GOBIND KHORANA. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1961. x + 141 pp. 15 × 22.5 cm. Price $5.25.

This book is based on lectures given in 1959 on some aspects of the chemistry of phosphate esters; particularly nucleotides and related compounds. Special emphasis was given to the recent (up to 1959) synthetic work.

Pharmacognosy. 4th ed. By EDWARD P. CLAUS. Lea & Febiger, Washington Square, Philadelphia 6, Pa., 1961. 565 pp. 17.5 × 25.5 cm. Price $12.50.

The editor has incorporated the latest available information into his biochemically classified, monograph arrangement of drugs. This revision includes U.S.P. XVI and N.F. XI material. A good index makes the book useful for reference as well as a teaching text.

Modern Pharmacology and Therapeutics. 2nd ed. By RUTH D. MUSSER and JOSEPH G. BIRD. The Macmillan Co., 60 Fifth Ave., New York 11, N. Y., 1961. xiv + 889 pp. 14 × 21 cm.

A textbook intended primarily for nurses, the second edition presents the principles of drug therapy and its practice. It includes most of the drugs that were new at the time of its revision. The text is clear and concise, and a good index is appended.

Problems of Pulmonary Circulation. Edited by A. V. S. DE REUCK and MAEVE O'CONNOR. Little, Brown and Co., 34 Beacon St., Boston, Mass., 1961. viii + 96 pp. 12 × 18.5 cm. Price $2.50.

Six reports and discussions related to the general title, which were given at the Ciba Foundation study group No. 8, are included in this pocket size booklet. The meeting was held November 1960. A subject index is appended.

Rogers' Inorganic Pharmaceutical Chemistry. 7th ed. By TAITO O. SOINE and CHARLES O. WILSON. Lea & Febiger, Washington Square, Philadelphia 6, Pa., 1961. 704 pp. 15.5 × 23.5 cm. Price $10.

Inorganic chemicals used in medicine and pharmacy are covered extensively in this edition of the widely used textbook. Useful material from U.S.P. XVI and N.F. XI has been incorporated. A good textbook and reference volume.

Histopathologic Effects of Local Anesthetic Drugs and Related Substances. By PHILIP PIZZOLATO and WALTER MANNHEIMER. Charles C Thomas, 301–327 East Lawrence Ave., Springfield, Ill., 1961. vii + 100 pp. 15 × 22.5 cm. Price $5.50.

Drugs which may produce local injury as they penetrate skin, subcutaneous tissues, muscles, and nerves are discussed. Many photographs illustrate the brief text.

Basic Biochemistry. By M. W. NEIL. Medical Dept. J. B. Lippincott Co., East Washington Square, Philadelphia 5, Pa., 1961. xii + 360 pp. 14 × 21.5 cm. Price $6.75.

The immediate relevance of some of the current biochemical knowledge is stressed in this preclinical textbook, but it also includes material which indicates the potentiality and scope of biochemistry.

Some Recent Developments in the Chemistry of Phosphate Esters of Biological Interest. By H. GOBIND KHORANA. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1961. x + 141 pp. 15 × 22.5 cm. Price $5.25.

This book is based on lectures given in 1959 on some aspects of the chemistry of phosphate esters; particularly nucleotides and related compounds. Special emphasis was given to the recent (up to 1959) synthetic work.

Pharmacognosy. 4th ed. By EDWARD P. CLAUS. Lea & Febiger, Washington Square, Philadelphia 6, Pa., 1961. 565 pp. 17.5 × 25.5 cm. Price $12.50.

The editor has incorporated the latest available information into his biochemically classified, monograph arrangement of drugs. This revision includes U.S.P. XVI and N.F. XI material. A good index makes the book useful for reference as well as a teaching text.

Modern Pharmacology and Therapeutics. 2nd ed. By RUTH D. MUSSER and JOSEPH G. BIRD. The Macmillan Co., 60 Fifth Ave., New York 11, N. Y., 1961. xiv + 889 pp. 14 × 21 cm.

A textbook intended primarily for nurses, the second edition presents the principles of drug therapy and its practice. It includes most of the drugs that were new at the time of its revision. The text is clear and concise, and a good index is appended.

Problems of Pulmonary Circulation. Edited by A. V. S. DE REUCK and MAEVE O'CONNOR. Little, Brown and Co., 34 Beacon St., Boston, Mass., 1961. viii + 96 pp. 12 × 18.5 cm. Price $2.50.

Six reports and discussions related to the general title, which were given at the Ciba Foundation study group No. 8, are included in this pocket size booklet. The meeting was held November 1960. A subject index is appended.

The Pfizer Handbook of Microbial Metabolites. By MAX W. MILLER. The Blakiston Division, McGraw-Hill Book Co., 330 W. 42nd St., New York 36, N. Y., 1961. x +772 pp. 15 × 23 cm. Price $15.

Basic data on microbial metabolites are compiled in this book. Also included are current information and theories on biosynthetic routes to microbial metabolites. Three separate indexes list compounds (metabolites) by chemical name, by empirical formula, or by producing organism. Over 1,300 metabolites are listed; products of the *Streptomyces* predominating. The book is a new and useful reference source.

Pharmacy State Board Questions and Answers. Edited by RALPH J. MILL. Clark & Wilson Co., Box 3, General Post Office, Detroit 32, Mich., 1961. 21 × 28 cm. Paperbound.

A study guide and review.

Somatic Stability in the Newly Born. Edited by G. E. W. WOLSTENHOLME and MAEVE O'CONNOR. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1961. xii + 393 pp. 13.5 × 20 cm. Price $10.

A compilation of papers and discussions at the Ciba Symposium held January 1961. General author and subject indexes are appended.

Book Notices

Synthetic Methods of Organic Chemistry. Vol. 15. By W. THEILHEIMER. Interscience Publishers Inc., 250 Fifth Ave., New York 1, N. Y., 1961. xvi + 68 pp. 15 × 22.5 cm. Price $46.75.

New and improved methods of synthesis are recorded continuously in this series of books. This is the final volume of the third series and it includes a cumulative index to volumes 11–15. The body of the text carries all the reaction titles of volumes 11–15. Methods are given in abstract form. A valuable reference work.

Pharmakologie. 4th ed. By KNUD O. MØLLER. Benno Schwabe & Co., Verlag, Basel, Switzerland. Sole representatives in U. S. and Canada, Intercontinental Medical Book Corp., 381 Park Ave. South, New York 16, N. Y., 1961. 916 pp. 16.5 × 24 cm. Price $17.

Widely used in the Scandinavian and other European countries, this book (in German) has been revised to include many new drugs. A good index enhances its value as a reference textbook.

Rogers' Inorganic Pharmaceutical Chemistry. 7th ed. By TAITO O. SOINE and CHARLES O. WILSON. Lea & Febiger, Washington Square, Philadelphia 6, Pa., 1961. 704 pp. 15.5 × 23.5 cm. Price $10.

Inorganic chemicals used in medicine and pharmacy are covered extensively in this edition of the widely used textbook. Useful material from U.S.P. XVI and N.F. XI has been incorporated. A good textbook and reference volume.

Histopathologic Effects of Local Anesthetic Drugs and Related Substances. By PHILIP PIZZOLATO and WALTER MANNHEIMER. Charles C Thomas, 301–327 East Lawrence Ave., Springfield, Ill., 1961. vii + 100 pp. 15 × 22.5 cm. Price $5.50.

Drugs which may produce local injury as they penetrate skin, subcutaneous tissues, muscles, and nerves are discussed. Many photographs illustrate the brief text.

Basic Biochemistry. By M. W. NEIL. Medical Dept. J. B. Lippincott Co., East Washington Square, Philadelphia 5, Pa., 1961. xii + 360 pp. 14 × 21.5 cm. Price $6.75.

The immediate relevance of some of the current biochemical knowledge is stressed in this preclinical textbook, but it also includes material which indicates the potentiality and scope of biochemistry.

Pharmacy State Board Questions and Answers. Edited by RALPH J. MILL. Clark & Wilson Co., Box 3, General Post Office, Detroit 32, Mich., 1961. 21 × 28 cm. Paperbound.

A study guide and review.

Somatic Stability in the Newly Born. Edited by G. E. W. WOLSTENHOLME and MAEVE O'CONNOR. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1961. xii + 393 pp. 13.5 × 20 cm. Price $10.

A compilation of papers and discussions at the Ciba Symposium held January 1961. General author and subject indexes are appended.

Gynecologic Endocrinology. By EDWARD A. GRABER. J. B. Lippincott Co., East Washington Square, Philadelphia 5, Pa., 1961. xiv + 218 pp. 15 × 22.5 cm. Price $7.50.

Designed as a practical guide for clinical diagnosis of glandular pathology, the book is a concise reference manual for the physician. The final section (X) of the book lists commonly used marketed hormone preparations and includes a table of comparative potencies. A general index is appended.

Separation of Heavy Metals. By A. K. DE. Pergamon Press Ltd., Headington Hill Hall, Oxford, England, 1961. 308 pp. 15.5 × 23 cm. Price $9.

Applications of liquid-liquid extraction and ion-exchange techniques to the separation of heavy metals if Groups I–VIII are given in the first two sections of this book. Analytical procedures are given in the third part of the test.

Phosphorus and Its Compounds. Vol. 2, Technology, Biological Functions, and Applications. Edited by JOHN R. VAN WAZER. Interscience Publishers, Inc., 250 Fifth Ave., New York 1, N. Y. xvi + 1,092 pp. 15 × 23 cm. Price $35.

The second volume of this treatise is intended for industrial and academic researchers and also for business administrators, sales and purchasing personnel, inventors, and technologists. Volume I covered the modern chemistry of phosphorus and its compounds. Patented products utilizing phosphates are given by number and are briefly abstracted in appendixes covering 50 pages. A general index is included.

Invitation to Chemical Research. By E. EMMET REID. Franklin Publishing Co., Inc., Palisade, N. J., 1961. xviii + 366 pp. 14 × 21 cm. Price $10.60.

A noted research scientist and inspiring teacher sets out guide lines for the enticement and introduction of the novice to chemical research. Many advanced researchers might benefit from a reading of this book. A general index is appended.

Antimicrobial Agents Annual 1960. Edited by PETER GRAY, BENJAMIN TABENKIN, and S. D. BRADLEY. Plenum Press, 227 West 17th St., New York 11, N. Y., 1961. xviii + 670 pp. 16 × 25 cm. Price $8.50 domestic, $10 foreign.

The more than 90 papers and pertinent comments reported at the Conference on Antimicrobial Agents sponsored by the Society for Industrial Microbiology and held October 26–28, 1960, in Washington, D. C., are compiled in this volume. It includes the latest information publicly available in this field at the time of publication and is, therefore, a very valuable reference source. All the papers and panel discussions are listed in the Table of Contents but a general index is not included. The general subject areas covered are: New products, Modes of action, Laboratory studies, Antifungal agents, Clinical studies, Antitumor agents, and other related topics.

Alkaloid-Bearing Plants and Their Contained Alkaloids. Technical Bulletin No. 1234. Agricultural Research Service, U. S. Dept. of Agriculture. Superintendent of Documents, Government Printing Office, Washington 25, D. C. 287 pp. 15 × 23 cm. Paperbound. Price $1.

A useful reference and cross-reference of alkaloids and the plants in which they occur. The tabulated entries include 3,671 plants, some containing many alkaloids. The most common alkaloid appears to be lycorine (narcissine) which is listed as a constituent in 85 different plants.

Russian-English Chemical Dictionary. 1st. ed. By EUGENE A. CARPOVICH. Technical Dictionaries Co., Box 144, New York 31, N. Y., 1961. 352 pp. 14 × 21.5 cm. Price $14.

Terms used in chemistry, physical chemistry, chemical engineering, pharmacology, and foods are included in this dictionary. The English words generally are given the spelling common to the U. S. and the "c" in ergot alcaloids is only a typographical error. A knowledge of at least the Russian alphabet is required; there is no English-Russian section.

Accepted Dental Remedies 1962. 27th ed. Council on Dental Therapeutics of the American Dental Association. American Dental Association, 222 E. Superior St., Chicago 11, Ill., 1962. xiv + 235 pp. 15.5 × 20.5 cm. Paperbound. Price $3.

Dentists must have this latest edition of ADR in order to be up-to-date in their practice. The book contains so much more than the "accepted" drugs that it might be subtitled "The Dentist's Therapeutic Handbook." Pharmacists also can find useful information in this concisely and clearly written volume.

The revised edition contains expanded sections on dental therapeutics. The monographs have been reviewed by the Council and its consultants and have been rewritten in the light of current scientific information.

"Accepted Dental Remedies 1962" contains 249 pages, including the provisions for acceptance of products, a general index, a distributors' index, an index of current reports from the Council and the Division of Chemistry, and an index of more recent reports on products not listed in the book, including those classified in Groups B, C and D.

The Council on Dental Therapeutics has again performed its task of revision in an exemplary manner.

An Algorithm for Translating Chemical Names to Molecular Formulas. By EUGENE GARFIELD. Institute for Scientific Information, 33 South 17th St., Philadelphia 3, Pa., 1961. ix + 68 pp. 21.5 × 28 cm. Paperbound. Price $5.

A doctorate dissertation which develops a procedure for converting chemical names to formulas. The term algorithm appears to be used synonymously with procedure; and it is defined (Webster's dictionary) as a procedure for calculating with symbols.

Gynecologic Endocrinology. By EDWARD A. GRABER. J. B. Lippincott Co., East Washington Square, Philadelphia 5, Pa., 1961. xiv + 218 pp. 15 × 22.5 cm. Price $7.50.

Designed as a practical guide for clinical diagnosis of glandular pathology, the book is a concise reference manual for the physician. The final section (X) of the book lists commonly used marketed hormone preparations and includes a table of comparative potencies. A general index is appended.

Separation of Heavy Metals. By A. K. DE. Pergamon Press Ltd., Headington Hill Hall, Oxford, England, 1961. 308 pp. 15.5 × 23 cm. Price $9.

Applications of liquid-liquid extraction and ion-exchange techniques to the separation of heavy metals if Groups I–VIII are given in the first two sections of this book. Analytical procedures are given in the third part of the test.

Phosphorus and Its Compounds. Vol. 2, Technology, Biological Functions, and Applications. Edited by JOHN R. VAN WAZER. Interscience Publishers, Inc., 250 Fifth Ave., New York 1, N. Y. xvi + 1,092 pp. 15 × 23 cm. Price $35.

The second volume of this treatise is intended for industrial and academic researchers and also for business administrators, sales and purchasing personnel, inventors, and technologists. "Accepted Dental Remedies 1962" contains 249 pages, including the provisions for acceptance of products, a general index, a distributors' index, an index of current reports from the Council and the Division of Chemistry, and an index of more recent reports on products not listed in the book, including those classified in Groups B, C and D.

The Council on Dental Therapeutics has again performed its task of revision in an exemplary manner.

An Algorithm for Translating Chemical Names to Molecular Formulas. By EUGENE GARFIELD. Institute for Scientific Information, 33 South 17th St., Philadelphia 3, Pa., 1961. ix + 68 pp. 21.5 × 28 cm. Paperbound. Price $5.

A doctorate dissertation which develops a procedure for converting chemical names to formulas. The term algorithm appears to be used synonymously with procedure; and it is defined (Webster's dictionary) as a procedure for calculating with symbols.

Gynecologic Endocrinology. By EDWARD A. GRABER. J. B. Lippincott Co., East Washington Square, Philadelphia 5, Pa., 1961. xiv + 218 pp. 15 × 22.5 cm. Price $7.50.

Designed as a practical guide for clinical diagnosis of glandular pathology, the book is a concise reference manual for the physician. The final section (X) of the book lists commonly used marketed hormone preparations and includes a table of comparative potencies. A general index is appended.

Separation of Heavy Metals. By A. K. DE. Pergamon Press Ltd., Headington Hill Hall, Oxford, England, 1961. 308 pp. 15.5 × 23 cm. Price $9.

Applications of liquid-liquid extraction and ion-exchange techniques to the separation of heavy metals if Groups I–VIII are given in the first two sections of this book. Analytical procedures are given in the third part of the test.

Phosphorus and Its Compounds. Vol. 2, Technology, Biological Functions, and Applications. Edited by JOHN R. VAN WAZER. Interscience Publishers, Inc., 250 Fifth Ave., New York 1, N. Y. xvi + 1,092 pp. 15 × 23 cm. Price $35.

The second volume of this treatise is intended for industrial and academic researchers and also for business administrators, sales and purchasing personnel, inventors, and technologists. Volume I covered the modern chemistry of phosphorus and its compounds. Patented products utilizing phosphates are given by number and are briefly abstracted in appendixes covering 50 pages. A general index is included.

Invitation to Chemical Research. By E. EMMET REID. Franklin Publishing Co., Inc., Palisade, N. J., 1961. xviii + 366 pp. 14 × 21 cm. Price $10.60.

A noted research scientist and inspiring teacher sets out guide lines for the enticement and introduction of the novice to chemical research. Many advanced researchers might benefit from a reading of this book. A general index is appended.

Antimicrobial Agents Annual 1960. Edited by PETER GRAY, BENJAMIN TABENKIN, and S. D. BRADLEY. Plenum Press, 227 West 17th St., New York 11, N. Y., 1961. xviii + 670 pp. 16 × 25 cm. Price $8.50 domestic, $10 foreign.

The more than 90 papers and pertinent comments reported at the Conference on Antimicrobial Agents sponsored by the Society for Industrial Microbiology and held October 26–28, 1960, in Washington, D. C., are compiled in this volume. It includes the latest information publicly available in this field at the time of publication and is, therefore, a very valuable reference source. All the papers and panel discussions are listed in the Table of Contents but a general index is not included. The general subject areas covered are: New products, Modes of action, Laboratory studies, Antifungal agents, Clinical studies, Antitumor agents, and other related topics.

Alkaloid-Bearing Plants and Their Contained Alkaloids. Technical Bulletin No. 1234. Agricultural Research Service, U. S. Dept. of Agriculture. Superintendent of Documents, Government Printing Office, Washington 25, D. C. 287 pp. 15 × 23 cm. Paperbound. Price $1.

A useful reference and cross-reference of alkaloids and the plants in which they occur. The tabulated entries include 3,671 plants, some containing many alkaloids. The most common alkaloid appears to be lycorine (narcissine) which is listed as a constituent in 85 different plants.

Russian-English Chemical Dictionary. 1st. ed. By EUGENE A. CARPOVICH. Technical Dictionaries Co., Box 144, New York 31, N. Y., 1961. 352 pp. 14 × 21.5 cm. Price $14.

Terms used in chemistry, physical chemistry, chemical engineering, pharmacology, and foods are included in this dictionary. The English words generally are given the spelling common to the U. S. and the "c" in ergot alcaloids is only a typographical error. A knowledge of at least the Russian alphabet is required; there is no English-Russian section.

Accepted Dental Remedies 1962. 27th ed. Council on Dental Therapeutics of the American Dental Association. American Dental Association, 222 E. Superior St., Chicago 11, Ill., 1962. xiv + 235 pp. 15.5 × 20.5 cm. Paperbound. Price $3.

Dentists must have this latest edition of ADR in order to be up-to-date in their practice. The book contains so much more than the "accepted" drugs that it might be subtitled "The Dentist's Therapeutic Handbook." Pharmacists also can find useful information in this concisely and clearly written volume.

The revised edition contains expanded sections on dental therapeutics. The monographs have been reviewed by the Council and its consultants and have been rewritten in the light of current scientific information.

"Accepted Dental Remedies 1962" contains 249 pages, including the provisions for acceptance of products, a general index, a distributors' index, an index of current reports from the Council and the Division of Chemistry, and an index of more recent reports on products not listed in the book, including those classified in Groups B, C and D.

Terms used in chemistry, physical chemistry, chemical engineering, pharmacology, and foods are included in this dictionary. The English words generally are given the spelling common to the U. S. and the "c" in ergot alcaloids is only a typographical error. A knowledge of at least the Russian alphabet is required; there is no English-Russian section.

Accepted Dental Remedies 1962. 27th ed. Council on Dental Therapeutics of the American Dental Association. American Dental Association, 222 E. Superior St., Chicago 11, Ill., 1962. xiv + 235 pp. 15.5 × 20.5 cm. Paperbound. Price $3.

Dentists must have this latest edition of ADR in order to be up-to-date in their practice. The book contains so much more than the "accepted" drugs that it might be subtitled "The Dentist's Therapeutic Handbook." Pharmacists also can find useful information in this concisely and clearly written volume.

The revised edition contains expanded sections on dental therapeutics. The monographs have been reviewed by the Council and its consultants and have been rewritten in the light of current scientific information.

"Accepted Dental Remedies 1962" contains 249 pages, including the provisions for acceptance of products, a general index, a distributors' index, an index of current reports from the Council and the Division of Chemistry, and an index of more recent reports on products not listed in the book, including those classified in Groups B, C and D.

The Council on Dental Therapeutics has again performed its task of revision in an exemplary manner.

An Algorithm for Translating Chemical Names to Molecular Formulas. By EUGENE GARFIELD. Institute for Scientific Information, 33 South 17th St., Philadelphia 3, Pa., 1961. ix + 68 pp. 21.5 × 28 cm. Paperbound. Price $5.

A doctorate dissertation which develops a procedure for converting chemical names to formulas. The term algorithm appears to be used synonymously with procedure; and it is defined (Webster's dictionary) as a procedure for calculating with symbols.

Gynecologic Endocrinology. By EDWARD A. GRABER. J. B. Lippincott Co., East Washington Square, Philadelphia 5, Pa., 1961. xiv + 218 pp. 15 × 22.5 cm. Price $7.50.

Designed as a practical guide for clinical diagnosis of glandular pathology, the book is a concise reference manual for the physician. The final section (X) of the book lists commonly used marketed hormone preparations and includes a table of comparative potencies. A general index is appended.

Separation of Heavy Metals. By A. K. DE. Pergamon Press Ltd., Headington Hill Hall, Oxford, England, 1961. 308 pp. 15.5 × 23 cm. Price $9.

Applications of liquid-liquid extraction and ion-exchange techniques to the separation of heavy metals if Groups I–VIII are given in the first two sections of this book. Analytical procedures are given in the third part of the test.

Phosphorus and Its Compounds. Vol. 2, Technology, Biological Functions, and Applications. Edited by JOHN R. VAN WAZER. Interscience Publishers, Inc., 250 Fifth Ave., New York 1, N. Y. xvi + 1,092 pp. 15 × 23 cm. Price $35.

The second volume of this treatise is intended for industrial and academic researchers and also for business administrators, sales and purchasing personnel, inventors, and technologists. Volume I covered the modern chemistry of phosphorus and its compounds. Patented products utilizing phosphates are given by number and are briefly abstracted in appendixes covering 50 pages. A general index is included.

Invitation to Chemical Research. By E. EMMET REID. Franklin Publishing Co., Inc., Palisade, N. J., 1961. xviii + 366 pp. 14 × 21 cm. Price $10.60.

A noted research scientist and inspiring teacher sets out guide lines for the enticement and introduction of the novice to chemical research. Many advanced researchers might benefit from a reading of this book. A general index is appended.

Antimicrobial Agents Annual 1960. Edited by PETER GRAY, BENJAMIN TABENKIN, and S. D. BRADLEY. Plenum Press, 227 West 17th St., New York 11, N. Y., 1961. xviii + 670 pp. 16 × 25 cm. Price $8.50 domestic, $10 foreign.

The more than 90 papers and pertinent comments reported at the Conference on Antimicrobial Agents sponsored by the Society for Industrial Microbiology and held October 26–28, 1960, in Washington, D. C., are compiled in this volume. It includes the latest information publicly available in this field at the time of publication and is, therefore, a very valuable reference source. All the papers and panel discussions are listed in the Table of Contents but a general index is not included. The general subject areas covered are: New products, Modes of action, Laboratory studies, Antifungal agents, Clinical studies, Antitumor agents, and other related topics.

Alkaloid-Bearing Plants and Their Contained Alkaloids. Technical Bulletin No. 1234. Agricultural Research Service, U. S. Dept. of Agriculture. Superintendent of Documents, Government Printing Office, Washington 25, D. C. 287 pp. 15 × 23 cm. Paperbound. Price $1.

A useful reference and cross-reference of alkaloids and the plants in which they occur. The tabulated entries include 3,671 plants, some containing many alkaloids. The most common alkaloid appears to be lycorine (narcissine) which is listed as a constituent in 85 different plants.

Russian-English Chemical Dictionary. 1st. ed. By EUGENE A. CARPOVICH. Technical Dictionaries Co., Box 144, New York 31, N. Y., 1961. 352 pp. 14 × 21.5 cm. Price $14.

Terms used in chemistry, physical chemistry, chemical engineering, pharmacology, and foods are included in this dictionary. The English words generally are given the spelling common to the U. S. and the "c" in ergot alcaloids is only a typographical error. A knowledge of at least the Russian alphabet is required; there is no English-Russian section.

Accepted Dental Remedies 1962. 27th ed. Council on Dental Therapeutics of the American Dental Association. American Dental Association, 222 E. Superior St., Chicago 11, Ill., 1962. xiv + 235 pp. 15.5 × 20.5 cm. Paperbound. Price $3.

Review Article

Pharmacology and Biochemistry of Drug Metabolism

By WILLIAM F. BOUSQUET

IN RECENT years, much emphasis has been placed on explaining drug action at the subcellular or biochemical level. In order that this be done in a meaningful and precise manner, it is necessary that such parameters as drug absorption, tissue distribution, elimination through excretory pathways, binding to constituents of cells and body fluids, and metabolism be thoroughly explored. Pharmacologists and biochemists appear agreed that the subcellular approach to drug action, whether from the enzymatic or physical biochemical points of attack, will yield a wealth of information concerning sites and mechanisms of drug activity. Metabolism of drugs is the parameter of prime concern in this review. The author will limit himself to a discussion of recent researches undertaken to define general metabolic pathways in which drug substances (and many other organic chemicals) participate. The reader should bear in mind that the related phenomena of drug absorption and elimination play an important role along with drug metabolism in the total spectrum of drug activity. Excellent reviews by Nelson (1), Wagner (2), and Butler (3) cover these topics.

The importance of drug metabolism as a contributing factor to the response noted with any drug *in vivo* is readily apparent upon consideration of the facts that (*a*) the duration of action of a drug can be related to the rate and manner in which it is metabolized, (*b*) the rate of elimination of a drug from the body is markedly dependent upon the physicochemical properties of its metabolic products, (*c*) the ability of a drug to penetrate cellular barriers and reach a site of action may be limited by its rate of biotransformation and the character of its metabolic products, (*d*) the toxicity of a drug can be reversed or, in certain cases, intensified upon conversion to a metabolite, and, (*e*) a metabolite may be formed *in vivo* which itself has a pharmacological effect ("active metabolite").

These points would indicate the importance of knowing the pathways of drug biotransformation as well as the degree of accumulation of metabolic products in tissue. It follows, too, that the toxicity and pharmacological effects of drug metabolites must be understood. From a more practical standpoint, recent legislation covering certain classes of physiologically active material (Food Additives Amendment) has made mandatory the identification and measurement of residual levels of drugs and drug metabolites which conceivably could gain entrance into the human food supply. Reviews on the subject of drug metabolism have appeared by Fishman (4, 135), Brodie, *et al.* (5, 6), and Maynert (7). The book, "Detoxication Mechanisms," by Williams (8) serves as an excellent source of information on the metabolism of drugs and other organic chemicals by providing encyclopedic treatment of the subject.

There is lack of agreement generally on the terms to be used in describing such studies. De-

Received from the Departments of Bionucleonics and Pharmacology, School of Pharmacy, Purdue University, Lafayette, Ind.

Supported in part by Grant A-4444 from the National Institute of Arthritis and Metabolic Diseases, National Institutes of Health, Bethesda, Md.

The author wishes to express his appreciation to Dr. John E. Christian, Bionucleonics Department, and Dr. Tom S. Miya, Pharmacology Department, for their suggestions and review of this paper.

toxication is obviously misleading since many drugs can be converted *in vivo* to more toxic compounds as exemplified by certain insecticides containing the —P=S grouping which is converted to the highly toxic —P=O form. This term has, nonetheless, withstood the test of time, and is currently favored by some authors. Others find fault with the use of "drug metabolism" in describing such work, preferring to retain the word metabolism to describe studies on endogenous substrates. The phrase, "drug biotransformation," attributable to Brodie, is perhaps the best terminology in such cases. The present author, however, prefers the use of "drug metabolism" and such will be employed in this review.

Although studies of the metabolic fate of drugs have been carried out since the end of the nineteenth century (9), it is only in the past decade that significant advances have been made concerning the enzymes involved. The excellent work of Axelrod, Brodie, and their co-workers (10–12) has established that the primary site of drug metabolizing activity in the mammal is in the microsomal fraction of the liver, necessary cofactors for the various reactions being found in the soluble fraction. It is of interest that the enzyme systems involved are apparently quite nonspecific in the sense that several reactions can be carried out by the same fraction. Specific enzymes have not been isolated to date. Nearly all of the classical reactions undergone by drugs *in vivo* including hydroxylation, dealkylation from amino nitrogen, ether cleavage, glucosiduronide formation, and reduction of the nitro and azo groupings have been duplicated under *in vitro* conditions using the mammalian liver microsomal system. Further, it has been established that the microsomal enzymes which act upon drugs and other foreign compounds appear unable to carry out the same reactions on endogenous substrates. Isolation and thorough understanding of the activity of the microsomal enzymes which metabolize drugs would seem to be the next step in the chain of events.

Biochemical Reactions Undergone By Drugs.—For purposes of discussion the more important metabolic pathways entered into by drugs can be classified into five groups. These five groups comprise some 15 distinct metabolic reactions, and cover the majority of the biotransformations which drugs and foreign compounds undergo. These are:

1. *Oxidation.*—Reactions considered under this heading are oxidations only in the sense that oxygen (as hydroxyl) takes part or is postulated to take part in one or more of the steps leading to the final metabolite, as proposed by Brodie, *et al.* (5): (*a*) hydroxylation of aromatic rings; (*b*) oxidation of aliphatic side chains to alcohols, ketones, or carboxyl groups; (*c*) dealkylation from oxygen (ether cleavage); (*d*) dealkylation from amino nitrogen; (*e*) deamination; (*f*) sulfoxide formation.

2. *Reduction.*—(*a*) Reduction of the nitro group, (*b*) cleavage and reduction of the azo linkage.

3. *Conjugation Processes.*—(*a*) Glucosiduronide formation, (*b*) formation of aryl sulfates, (*c*) conjugations with glycine, (*d*) acylation.

4. *Hydrolytic Reactions.*—(*a*) Cleavage of esters, (*b*) cleavage of amides.

5. *Exchange Reactions.*—(*a*) Replacement of sulfur by oxygen.

Table I indicates the character of each of these reactions and gives illustrative examples of drug substances known to undergo each of the biotransformations indicated.

Changes in Drug Properties through Metabolism.—Upon metabolism a drug is ordinarily converted to a more polar compound having a lipid solubility much less than that of the parent material. Current knowledge concerning the ability of organic compounds to pass tissue and cellular barriers indicates that it is the molecular form of the compound which is transported to the exclusion of the ionized species (13–15). Thus, the dissociation constant of the drug or metabolite and its inherent lipid solubility appear to be the primary factors governing its passage into cells. This is true whether one considers gut absorption (13), passage through barriers such as the blood-cerebrospinal fluid barrier (16, 17), or kidney elimination (18, 19). Thus it is likely that a drug having been converted to a more polar metabolite will, at physiological pH, be rather rapidly excreted, and will be unlikely to be returned to the tissues. This is indicated by recent studies in these laboratories on the metabolism of C-14 salicylamide and C-14 meprobamate. In neither case was it possible to demonstrate the presence of the relatively more polar metabolites of these drugs (salicylamide → 2,5-dihydroxybenzamide and glucosiduronides; meprobamate → hydroxymeprobamate and glucosiduronides) in body tissues of the rat (20, 21). Through metabolism, then, another factor is brought into play which contributes to termination of drug action, namely that the physical and chemical properties of the metabolite are such that it is unable to pass the lipid-like membranes between plasma and cells,

and it cannot readily be reabsorbed through the renal tubular epithelium.

Binding of drugs to proteins, particularly those of the plasma, can also play a role in determining the length of action of the drug, especially if therapeutic concentrations of free drug can be maintained from the storage depot. Liver, for example, shows a high capacity to bind mepacrine (22); antibiotics, sulfonamides, and certain barbiturates are bound in plasma to a significant degree. Through metabolism, one would expect this type of storage mechanism to be greatly altered. Storage of lipid-soluble drugs in body fat is frequently discussed as a contributing factor to the duration of drug action. This factor has been carefully studied in relation to certain of the thiobarbiturates (19, 23). A drug, upon being converted to a more polar metabolite, would be less lipid-soluble and less likely to be stored in fat depots.

Liver Enzymes Which Metabolize Drugs.— The report by Axelrod (10) who, in 1955, demonstrated that microsomes from rabbit liver could metabolize amphetamine to phenylacetone and ammonia was the first to demonstrate the localization of drug metabolizing activity. His studies of the cofactors involved indicated that the system required both reduced triphosphopyridine nucleotide (TPNH) and oxygen. Upon fractionation of whole liver into nuclei, mitochondria, microsomes, and soluble fraction, the microsomes alone could metabolize amphetamine, but at a very slow rate. Addition of the soluble fraction greatly increased the ability of microsomes to metabolize amphetamine. The soluble fraction containing glucose-6-phosphate and glucose-6-phosphate dehydrogenase serves as a TPNH generating system. Washed rabbit liver microsomes could metabolize amphetamine equally well with added TPNH as with the soluble fraction. Axelrod also showed that the addition of unheated rat liver microsomes to the rabbit microsomes markedly decreased activity, whereas addition of heated rat microsomes did not, suggesting the presence of a heat labile inhibitor in the rat microsomes.

In vitro studies on drug metabolism are ordinarily carried out using microsomes isolated from liver homogenate by differential centrifugation, all necessary cofactors being added in the buffer medium. Some prefer the use of a fraction containing both the microsomes and the soluble fraction, prepared by centrifugation of the whole homogenate at 9,000 × g. Homogenates may be prepared either in isotonic potassium chloride or in 0.25 *M* sucrose, both yielding highly active preparations. General methods of homogenate preparation and fractionation are applicable (47–49). Table II shows the distribution of drug metabolizing activity in various subcellular fractions of rabbit liver. In general, only the liver yields active drug metabolizing preparations; of the reactions listed in Table I, only nitro reduction and glucosiduronide formation occur at other sites in the body. Nitro reductase activity is associated with kidney, heart, lung, and brain, as well as liver. This reaction, however, requires anaerobic conditions and thus differs from the general TPNH-O_2 requirement (35). Coliform bacteria in the intestine can also reduce nitro compounds (50).

Glucosiduronide formation can take place in the kidney cortex and the gastrointestinal tract of several species (51).

The fact that the liver microsomal system appears to act only on exogenous substrates is difficult to explain. The phylogenetic distribution of drug metabolizing activity shows this function to be restricted, in the main, to the mammal. Aquatic animals are unable to carry out the oxidative reactions enumerated in Table I. An explanation for this may lie in the fact that aquatic species have excretory mechanisms which allow rapid removal of unchanged drug from the body, so that metabolic defense mechanisms are unnecessary (52). Brodie (52) suggests the evolution of liver microsomal enzymes in terrestrial animals. In explanation of the fact that endogenous substrates are not attacked by these enzymes, Gaudette and Brodie (30) have studied the dealkylation of a series of foreign and endogenous alkylamines. They show that only those compounds exhibiting a high chloroform/water partition ratio at physiological pH are dealkylated by the microsomal system. It is of interest that the endogenous substrates studied exhibit extremely low partition and are not metabolized. This suggests that the microsomes are protected by a lipid barrier which is impermeable to polar compounds. Such a hypothesis deserves further exploration. Their interesting data are partially reproduced in Table III. McMahon (67) has, in the main, confirmed the observations of Gaudette and Brodie (30) cited above.

Cofactor requirements for the microsomal enzymes carrying out oxidative reactions are quite similar for hydroxylation, ether cleavage, dealkylation, and deamination. pH optima are also similar varying only slightly from about pH 7.0 to 8.5, depending on the particular substrate. Reduced TPN is a general requirement for all of these reactions, as is molecular oxygen. DPNH

TABLE I.—SOME COMMON METABOLIC REACTIONS UNDERGONE BY DRUGS

Pathway or Reaction	Schematically[b]	Drugs which Undergo This Reaction (Reference)
1. Oxidation[a]		
(*a*) Hydroxylation		Acetanilide (24, 11), Salicylic acid (25), Salicylamide 50
(*b*) Side chain oxidation	$R—CH_2CH_3 \xrightarrow{(OH)} R—CHOHCH_3$	Pentobarbital (26, 27)
(*c*) Ether cleavage	$R—O—CH_3 \xrightarrow{(OH)} R—OH + HCHO$	Morphine (28) Phenacetin (29)
(*d*) Dealkylation from amino nitrogen	$R—NH—CH_3 \xrightarrow{(OH)} R—NH_2 + HCHO$	Morphine, Meperidine (12), Monomethyl-4-aminoantipyrine (30), Methamphetamine (31)
(*e*) Deamination	$R—CH_2CHNH_2CH_3 \xrightarrow{(OH)} R—CH_2COCH_3 + NH_3$	Amphetamine, Ephedrine (10)
(*f*) Sulfoxide formation	$R—S—CH_3 \xrightarrow{OH)} R—SO—CH_3$	Chlorpromazine (32, 33, 34)
2. Reduction		
(*a*) Nitro reduction	$R—NO_2 \longrightarrow R—NH_2$	Chloramphenicol (35)
(*b*) Azo reduction	$R—N{=}N—R \longrightarrow 2\ R—NH_2$	Prontosil (36)
3. Conjugation		
(*a*) Glucosiduronide formation	$R—OH + UDPGA \xrightarrow{\text{transferase}} RO\text{-glucosiduronide}$	Salicylates (20, 37), Morphine (38), Meprobamate (21), Codeine (39)
(*b*) Aryl sulfate formation	$R—OH + PAPS \xrightarrow{\text{transferase}} RO—SO_2OH$	Salicylamide (40)
(*c*) Conjugation with glycine	$R—COOH + H_2NCH_2COOH \longrightarrow R—CONHCH_2COOH$	Benzoic acid (41)
(*d*) Acylation	$R—NH_2 + \text{Acetyl-CoA} \longrightarrow R—NHCOCH_3$	Sulfonamides (42)
4. Hydrolytic reactions		
(*a*) Cleavage of esters	$R—COOR' \xrightarrow{\text{esterase}} R—COOH + ROH$	Procaine (43)
(*b*) Cleavage of amides	$R—CONH_2 \xrightarrow{\text{amidase}} R—COOH + NH_3$	Hydroxybenzamide (44)
5. Exchange reactions		
(*a*) Replacement of S by O	$R—CS—R \longrightarrow R—CO—R$	Thiopental (45) Parathion (46)

[a] As proposed by Brodie, *et al.* (5); detailed mechanisms and cofactors for the reactions to be discussed later. [b] Abbreviations used in review are as follows: AMP, ADP, ATP for adenosine mono-, di-, and triphosphates; UDP for uridine diphosphate; UDP-G for uridine diphosphoglucose; UDPGA for uridine dihosphoglucuronic acid; TPN and TPNH for the oxidized and reduced forms of triphosphopyridine nucleotide; DPN and DPNH for the oxidized and reduced forms of diphosphopyridine nucleotide; G-6-PO_4 for glucose-6-phosphate; APS and PAPS for adenosine-5′-phosphosulfate and 3′-phosphoadenosine-5′-phosphosulfate; acetyl-CoA for acetyl coenzyme A; PP for pyrophosphate.

TABLE II.—INTRACELLULAR DISTRIBUTION OF ACETANILIDE HYDROXYLATING ACTIVITY[a]

Cellular Fractions	*p*-Acetylaminophenol Formed, μm.	% Relative Activity
Whole homogenate	1.14	100
Supernatant (9,000 × g)	1.14	100
100,000 × g	...	...
Microsomes	0.01	0.9
Soluble fraction	0.01	0.9
Soluble + microsomes	1.14	100

[a] From Mitoma, *et al.* (24). Fractions equivalent to 250 mg. of liver incubated with 10 μm. of acetanilide. Activity of whole homogenate taken as 100%. The 9,000 × g centrifugation removes unbroken cells, nuclei, and mitochondria, showing that these fractions possess no metabolizing activity.

TABLE III.—LIPID SOLUBILITY AND DEALKYLATION OF A NUMBER OF ALKYLAMINES BY LIVER MICROSOMES[a]

% Compound Extracted into Chloroform	Compound	Relative Activity
Foreign Materials		
>95	Monomethyl-4-aminoantipyrine	100
>95	Ephedrine	110
>95	Demerol	95
>95	Parpanit	80
>95	Methadone	50
>95	Caffeine	20
12	Theophylline	0
Endogenous Compounds		
<3	Adrenaline	0
<3	Sarcosine	0
<3	Choline	0
<3	Creatine	0

[a] Data from Gaudette and Brodie (30). Distribution of each compound between chloroform and pH 7.4 phosphate buffer determined. Microsomes from 1 Gm. rabbit liver incubated with 5 μm. of substrate. Activity of 100 equivalent to the dealkylation of 1 μm. of substrate per hour.

cannot replace TPNH in the oxidative reactions. Nicotinamide is frequently added to homogenates to protect TPN, and Mg^{++} is a required ion. Glucose-6-phosphate and glucose-6-phosphate dehydrogenase are required to maintain TPN in the reduced state. That the drug metabolizing enzymes are not related to the cytochrome chain is indicated by the fact that cyanide does not influence the reactions. Gillette, *et al.* (53), have studied the role of TPNH and oxygen in the oxidative reaction. They show that microsomes contain a TPNH oxidizing system which gives rise to hydrogen peroxide. It is attractive to speculate that the hydrogen peroxide so produced serves as the source of "active hydroxyl" in the oxidative reactions. They further showed that only those tissues possessing significant TPNH oxidase activity could catalyze the dealkylation of monomethyl-4-aminoantipyrine, as shown in Table IV. Further work is required to explain fully this striking parallel.

Brodie (52) shows the requirement for TPNH more directly in a study of the oxidation of hexobarbital, as indicated in Table V.

TABLE IV.—TPNH OXIDATION AND MONOMETHYL-4-AMINOPYRINE DEALKYLATION BY MICROSOMES OF VARIOUS RABBIT TISSUES[a]

Tissue	TPNH Oxidation O.D. 340/5	4-Aminoantipyrine Formed, μm.
Liver	0.189	0.44
Lung	0.065	0.04
Kidney	0.047	0.02
Heart	0.028	0.03
Muscle	0.012	0.01
Brain	0.012	0.00

[a] Data from Gillette, *et al.* (53). TPNH oxidase activity measured spectrophotometrically. Microsomes from 1 Gm. of tissue incubated with 5 μm. of monomethyl-4-aminoantipyrine.

TABLE V.—REQUIREMENT FOR TPNH IN OXIDATION OF HEXOBARBITAL BY LIVER MICROSOMES[a]

Components	Hexobarbital Oxidized, μm.
Microsomes + 1.0 μm. TPN	0
Microsomes + 1.0 μm. TPN + 4 μm. G-6-PO_4	0
Microsomes + 1.0 μm. TPN + 4 μm. G-6-PO_4 + G-6-PO_4 dehydrogenase	0.30
Microsomes + TPNH	0.61
Microsomes + 0.5 ml. soluble fraction + 1 μm. TPN	0.57

[a] Data from Brodie (52).

Species, Sex, and Age Differences in Drug Metabolism.—It was mentioned that aquatic animals do not possess the enzymes necessary to metabolize drugs, this activity being restricted to the mammal. Within the mammalian group, wide quantitative differences are seen in relation to metabolizing activity, as well as some qualitative differences. Thus, amphetamine in rats and dogs is metabolized by hydroxylation of the aromatic ring, whereas in rabbits the compound is deaminated (10). Cats are not able to synthesize glucosiduronides (51).

There are well-known species differences in quantitative response to certain drugs (54, 55). In certain cases these differences are explainable on the basis of relative drug metabolizing activity, there being an inverse relationship between drug metabolizing ability and duration of pharmacological response. Thus, Quinn, *et al.* (55), have shown that the duration of action of hexobarbital is in inverse relationship to hexobarbital metabolism in several species. Their data are shown in Table VI.

Similar results were found in studies of the metabolism of antipyrine, amidopyrine, and aniline, and provide a sound basis for explaining differences in drug duration of action, sensitivity to various drugs, and toxicity.

TABLE VI.—SPECIES DIFFERENCE IN DURATION OF ACTION AND IN METABOLISM OF HEXOBARBITAL[a]

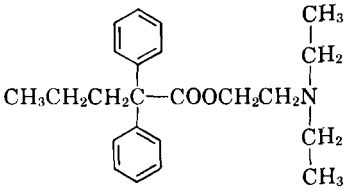
Species	Duration of Action, min.	Biological Half-Life, min.	Relative Enzyme Activity
Mouse	12 ± 8	19 ± 7	598 ± 184
Rabbit	49 ± 12	60 ± 11	196 ± 28
Rat	90 ± 15	140 ± 54	134 ± 51
Man	...	360	...

[a] Data from Quinn, *et al.* (55). Duration of action measured by sleeping time. Biological half-life determined by plotting plasma level *vs.* time at several intervals. Enzyme activity assessed by measuring mcg. of hexobarbital metabolized per gram of liver per hour. 100 mg./Kg. dose of hexobarbital in mouse, rabbit, and rat; 50 mg./Kg. in the dog.

Sex differences in drug metabolism appear to be restricted to the rat. Quinn, *et al.* (55), demonstrated that following a 100 mg./Kg. dose of hexobarbital, female rats sleep about four times as long as males, whereas their enzyme activity is about one-quarter that of the male. It is interesting that hexobarbital metabolizing activity can be significantly altered in rats by administration of testosterone to females and estradiol to males. Control male rats exhibited a hexobarbital metabolizing capacity of 682 mcg. of drug/Gm. of tissue/hr., whereas estradiol-treated males metabolize only 177 mcg./Gm./hr. Female controls metabolized 134 mcg./Gm./hr., whereas testosterone-treated females metabolized 543 mcg./Gm./hr. Sleeping times in these animals were altered to the same degree. Inscoe and Axelrod have recently demonstrated that glucosiduronide formation in rats is also markedly sex-dependent, male animals showing approximately four times the activity of females (56).

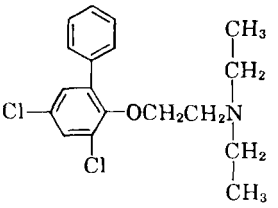
Fouts and Adamson (57) report that the newborn rabbit is essentially unable to carry out side chain oxidation, dealkylation, hydroxylation, and deamination. Enzyme activity appears at the second week of life, increasing to adult values at about four weeks. In an experiment to test the possibility of enzyme inhibitors being present in the livers of young animals, the addition of baby rabbit supernatant (9,000 × g) to adult supernatant caused an 82% reduction in the ability of the adult preparation to metabolize amphetamine. Jondorf, *et al.* (58), in a study of drug metabolism in newborn mice and guinea pigs, demonstrated that the newborn mouse is unable to carry out dealkylation, side chain oxidation, and ether cleavage. Enzyme activity appeared at 7 days and reached heightened values at 21 days. It is also of interest that sensitivity of mice to hexobarbital decreased as the animal's ability to metabolize the drug increased. Similar results were obtained in guinea pigs, and these young animals were also unable to synthesize glucosiduronides. These data are significant in that they provide a rational basis for explaining the heightened sensitivity of young animals to certain drugs, mainly central nervous system depressants, apart from differences in blood-brain barrier.

Physiological and Biochemical Control of Drug Metabolizing Enzymes.—Little is known about the extra-hepatic factors which control the activity of the microsomal enzymes. The observation (55, 56) that sex hormones can alter microsomal activity is apparently confined to the rat and does not seem to be of general significance. Remmer (59) has shown that adrenalectomy reduces the capacity of liver microsomes to oxidize barbiturates. Zauder (60) has reported that adrenalectomy in rats destroys the ability of liver slices to conjugate morphine. It is interesting to speculate on the role of the adrenal cortex (and of the pituitary gland) in regulating liver microsomal activity. It is well known, for example, that administration of corticoids increases protein synthesis (61, 62). It might therefore be expected that the adrenal cortical secretions regulate synthesis of microsomal enzymes, at least to some degree. Cochin and Sokoloff (63) have investigated the effects of L-thyroxin on the demethylation of morphine in mice and report that it depresses this function. Since the experiments were carried out in intact animals rather than those which had been thyroidectomized, it is not possible to make a definitive statement regarding thyroxin effects on drug metabolism. Conney and Garren (64) report that thyroxin stimulates the metabolism of zoxazolamine and decreases the metabolism of hexobarbital. In their work with zoxazolamine it is of interest that during the period of greatest zoxazolamine metabolism, the tissue level of G-6-PO_4 and G-6-PO_4 dehydrogenase were also markedly increased.



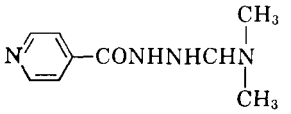
Recent studies by Dixon, *et al.* (65), demonstrate that the alloxan-diabetic rat shows a decreased ability to oxidize hexobarbital and chlorpromazine and to cleave the ether linkage in codeine. Administration of insulin to diabetic rats restores drug metabolizing activity to control values. A relationship is evident between glycogen levels in the liver and drug metabolizing activity, low levels of liver glycogen following alloxan paralleling depressed enzymatic function. McLuen and Fouts (66) show that livers from jaundiced rats possess a markedly decreased ability to carry out oxidation, deamination, ether cleavage, and dealkylation. They note that the effects seen in severely jaundiced animals are quite closely duplicated *in vitro* by the addition

of sodium deoxycholate ($10^{-3}M$) to tissue homogenates, and mention the possibility that effects seen in jaundiced rabbits may be due to increased concentrations of bile acids in the liver.



In 1954, Udenfriend, *et al.* (68), reported that a synthetic system consisting of ascorbic acid, ferrous sulfate, and EDTA in phosphate buffer and an oxygen atmosphere, was able to hydroxylate drugs and other foreign compounds to yield products identical to the hydroxylated metabolites of these drugs obtained *in vivo*. Thus, the hydroxylation of salicylic acid, acetanilide, aniline, and antipyrine was demonstrated (69). It has long been recognized that the administration of certain drugs can cause an increased excretion of ascorbic and glucuronic acids (70), which has been shown to be due to increased synthesis (71). Participation of ascorbic acid in certain drug metabolic reactions is thus suggested. Manthei (72) has shown that ascorbate-treated mice exhibit heightened tissue levels of isoniazid after dosing with this drug, and that a metabolite of isoniazid is recoverable in mice having the same chromatographic characteristics as a compound obtained by chemical reaction of isoniazid and dehydroascorbic acid. In an interesting study of the role of ascorbic acid in aromatic hydroxylation, Axelrod, *et al.* (73), studied the biological half-lives of acetanilide, aniline, and antipyrine in normal and scorbutic guinea pigs. They demonstrated that the biological half-lives of these drugs are significantly increased in the scorbutic animal. Ascorbic acid is known to participate, nonspecifically, in the biological oxidation of tyrosine (74). Before assigning a role to ascorbic acid in drug metabolism, the questions of specificity and detailed mechanism must be answered. For example, barbital, a drug which is not extensively metabolized, has a pronounced effect on stimulating ascorbic acid and glucuronic acid biosynthesis (75). A host of compounds, having different pharmacological effects and being metabolized along different pathways, also induce ascorbic acid synthesis (76). It is interesting to note that liver ascorbic acid is mainly concentrated in the microsomes and supernatant fractions, very little being found in the mitochondria and none in the nuclei (77).

The excellent work of Burns and his colleagues in providing us with details of the mechanism of ascorbic acid biosynthesis and its possible role in drug metabolism is deserving of mention (71, 75, 76, 78, 79).



Drug Metabolism Inhibitors.—Macko, *et al.* (80), reported in 1953 that SKF 525-A (β-diethylaminoethyl diphenylpropylacetate, I) has the ability to potentiate the action of certain spinal cord depressants and central nervous system stimulants. Cook, *et al.* (81), in a detailed study, have shown that the duration of action of hexobarbital is significantly increased under the influence of SKF-525A. Other compounds shown to be potentiated by this agent include secobarbital, amobarbital, phenobarbital, and chloral hydrate (82); *d*-tubocurarine (83); and certain antiepileptic drugs (84). Other compounds known to exert similar effects on drug metabolism include Lilly 18,947 (2,4-dichloro-6-phenylphenoxyethyl diethylamine, II), iproniazid, III, and JB-516 (1-phenylisopropylhydrazine, IV).

III

IV

SKF 525-A has been used extensively as a tool in drug metabolism studies. The mechanism of its action was explained first by Axelrod, *et al.* (85), who showed that it decreased the ability of the liver microsomes to carry out such reactions as side chain oxidation and demethylation and thus increased the duration of action of drugs being metabolized through these pathways. Axelrod, *et al.* (86), further demonstrated in a study of the effects of this compound on hexobarbital action that the increased duration of action was closely paralleled by an increase in the biological half-life of the drug. Of significance in this study was

the fact that upon return of the righting reflex in rats receiving 100 mg./Kg. hexobarbital, plasma levels of hexobarbital were no higher in the SKF 525-A-treated animals than in the control group. This would indicate that the increased sleeping time noted was not due to higher brain concentrations of the barbiturate. It has been shown (81) that administration of SKF 525-A after return of the righting reflex following hexobarbital treatment will not reinduce hypnosis.

In a study of the mechanism of SKF 525-A action, Cooper, *et al.* (87), demonstrated that the compound added to liver homogenates at concentrations of 10^{-4} *M* or greater can prevent oxidation of the barbiturates, hexobarbital, pentobarbital, and secobarbital; the demethylation of aminopyrine and meperidine; the deamination of amphetamine; ether cleavage of codeine, and the formation of morphine glucosiduronide. In order to test the possibility that the inhibition of drug metabolism seen with SKF 525-A might be due to its hydrolytic products, diethylaminoethanol and diphenylpropylacetic acid, *in vitro* experiments were run in which hexobarbital metabolism was studied under the effects of SKF 525-A and the hydrolytic products. Both SKF 525-A and diphenylpropylacetic acid were equally effective in preventing oxidation of the barbiturate, whereas diethylaminoethanol was without effect. SKF 525-A is considerably more active *in vivo* than is diphenylpropylacetic acid, presumably due to the fact that diphenylpropylacetic acid would be rapidly excreted. These authors examined the possibility that SKF 525-A might act by interfering with hydrogen transport from TPNH. They were able to show no effect of diphenylpropylacetic acid on the systems TPN-cytochrome c reductase, glucose-6-phosphate dehydrogenase, and isocitric dehydrogenase.

While the mechanism of action of this compound remains obscure, it has provided a useful tool in studies of drug metabolism in that certain inferences can be drawn about enzymes involved in various of the drug metabolic pathways by noting the quantitative effect of SKF 525-A on the pathway of interest. The possibility of several contributing factors to the mechanism of action of SKF 525-A must not be overlooked. For example, the effects of this compound on drug tissue distribution has not been extensively studied to date. Its ability to reduce the rate of excretion of S-35 pentothal has been reported by Achor and Geiling (88) and should be further investigated in relation to other compounds, quantitative studies being required of excretion rate *vs.* time-course of pharmacological response. The possibility of an interference by SKF 525-A in the function of a normal physiological or biochemical factor controlling the synthesis or function of the liver microsomal enzymes responsible for drug metabolism must not be overlooked.

Fouts and Brodie (89) have reported on the ability of compound Lilly 18,947 to block drug metabolic reactions. They show that this compound is about equally active with SKF 525-A in depressing demethylation, ether cleavage, deamination, and hydroxylation.

JB-516 has been shown by Pearce, *et al.* (90), to decrease the metabolism of hexobarbital in mice, presumably acting by a mechanism similar to that of SKF 525-A and Lilly 18,947. Welch, *et al.* (91), have demonstrated that chlorothion increases hexobarbital sleeping time in mice and, when added to liver slices, decreases the oxidation of the barbiturate. It is pointed out that both control and chlorothion-treated animals awaken when brain levels of hexobarbital are about 25 mcg./Gm. of tissue, again suggesting that receptor sensitization is not involved in the increased duration of pharmacological response.

Compounds Which Stimulate Drug Metabolism.—It was reported by Conney, *et al.* (92, 97), that pretreatment of rats with phenobarbital, barbital, 3-methylcholanthrene, or 3,4-benzpyrene markedly increases the activity of the liver enzymes azo N-demethylase, 3,4-benzpyrene hydroxylase, and zoxazolamine hydroxylase. The data can be confirmed by *in vivo* studies such as the fact that the duration of action of a paralytic dose of zoxazolamine can be shortened by pretreatment of the animals with 3-methylcholanthrene or 3,4-benzpyrene. It is of further interest that chronic administration of aminopyrine or phenylbutazone can increase activity of the liver microsomal enzymes responsible for their own metabolism. The possible implication of these findings in drug tolerance studies is apparent.

Conney, *et al.* (93), provide evidence that the increased activity of the liver microsomal system brought about by pretreatment of rats with phenobarbital is due to increased enzyme synthesis. They show that administration of ethionine, an amino acid antagonist, prevents the phenobarbital-induced increase in microsomal activity. Further, they point out that addition of phenobarbital to *in vitro* incubation mixtures is without effect in increasing the activity of azo N-demethylase activity, whereas administration

of the barbiturate to the intact animal yields homogenates with a substantially greater metabolic capacity. Such pretreated animals also exhibit increased total liver protein and increased liver microsomal protein. This evidence is consistent with a hypothesis of increased enzyme synthesis.

Cramer, *et al.* (94), have shown that the ability of liver homogenates or microsomes to hydroxylate the carcinogen 2-acetylaminofluorene is increased five to ten-fold in rats upon pretreatment with 3-methylcholanthrene. The effects seen with 3-methylcholanthrene were blocked when the animals were pretreated with *d,l*-ethionine. Von der Decken and Hultin (95) have confirmed the enzyme inductive effects of 3-methylcholanthrene in studies of the demethylation and reductive cleavage of *p*-monomethylaminoazobenzene, and the binding of 2-aminonaphthalene to soluble liver proteins. They show also that microsomes from 3-methylcholanthrene-treated rats have an increased capacity to incorporate leucine into protein and a higher RNA content, further substantiating the hypothesis of Conney, *et al.* (93), that increased drug metabolizing activity is due to increased enzyme synthesis.

It is interesting to note that some compounds which can elicit an increase in the activity of the liver microsomal enzymes metabolizing drugs, also markedly increase the biosynthesis and excretion of ascorbic acid (71, 76, 96).

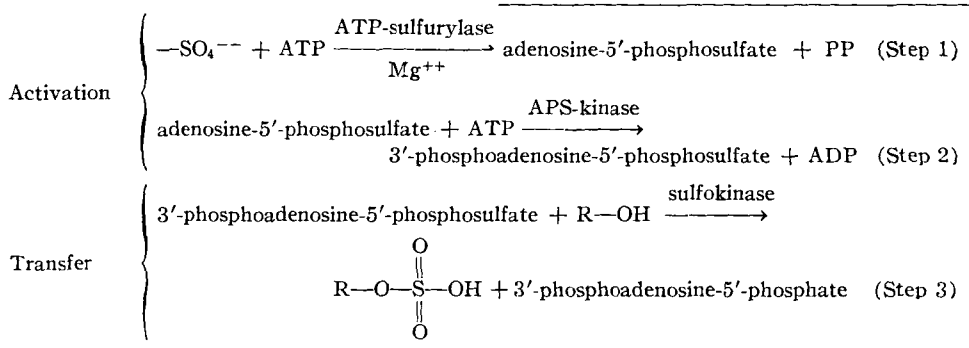
Mechanisms of Specific Metabolic Reactions.—Of the metabolic reactions undergone by drugs listed in Table I, those which are of more general significance biochemically have received a great deal of study in recent years. The mechanisms of such general (and truly "detoxifying") reactions as glucosiduronide formation and aryl sulfate formation have been thoroughly elucidated.

Glucosiduronide Formation.—This reaction occurs with hydroxy compounds primarily, as well as with carboxylic acids and, in certain cases, with amines (N-glucosiduronides), and has been recognized and described for over 60 years (8). The occurrence of this reaction *in vivo* is now known to take place primarily in the liver, although kidney cortex and the gastrointestinal mucosa are also active (51, 98). Regardless of whether an ether type glucosiduronide (from a hydroxy compound) or an ester type glucosiduronide (from a carboxyl group) is formed, carbon atom 1 of glucuronic acid participates in the linkage. Williams (8) covers the mechanism of glucosiduronide formation in detail as well as presenting a historical account of this metabolic pathway. Dutton (99) has outlined the pathway of this reaction as follows

$$\text{glycogen} \xrightarrow{H_3PO_4} \alpha\text{-glucose-1-PO}_4 \quad \text{(Step 1)}$$

$$\alpha\text{-glucose-1-PO}_4 + \text{UTP} \xrightarrow[\text{transferase}]{\text{uridyl}} \text{UDP-glucose} + \text{PP} \quad \text{(Step 2)}$$

$$\text{UDP-glucose} \xrightarrow[\text{UDPG dehydrogenase}]{DPN,O_2} \text{UDP-glucuronic acid} \quad \text{(Step 3)}$$



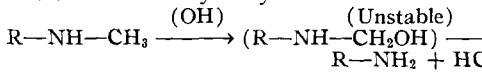
$$\text{UDP-glucuronic acid} + \text{R—OH} \xrightarrow[\text{glucuronyl transferase}]{} \text{R—O-glucuronic acid} + \text{UDP} \quad \text{(Step 4)}$$

That this pathway of metabolism is an important route leading to the elimination of drugs and other foreign compounds from the animal body is obvious; however, its role in normal biochemistry has not been well established. It is known, for example, that endogenous steroids are present in the blood as glucosiduronides (100) as well as being excreted in this form (101). Bilirubin is known to form such a conjugate (102). It has been postulated that steroids are "carried" in the blood as inactive conjugates being released by the enzyme β-glucuronidase which is widely distributed in mammalian tissues (103). The experimental and clinical significance of this is not clear.

Glucosiduronides, whether formed from foreign compounds or endogenous substrates, are rapidly hydrolyzed *in vitro* by the enzyme β-glucuronidase. This technique has proved useful in drug metabolism studies in providing a tool to confirm the suspicion that a conjugate of this type has been formed. The role which β-glucuronidase plays *in vivo* in nuclear. DeDuve (104) described the properties of a class of cytoplasmic particles found in liver, brain, and kidney, known as lysosomes, which appear to contain several enzymes including β-glucuronidase. It is stated that the particles are covered with a lipoprotein layer which is impermeable to the enzyme substrates. Enzyme activity can be released upon treatment of the particles with lecithinase, proteolytic enzymes, various detergents, or carbon tetrachloride. One questions the role which this "latent" β-glucuronidase might play in normal biochemistry.

Sulfate Conjugation.—This reaction represents another metabolic sequence of more general significance which is involved with the metabolism of a number of endogenous sub-

strates, as well as with a host of foreign compounds, including drugs. The so-called "ester sulfates" have been known since the work of Baumann in the last century (105), although the mechanism underlying the formation of such compounds has only recently come to light. Bernstein and McGilvery (106), and DeMeio, *et al.* (107), demonstrated that sulfate conjugation can occur in liver supernatants in the presence of adenylic acid, magnesium ion, and ATP. Lipmann (108) has reviewed developments on this problem, as have Bostrom and Vestermark (109). The generally accepted view for the mechanism of the synthesis is that it involves a two-step process, first, the activation of sulfate, and secondly, the transfer of sulfate to an acceptor molecule. The steps seem to be as follows



It is of interest that there appear to be at least three sulfate transferring enzymes (sulfokinases) which can take part in the last step of the sequence (108). One of these is called 3′-β-hydroxyl sulfokinase since it catalyzes sulfate transfer to steroids such as dihydroandrosterone, isoandrosterone, and progesterone which have a 3′-β-hydroxyl group. Another kinase appears to react with estrone forming estrone sulfate. The third is apparently quite nonspecific in that it can catalyze the transfer of active sulfate to a wide variety of phenolic acceptor substances. This is the enzyme of interest in drug metabolism studies. Of note in such studies is the suggestion by Anderton, *et al.* (110), that the pKa of the hydroxyl group should lie between 7 and 10 if the compound to which it is attached is to be conjugated with sulfate.

Little information is at hand relative to the role of sulfate conjugation in the normal animal. Certain end products of protein and steroid metabolism are excreted in the urine as sulfates, but the significance of this is not apparent. The lysosomes of DeDuve are stated to contain aryl sulfatase, an enzyme which can hydrolyze the ester sulfate linkage. Some properties of this enzyme have been reported by Webb and Morrow (111) and Roy (112). It appears to be activated by chloride ion (113).

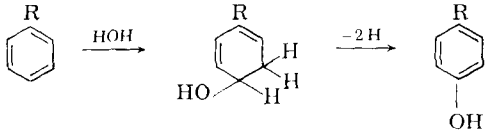
Boyland (114) has reviewed other biochemical conjugations and points out the significance of such reactions as phosphate ester formation and mercapturic acid synthesis through glutathione.

Dealkylation.—The general scheme proposed for the removal of N-alkyl groups is that of Gaudette and Brodie (30) who postulate that "active hydroxyl" plays a role in the mechanism. This is consistent with the TPNH requirement and the formation of hydrogen peroxide during TPNH oxidation (53), which could serve as the source of "active hydroxyl"

Gaudette and Brodie (30) present data indicating that more than one enzyme system is active in the microsomes in the dealkylation reaction. Their data indicate that the removal of alkyl groups from 4-aminoantipyrine is dependent upon the nature of the alkyl group when varied from methyl to dibutyl, whereas dealkylation of the same groups from aniline is not so affected. Additionally, they show that SKF 525-A effectively inhibits the dealkylation of mono- and dimethyl-4-aminoantipyrine, ephedrine, and meperidine, but is without effect on the dealkylation of methyl-, ethyl-, and butylaniline, and the ethyl and butyl 4-aminoantipyrines. Further evidence for the presence of at least two enzymes responsible for dealkylation is indicated by the work of Conney, *et al.* (97), who show that the administration of 3,4-benzpyrene to rats causes an increase in microsomal enzyme activities toward 3-methyl-4-monomethylaminoazobenzene, N-methylaniline, and monomethyl-4-aminoantipyrine, whereas the dealkylation of meperidine and diphenhydramine is decreased. They point out that the mitochondrial system which can dealkylate endogenous substrates such as sarcosine differs from the microsomal system in that

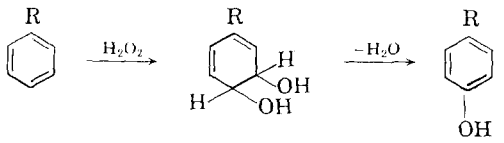
it does not require TPNH and it is blocked by cyanide. The authors postulate that the system dealkylating sarcosine is a cytochrome linked dehydrogenase, the mechanism of the reaction being as follows

$$R{-}NH{-}CH_3 \xrightarrow{-2\,H} R{-}N{=}CH_2 \xrightarrow{HOH}$$
$$(R{-}NH{-}CH_2OH) \longrightarrow R{-}NH_2 + HCHO$$



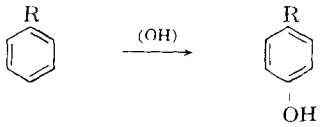
Other oxidative reactions such as sulfoxide formation, ether cleavage, and deamination are postulated to require "active hydroxyl" in sequences similar to that outlined for foreign N-alkylamines.

Aromatic Hydroxylation.—Several studies have confirmed that mammalian liver microsomes are the source of an enzyme(s) able to hydroxylate aromatic compounds (24, 25). TPNH and oxygen are requirements of the system as is the case with other oxidative reactions in the microsomes through which drugs are metabolized. The products of these hydroxylations may be phenols or, less commonly, dihydro diols in the case of condensed ring systems such as naphthalene.



Posner, *et al.* (115), present evidence that more than one enzyme is involved in the hydroxylation mechanism. They cite experiments run with inhibitors showing that the hydroxylation of acetanilide to its 2- and 4-hydroxy derivatives is nearly completely inhibited by 2,2′-dipyridyl whereas the hydroxylation of quinoline is only slightly affected. Microsomes incubated with Tween 80 rapidly lose their ability to hydroxylate acetanilide and quinoline, while the hydroxylation of naphthalene to 1,2-dihydronaphthalene-1,2-diol is little affected.

Endogenous substrates such as steroids (116) and phenylalanine (117) are also hydroxylated. Phenylalanine hydroxylase, while present in a 25,000 × g supernatant of liver, appears to differ from the hydroxylases involved in the metabolism of foreign compounds in that DPNH serves much better than TPNH as a cofactor.



Three possible routes by which an aromatic ring may be hydroxylated have been proposed by Udenfriend, *et al.* (68), in discussion of their Fe^{++}-ascorbic acid system. (*a*) Addition of water to a double bond followed by dehydrogenation

(*b*) Reaction with hydrogen peroxide to form a dihydro-diol intermediate followed by loss of water

(*c*) Direct substitution of hydroxyl for hydrogen

Posner, *et al.* (118), have recently studied the mechanism of aromatic hydroxylation using rabbit liver microsomes incubated in media containing HTO, H_2O^{18}, and in the presence of O_2^{18} in order to determine distribution of hydrogen and oxygen in the metabolite. The conversion of acetanilide to 4-hydroxyacetanilide contains no O^{18} arising from H_2O^{18} which indicates that addition of water plays no role in the mechanism. Phenolic oxygen in the metabolite is derived solely from O_2^{18}. No incorporation of tritium from HTO was found in the 4-hydroxyacetanilide formed. These data do not rule out the possibility that hydrogen peroxide arising during the oxidation of TPNH might be involved in the mechanism as a source of molecular oxygen or "active hydroxyl."

Imai and Sato (119, 120), in an attempt to localize hydroxylases from liver microsomes, report that an acetone powder prepared from microsomes is almost completely unable to carry out hydroxylations, whereas addition of the lipid-rich acetone-soluble fraction restores this function.

Formation of Active Metabolites.—There is now much data in the pharmacological literature suggesting that metabolites of drugs can contribute significantly to total drug response. This is to be expected and in no way conflicts with the general rule that drug metabolites are more rapidly excreted than the parent compound. This possibility should not be overlooked in studies of the metabolic products of any new drug, and is undoubtedly of significance with many older compounds in therapy which have not been fully investigated in the light of recent advances in methodology and understanding of drug metabolism in general.

Thus, the conversion of the barbiturate thiamylal, 5-allyl-5-(1-methylbutyl)-2-thiobarbituric acid, to the active metabolite, secobarbital, was demonstrated *in vivo* by Spector and

Shideman (121), as well as the conversion of the thiobarbiturate, thiopental, to the active species, pentobarbital through exchange of sulfur and oxygen (122). An excellent paper by Butler and Mahaffee (123) shows that the activity of the antiepileptic drug, trimethadione, is in fact due to its demethylated metabolite. Fishman (4) cites several other examples in the barbiturate and anticonvulsants groups in which active metabolites are formed.

It has long been recognized that acetylsalicylic and salicylic acids are converted *in vivo* to the hydroxylated metabolite, gentisic acid (124, 125, 126). This compound also exhibits analgetic properties and reduces fever (127, 128). Conversion of the salicylamide molecule to gentisic acid amide gives rise to a compound exhibiting antihistaminic properties (129), whereas salicylamide itself is devoid of this effect.

Levi and Snow (130) present data showing the *in vivo* conversion of bis-*p*-aminophenylsulfoxide to the corresponding sulfone which has antileprosy properties. Conversion of acetophenetidin to the active analgetic N-acetyl-*p*-aminophenol was demonstrated by Brodie and Axelrod (29). Burns, *et al.* (131), report that a hydroxylated metabolite of butazolidin has a pronounced anti-inflammatory activity as well as being more toxic than the parent drug. A sulfoxide metabolite of the 4-phenylthioethyl derivative of butazolidin has a uricosuric effect much greater than the unchanged drug (132).

Axelrod (133) comments on the formation of active metabolites from endogenous substrates as well as from foreign compounds.

Of related interest is the development of medicinal compounds containing structural groups known to undergo enzymatic attack with release of the active species (drug latentiation) as discussed by Harper (134). A fuller understanding of the metabolism, storage, and transport of drugs and drug metabolites will make this area of medicinal chemistry a fruitful field.

SUMMARY

Studies cited in this review indicate a rapid development of knowledge concerning the biological fate of drugs and other foreign organic chemicals since 1954, coincident with the discovery of systems present in mammalian liver microsomes which catalyze a wide variety of drug metabolic pathways. It is now possible, using this *in vitro* system, to carry out more refined and precise studies of drug metabolism than was the case with organ perfusion techniques and isolation of metabolites from excreta. This subcellular system duplicates exactly the metabolites formed and excreted by the intact animal, so that no question of specificity is involved. The contributions of Brodie, Axelrod, Udenfriend, and their co-workers of the National Institutes of Health are highly significant in the development of current knowledge on drug metabolism.

While recognizing that drugs can be converted *in vivo* to metabolic products exhibiting pharmacological activity, many questions remain to be answered relative to the quantitative importance of such conversions. Modification of drug response through administration of compounds known to stimulate or inhibit the liver microsomal system is an interesting area of study, and probably of future clinical significance. A thorough understanding of the factors operative in the normal animal which control the synthesis and function of the microsomal enzymes must be established in order to open another avenue of effort in modifying drug response. Isolation and characterization of the enzymes involved in drug metabolism is of paramount importance. Further data on the apparent discrimination of the liver microsomal enzymes against endogenous substrates are required to establish this point firmly. Such information will be forthcoming only if studies are carried out with highly purified enzymes, which has not been the case to date.

Study of Water Vapor Sorption by Pharmaceutical Powders

By W. A. STRICKLAND, Jr.

Water vapor sorption by pharmaceutical powders was studied by methods designed to yield data suitable for use in the preparation and stability testing of pharmaceuticals such as capsules, tablets, etc. The study yielded sorption-desorption isotherms near room temperature that permit the estimation of water sorption behavior of these powders in normal atmospheric conditions.

POWDERS may sorb water vapor from the surrounding atmosphere by physical and/or chemical bonding. The tenacity with which water is held by such powders as starch and certain metallic oxides is well known. The affinity of powders for water may be a factor of importance when considering the fabrication and stability of pharmaceutical preparations such as capsules, tablets, powders, and granules.

The literature reveals an abundance of work concerning sorption and diffusion of water and water vapor in such fields as textiles, foods, ceramics, and fuels, most of which has little application to the subject at hand. Leeson and Mattocks (1) recently studied the decomposition of aspirin at various water vapor levels. Babbitt (2) used a quartz spring sorption balance to study the sorption of water vapor by wheat. Dacey, *et al.* (3), used a similar apparatus to study the adsorption of water by saran charcoal. Hoover, *et al.* (4), applied polarization theory to sorption of water vapor by high polymers, principally protein. The surface area of porous solids such as soils, gels, and charcoals were determined from their water adsorption isotherms by Puri and Sharma (5).

The purpose of this work was to study the sorption and desorption of water vapor by representative pharmaceutical powders. This report describes methods used in the study and gives data obtained.

EXPERIMENTAL

Three distinct approaches were employed in this study, each will be discussed separately.

Screening

All powders were initially tested by placing accurately weighed, untreated samples of about 5 Gm., suitably spread in aluminum foil containers, into humidity chambers for a period of approximately 1 week. At the end of the equilibrium period, the samples were weighed a second time and loss or gain in weight noted. The humidity chambers, which consisted of large Pyrex glass desiccators, were kept in a room maintained at 21 ± 2°. The desired relative humidities were obtained by placing appropriate concentrations of sulfuric acid-water solutions (6) or saturated solutions of appropriate salts (7, 8) in the bottom of the desiccators. Corn starch was used as a reference in screening tests because it exhibited a predictable gain or loss of weight at various relative humidities.

Discussion of Results of the Screening Procedure.—Table I gives typical qualitative results of the screening procedure with powders that contain appreciable water or possess marked tendency to sorb water vapor. Powders showing such results were deemed suitable for further study. The amount of water held by the powder at 45% relative humidity was considered as a normal water content.

TABLE I.—RESULTS OF SCREENING TESTS SHOWING WATER VAPOR SORPTION OR DESORPTION ON UNTREATED POWDER SAMPLES

Compound	Gain or Loss of Weight, mg./Gm. Starting Weight, in Humidity Chambers				
	0% RH[a]	20% RH	45% RH	70% RH	90% RH
Casein	−50	−18	0	43	95
Magnesium trisilicate	−82	−20	3	17	30
Thiamine hydrochloride	−40	−6	2	4	30
Magnesium carbonate	−15	−2	0	8	22
p-Aminobenzoic acid	0	0	0	0	33
Methylene blue	−40	−2	0	113	135
Polyglycol E4000 (Dow)	−19	−18	−11	5	125
Polyglycol E20,000 (Dow)	−11	−10	−7	2	44
Sodium diphenylhydantoinate	−10	−2	4	239	291
Corn starch	−99	−24	2	40	88
Sodium phenobarbital	−16	..	6	..	91
Methocel 4000 cps. 90 Hg	−59	−20	10	69	141
Procaine base	0	0	0	0	154

[a] RH, relative humidity.

Received May 8, 1961, from the University of Arkansas, School of Pharmacy, Little Rock.
Accepted for publication June 30, 1961.
The author appreciates the suggestions and assistance of Drs. L. M. Wheeler and L. M. Lueck, Parke, Davis and Co.

If a powder neither gained nor lost weight it was presumed to be essentially free from water vapor sorption characteristics and was not further studied. Table II lists several powders that neither gained nor lost weight in these humidity chambers.

TABLE II.—POWDER SAMPLES THAT NEITHER GAINED NOR LOST WEIGHT (LESS THAN ±0.5%) DURING SCREENING TESTS IN HUMIDITY CHAMBERS

Sulfathiazole	Phenothiazine
Phenobarbital	Hydroquinone
Benzocaine	Diphenylhydantoin
Tetracaine base	Chloramphenicol
Talc	Codeine alkaloid
Quinine alkaloid	Holocaine hydrochloride
Cincophen	Prochlorperazine maleate
Niacin	Procaine hydrochloride
Niacinamide	Aminopyrine
dl-Amphetamine sulfate	Aminophylline

Determination of Water Vapor Sorption Isotherms in Humidity Chambers

Accurately weighed samples, approximately 2 Gm. each, of desiccated powders in tared glass weighing bottles of such diameter that the loosely spread powder was less than 0.5 cm. deep, were placed in a humidity chamber which consisted of a large Pyrex glass desiccator, and dried at 110° under reduced pressure for 4 hours, when melting points permitted. The powder samples, some of which were recrystallized, were seived through 100-mesh screens. After the final weighing, conducted in such manner as to avoid sorption of atmospheric water vapor, concentrated sulfuric acid was introduced into the lower portion of the chamber and the top sealed in place. Normal atmospheric pressure and content existed in the humidity chamber at all times during the determination. The assembly was placed in a constant temperature water bath maintained at 25 ± 0.2° and allowed to equilibrate for about 1 week. At the end of this time the powders were weighed swiftly on a projection balance with due caution to avoid sorption of atmospheric water vapor. Subsequently, solutions of sulfuric acid and water were introduced into the chamber bottom to give increases in relative humidity of 10–20% each week. An aliquot portion of this solution was titrated with standard base at each weighing time to determine precisely the equilibrium concentration. The relative humidity corresponding to concentration of sulfuric acid was found by reference to the International Critical Table (6).

The desorption isotherm was obtained by reducing the relative humidity in the chamber by weekly increments similar to those used in the sorption study.

Discussion of the Sorption and Desorption Isotherms Obtained in Humidity Chambers.—The shape of the isotherms obtained in this study (Figs. 1–4) were reproducible; however, precise reproduction of points on the curves was not usually achieved. Perhaps surfaces of the particles were altered during the several weeks of each study, for a second determination with a given sample did not yield precisely the same result as the first. Close agreements were obtained with successive samples of the same powder.

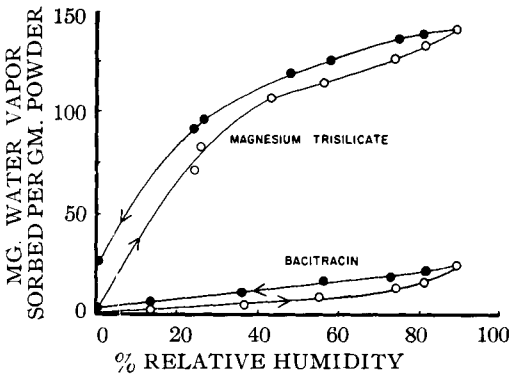

Fig. 1.—Sorption and desorption of water vapor in relative humidity chambers (25°) on 100-mesh powders. ○, Sorption; ●, desorption.

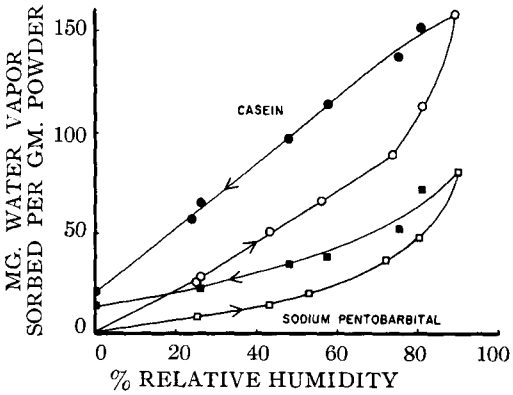

Fig. 2.—Sorption and desorption isotherms (25°) obtained in humidity chambers using 100-mesh powders. The closed points indicate desorption portion of curves.

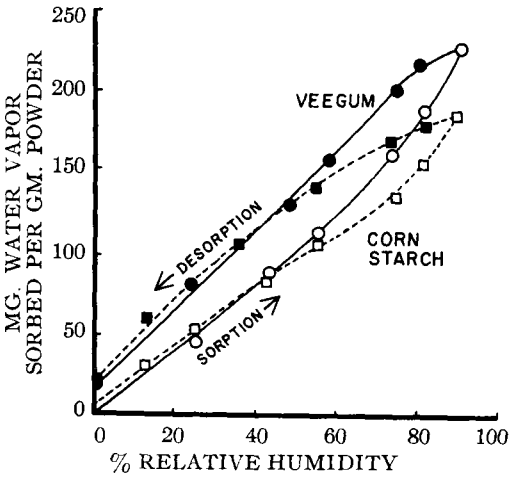

Fig. 3.—The sorption and desorption of water vapor observed in humidity chambers (25°). The Veegum (R. T. Vanderbilt Co., colloidal magnesium aluminum silicate) samples, used without sieving, consisted of particle sizes ranging from small flakes to fine powder.

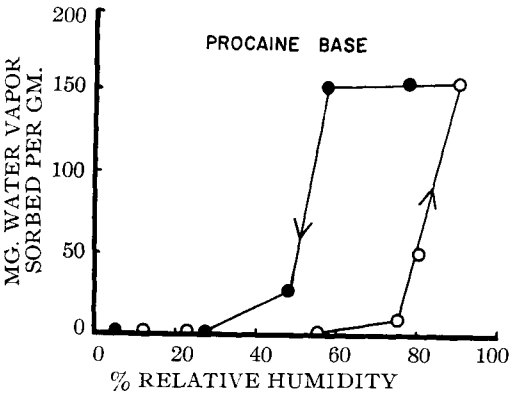

Fig. 4.—The sorption-desorption isotherm of procaine base powder, 100 mesh, in humidity chambers (25°) was influenced by formation of a dihydrate. This behavior was elucidated by further study in the quartz spring sorption apparatus. O, Sorption; ●, desorption.

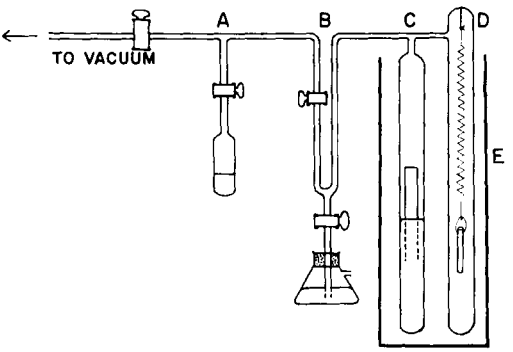

Fig. 5.—Diagram of the vapor sorption apparatus. A, Water vapor reservoir; B, mercury trap; C, Dubrovin gauge; D, sample chamber; E, water bath.

The pronounced hysteresis loop of the desorption curve found in many of these isotherms may be due in large measure to failure to attain equilibrium on the sorption curve and/or on the desorption curve. Hysteresis has been encountered in other systems and can be accounted for in different ways aside from lack of equilibrium, such as the "ink bottle" theory, but the hysteresis shown here was reproducible and it existed in the same magnitude even though extended periods were allowed for equilibration.

Determination of Water Vapor Sorption Isotherm with Quartz Spring Sorption Apparatus

The isotherm for procaine base (Fig. 4) was substantially different than that for most powders. Procaine base is known to form a dihydrate when recrystallized from ethanol-water solutions (9) and has been described as a hygroscopic powder (10); however, literature search did not reveal studies on the nature of this water vapor sorption. Consequently, an apparatus was constructed (Fig. 5) which permitted study of the mode of water vapor sorption and was capable of yielding data pertaining to the energy of hydration. The essential difference in the data obtained in this apparatus and that previously described was that this hydration takes place in the presence of water vapor alone and was not subject to the ambiguities introduced by the presence of atmospheric gases.

Equipment.—The apparatus (Fig. 5) consisted of two large connected tubes, one of which contained a quartz spiral spring from which the sample was suspended. The quantity of water sorbed by the powder was obtained gravimetrically by measuring the extension of the quartz spring, which had the following characteristics: unloaded length approximately 6 cm., extension of 1 cm. per 51 mg. added weight, and a maximum load of 2 Gm. The second tube contained a Dubrovin gauge (11) having a multiplication factor of 4.91. Both the extension of the quartz spring and the position of the Dubrovin tube were determined with a cathetometer which could be read to ±0.01 cm. The water bath, in which the assembly was immersed was maintained at 23.6 ± 0.1° by a temperature regulator-stirrer.

Procedure.—Recrystallized samples of procaine base were sieved through 100-mesh screen and dried under vacuum. An accurately weighed sample of approximately 1 Gm. was suspended, in a cylindrical waxed-paper container, from the lower hook of the quartz spring. After the sample and spring were sealed in place, the apparatus was evacuated at less than 0.1 cm. mercury pressure for approximately 3 hours, after which time the system was isolated by closing the stopcock and raising the mercury seal (Fig. 5). After initial readings of pressure and spring extension with the cathetometer, water vapor was introduced into the assembly from the water reservoir. Sorption appeared to be complete in about 8 hours, however, 24 hours was the usual time allowed for equilibration, after which pressure and spring extension were determined. Increments of 10 to 20 mg. of water vapor were admitted daily to the sample chamber. When the water vapor rose to about 2.10 cm. mercury corresponding to $p/p_0 = 0.96$ (p_0 for water at 23.6° is 2.185 cm. Hg) (12) the determination of the sorption isotherm was considered complete. The desorption isotherm was subsequently determined by removing daily increments of water vapor with the vacuum pump until the water vapor pressure was reduced to about 0.1 cm. of mercury.

Discussion of Results.—The sorption and desorption isotherms obtained in the quartz spring sorption apparatus were essentially identical and did not exhibit the hysteresis observed in results from humidity chambers. Since desorption data were somewhat more precise than that obtained on initial sorption, it was utilized in this report. The isotherm seen in Fig. 6 (data in Table III) indicated the formation of a dihydrate without evidence of a monohydrate, at an equilibrium water vapor pressure of 1.26 cm. Hg ($p/p_0 = 0.57$).

Equilibrium pressures obtained at other temperatures, shown in Table IV and plotted in Fig. 7 yielded a net ΔH (thermodynamic enthalpy of the reaction) of -29.6 ± 3 Kcal. per mole of procaine for the following reaction

$$\text{Procaine}_{(\text{solid})} + 2H_2O_{(\text{gas})} \rightarrow \text{Procaine}\cdot 2H_2O_{(\text{solid})}$$

The order of the reaction between water vapor and procaine base powder was investigated by

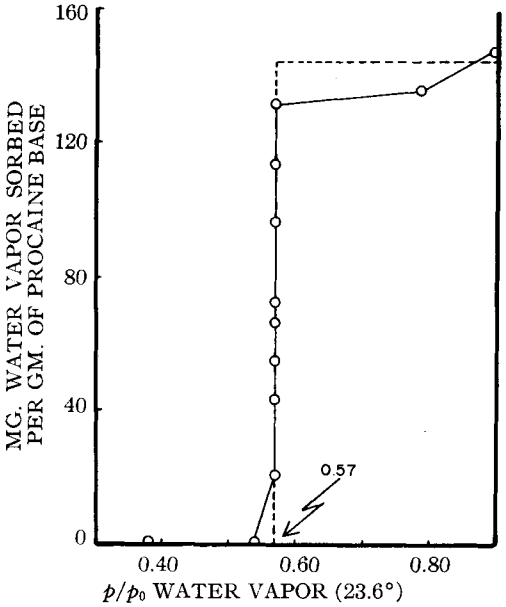

Fig. 6.—This isotherm shows the hydration of procaine base as it occurs in the presence of water vapor alone. The departure from theory at the upper portion of the isotherm may be due to failure to achieve equilibrium occasioned by the decreasing amount of unhydrated procaine base and the accompanying increase in difficulty of water vapor diffusion through the crystals as hydration nears completion. ---, Theory; ——, actual.

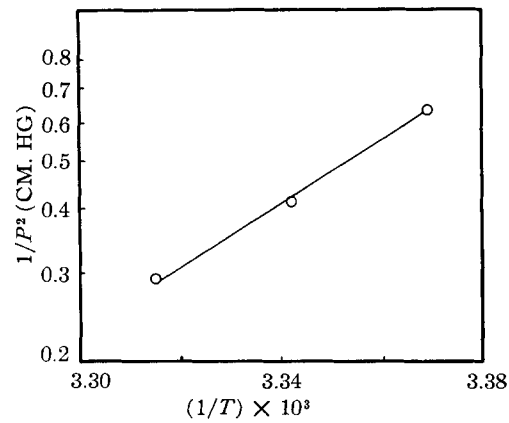

Fig. 7.—A Clausius-Clapeyron plot of temperature *vs.* equilibrium pressure between water vapor, procaine base, and procaine base dihydrate to obtain the energy evolved in this hydration (see Table IV).

studying the rate of hydration. This was accomplished by measuring the weight gain of the sample as a function of time while maintaining a relatively constant water vapor pressure of about 2.0 cm. Hg (corresponding to a p/p_0 of 0.90 to 0.95). The result, seen in Fig. 8, indicated a zero-order reaction. Perhaps the rate limiting factor was the diffusion of water molecules from the surface to the interior of crystals.

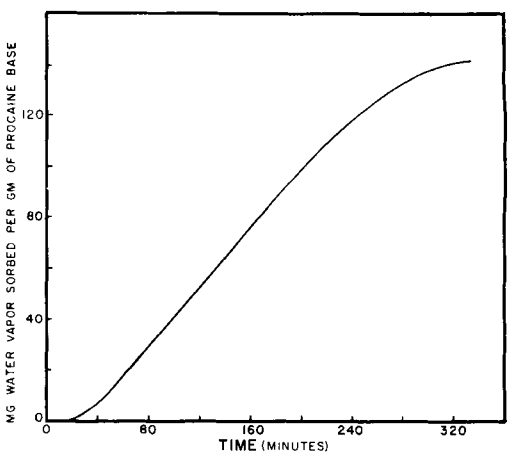

Fig. 8.—The rate of hydration of a sample of procaine base, 100-mesh powder, in water vapor (p/p_0 of 0.90-0.95) at 23.6°. The straight line portion of the curve indicated a zero-order reaction.

TABLE III.—EQUILIBRIUM PRESSURES OF WATER VAPOR WITH PROCAINE BASE OBTAINED IN THE QUARTZ SPRING SORPTION APPARATUS

Mg. of Water Sorbed per Gm. of Procaine Base	Water Vapor Pressure at Equilibrium, cm. Hg	p/p_0 at 23.6° (p_0 = 2.185 cm. Hg)

TABLE IV.—EQUILIBRIUM PRESSURES OF PROCAINE DIHYDRATE AND WATER VAPOR AT DIFFERENT TEMPERATURES

Temperature, °C.	$1/T \times 10^3$	Pressure, cm. Hg	$1/p^2$
23.6	3.369	1.26	0.630
26.0	3.342	1.56	0.411
28.5	3.315	1.85	0.292

CONCLUSIONS

The hygroscopic nature of several medicinal powders has been studied. The methods employed were designed to yield data suitable for use in the fabrication and study of pharmaceutical systems such as tablets, capsules, granules, and powders. The study of hygroscopic powders in relative humidity chambers yielded isotherms that exhibited hysteresis, indicating that sorption and desorption of water vapor by common

pharmaceutical powders was not a freely reversible process. Procaine base was cited as an example of powder exhibiting an unusual sorption of water vapor which can be accounted for by formation of a crystalline dihydrate.

Standardization of Fibrinolytic Preparations

Measurement of Proteolytic and Activator Activity of Streptokinase-Activated Human Plasminogen

By WERNER BAUMGARTEN, JOSEPH L. CIMINERA, and SUZANNE M. VAN PELT

Methods for the determination of proteolytic and activator activity of streptokinase-activated human plasminogen are presented. These assay procedures extend previously published methods by the incorporation of a suitable standard and improved experimental design. The experimental bias is minimized and, by test of validity, differences in preparations can be realized.

IN THE LAST few years fibrinolytic agents have been developed which can assist in the clinical dissolution of venous and arterial clots. Several of these agents have become commercially available and, consequently, standardization of these preparations has become of considerable interest.

A fibrinolytic preparation[1] has been made commercially available by our laboratory. This is a streptokinase-activated human plasminogen preparation. The activity of fibrinolysin has been determined by a fibrinolytic assay procedure (1) which measures the total activity of the preparation. It has been established, however, that fibrinolysin possesses two distinct properties which contribute to its enzymatic activity (2–4). Streptokinase reacts with a proactivator present in human plasminogen producing an activator. The resulting activator then converts the proteolytic precursor which is also present in the human plasminogen into the active enzyme.

In the fibrinolytic assay the total activity is measured; however, it is possible to determine the proteolytic and activator activity separately.

Several procedures (5, 7–9) have been described in the literature; however, they are lacking in statistical treatment and omit the use of an appropriate standard. In our laboratory a self-contained slope ratio assay for the caseinolytic and activator activity of fibrinolysin preparations has been developed. A self-contained assay includes a reference standard and provides statistical procedures for testing the validity of the assay and methods for estimating the relative potency and error of the assay.

Over a limited range of concentration, fibrinolysin preparations give a linear response and in the assay, concentrations are chosen which fall on this linear portion of the curve.

Measurement of the proteolytic activity is done by the direct caseinolytic assay in which the degree of hydrolysis of the casein substrate is determined. In the activator assay added plasminogen is first converted into the active proteolytic enzyme by the activator present in fibrinolysin. The amount of activator which is required for the enzymatic conversion of the

Standardization of Fibrinolytic Preparations

Measurement of Proteolytic and Activator Activity of Streptokinase-Activated Human Plasminogen

By WERNER BAUMGARTEN, JOSEPH L. CIMINERA, and SUZANNE M. VAN PELT

Methods for the determination of proteolytic and activator activity of streptokinase-activated human plasminogen are presented. These assay procedures extend previously published methods by the incorporation of a suitable standard and improved experimental design. The experimental bias is minimized and, by test of validity, differences in preparations can be realized.

IN THE LAST few years fibrinolytic agents have been developed which can assist in the clinical dissolution of venous and arterial clots. Several of these agents have become commercially available and, consequently, standardization of these preparations has become of considerable interest.

A fibrinolytic preparation[1] has been made commercially available by our laboratory. This is a streptokinase-activated human plasminogen preparation. The activity of fibrinolysin has been determined by a fibrinolytic assay procedure (1) which measures the total activity of the preparation. It has been established, however, that fibrinolysin possesses two distinct properties which contribute to its enzymatic activity (2–4). Streptokinase reacts with a proactivator present in human plasminogen producing an activator. The resulting activator then converts the proteolytic precursor which is also present in the human plasminogen into the active enzyme.

In the fibrinolytic assay the total activity is measured; however, it is possible to determine the proteolytic and activator activity separately.

Several procedures (5, 7–9) have been described in the literature; however, they are lacking in statistical treatment and omit the use of an appropriate standard. In our laboratory a self-contained slope ratio assay for the caseinolytic and activator activity of fibrinolysin preparations has been developed. A self-contained assay includes a reference standard and provides statistical procedures for testing the validity of the assay and methods for estimating the relative potency and error of the assay.

Over a limited range of concentration, fibrinolysin preparations give a linear response and in the assay, concentrations are chosen which fall on this linear portion of the curve.

Measurement of the proteolytic activity is done by the direct caseinolytic assay in which the degree of hydrolysis of the casein substrate is determined. In the activator assay added plasminogen is first converted into the active proteolytic enzyme by the activator present in fibrinolysin. The amount of activator which is required for the enzymatic conversion of the

proteolytic precursor to the active enzyme does not produce measurable casein hydrolysis if plasminogen has been omitted from the reaction mixture. Thus, the hydrolysis of the casein substrate by the activated enzyme is, for all practical purposes, a measure of the activator activity of the fibrinolysin preparation.

MATERIALS AND METHODS

Reagents.—*Preparation of Casein.*—Fifty grams of casein (Hammarsten)[2] is suspended in 1 L. of distilled water and stirred vigorously for 1 hour. The mixture is centrifuged for 10 minutes at 1500 r.p.m. and the supernatant discarded. The casein is resuspended in 1L. of water and the process repeated. The casein is now suspended in 800 ml. of 95% ethanol (3A) and the mixture filtered by suction. The casein is washed twice on the filter with 95% ethanol followed by three washings with absolute ether. Finally, the casein powder is air dried.

Phosphate-Saline Buffer.—Potassium dihydrogen phosphate, 13.6 Gm.; sodium chloride, 9.0 Gm.; *q.s.* to 1L. with distilled water; adjust pH to 7.4 with 5 *N* sodium hydroxide.

Trichloroacetic Acid (TCA), 5% and 10%.

Sodium Carbonate, 20%.

Folin-Ciocalteu Phenol Reagent, Fisher Scientific Co., King of Prussia, Pa.

Preparation of Casein Solution for Assay.—Five grams of dried casein is suspended in 100 ml. of phosphate-saline buffer, pH 7.4, and heated for 15 minutes in a boiling water bath. After cooling, the mixture is centrifuged for 10 minutes at 1500 r.p.m., the supernatant is decanted, and its pH adjusted to 7.4 with 5 *N* sodium hydroxide. The casein solution may be kept in the refrigerator for one week prior to use.

Fibrinolysin Standard.—A number of vacuum sealed vials of fibrinolysin were stored in the refrigerator and designated "standard fibrinolysin preparation."[3] This standard is employed in the caseinolytic as well as in the activator assay.

In the caseinolytic assay a vial of fibrinolysin is quantitatively restored to 10 ml. with distilled water, and aliquots of 0.2 and 0.4 ml. are employed at the two levels of the assay.

For the activator assay the vial of fibrinolysin is restored to a final volume of 5,000 ml. As in the caseinolytic assay, 0.2 and 0.4 ml. of this solution are employed for the two concentrations of the standard.

Assay Procedure.—*Proteolytic Assay.*—The fibrinolysin standard (50,000 fibrinolytic units per vial) is dissolved in distilled water and brought to 10 ml. in a volumetric flask. The standard 0.2 and 0.4 ml. quantities, are pipetted into $^5/_8 \times$ 5-in. test tubes and the volume is adjusted to 1 ml. with phosphate-saline buffer. Tubes containing 0.2 ml. are labeled S_L and tubes 0.4 ml. are labeled S_H. In order to minimize loss of enzymatic activity on standing the tubes are immediately immersed into an ice bath.

The concentration of the test preparation is adjusted by an initial dilution in order to give responses similar to those for the standard. This requires a prior knowledge of the approximate activity of the test preparation. Aliquots of the test solution with the low concentration at one-half that of the high are added to assay tubes labelled T_L and T_H and brought to a volume of 1 ml. with phosphate-saline buffer.

Tubes can be set up in replicate. If duplicate determinations are judged sufficient, a total of three test preparations can be assayed simultaneously against the standard.

While in the ice bath the assay tubes are arranged in the order schematized in Figs. 1, 2, or 3, corresponding to quadruplicate, triplicate, and duplicate tubes, respectively. Figure 3 represents a restricted random allocation for three test preparations and a standard, so that the same duplicate tubes do not appear in the same row or column. An incubated blank containing 1 ml. of phosphate-saline buffer is included in every caseinolytic assay and may be placed at random in the test tube rack.

At zero time, 4.0 ml. of the 5% casein solution is added to the first tube starting at the lower left-hand corner, the solution is mixed, and the tube is placed into the water bath at 37° and incubated for 60 minutes. Casein is added to the remaining tubes at 60-second intervals, the tubes are mixed and placed in the water bath according to the designated scheme. Casein is added to the tubes going from left to right and ending with the tube in the upper right-hand corner. All subsequent manipulations follow the same order as above. The blank is added last. After an incubation of 60 minutes, 2 ml. of the incubated casein mixture is withdrawn from each tube and pipetted into 2 ml. of 10% trichloroacetic acid. The suspension is mixed well, allowed to stand at room temperature for at least 15 minutes, and filtered through S & S

[2] Nutritional Biochemicals Corp., Cleveland 28, Ohio.
[3] Thrombolysin, 50,000 units per vial (1).

No. 576 filter paper by gravity.[4] The following mixture is prepared: 10 ml. distilled water, 3.0 ml. 20% sodium carbonate, and 1.5 ml. 5% TCA. A 0.5-ml. quantity of the filtered digestion mixture is added, followed by 1.0 ml. of the phenol reagent, and the contents of the tubes are mixed thoroughly.

Twenty minutes after the addition of the phenol reagent, the absorbance of the solution is read on a Beckman spectrophotometer at the wavelength of 650 mμ in a 5-cm. absorption cell with a light path of 50 mm. The readings are made against the casein blank.

Activator Assay.—This differs from the proteolytic assay. Human plasminogen is added to each tube and is allowed to react with the fibrinolysin standard or test preparation.

To each assay tube is added 3 mg. (0.3 ml.) of human plasminogen (fraction III-3) (9) and a predetermined volume of phosphate-saline buffer calculated to give a total volume of 1 ml. after taking into account the volume of the activator solution. The tubes are arranged according to the scheme in Fig. 4, which represents the same type of restricted random allocation as Fig. 3 except that only two test preparations are being assayed. This represents the maximum number of tubes that can be used practicably for this type assay.

R_3	T_L	S_H	U_L	U_H

Fig. 4.—For duplicate determinations and two test preparations.

If determinations are desired in triplicate, the scheme in Fig. 2 may be utilized.

At 90-second intervals precooled 0.2-ml. and 0.4-ml. aliquots of the standard and appropriate aliquots of the test solution with the low concentration at one-half that of the high are added to the appropriate assay tubes, followed immediately by 0.3 ml. of the casein solution, going from left to right, starting in the lower left-hand corner and ending with the tube in the upper right corner. All subsequent manipulations follow the same order as above. Each tube is immediately incubated for 18 minutes at 37°. At that time 3.7 ml. of casein solution is added, and after an additional incubation of 2 minutes, a 2-ml. aliquot is pipetted into 2 ml. of 10% trichloroacetic acid. A second aliquot is removed after an additional 60-minute incubation.

The suspension is mixed well, allowed to stand at room temperature for at least 15 minutes, and filtered. The filtrate is treated as described under proteolytic assay.

Statistical Evaluation of a 4-Point Slope Ratio Assay.—Preliminary trials showed that absorbance was linearly related to concentration of fibrinolysin (i.e., followed the Beer-Lambert law) at least up to an absorbance of 0.8. Variation among replicate tubes was small and constant up to an absorbance of about 0.4; above this the variation became much larger and was less constant. We decided, therefore, to limit the concentration of test materials to such that the absorbance would not exceed 0.5.

A uniformity trial was run in which a standard preparation was assayed against itself. The concentrations tested were S_L = 0.2 ml., S_H = 0.4 ml., T_L = 0.15 ml., and T_H = 0.3 ml. Four tubes of each concentration were tested. The order of placement of the tubes in the water bath was, according to Fig. 1, completely randomized in order to minimize possible positional bias. A protocol illustrating the calculations is shown in Table I. This represents a simplified approximate procedure and the formulas are valid only for the standardized conditions of this assay; i.e., two concentrations of each preparation with the low concentration at one-half that of the high, and four tubes at each concentration. Similar computations are used for triplicate and duplicate tubes, except that the formulas for F and P* are as shown in Table II.

Before proceeding with the estimation of relative potency, it is necessary to make a test for validity of the assay. This is done by comparing the absolute value of $|P|$ with 7W/3. If $|P| \geq 7W/3$, this would indicate that the two response lines do not have a common intercept, and the assay would be fundamentally invalid at $P \leq 0.01$. If $|P| \geq 5W/3$, this would show fundamental invalidity at $|P| \leq 0.05$; however, for most assays, a lack of validity at this level may, for practical reasons, either be ignored or the assay repeated.

A significant lack of common intercept would indicate either that the response(s) for one of the preparations is outside the linear range of response, or else that other factors such as inhibitors or potentiators are present which may modify the response of that preparation. If the apparent lack of common intercept is due to the former, the situation may be corrected by a better selection of concentrations.

The 95% confidence limits estimated from the intrinsic error of the assay may not necessarily reflect the "true" error of the assay. Weighing, dilution, and other technical errors may be larger than the intrinsic error. A more realistic estimate would require the combination of estimates from several replicate assays.

DISCUSSION

Kunitz (10) developed a method for the determination of trypsin based on its ability to digest a casein substrate. Remmert and Cohen (5) adopted this procedure and developed an assay for streptokinase activated human plasminogen. Succeeding authors introduced minor modifications.

The present assay procedure is patterned after that of Remmert and Cohen. It was found that results of identical samples submitted for assay to several independent laboratories varied considerably and it was thought advisable to standardize the assay procedures.

Arbitrarily, a standard fibrinolysin preparation was assigned a unit value and this preparation serves as a house standard in our laboratory. This fibrinolysin is prepared by streptokinase activation of human plasminogen. Earlier authors have ex-

[4] The suspension or filtrate may stand overnight in the refrigerator.

pressed their results in caseinolytic units. This unit was defined as the increase in absorbance at 280 mμ after 60 minutes of incubation at 37° and conversion of the absorbance to micrograms of acid-soluble tyrosine by reference to a standard curve. This procedure possesses definite disadvantages. Changes in experimental condition such as temperature of incubation, presence of inhibitors, and variations in casein substrate do not necessarily become apparent due to the lack of comparison to a standard response.

The new procedure evaluates fibrinolytic preparations by a self-contained statistical assay. The validity of the assay is evaluated and confidence limits are determined.

Separation and Identification of Barbiturates and Some Related Compounds by Means of Gas-Liquid Chromatography

By E. BROCHMANN-HANSSEN and A. BAERHEIM SVENDSEN

Barbiturates and certain related hypnotics have been separated and identified by direct gas chromatography on a number of different stationary phases. Depending on the type and concentration of stationary phase, column temperatures ranging from about 140 to 200° were used. No evidence of decomposition of the substances was observed. The method is rapid and extremely sensitive.

RELATIVELY PURE single barbiturates can easily be identified by a number of methods, including the melting points of derivatives (1–4), infrared spectrophotometry (5–9), X-ray diffraction (10–15), and crystallography (16–20). When several barbiturates are present in a mixture, or when the material is contaminated with decomposition products and/or substances of biological origin, it is usually necessary to perform a separation prior to the identification process. Fractional extraction (21) and countercurrent distribution (22) have been used with some degree of success. Column partition chromatography (23) and adsorption chromatography (24) have given good results for specific problems of limited complexity. However, paper chromatographic procedures with a variety of solvent systems have proved the most satisfactory for more difficult separations (25–29). Yet, there are several combinations of barbiturates which have not been adequately resolved by this method. Furthermore, paper chromatography is somewhat time-consuming and fairly insensitive with respect to barbiturates.

In recent years, gas-liquid chromatography has proved to be an exceptionally valuable tool for qualitative and quantitative analysis of many types of compounds. Development of highly sensitive detectors and the use of columns containing low concentrations of the stationary phase have made the gas chromatographic method applicable to substances of very low volatility.

Attempts to identify barbiturates by gas chromatography have been reported by Janák (30, 31). He pyrolyzed the sodium salts and gas chromatographed the pyrolysis products. This paper describes a method for direct gas chromatographic separation and identification of barbituric acid derivatives and some related substances (32).

EXPERIMENTAL

A Barber-Colman model 15 gas chromatograph equipped with an argon ionization detector was used for the experimental work. The columns were glass U-tubes, 6 feet in length, and having an inner diameter of 3 mm. The solid support was Chromosorb W, 60–80 mesh, washed with concentrated

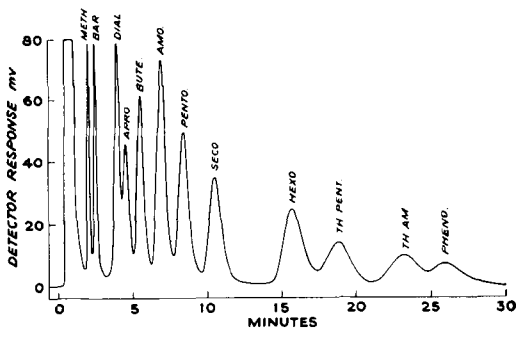

Fig. 1.—Gas chromatogram of 12 barbiturates on Apiezon L. The experimental conditions and the names of the barbiturates refer to Table I.

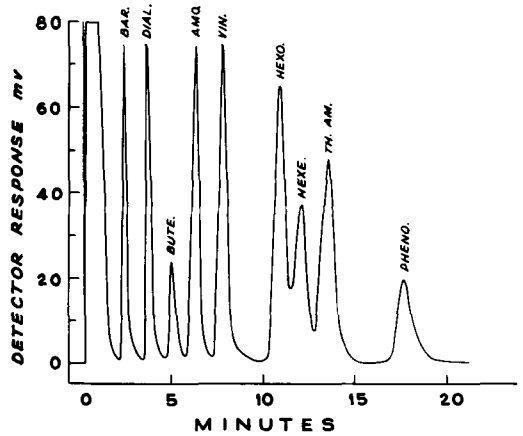

Fig. 2.—Gas chromatogram of nine barbiturates on SE-30. The experimental conditions and the names of the barbiturates refer to Table I.

Received July 25, 1961, from the University of California School of Pharmacy, Medical Center, San Francisco 22.
Accepted for publication September 18, 1961.
This work was supported by a research grant (M-3487) from the National Institutes of Health.

After this paper was submitted for publication, a paper entitled "Separation and Identification of Barbiturates by Gas Chromatography," by K. D. Parker and P. L. Kirk appeared in *Anal. Chem.*, 33, 1378(1961).

hydrochloric acid and methanolic potassium hydroxide, and treated with hexamethyldisilazane to reduce adsorptive effects (33). The stationary phase was applied by means of a solution in toluene or acetone as described by Horning, *et al.* (34).

The barbiturates were introduced with a Hamilton microsyringe as 1.0 μl. of a 0.5 to 1.0% solution in acetone. Sodium salts of barbiturates were converted to free acids by means of dichloroacetic acid in acetone (35).

The results for 21 barbiturates and two related compounds, glutethimide and allylisopropylacetylurea in several stationary phases ranging from nonpolar to very polar materials are shown in Table I. Pentobarbital was used as standard for calculation of the relative retention times. The temperature and pressure were adjusted so as to produce nearly the same retention time for pentobarbital on all columns. This required a temperature of 200° for neopentyl glycol sebacate, while about 140° was sufficient for the silicone rubber materials. Most substances investigated gave sharp single component peaks consistent with absence of decomposition. In a few instances, one or two small additional peaks were observed due, presumably, to impurities in the samples available. The efficiency of the gas chromatographic method for separation of mixtures of barbiturates is illustrated in Figs. 1–4. Amobarbital and pentobarbital which are difficult to separate by paper chromatography, are separated nicely on an Apiezon L column (Fig. 1). Figure 4 shows a gas chromatogram obtained with nonlinear temperature programming from 150 to 225° on a polyester column. Temperature programming extends the range of application, shortens the time, and makes the component peaks sharper. Not all

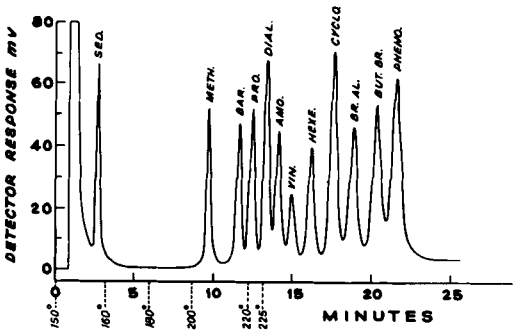

Fig. 4.—Gas chromatogram of 11 barbiturates and allylisopropylacetylurea (Sedormid) on NGSE obtained by nonlinear temperature programming.

substances examined could be separated on the same column. However, by using two columns, one with a nonpolar stationary phase such as Apiezon and one with a moderately polar polyester phase, a large number of possible combinations could easily be separated. The components were identified on the basis of their relative retention times (Table I). This method was used for identification of barbiturates in a number of pharmaceutical preparations.

DISCUSSION

The rate at which a solute travels through a gas chromatographic column depends on the vapor pressure of the pure compound and its activity coefficient in the stationary phase. With a nonpolar stationary phase where there is little or no interaction between solute and solvent, the separation in the column is largely a function of the vapor pressures of the pure substances. With an increase in the polarity of the stationary phase, various types of solute-solvent interaction take place, and the activity coefficient, expressing the lack of ideality of the solution, becomes an important component of the partition coefficient (36). For example, phenobarbital is eluted before cyclobarbital on an Apiezon column, as one might expect on the basis of their relative vapor pressures. On a polar column, such as a polyester or polyethylene glycol, the stationary phase causes more polarization of the phenyl ring than of the cyclohexenyl ring, and the elution sequence is reversed. A similar situation exists in the case of pentobarbital and vinbarbital which only differ by a double bond in one of the substituents in position 5.

Pentobarbital and secobarbital can easily be separated from their corresponding thio analogs on a nonpolar liquid (Fig. 1), but not on a polar liquid such as polyethylene glycol.

In Fig. 5 the relative retention times of a selection of barbiturates are plotted against the stationary phases arranged in the order of increasing polarity. The slopes of the curves indicate the degree of interaction between solute and solvent relative to that of pentobarbital. A positive slope would mean an increase in the activity coefficient over that of pentobarbital, and vice versa. As one would expect, the 1-substituted barbiturates, as well as the 2-thio barbiturates, exhibit negative slopes.

Dow Corning fluorosilicone fluid QF-1-0065 is a polar compound and has been used successfully for separation of steroids because of its great selectivity (37). It did not prove to be of any particular value for separation of barbiturates. It behaved as a very polar liquid in preventing the separation of pentobarbital and secobarbital from their corresponding thio analogs. On the other hand, it showed nonpolar behavior toward phenobarbital and cyclobarbital and similarly related compounds.

The gas chromatographic method gives promise of being an excellent tool, not only for analysis of barbiturates in pharmaceutical dosage forms, but also for fundamental studies of their rates and mechanisms of *in vitro* and *in vivo* transformations.

SUMMARY

Twenty-three barbiturates and related compounds, including glutethimide and allylisopropylacetylurea have been gas chromatographed on columns containing stationary phases of varying polarity. By means of two columns, one with Apiezon L and one with a moderately polar polyester, most commonly used barbiturates can be separated. This method has been used for rapid identification of barbiturates in pharmaceutical preparations.

Color Stability of Tablet Formulations V

Effect of Ultraviolet Absorbers on the Photostability of Colored Tablets

By L. LACHMAN, T. URBANYI, S. WEINSTEIN, J. COOPER, and C. J. SWARTZ

The photostabilizing effect of the ultraviolet absorber 2,4-dihydroxybenzophenone for tablets colored with three certified dyes was evaluated. Two sources of light were employed; one approximating the spectral energy distribution of sunlight and the other simulating ordinary room illumination. The apparent rates of fading for FD&C Yellow No. 5, FD&C Blue No. 1, and FD&C Red No. 3 were determined under each light source. The relationship existing between the protective properties of the ultraviolet absorber, the absorption characteristics of the dyes, and the spectral energy distribution of the artificial light sources is discussed.

THE STATUS of certified colorants continues to be closely scrutinized by the Food and Drug Administration. With the delisting of FD&C Red No. 1, there remain 11 certified dyes available for use in foods, drugs, and cosmetics. Temporary authorization for the continued use of FD&C and D&C colorants has been given, subject to the possibility that such use may be terminated or restricted. In view of the pending restrictions inherent with the use of colorants, maximum utilization of the certified dyes has become essential. This has stimulated interest in the pharmaceutical industry for developing methods of improving the stability of the limited number of available certified dyes.

One approach for improving the photostability of dyestuffs has been the use of ultraviolet absorbing chemicals. Chemical compounds such as 3,5-dinitrobenzoic acid (1), benzoyl resorcinols (2), alkylated 2-hydroxyphenylbenzotriazole, and derivatives of 2-hydroxybenzophenones (3) have been employed effectively as photostabilizing agents in industries such as textiles, plastics, paints, and cosmetics. These compounds are selected because they possess high absorptivity and good stability in the 300–400 mμ ultraviolet region without absorbing in the 400–800 mμ visible region. Since many FD&C colorants absorb radiation in the near ultraviolet and visible region of the spectrum, the use of an ultraviolet absorber in conjunction with these colorants should result in some stabilizing influence. This effect, however, would be governed by the spectral energy distribution of the light source used and the absorption characteristics of the colorants.

This study was initiated to determine the influence of an ultraviolet absorber, namely 2,4-dihydroxybenzophenone, on the photostability of tablets colored with three FD&C dyes representing different chemical classes. The colorants were selected so that they would exhibit absorption maxima throughout the visible spectrum (430, 540, and 640 mμ). The photostability of

Color Stability of Tablet Formulations V

Effect of Ultraviolet Absorbers on the Photostability of Colored Tablets

By L. LACHMAN, T. URBANYI, S. WEINSTEIN, J. COOPER, and C. J. SWARTZ

The photostabilizing effect of the ultraviolet absorber 2,4-dihydroxybenzophenone for tablets colored with three certified dyes was evaluated. Two sources of light were employed; one approximating the spectral energy distribution of sunlight and the other simulating ordinary room illumination. The apparent rates of fading for FD&C Yellow No. 5, FD&C Blue No. 1, and FD&C Red No. 3 were determined under each light source. The relationship existing between the protective properties of the ultraviolet absorber, the absorption characteristics of the dyes, and the spectral energy distribution of the artificial light sources is discussed.

THE STATUS of certified colorants continues to be closely scrutinized by the Food and Drug Administration. With the delisting of FD&C Red No. 1, there remain 11 certified dyes available for use in foods, drugs, and cosmetics. Temporary authorization for the continued use of FD&C and D&C colorants has been given, subject to the possibility that such use may be terminated or restricted. In view of the pending restrictions inherent with the use of colorants, maximum utilization of the certified dyes has become essential. This has stimulated interest in the pharmaceutical industry for developing methods of improving the stability of the limited number of available certified dyes.

One approach for improving the photostability of dyestuffs has been the use of ultraviolet absorbing chemicals. Chemical compounds such as 3,5-dinitrobenzoic acid (1), benzoyl resorcinols (2), alkylated 2-hydroxyphenylbenzotriazole, and derivatives of 2-hydroxybenzophenones (3) have been employed effectively as photostabilizing agents in industries such as textiles, plastics, paints, and cosmetics. These compounds are selected because they possess high absorptivity and good stability in the 300–400 mμ ultraviolet region without absorbing in the 400–800 mμ visible region. Since many FD&C colorants absorb radiation in the near ultraviolet and visible region of the spectrum, the use of an ultraviolet absorber in conjunction with these colorants should result in some stabilizing influence. This effect, however, would be governed by the spectral energy distribution of the light source used and the absorption characteristics of the colorants.

This study was initiated to determine the influence of an ultraviolet absorber, namely 2,4-dihydroxybenzophenone, on the photostability of tablets colored with three FD&C dyes representing different chemical classes. The colorants were selected so that they would exhibit absorption maxima throughout the visible spectrum (430, 540, and 640 mμ). The photostability of

Received April 28, 1961, from the Research Department, Ciba Pharmaceutical Products, Inc., Summit, N. J.

these colorants in tablets with and without an ultraviolet absorber was studied upon exposure to two light sources, one approximating the spectral energy distribution of sunlight and the other ordinary artificial room illumination under normal and exaggerated light intensity.

EXPERIMENTAL

Materials.—FD&C Blue No. 1 (triphenylmethane dye), FD&C Red No. 3 (xanthene dye), and FD&C Yellow No. 5 (pyrazolone dye), H. Kohnstamm Co. 2,4-Dihydroxybenzophenone, Antara Chemical Co.

Equipment.—Gossen Tri Lux foot candle light meter, model C. Stokes model F tablet press. Beckman spectrophotometer model DU with reflectance attachment (5). Light stability cabinets exhibiting normal and exaggerated illumination. Light cabinet utilizing a General Electric type R.S. sunlamp (similar to the cabinet employed for normal illumination studies). In a previous report (4) a detailed description and discussion were presented on the light sources employed to simulate normal and exaggerated room illumination. However, a description of the light source used to simulate sunlight has not hitherto been presented. The lamp used is a self-contained unit with a 100-watt mercury discharge element and a 175-watt tungsten-filament resistance ballast incorporated into an ultraviolet transmitting reflector type bulb. The sunlamp emits energy in the ultraviolet and visible spectrum as shown in Fig. 1. It is interesting to note that its visible energy spectrum encompasses approximately the same wavelength range as does the cool white fluorescent lamp used in the normal illumination cabinet. The peak energy output for the sunlamp within this spectral range is greater than that emitted by the fluorescent lamp. The sunlamp is made with special glass which absorbs the shorter ultraviolet rays up to 280 mμ, thus simulating atmospheric absorption of the shorter violet rays emitted by the sun.

Preparation of Tablets.—Tablets containing water-soluble dyes with and without ultraviolet absorbers were prepared according to the following formulas

	With Ultraviolet Absorber, %	Without Ultraviolet Absorber, %
Calcium sulfate dihydrate	94.49	96.99
Tragacanth U.S.P.	2.00	2.00
2,4-Dihydroxybenzophenone	2.50	...
Magnesium stearate U.S.P.	1.00	1.00
Dye	0.01	0.01
Ethyl alcohol 50%	*q.s.*	*q.s.*

Granulations were prepared in accordance with commonly employed tabletting techniques. The colorants and the ultraviolet absorber were dissolved in 50% alcohol which was then used as the granulating solution. The granulations were dried to a moisture content below 0.5% and compressed into tablets using $^{8}/_{32}$ inch flat faced punches, uppers bisected, on a Stokes model F tablet press. The tablets were compressed to a weight of 100 mg. with a thickness of 1.5 mm. and a hardness of 8 Kg./in.^{2}.

Storage of Samples.—Samples of each of the colored tablets, with and without ultraviolet absorber, were placed into glass Petri dishes and then stored in light cabinets simulating normal and exaggerated room illumination. Samples were also stored in a light cabinet in which a General Electric type R.S. sunlamp emitted light with a spectral energy distribution simulating sunlight. The heat radiated by the sunlamp was dissipated by an integrated blower system which maintained the temperature in the cabinet at 40°. The intensity of the light incident on the tablets in the respective cabinets was kept at a constant level through measurement with a Gossen Tri Lux meter at regular time intervals. The light intensities on the tablets in the normal and exaggerated light cabinets were 45 and 550 foot candles, respectively, with a spectral energy range from 350 to 700 mμ (Fig. 1). The intensity of light incident on the tablets in the cabinet using the sunlamp was 700 foot candles with a spectral range of 280 to 700 mμ (Fig. 1). Tablet samples were removed from the cabinets at designated time intervals for reflectance measurements.

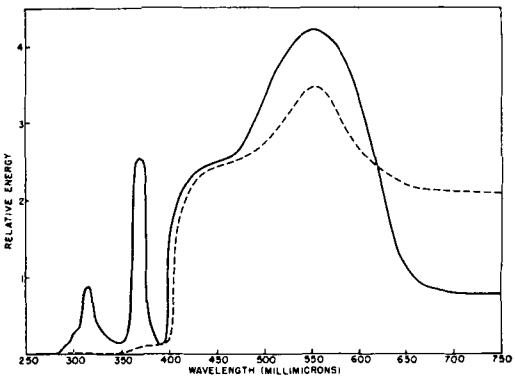

Fig. 1.—Spectral energy distribution of R.S. sunlamp and standard cool white fluorescent lamp. ——, R.S. sunlamp; – – –, cool white fluorescent lamp.

Measurement of Tablet Reflectance.—The procedure and equipment employed to follow changes in reflectance at the surface of the tablet were described in previous reports (5, 6). Reflectance measurements were taken at 430 mμ for FD&C Yellow No. 5, 540 mμ for FD&C Red No. 3, and 640 mμ for FD&C Blue No. 1.

RESULTS AND DISCUSSION

The protection provided by 2,4-dihydroxybenzophenone on the light-induced fading of tablets colored with FD&C Blue No. 1, FD&C Red No. 3, and FD&C Yellow No. 5 was evaluated after exposure to three lighting conditions. This ultraviolet absorber was chosen because it did not impart any significant color to the tablets, exhibited good ethanol solubility, was nontoxic, and had high absorptivity throughout the ultraviolet region and into the violet-blue region of the visible spectrum. Representative curves showing the transmission characteristics of this ultraviolet absorbing chemical at 0.025% and 0.25% concentrations in methanol are presented in Fig. 2.

The plots in Figs. 3–8 show the influence of sunlamp illumination and normal and exaggerated room

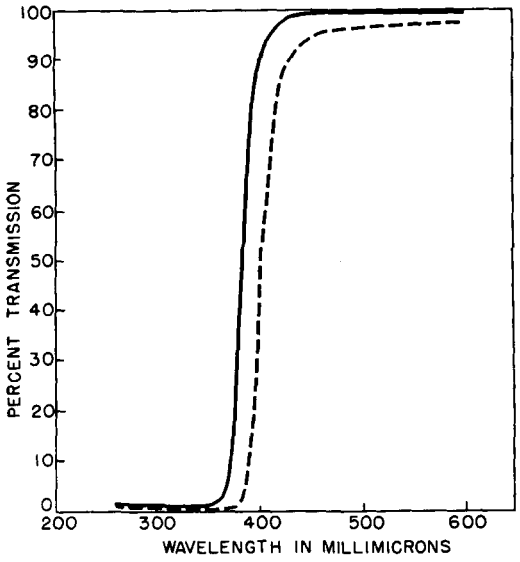

Fig. 2.—Absorption characteristics of ultraviolet absorber 2,4-dihydroxybenzophenone. ——, 0.025%, 2,4-dihydroxybenzophenone 400 in methanol; – – –, 0.25%, 2,4-dihydroxybenzophenone 400 in methanol.

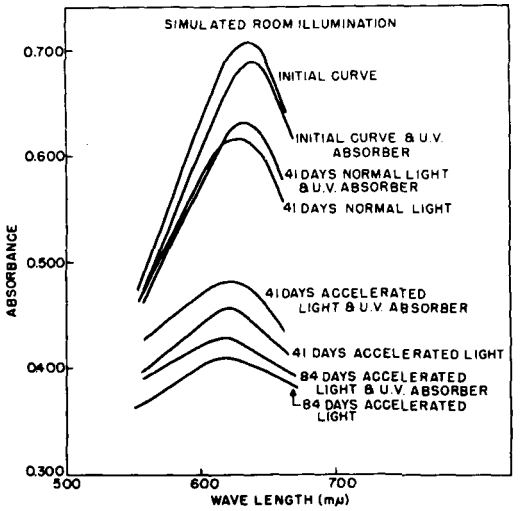

Fig. 5.—Visible absorption spectra of FD&C Blue No. 1 after intervals of storage under normal and exaggerated illumination.

lighting on the spectral absorbance at the surface of the colored tablets. It is apparent from Figs. 3 and 4 that the ultraviolet absorber does not significantly protect tablets colored with FD&C Red No. 3 when these are exposed to the three light sources. It is evident, however, that the tablets exposed to the radiations emitted from the sunlamp undergo more rapid fading than those exposed to exaggerated room lighting. This was also found to be true for the tablets colored with FD&C Blue No. 1 and FD&C Yellow No. 5.

The tablets colored with FD&C Blue No. 1 containing an ultraviolet absorber, were significantly protected from fading when exposed to each light source. The greatest protection occurred with regard to radiations from the sunlamp, as shown in Figs. 5 and 6. In studying the curves in Fig. 5, it is difficult to explain the protective action of the ultraviolet absorber for the FD&C Blue No. 1 dye when considering its ineffectiveness with FD&C Red No. 3. In fact, the absorption maximum for FD&C Blue No. 1 is at 640 mμ which is about 100 mμ further in the visible spectrum than FD&C Red No. 3. However, by studying the complete absorption curve for FD&C Blue No. 1 as shown in Fig. 6, it becomes readily apparent that the blue color has two absorp-

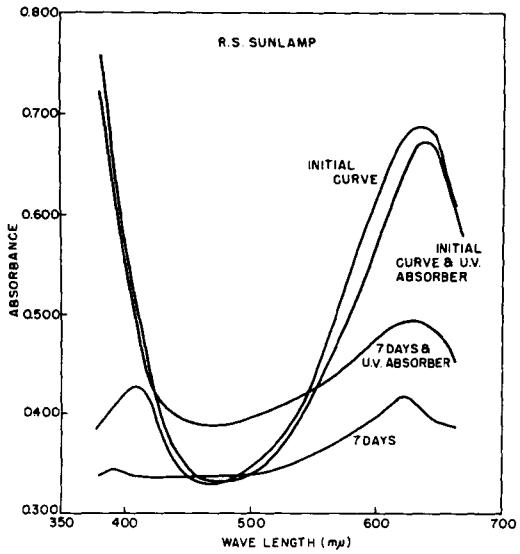

Fig. 6.—Visible absorption spectra of FD&C Blue No. 1 after intervals of storage under simulated sunlight.

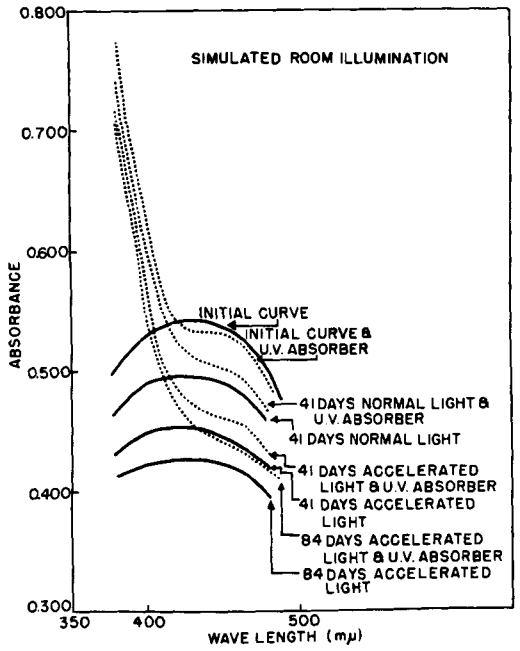

Fig. 7.—Visible absorption spectra of FD&C Yellow No. 5 after intervals of storage under normal and exaggerated illumination.

tion maxima, one at 640 mμ and another approaching the near ultraviolet 410 mμ. The absorption maximum at 640 mμ is much stronger than the one at 410 mμ. However, because of the strong absorbing tendencies of the ultraviolet absorber in the vicinity of 410 mμ peak of blue color, it would tend to protect this portion of the absorption curve of the dye. In turn, this would lessen the extent of fading at the absorption maximum of 640 mμ. This effect is clearly shown in the absorption curves obtained for

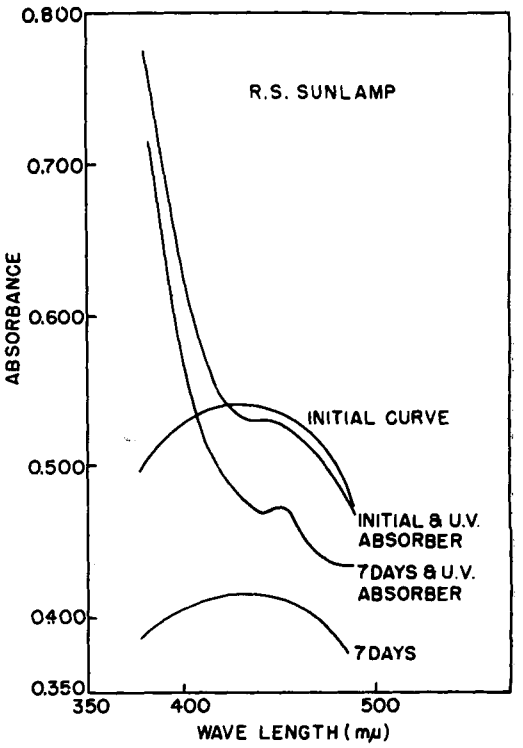

Fig. 8.—Visible absorption spectra of FD&C Yellow No. 5 after intervals of storage under simulated sunlight.

the tablets exposed to the radiations from the sunlamp (Fig. 6).

Of particular interest are the absorption curves obtained from the tablets colored with FD&C Yellow No. 5. It is evident from the curves in Figs. 7 and 8 that the absorption characteristics of the yellow color in tablets containing the ultraviolet absorber are drastically altered. This change can be ascribed to the strong absorbing properties of the 2,4-dihydroxybenzophenone in the vicinity of the absorption maximum of the yellow dye, which causes the overall spectral curve to take on the characteristics of the ultraviolet absorber.

The ultraviolet absorbing chemical exhibited its strongest stabilizing effect for the tablets colored with FD&C Yellow No. 5. This can be attributed to the close proximity of the absorption maximum of the color to that portion of the spectrum where the ultraviolet absorber exerts its strongest protective properties.

Representative plots showing the effect of the ultraviolet absorber on the rate of fading of tablets colored with FD&C Blue No. 1 and exposed to R.S. sunlamp and normal and exaggerated room illumination are presented in Figs. 9 and 10. From the linear regression of absorbance with time, it is apparent that the fading is proceeding according to apparent first-order kinetics. The plots show more than one slope and, in each instance, the initial rate of fading was greater than that obtained from the subsequent sections of the curve. Similar plots were obtained for FD&C Yellow No. 5 and FD&C Red No. 3. These results are similar to that found in our previous studies (6–8) and to those found by Baxter, *et al.*

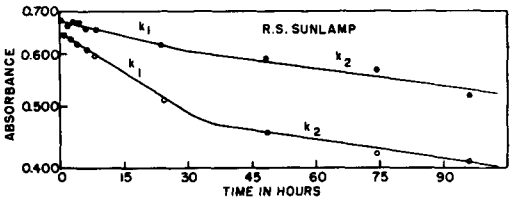

Fig. 10.—Influence of simulated sunlight on the fading of the surface of tablets colored with FD&C Blue No. 1. ○, Without ultraviolet light absorber; ●, with ultraviolet light absorber.

(9), in their investigations of fastness of dyes in textiles. As was indicated previously, the changes in reaction rates that are observed as the duration of irradiation is increased do not necessarily indicate that the fading mechanism consists of a series of consecutive reactions of different rates. Rather, they are generally due to several contributing factors, amongst which are: (*a*) alterations of the quantity of light reflected and absorbed at the surface of the tablet as fading proceeds, (*b*) subsequent changes in the amount of energy available to bring molecules to the excited state, (*c*) possible absorption of certain amounts of energy by the decomposition products, (*d*) porous nature of the tablets, (*e*) influence of substrates on the photoreaction, (*f*) the possibility of reaction between dye and its decomposition products, and (*g*) secondary reactions involving the dye and atmosphere.

Since the rate constants obtained from the first slope of the curve most accurately represent the photodegradation of the dye at the tablet surface, only the initial rate constants will be used in the subsequent discussions. The rate constants calculated from the initial slopes of the plots of log absorbance *vs.* time are summarized in Table I.

The data presented in this table demonstrate that the ultraviolet absorber exerted no significant protective action against fading from the surface of tablets colored with FD&C Red No. 3. However, for tablets colored with FD&C Yellow No. 5 the ultraviolet absorber reduced substantially the fading rate at the tablet surface. It is also apparent from the data in this table that the ultraviolet absorber was most effective against the light radiations from the sunlamp which was composed of significant energy in the near ultraviolet. This can be attributed to the fact that the ultraviolet absorber transmits essentially no light energy up to 400 mμ. The protective action of the ultraviolet absorber against ordinary and exaggerated room illumination was minor as compared to that observed under sunlamp illumination.

The radiations from the sunlamp caused the most rapid fading for each color studied. This may be explained by the fact that the radiations in the ultraviolet spectrum emitted by the sunlamp are more active chemically than the longer visible wavelength radiations.

It is important to note that the R.S. sunlamp radiates a substantial amount of heat as well as light radiations. In order to diminish the influence of heat on the rate of fading of the colored tablets, an exhaust fan was placed into the light cabinet. This reduced the temperature to a constant level of 40°. Thus, in evaluating the data obtained under this light source, one must realize that the fading is due to both light and thermal radiations. In the studies performed under normal and exaggerated room illuminations the temperature of the tablets was maintained at approximately 25°.

From the information obtained in this investigation, it is apparent that ultraviolet absorbing chemicals exert only small, if any, stabilizing effects against fading of colored tablets exposed to normal and exaggerated artificial room illumination. On the other hand, with respect to protection against sun radiations, ultraviolet absorbers can be very beneficial. In certain instances, however, the use of ultraviolet absorbers in the presence of sun radiations may not exert any protective action, as evidenced by the data obtained for tablets colored with FD&C Red No. 3. Hardy and Coleman (10) and Gantz and Sumner (11) also found that ultraviolet absorbers do not protect all dyestuffs.

SUMMARY

1. The photostabilizing effect of the ultraviolet absorber 2,4-dihydroxybenzophenone for tablets colored with three certified dyes was evaluated. These studies were performed under light sources simulating the spectral energy distribution of sunlight and normal and exaggerated room illumination.

2. The relative protective effect of this ultraviolet absorber for the three colors studied was as follows: FD&C Yellow No. 5 > FD&C Blue No. 1 > FD&C Red No. 3.

3. The complete absorption characteristics of the color must be studied when determining the factors responsible for the photostabilizing effects of the ultraviolet absorber.

4. The ultraviolet absorber was most effective against color fading for tablets exposed to simulated sunlight. However, it must be remembered that drugs are rarely exposed to direct or indirect sunlight.

Color Stability of Tablet Formulations VI

Preliminary Study of Temperature Dependency of Colorant Loss in Tablets at Various pH Levels

By C. J. SWARTZ, L. LACHMAN, T. URBANYI, S. WEINSTEIN, and J. COOPER

The influence of temperature and pH on the surface color and total dye content of tablets colored with selected dyes was studied. The representative dyes included were FD&C Red No. 4, Blue No. 1, and Yellow No. 5. Samples of tablets colored with these dyes and buffered at several pH levels were stored at elevated temperatures and tested for both residual dye concentration and fading at their surface. FD&C Red No. 4 was found to be the most stable of the three dyes tested. However, from the results of this study there appears to be no correlation between the fading at the surface of the tablets and the loss in colorant concentration at elevated temperatures.

THE USE of accelerated stability tests for predicting the extended shelf life of pharmaceutical dosage forms has gained considerable acceptance in recent years. Through the application of chemical kinetic principles to elevated temperature storage data, it has been possible to predict accurately the stability of active ingredients at ambient temperatures.

In the past several years a number of reports have appeared in the literature relative to the thermal stability of certified colorants in liquid preparations (1–3). However, little information on the thermal stability of colorants in tablets has been reported. Since tablets constitute the major dosage form in most pharmaceutical companies, a study of color degradation in tablets was essential. Consequently, this study was initiated to evaluate the influence of thermal radiations on dyes when used in tablets.

EXPERIMENTAL

Materials Used.—FD&C Blue No. 1, FD&C Yellow No. 5, and FD&C Red No. 4, H. Kohnstamm and Co. 0.2 *M* Tartrate buffer at pH 3. 0.2 *M* Phosphate-citrate buffer at pH 5. 0.2 *M* Phosphate-tartrate buffer at pH 7.

Equipment.—Precision and Hotpack ovens. Comprex tablet press. Beckman spectrophotometer model DU with reflectance attachment (4). Cary

recording spectrophotometer model 11. Beckman Zeromatic pH meter. Fitzpatrick Homoloid mill. Beckman Aquameter.

Preparation of Tablets.—Tablets containing the water-soluble dyes were prepared unbuffered and at the three pH levels: 3, 5, 7. The tablet formulations prepared for this study were as follows

	Unbuffered, %	pH 3, %	pH 5, %	pH 7, %
Calcium sulfate $\cdot 2H_2O$	96.90	93.42	91.98	89.17
Tragacanth U.S.P.	2.00	2.00	2.00	2.00
Magnesium stearate U.S.P.	1.00	1.00	1.00	1.00
Dye	0.10	0.10	0.10	0.10
Tartaric acid	...	0.75	...	...
Sodium tartrate $\cdot 2H_2O$	...	2.73	...	2.73
Sodium phosphate, primary	...	...	1.58	...
Sodium citrate	...	...	3.34	...
Sodium phosphate, dibasic $\cdot 7H_2O$	...	...	...	5.00
Purified water	*q.s.*	*q.s.*	*q.s.*	*q.s.*

The granulations were made by dissolving the buffer salts in 150 ml. of water at 80° and the dye in 50 ml. of water at 40°. The dye solution was added first to the mixed powders, followed by the buffer solution. The separate addition of the dye and buffer solutions was necessary in order to prevent precipitation of the dye by the buffer salts. All granulations were terminally milled through a Fitzpatrick Homoloid mill using a 050 screen to insure uniform color distribution in the finished tablet. The tablets were compressed on a Comprex tablet press using flat faced $^{8}/_{32}$ inch punches to a hardness of 7 Kg./in.^{2} with a weight of 100 mg. The moisture content of the dried granulations was maintained below 0.5%. The use of the dyes at the 0.1% concentration level was necessary so that sufficient dye would be available to permit accurate extractions for quantitative determination.

Storage of Samples.—Tablets colored with FD&C Red No. 4, Blue No. 1, and Yellow No. 5 were studied in such a manner that light or moisture-induced effects on the color degradation would be kept to a minimum. Indicating Drierite, 100 Gm., was placed into 8-oz. wide-mouth amber bottles which had been previously covered with opaque masking tape. The Drierite was covered with glass wool and 1,000 tablets were added to each bottle and the bottles capped. Sample bottles were stored at 25, 60, and 80 ± 1°. Test samples were withdrawn at designated time intervals for chemical assay and reflectance measurements.

Measurement of Tablet Reflectance.—The techniques and equipment employed to follow changes in the reflectance at the surface of the tablets were described in a previous publication (4). Reflectance measurements were made on the colored tablets at 630 mμ for FD&C Blue No. 1, at 505 mμ for FD&C Red No. 4, and at 430 mμ for FD&C Yellow No. 5.

Spectrophotometric Analysis for Dye Content of Tablets.—The changes in dye concentration with storage were determined in accordance with the following procedure: An adequate number of tablets were ground in a mortar from which a 1.0-Gm. aliquot was accurately weighed and transferred into a glass-stoppered 40-ml. centrifuge tube. The sample was extracted with two 25-ml. portions of methanol followed by two 20-ml. portions of water. Prior to the first aqueous extraction, 5 Gm. of sodium chloride was added to each centrifuge tube. Each extract was filtered through a medium porosity sintered-glass filter into a 100-ml. volumetric flask containing an additional 5 Gm. of sodium chloride. The sodium chloride was employed to coagulate the colloidal tragacanth present in the extract. Following thorough agitation, the solution was brought to 100 ml. with water. A quantity of this solution was passed through a medium sintered-glass filter and complete absorption curves in the visible spectrum were run on the Cary spectrophotometer. As a result of the intense absorption of FD&C Blue No. 1, only 0.5-Gm. samples of tablets containing this dye were used.

Determination of Tablet pH.—Ten tablets were crushed in a mortar and triturated with 10 ml. of purified water. The material was then transferred to a 20-ml. beaker and stirred for 5 minutes. The pH of the suspension was determined, using the Beckman Zeromatic pH meter. The results are recorded in Table I.

TABLE I.—APPARENT pH OF SUSPENSIONS OF CRUSHED TABLETS IN WATER

pH	FD&C Red No. 4	FD&C Yellow No. 5	FD&C Blue No. 1
Unbuffered	6.4	5.9	6.5
3	3.0	3.1	3.0
5	4.9	5.1	5.2
7	6.8	6.6	6.5

RESULTS AND DISCUSSION

The influence of temperature and pH on the thermal stability of colorants in tablets has been investigated. In addition to studying the changes that take place in dye concentration, observations of fading at the tablet surface were made.

A representative plot showing the decrease in the concentration of FD&C Yellow No. 5 stored at 80° for 60 days is shown in Fig. 1. It is evident from this figure that the absorption decreases with storage. The complete curves, however, maintain their characteristics at all the temperature and pH levels tested. The tablets buffered to pH 7 showed the greatest loss of colorant. The curves for the unbuffered and pH 3 tablets have not been presented here, as no breakdown was observed under these conditions.

The per cent total loss of colorants after storage for 60 days at 25, 60, and 80° is summarized in Table II. It is apparent from this data that the tablets colored with FD&C Red No. 4 have exhibited the greatest stability under the conditions of study. Only the tablets buffered at pH 5 showed any loss of

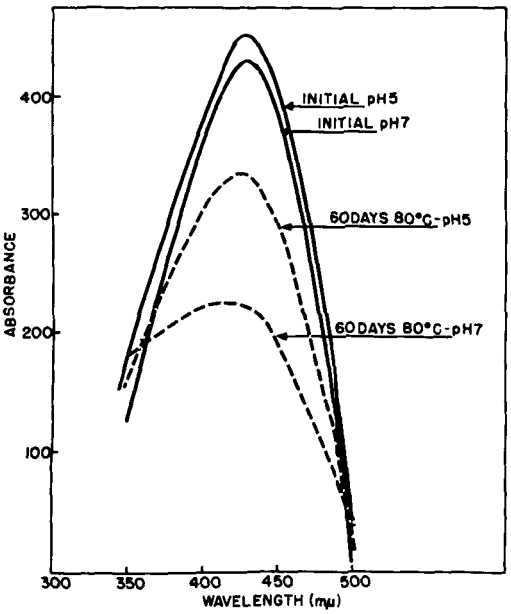

Fig. 1.—The effect of temperature, 80°, on the visible absorption spectra of FD&C Yellow No. 5 dye extracted from tablets.

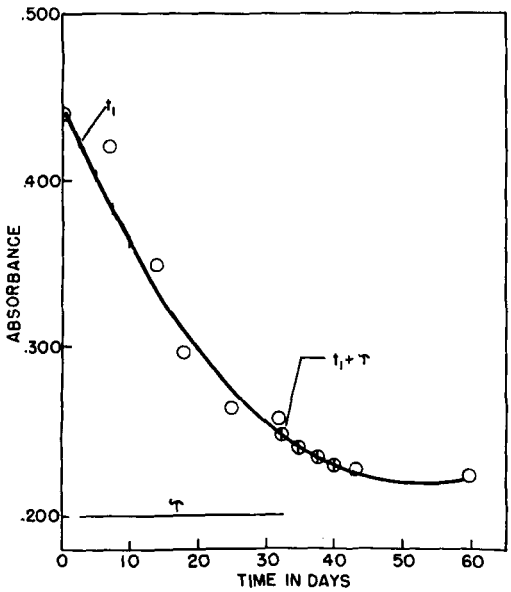

Fig. 2.—Plot of change of absorbance of FD&C Yellow No. 5 at 80°, pH 7, with time.

dye content. In the case of tablets colored with FD&C Yellow No. 5, poor stability is noted in the tablets buffered to a pH of 5 and 7, with the tablets at pH 7 showing approximately twice the loss of those at pH 5. This may be attributed to the action of the buffer salts and/or pH environment created by them. The data for the tablets colored with FD&C Blue No. 1 indicate that loss of dye concentration is essentially pH independent. The per cent loss in dye concentration both at 60 and 80° are of a similar magnitude. It should be noted that at 25° no change in dye concentration resulted for the tablets colored with the three dyes and at the several pH levels.

A representative plot for the change in absorbance with time for the tablets colored with FD&C Yellow No. 5 is shown in Fig. 2. It is evident from this curve that the reaction proceeds to an infinity value. In order to obtain an accurate estimate of the rate of loss of color from the tablets, the loss data was treated according to the method of Guggenheim (5). By employing this technique it is unnecessary to know the value at infinity time. The method is applicable where a property other than concentration is being followed. If t_1, t_2, t_3, and t_4 and $t_1 + \tau$, $t_2 + \tau$, $t_3 + \tau$, and $t_4 + \tau$, are selected where τ is a constant increment, the differential equation for a first-order reaction takes the form

$$\ln (P_t - P_{t+\tau}) + kt = \text{constant}$$

By plotting $\log (P_t - P_{t+\tau})$ *vs.* t, the slope of the line will be equivalent to $-k/2.3$. Therefore, by measuring the slope of this line, one is able to obtain the first-order rate constant for the reaction ($k = -\text{slope} \times 2.3$). The interval τ should be at least two or three times as great as the half-life period of the reaction in order to obtain maximum accuracy.

By the application of the Guggenheim method, the rate constants (k) for loss in colorant concentration were obtained for tablets colored with FD&C Yellow No. 5 at pH 5 and 7 stored at 60 and 80°.

At pH 5: 60° = 5.6×10^{-2} days $^{-1}$; 80° = 12.7×10^{-2} days^{-1}. At pH 7: 60° = 1.43×10^{-2} days^{-1}; 80° = 4.1×10^{-2} days^{-1}.

It is interesting to note that although the samples buffered at pH 5 are degrading at a faster rate, these tablets show only about one-half the loss in total dye concentration when compared with the tablets buffered to pH 7 (Table II). This is due to the fact that the loss curve has a higher infinity value for the tablets buffered to a pH 5 than those at pH 7, thus a lower net rate results. But the rate at which the loss in color reaches the infinity value at pH 5 is faster than that at pH 7 and, according to chemical kinetic principles, the rates obtained here must be used.

In Table III a summary is presented of the surface fading of tablets colored with FD&C Yellow No. 5 and Blue No. 1 and at several pH levels. Uncolored tablets were used as a control and reflectance readings obtained from the surface of these tablets, after storage, were subtracted from the reflectance values obtained with the colored tablets after similar storage. These results show that the fading from the surface of the tablets colored with FD&C Blue No. 1 was small and in the same range for all pH levels. However, for the tablets colored with FD&C Yellow No. 5, a significant surface color change was observed in all the buffered samples. Although there appears to be considerable surface fading for the tablets at pH 3, the color concentration loss obtained at this pH was not of the same order.

As a result of irregularities in the surface hue of tablets colored with FD&C Red No. 4, reflectance data for these tablets have been omitted. It is apparent from the information presented in Tables II and III that there appears to be no correlation between the fading at the surface of the tablets and the loss in colorant concentration. A possible

TABLE II.—PER CENT LOSS OF DYE IN BUFFERED TABLETS AFTER 60 DAYS STORAGE AT VARIOUS TEMPERATURES

60	0	0	0	0	0	0	15	29	11	11	13	8
80	0	0	6	0	0	0	25	48	13	11	19	12

TABLE III.—REFLECTANCE CHANGES AT THE SURFACE OF TABLETS FOLLOWING STORAGE

	FD&C Blue No. 1				FD&C Yellow No. 5			
	Unbuffered	pH 3	pH 5	pH 7	Unbuffered	pH 3	pH 5	pH 7
Initial	1.200	1.120	1.045	1.080	0.825	0.768	0.785	0.770
25°, 60 days	1.175	1.110	1.020	1.030	0.825	0.760	0.760	0.750
80°, 60 days	1.000	0.884	0.851	0.885	0.715	0.500	0.515	0.475

explanation for this is the high concentration of dye used for the tablets.

The pH of the colored and uncolored tablets showed similar variations relative to maintenance of initial pH with storage. A slight decrease in pH was noticed in all cases except for the tablets buffered at pH 3 where essentially no change took place. Initially, it was intended to utilize the same buffer salts (phosphates) for the entire pH range of this investigation; however, it soon became apparent that the buffer capacity of the phosphate salts was not adequate at all the pH levels required. Therefore, varied buffered salt combinations were used for the different pH's to give optimum buffer capacity.

This study was designed to obtain an initial insight into the thermal stability of colorants when used in tablets. Although only limited data have been obtained, further experiments are necessary to define the complex factors contributing to dye instability. As a result of this information, additional investigations are contemplated to evaluate thoroughly the thermal stability of all FD&C colorants when employed in solid dosage forms.

Stability of Metal Complexes of Nuclear-Substituted Salicylic Acids: Correlation with Biological Effects

By WILLIAM O. FOYE and JOSEPH G. TURCOTTE

Stability constants are reported for the chelation of ferric and aluminum ions by a series of salicylic acid derivatives having amino, alkyl, chloro, and nitro groups in the ring. The sequence of complex stabilities found is in agreement with current organic theory and shows a parallelism with the ionization constants. Three of the biological effects known for salicylates, antibacterial, analgesic-antipyretic, and fungicidal, can be related to the magnitude of complex stability or ionization constant.

A NUMBER of experimental approaches have been made in the attempt to explain the biological effects of the salicylates. One explanation for these effects has implicated the metal-binding ability of the salicylates (1–4), since the *meta*- and *para*-hydroxybenzoic acids, which are incapable of binding metal ions through complexation, exert none of the classical salicylate effects (1). The literature, however, does not provide much information regarding the relative abilities of the various salicylates to bind metal ions. The measurement of stability constants should provide a much fuller knowledge of these abilities and give us a better insight as to the importance of metal-binding in salicylate actions.

The measurement of stability constants should provide a much fuller knowledge of these abilities and give us a better insight as to the importance of metal-binding in salicylate actions.

Received April 28, 1961, from the Department of Chemistry, Massachusetts College of Pharmacy, Boston.
Accepted for publication June 26, 1961.
Part II of a series dealing with the metal-binding abilities of salicylates.
Abstracted from a thesis submitted by J. G. Turcotte as a requirement for the degree of Master of Science, 1960.
This project was supported in part by a grant awarded by the Sterling-Winthrop Research Institute.
Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.

TABLE I.—KNOWN STABILITY CONSTANTS FOR VARIOUS SALICYLATES AND METAL CATIONS (Water, 20°)

Ligand	Cation: Fe^{+++} log K'	Fe^{+++} log K''	Cu^{++} log K'	Cu^{++} log K''	Fe^{++} log K'	Fe^{++} log K''	Ref.
Salicylic acid	16.35	11.90	10.60	7.85	6.55	4.7	(6)
5-Sulfosalicylic acid	14.60	10.55	9.50	6.80	5.90	<4.0	(6)
5-Aminosalicylic acid	16.97	12.04	..	..	..	..	[a]
Methyl salicylate	..	..	5.90	..	9.74[a]	..	(6)
Salicyl aldehyde	..	..	5.75	..	..	..	(6)
Gentisic acid	10.8	8.0	7.0	4.9	..	..	(7)
Salicyluric acid	9.0	7.0	6.1	5.6	..	..	(7)
Salicylamide	10.02	6.24	..	..	..	..	[a]

[a] Ågren, A., *Acta Chem. Scand.*, **9**, 39(1955).

Stability constants for the chelation of biologically important metal ions by salicylic acid (5–7), as well as those of a few salicylic acid derivatives, have been recorded. The latter include methyl salicylate, salicylamide, 5-sulfo- and 5-aminosalicylic acids, gentisic acid, and salicyluric acid. The constants for these substances with pertinent metal ions are listed in Table I.

The literature provides ample indication that salicylic acid or its derivatives become involved in enzymatic reactions, for which temporary binding of the prosthetic metal is a likely possibility. Among the more recent reports of this nature are those of Piccinelli (8), in which sodium salicylate was found to cause marked change in sugar metabolism; Messer (9), who found that sodium salicylate and sodium acetylsalicylate inhibit the synthesis of glutamine; Adams (10), who found a correlation between anti-inflammatory activity, increase in oxygen consumption, and uncoupling of oxidative phosphorylation; Durham (11), who showed that *p*-aminosalicylic acid antagonized the oxidative dissimilation of *p*-aminobenzoic acid in flavobacteria; and Janota (12), who reported that prolonged administration of salicylates increased the activity of plasma enzymes in rabbits. Direct inhibition of a copper oxidase, tyrosinase, by salicylic acid is also known.[1]

Stability constants have now been determined for the reaction with metal ions of a series of salicylic acids, having various substituents in the 3, 4, and 5 positions of the ring, with the expectation that a correlation might be found between either strength or weakness of metal-binding and a salicylate action. Where a temporary combination with the constituent metal of an enzyme might take place, as previously postulated (13), a lowering of stability constant (from that of salicylic acid with metals) should indicate more effective compounds. That these substituents might affect other physical properties of the molecules, such as solubility characteristics, is presently under consideration.

[1] C. W. Bauer, personal communication.

The metal ions selected for this experiment were ferric and aluminum. Ferric ion was considered more appropriate than cupric, for instance, since Perrin's calculations (6) revealed that salicylic acid has a stronger affinity for ferric ion than has glycine, a representative cellular ligand, by a factor of 400:1, whereas glycine has the stronger affinity for cupric ion, by a factor of 45:1. Aluminum was selected as a suitable trivalent ion for comparative purposes. The possibility of the same chelating strength sequence for two metal ions could then be determined.

METHODS

Materials.—The metal salts used were Baker analyzed reagents $FeCl_3 \cdot 6H_2O$ and $AlCl_3 \cdot 6H_2O$. The organic ligands selected for study (listed in Table II) were commercially available with the exception of the diisopropyl and *tert*-butyl derivatives of salicylic acid which had to be prepared. The ligands obtained commercially were purified by several recrystallizations from aqueous alcohol and charcoal. Purity was confirmed by melting points and paper chromatography using butanol saturated with ammonia.

Carbonate-free 0.1000 *N* sodium hydroxide solution was prepared from a concentrated solution of sodium hydroxide U.S.P. appropriately diluted with recently boiled and cooled distilled water. It was treated with saturated barium hydroxide solution for 12 hours, filtered, and standardized.

TABLE II.—IONIZATION CONSTANTS (20°)

Compound	pKa′ ($-CO_2H$)	pKa ($-OH$)
4-Aminosalicylic acid	6.75	13.33
4-Methylsalicylic acid	5.72	13.32
3-Methylsalicylic acid	5.70	13.30
3,5-Diisopropylsalicylic acid	5.92	13.28
5-*tert*-Butylsalicylic acid	5.64	13.20
3-Isopropyl-6-methylsalicylic (*o*-thymotic) acid[a]	5.60	13.21
Salicylic acid	5.57	13.14
5-Chlorosalicylic acid	4.85	13.34
5-Nitrosalicylic acid	3.92	12.83
3-Nitrosalicylic acid	3.81	12.77

5-Nitrosalicylic acid	14.51	12.67	26.86	14.31	12.16	26.47

[a] Calculated from $\log Ks = -2 \log (Sc)$, when $\bar{n} = 1$. [b] Calculated from $Ks = \log K' + \log K''$.

Preparation of 3,5-Diisopropylsalicylic Acid.—The procedure of Meyer and Bernhauer (14) for 5-isopropylsalicylic acid was used with modifications. A 1,600-ml. portion of 80% sulfuric acid, 60 Gm. (0.43 mole) of salicylic acid, and 40 ml. of 2-propanol were stirred rapidly at 70° for 1 hour. The flocculant product was isolated and recrystallized from glacial acetic acid. A yield of approximately 80% of white, crystalline material was obtained which melted at 117–118°. Literature values for the melting points of both the 5-isopropyl and 3,5-diisopropyl derivatives were found to be in the range 116–118°.

Anal.[2]—Calcd. for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16. Found: C, 70.90; H, 8.20.

Preparation of 5-*tert*-Butylsalicylic Acid.—Use of the method of Meyer and Bernhauer (14) was found to give a sulfonated product, so it was modified as follows. Sixty grams (0.43 mole) of salicylic acid, 75 ml. of *tert*-butyl alcohol, and 1,600 ml. of 80% sulfuric acid were stirred for 1 hour, during which time the temperature was raised to 75°. The resulting solution was allowed to cool overnight, charcoal was added, and the mixture was boiled for 5 minutes. It was filtered and allowed to cool, and the white, crystalline product was isolated and recrystallized from dilute acetic acid; m.p. 151–152°.

Anal.—Calcd. for $C_{11}H_{14}O_3$: C, 68.02; H, 7.26. Found: C, 68.00; H, 7.30.

Ionization Constants.—Values for primary and secondary ionization constants for each compound were determined by the potentiometric procedure of Osol and Kleckner (15), using 0.01 *M* solutions of the salicylates in 95% ethanol. A Beckman model E-2 electrode sensitive over the entire pH range was employed to give more accurate constants for the phenolic group. Table II lists the constants obtained.

Titrations.—The titrations were carried out under nitrogen as previously described (7) except that 0.01 *M* solutions of the ligands were made in 95% ethanol instead of in water. Aqueous base was used as before for titration, and the same volumes and concentrations were used for the determination of ionization constants as for the stability constants. The final solutions in each case contain approximately 79% alcohol. A Beckman Zeromatic pH meter with a Beckman model E-2 electrode was employed. Titrations were repeated for each system until pH values agreed to within 0.02–0.05 units for each run. A Friden fully automatic calculator, model SRW, was used for most of the calculations, which were carried out as previously described (7). The constants obtained are listed in Table III.

[2] Carbon-hydrogen analyses were done by Carol K. Fitz, Needham, Mass.

RESULTS AND DISCUSSION

In Table III are listed the values calculated for the first and second stability constants (log K' and log K'') of the metallic complexes, which correspond to the extent of formation of those having 1:1 and 2:1 ligand-metal ratios. In some cases, precipitation of the complexes prevented the determination of the log K''' values, and in other cases the values obtained were of doubtful accuracy. For purposes of comparison, "log Ks" values are listed, which indicate the overall stability of complex formation through the 2:1 complex stage. It would be unlikely that values for the third stability constant would alter the sequence of chelating abilities as shown. Therefore the log Ks values for the first and second stability constants, calculated by two different procedures (that one being listed that gave the greatest spread of values in each case) should be adequate for comparison.

The sequence of chelating abilities found was essentially the same for both the Fe^{+++} and Al^{+++} complexes. This sequence is also in agreement with that determined for copper complexes of substituted salicylaldehydes by Calvin and Wilson (16). The results reported for the salicylaldehydes in general resemble those reported here for the substituted salicylates: there was but a small variation in stability constants among the alkyl derivatives which in general were slightly higher than the value for salicylaldehyde itself, the halogen-substituted salicylaldehydes gave somewhat lower values, and the 3- and 5-nitro derivatives gave the lowest constants. No amino derivatives were included.

Comparison of the stability constants of the complexes with the ionization constants of the acids shows a rough parallelism between acidity (of both carboxyl and phenolic groups) and complex stability. One immediately questions the position of the 5-chlorosalicylic acid complexes in the stability sequence, since its phenolic ionization constant would indicate a stability comparable to that of the 4-amino- or 4-methylsalicylic acids, while its carboxyl ionization constant would place it just above the nitrosalicylic acids in the stability sequence. That the stability of the ferric complex falls between the values for the ferric complexes of the alkyl

and nitro acids indicates that the acidity of the carboxyl group contributes fully as much to the complex stability as the acidity (or basicity) of the phenolic group. However, with the aluminum complex of 5-chlorosalicylic acid, the stability of the complex is almost as great as that of the 4-amino derivative. In both cases, the value of log K' approaches that for the more stable complexes, as might be predicted from the value of the phenolic ionization constant.

The stability of the 3-methylsalicylic acid complexes is also seen to be out of position with regard to the ionization constants. In this case, a possible explanation is suggested immediately in steric hindrance which would tend to lower the stability constant to its observed value. That the 3,5-diisopropyl derivative does not produce the same demotion of stability constant may be due to the lesser numbers of α-hydrogen atoms in the 3-substituent.

A conclusion regarding the electronic effects of the substituents on complex stability can be readily seen from the constants reported here and is consistent with current organic chemical theory. Those groups capable of contributing electrons to the ring increase the basicity of the phenolic group and thus increase complex stability, whereas those groups that attract electrons decrease the phenolic basicity and complex stability as well. The 4-substituents apparently increase the basicity of the carboxyl function thus supporting the structure of the free chelating species shown in the previous paper (7). Similar observations regarding the effect of ionization constant on complex stability have been made before (7, 17).

A complete understanding of the role that complex stability plays in the biological effects of salicylates probably cannot be reached until the limiting effects of other properties, such as liposolubility, are known. However, the possibility may be advanced that the analgesic effects of salicylates do not require a high stability for possible metal complexes, whereas the antibacterial ability does. This may be concluded from the high stability noted for the complexes of 4-aminosalicylic acid, the only effective antitubercular agent among the salicylates, and the lower stability noted for the complexes of *o*-thymotic acid, reported to have a greater analgesic effect than has aspirin (18). The cresotinic acids (3-, 4-, and 5-methylsalicylic acids) have approximately the same antirheumatic efficacy as salicylic acid (19), and 4,5-dimethylacetylsalicylic acid has a similar antipyretic ability to that of aspirin (20). These observations are all in accord with the similar constants found for salicylic acid and its alkyl derivatives. It appears doubtful that the fungicidal activity of the salicylates is related to metal binding, since the most effective derivatives, the salicylanilides and alkyl ethers (21) would not be expected to bind metal ions to an appreciable extent.

SUMMARY

1. The avidities of a series of salicylic acids, having various substituents in the ring, for ferric and aluminum ions have been measured potentiometrically and recorded as stability constants.

2. The sequence of complex stabilities found with both metal ions is in agreement with that predicted from the electron-attracting and -repelling effects of the substituents, and shows a parallelism with the ionization constants of the ligands.

3. A relation between the magnitude of the complex stability constant and three of the biological effects of the salicylates has become evident. This has made possible the classification of these biological effects in terms of a physical constant (either complex stability or ionization constant). Antibacterial ability apparently requires high constants, analgesic-antirheumatic effects appear in compounds having constants similar to those of salicylic acid itself, and fungicidal ability has been found in those salicylates having no or very low metal-binding strength.

Triphenyltetrazolium Determination of 17,21-Dihydroxy-20-ketosteroids in Tablets

By JOHN J. CALLAHAN, FRANK LITTERIO, ELI BRITT, BERNARD D. ROSEN, and JOHN OWENS

The recommended color development conditions of Johnson, King, and Vickers (1) for the triphenyltetrazolium determination of bulk hydrocortisone have been applied to the tablet dosage forms of prednisone and prednisolone.

THE U.S.P. XVI method (2) for the assay of the 17,21-dihydroxy-20-ketone side chain of steroids is the Mader-Buck (3) procedure. During the application of this method to tablets, it was noted that the variations obtained were greater than might have been anticipated. The recent publication of Johnson, King, and Vickers (1) using hydrocortisone bulk powder had conclusively demonstrated some of the sources of variance and had outlined a procedure to overcome them. The utilization of the Johnson, King, and Vickers color development conditions to the tablet dosage form of 17,21-dihydroxy-20-ketosteroids therefore seemed desirable.

EXPERIMENTAL

Reagents.—U.S.P. 95% ethanol. Triphenyltetrazolium chloride reagent solution; dissolve 50 mg. of 2,3,5-triphenyltetrazolium chloride in 10 ml. of U.S.P. ethanol, this solution should be freshly prepared and kept protected from light. Tetramethylammonium hydroxide reagent solution; dilute 5 ml. of 10% aqueous solution to 100 ml. with U.S.P. ethanol. Chloroform. Dry nitrogen.

Tablet Extraction.—The steroid is extracted from the tablets by suspending a crushed aliquot of the tablets in water and shaking with multiple portions of chloroform as directed in U.S.P. XVI. A 10-ml. aliquot of the chloroform extract is evaporated in a 50-ml. nitrogen-flushed low-actinic glass volumetric flask (or a glass-stoppered Erlenmeyer flask) under a stream of nitrogen, on a steam bath. Heating with nitrogen is continued for 3 minutes after dryness is observed.

Color Development.—After the addition of 20 ml. of U.S.P. alcohol, the stoppered flask is mechanically shaken for 15 minutes, 2 ml. of triphenyltetrazolium chloride reagent solution is added, followed by 2 ml. of tetramethylammonium hydroxide reagent solution. The surface of the solution is swept with nitrogen for 15 seconds, the flask immediately stoppered, and placed in a 30° water bath. The reaction is allowed to proceed for 45 minutes for prednisone (Meticorten) tablets and 60 minutes for prednisolone (Meticortelone) tablets. The absorbance at 485 mμ is measured against a reagent blank.

Received May 16, 1961, from Schering Corp., Bloomfield, N. J.
Accepted for publication June 20, 1961.

RESULTS AND DISCUSSION

The application of the U.S.P. XVI procedure for the assay of 17,21-dihydroxy-20-ketosteroids has resulted in a large variation both in the results obtained in any given day as well as those obtained from day to day. Very poor reproducibility is often obtained in duplicate determinations of the standards themselves. Table I shows the results obtained by two analysts on five batches of tablets assayed on five consecutive days.

The major differences between U.S.P. XVI and the Johnson, King, and Vickers procedure are the use by the latter of low actinic glassware, removal of air in the reaction flasks by nitrogen, use of a 30° bath for the color development, and the reversal of the order of addition of the two reagents, tetramethylammonium hydroxide and triphenyltetrazolium chloride.

Before proceeding with the tablet assays, the effect of the variables studied by Johnson, *et al.*, were re-examined using prednisone and prednisolone standards.

Effect of Alcohol.—Anhydrous ethanol and 95% ethanol are the solvents used in most published procedures (1–5). The effects of different alcohols both on the steroid and on the reagent blanks are shown in Table II. It is not known whether the exceedingly high values of the blank readings obtained with isopropanol and *t*-butanol are due to the alcohols themselves or to some possible contaminant in them. Ethanol is the best alcohol to use in this procedure.

Effect of Water.—Increasing the water content in ethanol decreased the rate of color development. However, when longer development times were used, the absorbance readings were comparable to those obtained with the anhydrous ethanol. Consequently, the use of U.S.P. 95% ethanol was found to be very satisfactory.

Effect of Contaminants.—Low absorbance values were obtained in the presence of air, oxygen, and acetic acid. If these were present in relatively large amounts, the color development was inhibited. The presence of small amounts of chloroform and benzene did not interfere with the reaction Small amounts of acetaldehyde increased the absorbance readings.

Effect of Tetramethylammonium Hydroxide Concentration.—Both the U.S P. XVI and the Johnson, King, and Vickers procedures specify the same concentration of tetramethylammonium hydroxide. When this concentration was halved, the rate of color formation was identical but higher absorbance

5	0.310	0.380
10	0.272	0.370
15	0.214	0.365
20	0.180	0.380

[a] Prednisone concentration = 0.25 mg. per 24 ml. [b] Tetramethylammonium hydroxide. [c] Triphenyltetrazolium chloride.

values were obtained as well as slightly improved color stability as shown in Table III.

Order of Reagent Addition.—The order of addition of tetramethylammonium hydroxide reagent solution and triphenyltetrazolium chloride reagent solution was relatively unimportant when only a few samples were run. However, when multiple samples were run, such as is usual in a quality control laboratory, the addition of one reagent to all the reaction flasks before the next reagent addition may introduce a 5 to 10-minute interval between the addition of the tetramethylammonium hydroxide and the triphenyltetrazolium chloride. In this case, the order of reagent addition becomes very important. If triphenyltetrazolium chloride was added first to each reaction flask, no difficulty was encountered. However, if the tetramethylammonium hydroxide was added first, drastic reductions in absorbance values were encountered as the time interval between reagent additions was increased (Table IV), when using identical color development times measured from the time of addition of the last reagent.

TABLE V.—EFFECT OF TIME ON COLOR STABILITY[a,b]

Time, min.	Absorbance	
	Prednisone	Prednisolone
15	0.415	0.310
30	0.430	0.430

90	0.425	0.455
120	0.422	0.455

[a] Steroid concentration = 0.25 mg. per 24 ml. [b] 30° water bath, U.S.P. 95% ethanol, and 1:20 base dilution used.

TABLE VI.—EFFECT OF NITROGEN FLUSHING PRIOR TO COLOR DEVELOPMENT[a]

Experiment	Absorbance	
	Standard	Tablet
A[b]	0.387	0.420
B[c]	0.399	0.402
C[d]	0.428	0.430

[a] Prednisolone concentration = 0.25 mg. per 24 ml. [b] Chloroform evaporated under nitrogen but standard and blank flasks were not nitrogen flushed. [c] Chloroform evaporated in air. Standard and blank flasks were not flushed with nitrogen. [d] Chloroform evaporated under nitrogen. Standard and blank flasks were also flushed with nitrogen.

TABLE VII.—EFFECT OF TIME ON COLOR STABILITY OF TABLET EXTRACT[a]

Time, min.	Absorbance	
	Standard	Tablet Extract
30	0.442	0.443
60	0.441	0.441
90	0.435	0.439

[a] Prednisone concentration = 1.0 mg. per tablet.

Effect of Temperature on Color Development.—The rate of color development increases with temperature. Some fluctuations in assay results were obtained when (room) temperature fluctuations were present. For this reason, it was found expedient to adopt a standardized bath temperature of 30° as recommended by Johnson, King, and Vickers (1).

Color Stability.—When the stated precautions were observed, the stability of the developed color was very good. Almost no drop in absorbance was found after 2 hours in the 30° water bath, as shown in Table V.

Tablet Extract Preparation.—It was found that improper evaporation of the aliquot of the chloro-

[a] Steroid concentration = 5 mg. per tablet.

form extract of the tablet led to variable results if the higher boiling residues in the chloroform were not removed. This was easily effected by further heating the reaction flasks at about 95° under a stream of nitrogen for about 3 minutes longer after the flasks appeared to be dry. The flasks in which the standard and reagent blank were run also had to be flushed with nitrogen while still empty. This was found to be necessary because a comparison of the absorption readings of the solutions (obtained from the flasks nitrogen flushed and not nitrogen flushed at the start) indicated that higher absorbance values were obtained for the flushed flasks, as shown in Table VI.

It was also found that nitrogen flushing all the flasks while empty (as in the cases where chloroform was evaporated, just after the 3-minute extra heating time but before the addition of the alcohol) and nitrogen flushing again after all the reagents had been added was just as effective as the Johnson, King, and Vickers procedure of nitrogen flushing after each addition of reagent.

Tablet Extract Color Stability.—Table VII shows the rate of color development for prednisone extracted from tablets compared to standard prednisone. No substantial difference was found when ethanol U.S.P., 0.5% tetramethylammonium hydroxide concentration, and a 30° bath were used.

Tablet Analysis.—The assays performed on batches A through E whose results by the U.S.P. XVI procedure are shown in Table I were repeated using the new modified procedure. Aliquots of tablet powder from the same crushed tablets were used. Table VIII shows the results obtained by the two analysts on the five batches of tablets assayed on 5 consecutive days. The poor reproducibility previously noted on the standards and the day to day variation have practically disappeared.

Precision.—A comparison of the precision of the analyses between the U.S.P. XVI method (Table I) and the modified method (Table VIII) using the variances generated by the replicates indicates that the modified method is significantly better than the U.S.P. XVI method as indicated below.

Precision, calculated as σ (from replicates) $\times$ 100/(mean absorbance)

Sample	Method	Precision, %
Standards	U.S.P. XVI	2.3
	Modified	0.8
Tablets	U.S.P. XVI	1.7
	Modified	0.6

Applicability to Other Steroids.—Table IX indicates the rate of color development for steroids having modified environment in the side chain.

TABLE IX.—RATE OF COLOR DEVELOPMENT FOR VARIOUS STEROIDS[a]

	Molar Absorbance		
Steroid	1 Hour	2 Hours	3 Hours
Prednisone	16,600	16,900	16,800
Prednisolone	16,850	16,800	16,900
9α-Fluoro-16α-methyl prednisolone	17,150	17,450	17,100
9α-Fluoro-16β-methyl prednisolone	11,475	15,250	16,450
Desoxycorticosterone	16,500	16,300	16,200
Prednisone-21-acetate	17,000	17,300	17,400
Prednisone-21-hemisuccinate	13,100	15,100	15,150
9α-Fluoro-16α-methyl prednisolone phosphate	0	0	0
9α-Fluoro-16α-methyl prednisolone sulfate	0	0	0

[a] 30° water bath, U.S.P. 95% ethanol, and 1:20 base dilution used.

The color development fails completely when the 21-hydroxyl is firmly bound as in a phosphate or sulfate ester.

SUMMARY

The procedure reported by Johnson, King, and Vickers for bulk hydrocortisone has been extended to the assay of prednisone and prednisolone in tablets. The conditions found necessary to obtain satisfactory reproducibility are use of low actinic glassware, complete evaporation of the chloroform extracts under nitrogen, use of smaller tetramethylammonium hydroxide concentration and its addition last, flushing the empty part of the flasks containing the reagent solution with nitrogen, development of the color in a 30° water bath, and the use of ethanol with controlled water content such as U.S.P. 95% ethanol. When these conditions are fulfilled, the color shows no deterioration even after 2 hours at 30° in a closed flask.

Application of $\Delta\epsilon$-Analysis to Pharmaceuticals II

Determination of Morphine

By JOSEPH L. CASINELLI and JOSEPH E. SINSHEIMER†

Morphine exhibits a bathochromic displacement typical for phenols of its U.V. absorption spectrum in alkaline solution as compared to its spectrum in acid solution. Subtracting the absorbances of the U.V. spectrum in acid solution from those of the U.V. spectrum in alkaline solution results in a characteristic $\Delta\epsilon$-spectrum (differential spectrum). This difference spectrum exhibits a maximum at 298 mμ of sufficient magnitude to be suitable for quantitative determinations in a manner analogous to the use of the usual U.V. absorption spectra but with added specificity. The method has been applied to the determination of morphine in tablets, tincture of opium, and camphorated tincture of opium.

THE application of $\Delta\epsilon$-analysis (differential analysis) for the determination of eugenol in pharmaceuticals has been described in a previous paper from these laboratories (1). Williams (2, 3) has suggested a similar procedure for the analysis of barbiturates and salicylates. It is the purpose of this investigation to use $\Delta\epsilon$-analysis for the assay of morphine in some representative dosage forms.

Morphine exhibits a bathochromic displacement, typical for phenols, of its U.V. absorption spectrum in alkaline solution as compared to its spectrum in acid solution (4, 5). Subtracting the absorbances of the U.V. spectrum in acid solution from those of the U.V. spectrum in alkaline solution results in a characteristic $\Delta\epsilon$-spectrum (6). This difference spectrum exhibits maxima of sufficient magnitude to be suitable for quantitative determinations in a manner analogous to the use of the usual U.V. absorption spectra.

The difference in absorbance of a sample of morphine was determined at a difference maximum and this value served as the basis for the determination of morphine in tablets, tincture of opium, and camphorated tincture of opium.

EXPERIMENTAL

Ultraviolet absorption measurements were made with a Beckman, model DU spectrophotometer. A Beckman Zeromatic meter was used to determine pH.

Materials.—Morphine monohydrate (Mallinckrodt) was purified by chromatography (7) followed by two recrystallizations from alcohol-water. All reagents were of C.P. grade and were used without additional purification.

Received April 28, 1961, from the Colleges of Pharmacy, University of Rhode Island, Kingston, and University of Michigan, Ann Arbor.

Accepted for publication July 18, 1961.

Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.

Following the acceptance of this paper, a similar procedure has been described by Milos, C., THIS JOURNAL, **50**, 837 (1961).

† Present address: College of Pharmacy, University of Michigan, Ann Arbor.

Determination of Morphine Spectra.—Samples of about 80 mg. of morphine, accurately weighed, were dissolved in alcohol in 100-ml. volumetric flasks. Ten-milliliter aliquots were transferred to a second set of 100-ml. volumetric flasks and diluted to volume with a series of solutions prepared from standard solutions of sodium hydroxide and sulfuric acid. In this manner the U.V. spectra for 12 solutions of morphine ranging in pH from 3.0 to 12.0 were determined.

Determination of $\Delta\epsilon$ for Morphine.—Samples of about 80 mg. of morphine were accurately weighed, transferred to a 100-ml. volumetric flask, and dissolved by adding alcohol to volume. One 10-ml. aliquot of this solution was diluted to volume with water and 1.00 ml. of 1.000 *N* sodium hydroxide in a 100-ml. volumetric flask. A second 10-ml. aliquot of the alcoholic morphine solution was transferred to a 100-ml. volumetric flask and diluted to volume with water and 1.00 ml. of 0.100 *N* sulfuric acid. The absorbance of the alkaline solution was determined at 298 mμ relative to the acid solution in the reference cell. Blank solutions were run under the same conditions in order to correct for any contribution due to solvents and reagents. A total of 18 determinations were made in this manner. The alkaline solutions were recorded with a pH of 12.0 $\pm$0.1 and the acid solutions with a pH of 3.0 $\pm$0.1.

Assay of Morphine Sulfate Tablets.—Twenty 1/4 gr. tablets of morphine sulfate were weighed and powdered. A portion of this powder, about 90 mg., was accurately weighed, transferred to a 100-ml. volumetric flask, and dissolved by adding water to volume. Two 10-ml. aliquots of this solution were diluted, buffered, and the relative absorbance at 298 mμ was determined as described under the determination of $\Delta\epsilon$ for morphine.

Assay of Tincture of Opium.—A 5-ml. portion of the tincture was transferred to a beaker by pipet, mixed with 5 ml. of water, and reconcentrated on a steam bath to about 5 ml. To insure the removal of alcohol, a second 5-ml. portion of water was added and the mixture reconcentrated to about 5 ml. After cooling, 0.5 ml. of ammonia solution was mixed with the opium extract followed by 2 Gm. of Celite 545. This mixture was quantitatively transferred to the top of a column containing 5 Gm. of Celite 545. A total of 150 ml. of benzene was used to complete the transfer of the Celite-opium residue to the column and to develop the chromatogram. The

elution with benzene was followed by a mixture of chloroform-absolute ethanol (3:1). The material eluted before this change in solvents was discarded, while the eluate after the change was collected to volume in a 100-ml. volumetric flask. A 10-ml. aliquot of this eluate was transferred to a 100-ml. volumetric flask, diluted with 50 ml. of alcohol, 0.50 ml. of 1.000 *N* sodium hydroxide, and water to volume. In a like manner a second 10-ml. aliquot was diluted with 50 ml. of alcohol, 2.00 ml. of 0.100 *N* sulfuric acid, and water to volume in a 100-ml. flask. The differences in absorbances of these two solutions and a set of blank solutions were determined at 298 mμ.

Assay of Camphorated Tincture of Opium.—A 100-ml. portion of camphorated tincture of opium was evaporated to constant volume with the aid of a steam bath and a jet of air. The residue was mixed with 10 ml. of water, reconcentrated to constant volume, treated with ammonia, and chromatographed as described under the assay of tincture of opium. However, 250 ml. of the chloroform-alcohol mixture was required for the complete elution of the morphine. Therefore, a 25-ml. aliquot of this eluate was then transferred to a 100-ml. volumetric flask and brought to volume with alcohol and 0.50 ml. of 1.000 *N* sodium hydroxide. A second 25-ml. aliquot was diluted to volume with alcohol and 2.00 ml. of 0.100 *N* sulfuric acid in a 100-ml. flask. The differences in absorbances of these two solutions and a set of blank solutions were again determined at 298 mμ.

RESULTS AND DISCUSSION

A Δ-absorbance curve for morphine, that is the curve obtained by subtracting the absorbances of the U.V. spectrum in acid solution from those of the U.V. spectrum in alkaline solution, shows maxima at 256 and 298 mμ. The maxima at 298 mμ, even though it is of lower intensity, was utilized because of its stability over larger pH ranges. The difference at 298 mμ was found to be constant provided that the acid solution was at a pH of 5.0 or less and the basic solution was greater than 11.4. To serve as the basis for quantitative determinations of morphine solutions, the difference in molar absorptivity, $\Delta\epsilon$, at this maximum was determined for solutions of known concentrations of anhydrous morphine. The average of 18 determinations resulted in a value of 2,346 for $\Delta\epsilon$, or the difference in absorbance at 298 mμ for molar solutions of morphine at a pH of 12 ±0.1 as compared to molar solutions at a pH of 3.0 ±0.1.

Based upon this value for $\Delta\epsilon$, the assay of various dosage forms of morphine was undertaken. The assay of morphine sulfate in tablets involves the solution of the tablets and the selection of aliquots of this solution so that the difference in absorbance, ΔA, in a basic solution as compared to an acid solution is in the order of 0.3. The amount of morphine sulfate pentahydrate in the aliquot is then calculated by the formula: X Gm./100 ml. = $379.4\ \Delta A/(10\ \Delta\epsilon)$. Table I contains a summary of the results of this analysis of morphine sulfate pentahydrate in 1/4 gr. tablets.

The assay of opium preparations for their morphine content by this procedure still requires preliminary separation. For example, the opium alkaloids narceine, narcotine, and papaverine, as well as some of nonalkaloidal constituents of opium, exhibit differences in U.V. absorption in acid and basic media at 298 mμ.

Grosfeld-Nir, *et al.* (7), have described a chromatographic separation for the determination of morphine in opium. While this procedure is efficient for the separation of morphine from the other opium alkaloids, its application to opium depends upon the careful control of the original extraction of the drug. Under such controlled conditions it is possible to assay for morphine by alkalimetry following chromatographic separation. Tincture of opium or camphorated tincture of opium assayed by this procedure did not give quantitative results for morphine. However, the chromatographic procedure in combination with $\Delta\epsilon$-analysis did give satisfactory results.

Table II is a summary of the results of the analysis of these tinctures by chromatography followed by $\Delta\epsilon$-analysis. The labeled concentration of the commercial tincture of opium was 1 Gm. per 100 ml. The camphorated opium tincture was prepared from the tincture of opium. On the basis of our analysis of 1.08 Gm. of morphine per 100 ml. for this tincture of opium, the camphorated tincture was calculated to contain 0.0432 Gm. of morphine per liter.

CONCLUSION

It is concluded from the results of this investigation that $\Delta\epsilon$-analysis has value for the determi-

nation of morphine in dosage forms and has the advantage of greater specificity as compared to direct U.V. measurements.

Evaluation and Mechanisms of Action of Several Experimental Hypotensive Agents

By WILLIAM J. HUDAK†, WILLIAM J. KINNARD, Jr., and JOSEPH P. BUCKLEY

The hypotensive activity of [1-methyl-3-(2'5'6'-trimethyl-1'-cyclohexenyl)propyl] [3-morpholinopropyl] dimethyl ammonium bromide methobromide (RO 2-7832), (+) - 6 - methyl - 9 - diethylaminomethyl - 10 - hydroxy - 1,2,3,3a,5,6,6a,7,11b,11c-decahydro-4H-dibenzo [de,g] quinoline dihydrobromide (RO 2-9618), and 8,8'-bis(2-dimethylaminoethoxy)-6,6'-bithiachroman-4,4'-dione dihydrochloride (RO 2-9811) were investigated in anesthetized rats and dogs. Central and peripheral hypotensive activities were studied utilizing dog cross circulation preparations; and included trimethidinium methosulfate and beta-dimethyl-aminoethyl-N-methylpipecolinate dimethobromide (JB-591) as well as the previously mentioned compounds. RO 2-7832 and trimethidinium appeared to act as potent ganglionic blockers. The hypotensive activity of RO 2-9618 was due to both ganglionic blockade and mild adrenolytic activity. JB-591 was the only compound that demonstrated any central hypotensive activity.

ALTHOUGH the etiology of essential hypertension is still not fully understood, many investigators agree that the reduction in arterial blood pressure is beneficial to the hypertensive patient and will, in many instances, prolong life (1–4). Even though there are many hypotensive compounds available, there is still a need for safer therapeutic agents possessing a minimum of side effects, thereby permitting the patient to lead a useful, productive life. The mechanism of action of the compound should be understood so that the drugs can be intelligently used by the physician in the control of hypertensive cardiovascular disease. This present report is mainly concerned with the evaluation of the hypotensive activity of RO 2-7832,[1] RO 2-9618,[1] and RO 2-9811[1] (Fig. 1), and the mechansim of action of these compounds, and trimethidinium[2] (5) and JB-591[3] (6–8).

EXPERIMENTAL

Hypotensive Activity in Rats.—The RO compounds were screened and evaluated in anesthetized Wistar rats (urethan, 1.25 Gm./Kg., i.p.) utilizing the method described in a previous paper (9). Direct blood pressure was recorded via the left common carotid artery onto a slowly moving kymograph. The compounds were dissolved prior to use in distilled water and administered via a femoral vein. Hexamethonium, 5 mg./Kg., was utilized as a control compound in this phase of the study.

The oral activity of the three RO compounds was investigated in: (*a*) anesthetized normotensive albino rats, (*b*) unanesthetized normotensive rats, and (*c*) unanesthetized hypertensive rats.

The animals in (*a*) were fasted for 24 hours prior to their use. They were anesthetized with urethan, 1.25 Gm./Kg., i.p., and prepared for direct blood pressure recording. The proximal end of the trachea was cannulated with polyethylene tubing (2 mm. o.d. and 1.5 mm. i.d.). Fresh solutions of the compounds were administered via gastric intubation utilizing a Davol No. 8 French rubber catheter, and each dose was diluted with distilled water to a volume of 2 ml.

The blood pressures of unanesthetized normotensive rats (*b*) were obtained utilizing the photoelectric tensometer (10). Albino Wistar rats were trained for a period of one week prior to the initiation of the study. The animals were fasted for 24 hours, after which fresh solutions of the compounds were administered via gastric intubation as previously described. Blood pressures were obtained periodically prior to and after drug administration.

nation of morphine in dosage forms and has the advantage of greater specificity as compared to direct U.V. measurements.

EXPERIMENTAL

Hypotensive Activity in Rats.—The RO compounds were screened and evaluated in anesthetized Wistar rats (urethan, 1.25 Gm./Kg., i.p.) utilizing the method described in a previous paper (9). Direct blood pressure was recorded via the left common carotid artery onto a slowly moving kymograph. The compounds were dissolved prior to use in distilled water and administered via a femoral vein. Hexamethonium, 5 mg./Kg., was utilized as a control compound in this phase of the study.

The oral activity of the three RO compounds was investigated in: (*a*) anesthetized normotensive albino rats, (*b*) unanesthetized normotensive rats, and (*c*) unanesthetized hypertensive rats.

The animals in (*a*) were fasted for 24 hours prior to their use. They were anesthetized with urethan, 1.25 Gm./Kg., i.p., and prepared for direct blood pressure recording. The proximal end of the trachea was cannulated with polyethylene tubing (2 mm. o.d. and 1.5 mm. i.d.). Fresh solutions of the compounds were administered via gastric intubation utilizing a Davol No. 8 French rubber catheter, and each dose was diluted with distilled water to a volume of 2 ml.

The blood pressures of unanesthetized normotensive rats (*b*) were obtained utilizing the photoelectric tensometer (10). Albino Wistar rats were trained for a period of one week prior to the initiation of the study. The animals were fasted for 24 hours, after which fresh solutions of the compounds were administered via gastric intubation as previously described. Blood pressures were obtained periodically prior to and after drug administration.

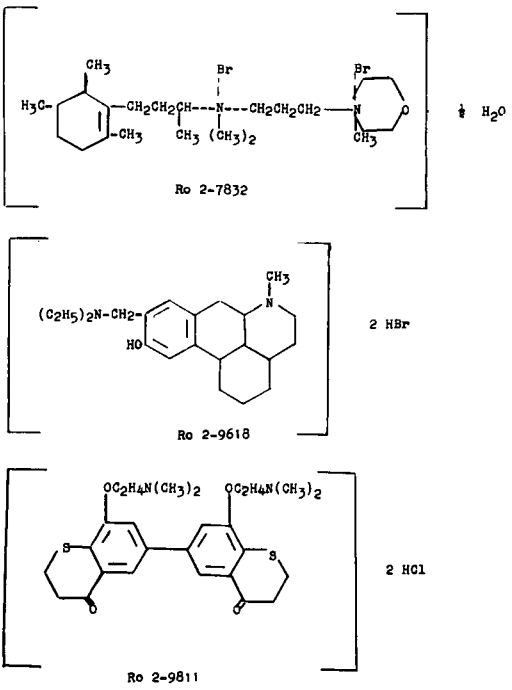

Fig. 1.—Structures of the compounds evaluated for hypotensive activity.

Hypertensive rats (*c*) were prepared by applying a figure-of-eight ligature to the right decapsulated kidney and removing the contralateral kidney 1 week later. After an additional 4-week period, the rats received 6.25 mg. of desoxycorticosterone trimethylacetate,[4] intramuscularly, and 0.9% saline drinking solution once weekly. Of 48 rats, 40 developed arterial pressures in excess of 180 mm. Hg 8 weeks after the initial operation. Fresh solutions of the compounds were administered orally to rats fasted for 24 hours and the blood pressures determined, utilizing the photoelectric tensometer, prior to and periodically after administering the compounds.

Ganglionic Blocking Activity.—Adult cats of both sexes were anesthetized with an intraperitoneal injection of pentobarbital sodium, 35 mg./Kg. Blood pressure was recorded from the right femoral artery via a mercury manometer. The preganglionic segment of the cervical sympathetic nerve was stimulated with a submaximal stimulus (determined for each animal) using a Harvard stimulator at a frequency of 60 impulses per second for 10 seconds, and the effect on the nictitating membrane recorded. Three such stimuli were applied at 5-minute intervals and the average response determined. The submaximal stimulus was also determined for the postganglionic fiber. The responses obtained after injection of the test compound were reported as per cent of the mean response. The antagonism of the experimental compounds to the hypertensive activity of 1,1-dimethyl-4-phenyl-piperazinium iodide (DMPP) (11–13) were also studied in the same preparations. The mean pressor response to several 10 mcg./Kg. intravenous injections of DMPP prior to administering the experimental compounds was obtained, and the degree of inhibition of the pressor response after administration of the compounds was calculated in terms of per cent of the mean control response. The effects of the compounds in antagonizing the pressor response obtained by bilateral carotid occlusion were also determined in a similar manner.

Hypotensive Activity in Dogs.—The hypotensive activities of the compounds were studied in unanesthetized normotensive dogs. A permanent catheter (Bardic 10) was inserted into a femoral artery permitting direct recording of the blood pressure onto a slowly moving kymograph by way of a mercury manometer (14). Each animal received a particular compound via the oral or intravenous routes to determine the approximate degree of oral absorption. The dogs were starved 24 hours prior to oral administration, and the oral dose equivalent to 10 times the i.v. dose was administered in capsule form. A minimum of two days elapsed prior to administering the compounds via the intravenous route. Approximately one week after receiving the last dose of the compound, the animal was anesthetized with pentobarbital sodium, 35 mg./Kg., i.v., and the blood pressure recorded via the femoral catheter onto a slowly moving kymograph. The trachea was cannulated and the common carotid arteries isolated in the usual manner. The vagi were isolated, doubly ligated, and the nerves sectioned between the ligatures. The following tests were utilized at 5-minute intervals: (*a*) the stimulation of the central vagal stump (35 volts at a frequency of 60 per second for 10 seconds); (*b*) stimulation of the caudal vagal stump utilizing the same stimuli as described above; (*c*) bilateral carotid occlusion for 10 seconds; (*d*) DMPP (10 mcg./Kg.) i.v.; (*e*) epinephrine (1 ml. of 1:100,000) i.v.; (*f*) histamine base (2.5 mcg./Kg.) i.v. The mean per cents of two responses prior to medication were utilized as controls and the degree of augmentation or inhibition was calculated in terms of the per cent of this mean control response.

Dog Cross Circulation Studies.—The following procedure was utilized to produce a vascularly isolated, neurally intact head preparation: The recipient dog was anesthetized with pentobarbital sodium, 35 mg./Kg., i.v., and the blood pressure recorded via the right femoral artery by way of a mercury manometer onto a slowly moving kymograph. The trachea was cannulated and both common carotid arteries and jugular veins isolated. The internal jugular veins were doubly ligated and sectioned. A circumferential incision was then made around the midneck and the skin retracted. All the neck musculature from C-2 to C-5 was separated and removed using electrocautery. A dorsal laminectomy was performed between C-2 and C-3 or C-3 and C-4 to expose the underlying cord. The cord was gently retracted and a soft rubber sponge (0.75 cm. × 4.0 cm. × 0.25 cm.), through which a length of 21-gauge steel wire had been passed, was inserted between the spinal cord and dorsal surface of the centrum. The wire was looped around the central portion of the spinal column and guided into the intervertebral space and passed between the two common carotid arteries. The wire was then tightened with a Shifrin wire tightener

[4] Generously supplied as Percorten by Ciba Pharmaceutical Products, Inc., Summit, N. J.

to occlude the venous sinuses and vertebral arteries and the tightener left in place. The dog was placed ventral side up and artificial respiration administered. The left rib cage was exposed and the pleural cavity opened between the third and fourth ribs, utilizing a chest spreader. Loose ligatures were placed around the innominate and left subclavian arteries and superior vena cava (caudal to the entry of the vertebral veins). The donor dog (approximately 25% larger than the recipient) was anesthetized and the blood pressure recorded via the right femoral artery. The donor was heparinized with 2,000 to 4,000 units of heparin intravenously, and 50 mg. of pyribenzamine was administered subcutaneously to prevent possible anaphylactic reactions. Anastomosis between the recipient's two common carotid arteries and two external jugular veins with the corresponding left vessels of the donor was accomplished, and the ligatures around the innominate and left subclavian arteries and superior vena cava tightened securely (see Fig. 2). After both donor and recipient blood pressures had stabilized, 0.25 ml. of Lugol's solution (U.S.P.) was injected into the tubing supplying the blood to the head of the recipient. Approximately 15 minutes later, 10 μc. of iodine^{131} (radio-iodinated serum albumin, human, Squibb) was administered intra-arterially into the head of the recipient. Circulatory leakage between the head and body of the recipient animal was determined at 5, 15, 30, 60 minutes, and then at hourly intervals after administration of radioactive iodine, using the procedure described in a previous paper (15). The mean leakage in 19 experiments, at the end of 3 hours, was 3.1%. The compounds were administered via the arterial inflow to the recipient's head.

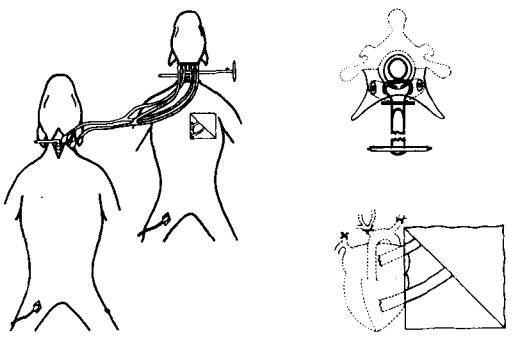

Fig. 2.—Diagrammatic illustration of the cross circulation technique used.

RESULTS

Hypotensive Activity in Rats.—The hypotensive activity of the RO compounds, administered intravenously, is summarized in Table I. RO 2-7832 appeared to be the most active hypotensive compound investigated as 1 mg./Kg., i.v., produced marked hypotensive effects persisting for over 4 hours. The compound was also very active when administered orally to anesthetized normotensive rats. RO 2-7832, in doses ranging between 1 and 20 mg./Kg., produced drops in blood pressure between 40 and 55%, the onset of action occurring between 15 and 31 minutes, and the hypotensive effects persisting for approximately 8 hours after the onset of action. RO 2-7832 was also the most active compound when administered orally to unanesthetized normotensive albino rats. The onset of action usually occurred within 60 minutes, and the duration of action was usually over 8 hours. A decrease in oral and nasal secretions and marked pupil dilatation were observed with the onset of the hypotensive effects. RO 2-7832 was administered to 10 hypertensive rats. Doses of 20 mg./Kg. produced a mean drop in blood pressure of 26% and the maximum hypotensive effect occurred approximately 100 minutes after the administration of the compound (see Tables II and III). The average duration of action was in excess of 354 minutes; however, the blood pressures of four of the rats had not returned to predrug levels after 8 hours. Dryness of the mouth and marked pupil dilatation were observed with the onset of drug action.

Ganglionic Blocking Activity.—The ganglionic blocking activity and the effect on bilateral carotid occlusion pressor response of the RO compounds on normotensive cats are summarized in Table IV. RO 2-7832 elicited powerful ganglionic blockade and almost completely blocked the pressor response to DMPP. Moderate ganglionic blocking activity was produced by RO 2-9618, and RO 2-9811 had little effect on ganglionic transmission. All of the compounds inhibited the pressor response to bilateral carotid occlusion with RO 2-7832 demonstrating the least activity in inhibiting this pressor reaction.

Hypotensive Activity in Dogs.—The effects of the RO compounds on the blood pressure of unanesthetized normotensive dogs are summarized in Table V. RO 2-7832 appeared to be the most active compound when administered either intravenously or orally. The compound produced almost complete relaxation of the nictitating membrane, dryness of the eyes and mouth, mydriasis, and loss of pupillary reflex. The effects of the RO compounds on the blood pressure of anesthetized normotensive dogs and the physiological responses to electrical stimulation of the central vagal stump and caudal vagal stump, bilateral carotid occlusion, DMPP, epinephrine, and histamine are summarized in Table VI. The pressor response to central vagal stump stimulation was completely inhibited in one instance by 2 mg./Kg. of RO 2-7832. RO 2-9811 had no apparent effects upon this physiological response. The depressor response to stimulation of the caudal vagal stump was completely blocked by RO 2-7832 in one dog, and a pressor response was obtained in another. The other compounds decreased the depressor response. The pressor response produced by bilateral carotid occlusion was completely inhibited by RO 2-7832, RO 2-9618 had little or no effect, and RO 2-9811 inhibited this response by 40 and 68%. The pressor response to DMPP, i.v., was blocked by RO 2-7832 and augmented by RO 2-9811 and RO 2-9618. The pressor response to exogenous epinephrine was enhanced by RO 2-7832 and RO 2-9811 and slightly diminished by RO 2-9618.

Cross Circulation Studies.—The effects of the compounds on the dog cross circulation preparations are summarized in Table VII. JB-591 was the only compound which appeared to produce a centrally mediated hypotensive effect (Fig. 3). Marked de-

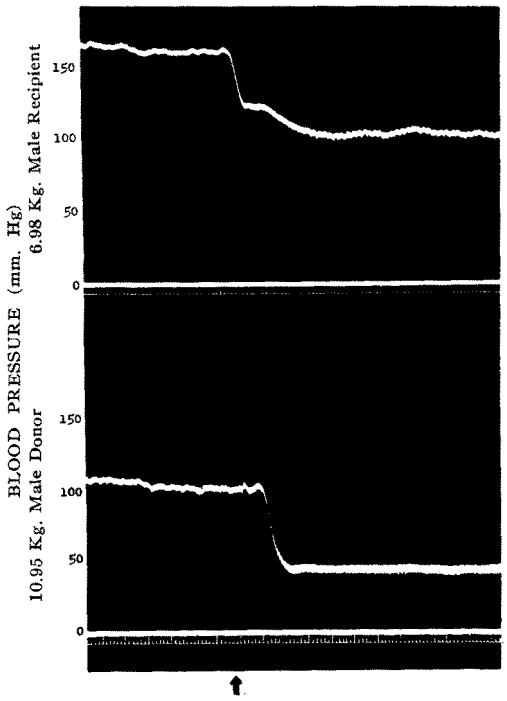
[a] Pressor response obtained.

pressor responses were produced in all of the recipient animals by JB-591. In most instances, the maximum hypotensive effect occurred more rapidly in the donor than in the recipient. All of the compounds produced marked hypotensive effects in the donor animals. Neither hexamethonium chloride nor trimethidinium (Fig. 4) produced any effect upon the recipient's blood pressure and it would appear that these compounds induce hypotensive effects purely through their peripheral ganglionic blocking activity.

DISCUSSION



RO 2-7832 appeared to be the most potent of the RO compounds investigated. It produced marked hypotensive effects for prolonged periods of time in normotensive anesthetized rats, dogs, and cats. The cats appeared to be especially sensitive to this compound as minute doses produced marked hypotensive responses. The depressor response, produced by 10 times the intravenous dose of RO 2-7832 administered orally to unanesthetized normotensive and hypertensive rats, was approximately 50% that produced by intravenous administration to anesthetized rats. The depressor response produced by the compound following oral or intravenous administration to unanesthetized dogs was also markedly reduced in contrast to the response in anesthetized animals. This would indicate that the anesthesia had an augmentory action on the hypotensive activity of RO 2-7832. The following physiological responses indicate that RO 2-7832 is a ganglionic blocking agent: (*a*) complete inhibition of the pressor response of DMPP; (*b*) inhibition of the contraction of cat nictitating membrane to preganglionic stimulation of the superior cervical sympathetic nerve (nictitating membrane responded to stimulation of the postganglionic fiber); (*c*) inhibition of the depressor response produced by bilaterial carotid occlusion· (*d*) inhibition of the depressor response produced by caudal vagal stump stimulation; (*e*) marked enhancement of the pressor response to exogenous epinephrine. The compound did not exhibit any evidence of central hypotensive activity (Fig. 5).

Although RO 2-9618 was the least effective of the compounds investigated in the anesthetized rat evaluation studies, it appeared to be one of the most effective compounds when administered via the oral route; however, the duration of action was extremely short. The compound augmented the response produced by DMPP in the dog and suppressed the depressor response produced by stimulation of the caudal vagal stump in the dog. It also partially blocked the pressor response produced by DMPP and contraction of the nictitating membrane to preganglionic stimulation in the cat. Slight adrenergic blocking activity was also indicated by the partial suppression of the pressor response to exogenous epinephrine, and it appears that the hypotensive activity of RO 2-9618 is due to ganglionic blockade and a mild adrenergic blocking action.

0.5 mg./Kg. WY-1395 Time in Hours

Fig. 4.—The effects of trimethidinium (WY-1395), 0.5 mg./Kg., via the recipient carotid inflow, on the peripheral arterial pressures of the recipient and donor dogs.

RO 2-9811 produced mild hypotensive effects when administered intravenously and orally to dogs. It also produced a marked depression of respiration. The pressor response caused by bilateral carotid occlusion was inhibited approximately 50%, suggesting possible reflex or ganglionic blocking activity; however, the compound had relatively little effect on ganglionic transmission. It appears that RO 2-9811 may possibly lower blood pressure through some reflex mechanism.

Although trimethidinium has been suggested to have a dual mechanism of action (ganglionic

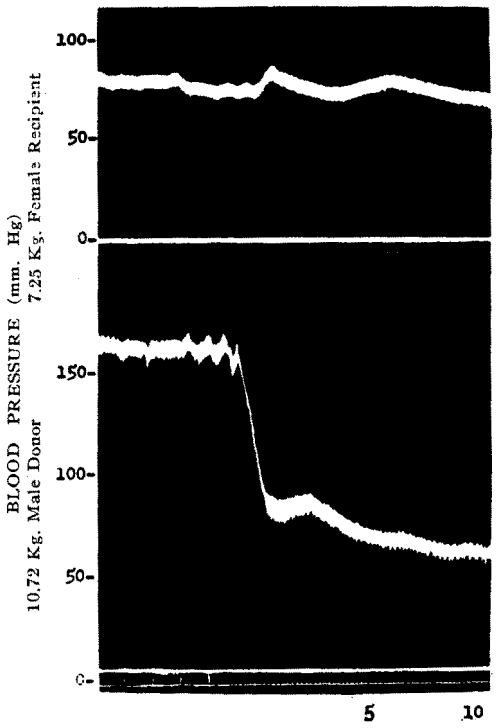

Fig. 5.—The effects of RO 2-7832, 5.0 mg./Kg., via the recipient carotid inflow, on the peripheral arterial pressures of the recipient and donor dogs.

blockade and some form of central depression) (16), the cross circulation studies indicated that the compound does not possess any central hypotensive activity. Since both trimethidinium and hexamethonium have been reported to be potent ganglioplegic agents, it would appear that the hypotensive effects produced by both trimethidinium and hexamethonium are essentially due to their ganglionic blocking activity.

JB-591 was the only compound to demonstrate a centrally mediated hypotensive response. Previous papers have shown the compound to possess ganglionic blocking properties, and it appears that the compound has a dual mechanism of action, namely ganglionic blockade and a central hypotensive action. Clinical studies have shown this compound to possess some tranquilizing action which would further strengthen the possibility of the compound possessing a centrally mediated hypotensive property.

SUMMARY

1. Three new compounds were evaluated for their hypotensive activity in anesthetized normotensive rats.

2. [1 - Methyl - 3 - (2′,5′,6′ - trimethyl - 1′-cyclohexenyl) propyl] [3-morpholinopropyl] dimethyl ammonium bromide methobromide (RO 2-7832) was the most potent hypotensive compound investigated.

3. Central hypotensive activities were studied utilizing dog cross circulation preparations.

4. Trimethidinium and hexamethonium did not elicit central hypotensive responses and apparently act through peripheral ganglionic blockade.

5. JB-591 (β-dimethyl-aminoethyl-N-methyl-pipecolinate dimethobromide) was the only compound to produce a centrally mediated hypotensive response and apparently lowers blood pressure through both ganglionic blockade and some central depressor mechanism.

6. The hypotensive activity of RO 2-7832 was produced predominantly by ganglionic blockade.

Yohimbine Potentiation of Reserpine Blepharoptosis

By MARVIN H. MALONE and ROBERT H. ROTH, Jr.†

Yohimbine, with an oral LD_{50} in mice of 36.5 mg./Kg. (S.E. = ±3.02), does not show any reserpine-like sedative-blepharoptotic activity in nonlethal dosage. Using factorially designed, graded response assays, yohimbine was shown to potentiate reserpine palpebral ptosis significantly for at least 5 hours when administered concurrently with and at the same oral dosage level as reserpine. Yohimbine administered in higher dosage extended the potentiation effect to a greater degree and for longer periods of time (≥24 hours). Since yohimbine is reported to be both an adrenolytic agent and an antimetabolite of serotonin, this study may indicate that the mechanism of action of reserpine sedation involves depletion of norepinephrine more than serotonin release as a neurohormone. Male mice were more susceptible to reserpine ptosis than females.

YOHIMBINE is a classic adrenolytic agent and recently has been shown to have central nervous system activity (1, 2). Yohimbine is also an antimetabolite of serotonin (3). At the present time there are several theories as to the mechanism of action of reserpine, but all theories implicate two compounds with possible neurohormonal activity in the central nervous system; these compounds are serotonin and norepinephrine (4–6). Since both reserpine and yohimbine have been reported to be natural constituents of *Rauwolfia serpentina* Benth (7, 8), it appeared to be of theoretical and practical interest to determine whether yohimbine would either potentiate or antagonize the action of reserpine. A persistant blepharoptosis is characteristic only of the reserpine-like ataraxics, since the eyelid closure of the phenothiazine ataraxics is easily reversed by environmental stimulation. Rubin, *et al.* (9, 10), have devised a graded response assay for reserpine-like activity utilizing the palpebral ptosis of mice recorded 5 hours after oral dosage. This ptosis is generally considered to be due to central depression and is seen concurrent with facilitation of caffeine and pentylenetetrazol induced extensor seizures; these phenomena are antagonized by prior or simultaneous iproniazid administration (11). Since localized lesions of the human hypothalamus, as in Horner's syndrome, produce reserpine-like symptoms: miosis, enophthalmus, hypothermia, lethargy, and palpebral ptosis (12), it was decided to utilize the mouse ptosis assay to determine the interactions of reserpine and yohimbine.

Received April 28, 1961, from the Division of Pharmacology and the Pharmacy Research Institute, University of Connecticut, Storrs.

Accepted for publication June 6, 1961.

Presented to the Scientific Section, A.PH.A., Chicago meeting, April, 1961.

This project was supported in part by a Lederle Pharmacy Faculty Award.

This paper is dedicated to Dr. Harald G. O. Holck on the occasion of his retirement from the Institute for Cellular Research and the Department of Pharmacology of the University of Nebraska.

EXPERIMENTAL

General.—White mice were obtained from Joseph E. Stocker, Ramsey, N. J., and were maintained in this laboratory on Purina Laboratory Chow and water *ad libitum* for at least 4 days prior to test. Only mice within a weight range of 15–25 Gm. were used for the ptotic assays. Animals were taken off food 3 to 4 hours prior to dosing and placed back on food 10 hours after dosing. Water was allowed throughout the entire test period. A dosage volume of 0.6 ml./20 Gm. of mouse was constant throughout this study. Animals were dosed utilizing precision grade syringes and cut-off, blunted, polished, 30-mm. long, 20 gauge hypodermic needles. Test solutions were coded using randomized numbers, so that the two dosing technicians did not know the actual dosage or identity of any of the test groups. For the ptotic assays, the animals were randomized in respect to the six test groups of the 3 × 3 assay format, and also randomized between the two sexes, and between the two dosing technicians. The mean time off food prior to dosing for each group was statistically constant. Only one technician read the ptosis values for all animals at all indicated times, and this technician did not know the dosage level or identity of any of the test groups. Each mouse was permanently and individually identifiable throughout the test period due to spot applications of a 0.5% picric acid solution in 70% ethanol. Ptosis for each eye was scored following the scale adopted by Rubin, *et al.* (10): 4 = complete, 3 = 3/4, 2 = 1/2, 1 = 1/4 closure of the eyelids from the normal aperture. A nonptotic response was scored as 0. The individual metameter was the sum of the ptotic scores for both eyes, so that the graded test response varied from 0–8 per mouse. Prior to ptotic scoring, each mouse was manually aroused, then placed on a screen and held by the tail facing the scorer at the scorer's eye level. Eye scores of a 4 rating were checked to insure that the lid was not encrusted shut and that the ptosis was an active phenomenon.

Yohimbine hydrochloride and reserpine alkaloid were obtained from California Corporation for Biochemical Research. Reserpine was solubilized by glacial acetic acid and sufficient double-distilled water was added to make a 10 mg./ml. solution in 10% acetic acid. All dosages of reserpine and yohimbine are expressed here in terms of the alkaloid rather than the alkaloidal salt. Where

[a] The constant dosage volume for each test dose was 30 ml./Kg. [b] 54 mice per dosage group, equally divided between sexes. [c] 36 mice per dosage group, equally divided between sexes. [d] 54 mice per dosage group. The "standard" group is all female; the "unknown" group is all male.

yohimbine and reserpine were administered concurrently, they were given together in the same vehicle.

RESULTS AND DISCUSSION

Preliminary Evaluation of Yohimbine.—As calculated by the Bartlett modification of the Miller and Tainter log-probit method (13), the oral LD_{50} for yohimbine was determined to be 36.5 mg./Kg. with a standard error of ±3.02. The dosage increment used was 1.414×, and the number of animals (N') contributing to effects between probits 3.5 and 6.5 was 37. The estimated LD_5/LD_{95} values were 20.4/65.0 mg./Kg. Acute death from yohimbine was preceded by the following major symptoms listed in order of appearance: respiratory stimulation, respiratory depression, hyperkinetic phenomena (increased motor activity, fine body tremors, Straub tail erection), transient minimum ptosis (maximum rating of 1 per eye), clonic convulsions, cyanosis, and death by respiratory arrest. No evidence of priapism was seen in the males. The transient ptosis was seen only at dosage levels of 45.2 mg./Kg. or greater and was always seen prior to convulsions and death. Considering only quantal incidence of detectable ptosis, reserpine has a PtD_{50} (ptotic dose for 50% of a population) graphically estimated at 0.5 mg./Kg.; in this respect, reserpine is $\geq$128× the ptotic potency of yohimbine. Considered as a graded response, reserpine was graphically determined to be $\geq$64× the ptotic potency of yohimbine. Previous work in this laboratory has indicated that the acute oral LD_{50} of reserpine (acetate) was $\geq$150 mg./Kg. Therefore, the LD_{50}/PtD_{50} ratio for reserpine is $\geq$300; while for yohimbine, this ratio only equals 0.6. Yohimbine qualitatively displays little to no reserpine-like, sedative-ptotic activity.

Yohimbine Potentiation of Reserpine-Induced Palpebral Ptosis.—Four balanced log dose-response assays were conducted, assaying various reserpine-yohimbine mixtures against reserpine alone as a standard. The yohimbine content of the mixtures ranged from 0–4× the reserpine content. The maximum dose of yohimbine given with reserpine was 16 mg./Kg. Ptosis was rated for all test groups at 3, 5, 10, and 24 hours after dosing. Maximal mean ptotic effects after reserpine alone were seen 10 hours after dosing, in conflict with previous reports indicating that maximal effects were seen 5 to 7 hours after dosing (10). Mean results are tabulated in the first sections of Table I. Not reported in Table I are the mean ptotic scores of the 2 control groups receiving 8 and 16 mg./Kg. of yohimbine orally, respectively. Each group consisted of 18 mice, the number divided equally between the sexes, dosed and scored concurrently with the assay test groups. Mice receiving 8 mg./Kg. of yohimbine did not have detectable ptosis at any time, while the group receiving 16 mg./Kg. was observed to have a mean ptotic score of 0.18 and 0.12 at the 3- and 5-hour readings, respectively, with complete absence of ptosis at the 10- and 24-hour readings.

The statistical treatment for the 3 × 3 and 2 × 2 assays involved analysis of variance, factorial analysis, and calculation of potency and confidence limits as per the techniques outlined by Bliss (14). The results are tabulated in the first sections of Table II, with graphical interpretations illustrated in Figs. 1 and 2. An average λ value (s/b) of 0.29 was obtained with the 16 3 × 3 assays calculated; standard error was determined to be ±0.015. With this λ value, a population of 210 mice per assay would have been needed to insure a standard error for potency of ±10% (14). The number of mice used in this study was either 216 (36 mice/dose) or 324 (54 mice/dose) per each 3 × 3 assay.

Peak potentiation was noted at the third hour for 1:1 and 1:2 reserpine-yohimbine mixtures, while peak effects were reached with the tenth-hour readings with the 1:4 mixture (Fig. 1), indicating that at these concentrations and at these times, the presence of yohimbine in an unknown preparation will maximally distort any ptotic assay attempting to document only reserpine activity. The control

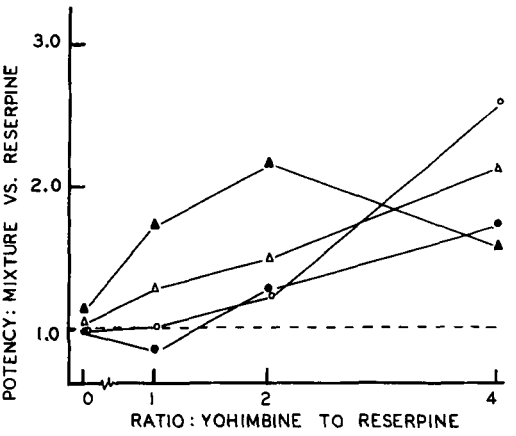

Fig. 2.—Variation of ptotic potency with ratio of yohimbine to reserpine in reserpine-yohimbine mixtures: ▲, 3-hour ptosis response; △, 5-hour; O, 10-hour; ●, 24-hour.

assay with no yohimbine in the unknown showed no potentiation at any of the time intervals.

Yohimbine in a 1:1 ratio in a reserpine-yohimbine mixture potentiated the 3- and 5-hour ptosis readings, had no effect on the 10th-hour ptosis, and may have been actually instrumental in reversing the residual 24-hour reserpine ptosis (Fig. 2). Yohimbine, in a ratio of 1:2 in reserpine-yohimbine mixtures, potentiated reserpine on the 3-, 5-, and 10-hour ptotic responses, but the effect on the 24-hour ptosis was not statistically significant. Yohimbine potentiated at all observed time intervals when in a 1:4 reserpine-yohimbine mixture indicating that in high levels, yohimbine is capable of exerting considerable sustained effects.

Sex Variation in Response to Reserpine.—In the preceding assays a consistent sex variation to the reserpine-induced blepharoptotic response was detected, so a factorially designed assay was performed to document this observation. The results are tabulated in the last part of Table I, and the statistical evaluation noted in the last lines of Table II. At 5, 10, and 24 hours after dosing with reserpine alone, the males were significantly more susceptible than the females, with the greatest sensitivity being apparent at the 5- and 10-hour ptotic readings.

CONCLUSIONS

Yohimbine, although lacking true ptotic activity, potentiated reserpine-induced blepharoptosis without altering slope, dose-response relationships of this phenomenon, thus indicating that the mechanism of action of reserpine may involve depletion of norepinephrine more than the release of serotonin as a neurohormone. In mice, the males are more susceptible to oral

reserpine than the females. The presence of yohimbine in crude plant material may distort results obtained by mouse blepharoptotic assays where the goal of the assay is the quantitation or the detection of only reserpine-like alkaloids.

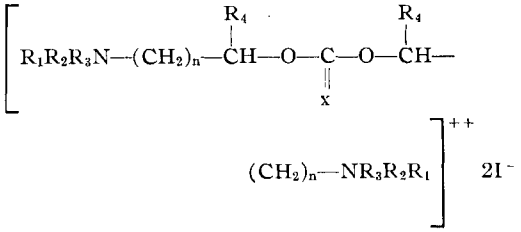
Synthesis and Pharmacological Effects of Bis-trialkylammonium Alkanol Carbonates



By LEO A. POHORYLES, L. WISLICKI, and SHALOM SAREL

The synthesis and pharmacological effects of a series of bis-trialkylammonium alkanol carbonates of the type I, are described. The compounds were tested in the cat for their effects on electrical excitability of striated muscle, respiration, and blood pressure, and in the frog rectus abdominis. While the ethyl derivative, (I-1), lowers blood pressure without affecting the muscle twitch, the propyl-(I-3) and, to a much higher extent, the butyl derivative, (I-6), depress neuromuscular transmission and also direct muscle excitability. Branching of the alkanol moiety (I-2), or replacement of the carbonate oxygen by sulfur (I-7), or insertion of ethyl for the methyl groups on the quaternary nitrogen (I-4 and I-5), weaken the effect. The block is similar to that caused by depolarizing agents.

IT IS WELL known that the curarizing activity of bis-quaternary ammonium compounds of the structure $R_3\overset{+}{N}—(CH_2)_x—\overset{+}{N}R_3$ is not substantially weakened by inserting in the linear polymethylene chain bivalent radicals like carbonyl and/or oxygen for the methylene groups. Introduction of one or more ester groupings into the chain linking the two ammonium groups provides powerful curare-like neuromuscular blocking agents; thus, choline esters of dicarboxylic acids, particularly that of succinic acid, proved to be valuable clinically. However, these substances were found to be not without drawbacks. These include, for the nondepolarizing drugs, their long action and side effects on heart rate or blood pressure. With suxamethonium, which *in vivo* is usually quickly decomposed by enzymatic hydrolysis, a high incidence of muscle pain (1, 2), the absence of an effective antagonist, and instability within a range of pH's (3) have been troublesome.

Received June 21, 1961, from the Hebrew University-Hadassah Medical School, Jerusalem, Israel.
Accepted for publication August 4, 1961.

In view of the great stability shown by open chain carbonates toward hydrolysis both in acid and alkaline solutions (4), the synthesis of a series of bis-trialkylammonium alkanol carbonates of the structure I was undertaken.

While the ethyl derivative, (I-1), lowers blood pressure without affecting the muscle twitch, the propyl-(I-3) and, to a much higher extent, the butyl derivative, (I-6), depress neuromuscular transmission and also direct muscle excitability. Branching of the alkanol moiety (I-2), or replacement of the carbonate oxygen by sulfur (I-7), or insertion of ethyl for the methyl groups on the quaternary nitrogen (I-4 and I-5), weaken the effect. The block is similar to that caused by depolarizing agents.

IT IS WELL known that the curarizing activity of bis-quaternary ammonium compounds of the structure $R_3\overset{+}{N}—(CH_2)_x—\overset{+}{N}R_3$ is not substantially weakened by inserting in the linear polymethylene chain bivalent radicals like carbonyl and/or oxygen for the methylene groups. Introduction of one or more ester groupings into the chain linking the two ammonium groups provides powerful curare-like neuromuscular blocking agents; thus, choline esters of dicarboxylic acids, particularly that of succinic acid, proved to be valuable clinically. However, these substances were found to be not without drawbacks. These include, for the nondepolarizing drugs, their long action and side effects on heart rate or blood pressure. With suxamethonium, which *in vivo* is usually quickly decomposed by enzymatic hydrolysis, a high incidence of muscle pain (1, 2), the absence of an effective antagonist, and instability within a range of pH's (3) have been troublesome.

Received June 21, 1961, from the Hebrew University-Hadassah Medical School, Jerusalem, Israel.
Accepted for publication August 4, 1961.

In view of the great stability shown by open chain carbonates toward hydrolysis both in acid and alkaline solutions (4), the synthesis of a series of bis-trialkylammonium alkanol carbonates of the structure I was undertaken.

I

I-1 $R_1 = R_2 = R_3 = CH_3$; $R_4 = H$; $n = 1$; $x = O$.
I-2 $R_1 = R_2 = R_3 = R_4 = CH_3$; $n = 1$; $x = O$.
I-3 $R_1 = R_2 = R_3 = CH_3$; $R_4 = H$; $n = 2$; $x = O$.
I-4 $R_1 = R_2 = CH_3$, $R_3 = C_2H_5$, $R_4 = H$, $n = 2$, $x = O$.
I-5 $R_1 = R_2 = C_2H_5$; $R_3 = CH_3$; $R_4 = H$; $n = 2$; $x = O$.
I-6 $R_1 = R_2 = R_3 = CH_3$; $R_4 = H$; $n = 3$; $x = O$.
I-7 $R_1 = R_2 = R_3 = CH_3$; $R_4 = H$; $n = 3$; $x = S$.

Differences in structure were designed with a

view toward studying their effect on the pharmacological pattern. As expected, the new quaternary ammonium iodides reported here exhibited remarkable stability in water solutions for a long period of time and could even be sterilized at 80° for 2 hours without chemical decomposition or changes in their pharmacodynamic effect.

EXPERIMENTAL PROCEDURE[1]

Materials.—The sources and purification procedures for the dialkylaminoalkanols used were as follows: commercial dimethylaminoethanol was fractionated and the cut b_{690} 130–133°, n_D^{22} 1.4280 was used. The 3-diethylamino-1-propanol (Eastman Chemical Co.) was fractionally distilled and the cut b_{23} 91–93° was collected. The 3-dimethylamino-1-propanol (Light's Organic Chemicals) was fractionated and the fraction b_{690} 185–190° was used. Thiophosgene (Matheson Coleman and Bell) was used without purification.

1-Dimethylamino-2-propanol was prepared in 30% yield by reacting dimethylamine with propylene oxide following Goldfarb's procedure,[5] b_{690} 116–119° (reported (5) b_{758} 124.5–126°), n_D^{17} 1.4115.

4-Chloro-1-butanol, b_4 62–66°, n_D^{20} 1.4490, was prepared in 50% yield following the method of Starr and Hixon (6).

4-Dimethylamino-1-butanol was prepared by reacting 4-chloro-1-butanol with aqueous dimethylamine at elevated temperature in a sealed system, as described below: a mixture of 4-chloro-1-butanol (109 Gm., 1 mole) and 30% aqueous dimethylamine (90 Gm., 2 moles) was placed in an autoclave and then gradually heated to 150°, causing the pressure to rise to 20 Atm. After 6 hours, heating was stopped and the reaction mixture was continuously extracted with ether during 4 days. The desired dimethylamino-butanol was isolated and purified by its fractionation through an efficient column, giving 56 Gm. (50% yield), of a colorless oil b_{20} 90–93°, n_D^{20} 1.4405 (Avison (7) reported b_{12} 78°, and Breckpot (8) reported n_D^{20} 1.4408).

The synthetic method used in this study involved: (*a*) the phosgenation of the appropriate ω-dialkylaminoalkanol (the resulting bis-dialkylaminoalkyl carbonate being not always isolated), followed by (*b*) quaternization of the corresponding base by means of methyl iodide.

Preparation of Bis-trialkylammonium-alkyl Carbonate Halogenides.—In a typical experiment, a cooled solution of 27 Gm. (0.27 mole) of phosgene in 135 ml. dry toluene was added with stirring to a solution of 4-dimethylamino-1-butanol (58.4 Gm., 0.4 mole) in dry toluene (100 ml.) at 0°, at such a rate that the temperature of the reaction mixture was maintained at 14 to 20°. After the addition was completed, the reaction mixture was stirred for an additional 2 hours, giving a heavy hygroscopic white precipitate (72 Gm.) of the required ester dihydrochloride. It was collected by quick filtration at the water pump, washed with dry ether, and then dissolved in dry ethanol. The free bis-dimethylaminobutyl carbonate was obtained by saturating the above ethanolic solution with dry gaseous ammonia at 0°. The free base, which is very soluble in ethanol, remained in the solvent; whereas the insoluble ammonium chloride separated, giving a white crystalline precipitate. Excess of ammonia was first removed by passing through the reaction mixture a stream of dry nitrogen and then the precipitate of ammonium chloride was removed by filtration. The free base was used in the subsequent step without being isolated.

Bis-trimethylammonium-butyl Carbonate Iodide.—To the resulting solution of bis-dimethylaminobutyl carbonate in ethanol (500 ml.) described above, there was added dropwise, with shaking, methyl iodide (80 Gm.) at such a rate that the temperature of the reacting system was maintained at 25°. After addition was completed, the reaction mixture was heated at 40° for 2 hours and then it was concentrated to half its volume by evaporating the solvent at reduced pressure. On cooling, the required bis-trimethylammonium-butyl carbonate iodide separated as a semisolid product. The purification of the bis-quaternary ammonium salt was effected by the dropwise addition of either *n*-butanol or dry ether to its stirred methanolic solution, providing 25 Gm. of the pure compound as a white powder.

Bis-trimethylammonium-butyl Thiocarbonate Iodide.—A solution of 4-dimethylaminobutanol-1 (20 Gm., 0.17 mole) in 100 ml. dry toluene was reacted with thiophosgene (10 Gm., 0.087 mole) dissolved in 50 ml. toluene in the fashion described above. After removing half of the amount of solvent by distillation at reduced pressure, the thiocarbonate derivative thus formed was not isolated but reacted with an excess of methyl iodide. The desired quaternary ammonium iodide could not be induced to recrystallize from ordinary solvents; it was purified by its repeated dissolution in methanol and precipitation by adding ether.

The melting points and yields of the compounds prepared are given in Table I.

PHARMACOLOGY

The experiments were performed on cats under pentobarbital anesthesia following induction with ether; a total of 34 animals was used. An external jugular vein was cannulated for injections, and a femoral or carotid artery for measurement of blood pressure. Respiration was recorded by means of a tambour connected to a tracheal cannula which was fitted with an adjustable air leak.

To test muscle excitability, an Achilles tendon was separated from the bone and connected to an isometric lever. The ipsilateral sciatic nerve was divided high in the thigh and its distal portion mounted on a pair of shielded silver electrodes, the distal electrode serving as cathode. The anode of a second pair of electrodes was attached to the gastrocnemius near its origin and the cathode placed on its tendon. Supramaximal square wave stimuli were administered with a Fleming stimulator; pulse width of indirect stimuli was 0.15 msec. and that of direct stimuli 1.2 msec. By means of relays, indirect and direct stimuli could be delivered alternately; they were applied either at a rate of 15/min. or in pairs, an indirect stimulus preceding a direct

[1] All m.p.'s were taken on Dr. Tottoli melting point apparatus and are uncorrected.

one by 2 seconds and each pair being separated from the next by 6 seconds.

For preparations of the rectus abdominis muscle, *Rana ridibunda* was used.

RESULTS

The lower homolog in the series, compound I-1, in which the ammonium groups are separated by a linear chain of seven atoms, did not affect muscle excitability, but 0.2–0.5 mg./Kg., given intravenously, reduced blood pressure by 40–55 mg. Hg for a few minutes. Intramuscular injection of 16 mg./Kg. was ineffective (3 observations).

With the next higher homolog in this series, compound I-3, in which the ammonium groups are separated by a linear carbonate chain of nine atoms, inhibition of muscle excitability appeared while the hypotensive action receded (2 observations). As Fig. 1 shows, 0.3 mg./Kg. i.v. depressed neuromuscular transmission and, to a lesser extent, the response to direct stimulation and respiratory movements; 1 mg./Kg. abolished indirect excitability for 75 minutes, halved the response to direct stimulation for 50 minutes, and caused apnea for one-half hour.

The blocking effect on muscle was strongly enhanced in I-6 (16 observations). Sensitivity of the animals to this substance varied greatly: usually

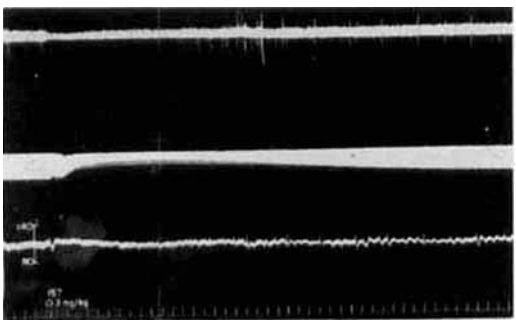

Fig. 1.—Cat, ether-pentobarbital anesthesia. Alternating direct and indirect supramaximal stimulation of gastrocnemius muscle. From top down: respiration, gastrocnemius twitch, blood pressure, time, in minutes, and signal. Effect of 0.3 mg./Kg. I-3 i.v.

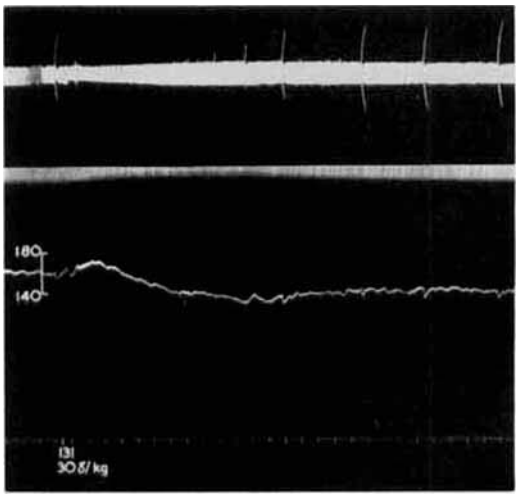

Fig. 2.—Arrangement as in Fig. 1. Effect of 30 mcg./Kg I-6 i.v.

15–30 mcg./Kg. produced only a partial block in the gastrocnemius and very slight depression of respiration (Fig. 2); 40 mcg./Kg. (Fig. 3) caused, after fast injection, potentiation of the twitch response and general fasciculations which lasted for a few minutes; neuromuscular transmission and spontaneous respiration were abolished and direct muscle excitability depressed for longer periods. Recovery of respiration was much quicker than that of the leg muscle.

Neostigmine did not restore neuromuscular transmission though two intravenous injections of 30 mcg./Kg. each, administered within 1 minute, stimulated respiration and speeded up return of excitability slightly.

The onset of the block after substance I-6 was similar to that after depolarizing agents, e.g., suxamethonium, in that it was characterized by augmentation of twitch height and by fasciculations; it also caused in the frog rectus abdominis a contraction whose speed rose with the dose administered without, however, approaching that observed after similar doses of acetylcholine (Fig. 4); tachyphylaxis did not appear with the amounts used.

The thio-derivative of the carbonic acid, I-7, proved to be about 100 times less effective as a

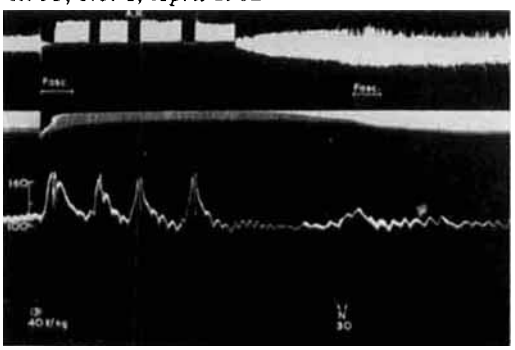

Fig. 3.—Arrangement as in Fig. 1. A.R., artificial respiration; Fasc., general fasciculations; N, 30 mcg./Kg. neostigmine i.v.; effect of 40 mcg./Kg. I-6 i.v.

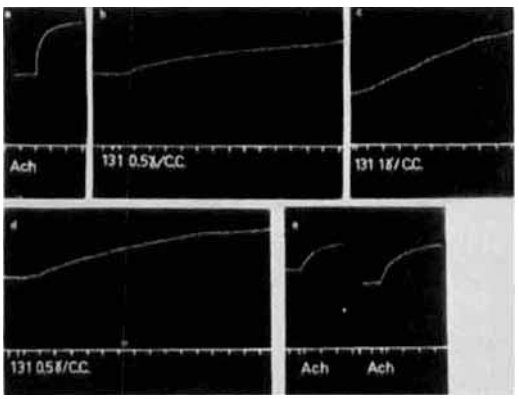

Fig. 4.—Effects of 0.5–1 mcg./ml. I-6 on frog rectus abdominis muscle compared to that of 0.7 mcg./ml. acetylcholine (Ach). Intervals between curves, 5 minutes when the muscle was washed three times. Time in min.

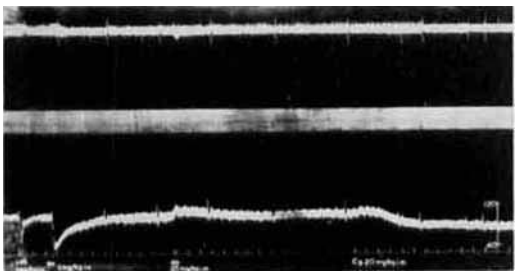

Fig. 5.—Arrangement as in Fig. 1. Effect of 1 and 5 mg./Kg. I-2 i.v. and of 25 mg./Kg. I-2 i.m. compared to that of 20 mg./Kg. hexamethonium i.m.

blocking agent than the parent compound (3 observations). About 3 mg./Kg. were required to produce effects on muscle excitability, respiration, and blood pressure similar to those observed after 15–40 mcg./Kg. of I-6.

Unlike lengthening of the chain in the linear homologs of the series, branching at the carbons linked to the oxygens resulted in compounds with diminished potency. Thus, 1–5 mg./Kg. of I-2, given i.v., produced a brief hypotension, but 25 mg./Kg., injected i.m., did not lower blood pressure (4 observations). In the experiment shown in Fig. 5 these effects are compared with that of hexamethonium. Substitution in the quaternary ammonium group of methyls by ethyls also weakened the biological actions. Thus I-4, which has one ethyl group linked to each ammonium group, had a shorter paralyzing action than the trimethyl analog, and the di-ethyl methyl analog (I-5) was even ten times less effective (3 observations).

DISCUSSION

The weak hypotensive action of I-1 and the absence of this effect in I-3 is in keeping with the observations made by Paton and Zaimis (9) on the cat's superior cervical ganglion.

As far as neuromuscular blocking potency was concerned, Paton and Zaimis' curve shows highest activity for decamethonium (C_{10}) and a steep fall for longer chain substances; for the series reported in this paper, the distance of 11 atoms resulted in a compound which was 10–20 times more powerful in depressing muscle excitability than the one whose chain was shorter by two carbons.

The decreasing tendency in curarizing action resulting either from substituting methyls for ethyls on the quaternary nitrogen or from branching of the polymethylene chain corresponds to that reported by Bovet and co-workers (10).

Augmentation of the twitch and general fasciculations which frequently appear immediately after injection of I-6 indicate that the block caused by this substance is of the depolarizing type. A comparable action is the failure of neostigmine to antagonize the block, which conforms to that described for decamethonium, and the stimulating action on the frog rectus abdominis, which corresponds to that of suxamethonium and other depolarizing agents (9, 11).

Unlike suxamethonium which undergoes partial hydrolysis upon keeping its aqueous solutions at room temperature (12), I-6 was found to be stable for at least 1 year under comparable conditions.

Preliminary Phytochemical Study of *Lychnis alba* Saponin

By KARLIS K. KAZEROVSKIS

Distribution of *Lychnis alba* saponin in the plant is determined. A method for the isolation of the saponin by column chromatography and the detection of the saponin on paper chromatograms with a gelatin blood suspension gel is reported.

SAPONIN containing plants have been used in therapeutics and in the household for centuries. In recent years, these plants have become a focal point in pharmaceutical research. Discovery of the adrenal cortical steroids resulted in a large scale and systematic investigation of plants containing sterol saponins in the United States as possible sources of the precursors essential to the synthesis of cortisone and its derivatives. U. S. Department of Agriculture research groups (1) have tested about 5,000 samples representing a large number of the genera and plant families of the United States and abroad for their saponin, alkaloid, flavanoid, and sterol content. In an earlier phytochemical study (2), 21 wild growing plants in Latvia were tested for the presence of saponins.

In the phytochemical studies of wild growing plants in Michigan, *Lychnis alba* Mill., a member of the family *Caryophyllaceae*, seemed to deserve a closer investigation due to its hemolytic properties, abundance, and relationship to *Saponaria officinalis* L., a well-known source of a saponin. *Radix saponariae* is used in Germany as an expectorant (3).

EXPERIMENTAL

Plant.—*Lychnis alba* Mill. (Fig. 1) known also as *Melandrium album* Rydb. was originally described by Miller. This plant is also known as white cockle, campion, and evening lychnis (4).

The morphological description of the plants collected for the investigation were checked (4, 5) and identification of the plants was confirmed by Drs. Virginia and Harold E. Bailey of Wayne State University, Detroit, Mich.

Lychnis alba Mill. is a naturalized plant from Eurasia growing on the waste places, along the roadsides and borders of the fields, and on the recently idled farm lands. The Northern boundary of its distribution extends from Quebec to British Columbia, and to the South as far as North Carolina, Ohio, Illinois, Colorado, and California.

It is a dioecious annual or short-lived perennial plant, 2 to 3 feet tall, with a stout root system. Inflorescence is usually branched. Flowers are white, fragrant, and opening in the evening. Fruit is an ovoid capsule.

Fig. 1.—*Lychnis alba* Mill. staminate and pistillate plants.

Material and Method.—The plant material was collected in Mecosta County, Mich., in June and October 1959, dried in a drying oven, and powdered to pass through a No. 40 mesh.

Distribution of the saponin in the plant was determined by Kobert's hemolytic index (6) see Table I. Citrated rat blood was used. Plant extracts were prepared in a normal saline solution on a steam bath.

In this study 2 Kg. of the dried roots were used. Fatty and waxy substances were removed with petroleum ether (b.p. 30–60°) and ether. Hemolysis was used as a test to follow the course of the isolation of the saponin.

Solubility and heat stability tests of *L. alba* saponin indicated that the saponin could be ex-

TABLE I.—HEMOLYTIC INDEXES OF PARTS OF *L. alba*

Part Used	Concn. of Saline Extract Prepared	Hemolytic Index
Root	1:250	1250
Seeds	1: 50	166
Leaves	1: 50	166
Flowering tops	1: 50	did not hemolyze

tracted by hot water or hot alcohol. From the hot 95% alcoholic extract, a part of the saponin precipitates as a white amorphous substance. Preliminary adsorption tests on alumina and Florisil columns revealed that *L. alba* saponin is adsorbed on the alumina as well as on the Florisil when water or 95% alcohol is used as a solvent. From developed chromatograms the saponin could be eluted with a 25% alcohol.

Three fractions of *Lychnis alba* saponin (fractions A, B, and C) were prepared in the following manner:

Fraction A.—A 1-Kg. portion of the dried powdered root was extracted with water on a steam bath four times for 4 hours each time. Saponin fraction was adsorbed on a Florisil column and eluted with 25% alcohol. After removal of the solvent in a flash evaporator, an amorphous, slightly yellowish substance was obtained, fraction A. Hemolytic index of this fraction was 13,300.

Fraction B.—Dried powdered root, 1 Kg., was extracted with 95% alcohol on a steam bath six times for 4 hours each time. From the hot alcoholic extract, a part of the saponin precipitated out, fraction B. Hemolytic index of this fraction was 6,600.

Fraction C.—That saponin fraction remaining in the solution of 95% alcohol was again adsorbed on a Florisil column and eluted with 25% alcohol. After removal of the solvent, an amorphous yellowish substance was obtained, fraction C. Hemolytic index of this fraction was 6,600.

All efforts to crystallize the saponin fractions failed. The same was true in using cholesterol for purification.

Paper Chromatography.—In available literature glycosides as well as saponins have been detected on the paper chromatograms by using reagents forming colored spots with the glycone of the glycoside, or specific reagents are used to detect the aglycone.

Bliss and Ramstad (7) used paper chromatography for the glycoside separation and located the glycosides on the chromatograms after hydrolysis with carbohydrases and spotting the sugars with an aniline hydrogen phthalate reagent. Dutta (8) has used a sodium *meta*-periodate in alkaline potassium permanganate solution to identify the saponin spots on paper chromatograms.

Gelatin blood suspension in an isotonic solution has been used for a long time for the microchemical detection of the saponins in the plant materials as indicated by Fischer (9).

In this study a gelatin blood suspension gel was used to reveal the saponin spots on the paper chromatograms.

Strips of Whatman filter paper No. 1 were spotted with a 2% solution (5 λ) of saponin fractions A, B, and C, then dried and placed in a chromatographic chamber. When the equilibrium in the chamber was reached, chromatograms were developed with several developers. Gelatin blood suspension (5 Gm. gelatin, bacteriology grade, was dissolved in an isotonic solution containing 0.7% sodium chloride and 0.6% secondary sodium phosphate; to 100 ml. of such a solution, 5 ml. of citrated rat blood was added) was poured through muslin, to retain the air bubbles, on a leveled glass plate on which the desired area was enclosed with melted paraffin.

In order to provide a closed chamber around the blood gelatin suspension, another glass plate was placed on rubber tubing surrounding the designated area. When gel was formed, paper chromatograms were placed on the gel. After 2 to 4 hours, red blood cells hemolyzed under the saponin spots on paper chromatograms and the filter paper in that area stained reddish-brown. See Table II and Fig. 2.

TABLE II.—R_f VALUES OF THE SEPARATE FRACTIONS OF *L. alba* SAPONIN USING ASCENDING CHROMATOGRAPHY

Developer	Fraction A	Fraction B	Fraction C
No. 1 *n*-Butanol, 60 ml. Ethanol, 13 ml. 1 *N* Ammonia, 27 ml.	0.33	0.33	0.33
No. 2 *n*-Butanol saturated with 1 *N* HCl	0.14	0.14	0.14
No. 3 *n*-Butanol, 4 ml. Acetic acid, 1 ml. Distilled water, 5 ml.	0.15	0.16	0.16
No. 4 *n*-Butanol saturated with water	0.09	0.11	0.10

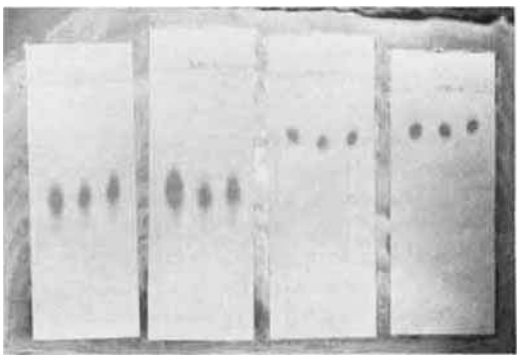

Fig. 2.—Saponin spots on paper chromatograms after hemolysis. The first two chromatograms are digitonin, the second two chromatograms are *Lychnis alba* saponin.

As long as developer No. 1 provided the highest R_f value for *L. Alba* saponin, several experiments were performed by spotting wide paper strips with all three saponin fractions and developing by developer No. 1. According to the results obtained, each of the three fractions contains one saponin and it is likely the saponin in each fraction is the same compound.

SUMMARY

Lychnis alba Mill. is a plant which contains a saponin. Most of the saponin is in the root.

Saponin can be extracted with hot water or hot alcohol, concentrated and purified on a Florisil column, and eluted with 25% alcohol.

Three fractions of *L. alba* saponin have been prepared and it is very likely that they contain just one saponin.

Gelatin blood suspension gel is useful in the detection of saponin on paper chromatograms.

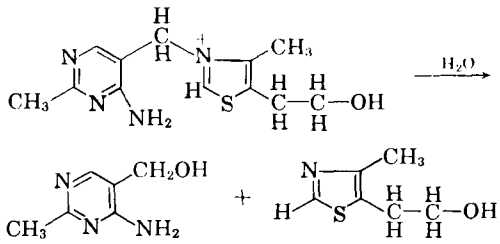
Kinetics of Thiamine Hydrolysis



By JOHN J. WINDHEUSER and TAKERU HIGUCHI

The pH-rate profile of the hydrolytic cleavage of thiamine determined from kinetics measurements has been found to be unusually complex. Under essentially buffer-free conditions, the overall behavior suggests existence of at least four separate reactions: (*a*) acid catalyzed mechanism leading to the formation of oxythiamine at pH below 1; (*b*) water cleavage of protonated thiamine yielding a pyrimidine and a thiazole fraction between pH 1–6; (*c*) at pH 2–6.5, hydroxyl ion catalysis of protonated thiamine producing the same products found in reaction (*b*); (*d*) above pH 6.5, water cleavage of thiol thiamine to yield a pyrimidine diamine and other undetermined products. The ionic strength and temperature dependency of the reaction has also been determined. Contrary to earlier works, the hydrolytic reaction appears not to be subject to major negative or positive catalysis by amino acid species. The rate, however, is pronouncedly influenced by what appears to be general base catalysis by several buffer species.

ALTHOUGH hydrolytic cleavage of thiamine, an important pharmaceutical product, represents the major mode of anaerobic degradation of the vitamin, the kinetic dependency of this reaction on pH has not previously been reported in terms of the reactive species present. The present contribution is concerned with the results of an investigation designed to establish the pH profile of this important reaction, to reconfirm the degradation products under the conditions of the experiments and to correlate them with the kinetic observations, to determine whether agents other than hydroxyl and hydrogen ions can accelerate or inhibit the cleavage, and to establish its dependency on other kinetic variables.

Some doubt has been expressed previously on the question of whether the cleavage followed a strictly first-order kinetic expression with respect to the vitamin (1–3), although it appears generally agreed that the rate of hydrolysis was enhanced by increasing pH and the temperature (4–8). Others (9, 10) have also noted that buffers increased the rate of the reaction, although no attempts were made to evaluate the specific effects. McIntire and Frost (2), studying the effects of various compounds on the hydrolytic rate, claimed to have found inhibitory and catalytic effects but did not establish mechanisms for the observed results.

Several cleavage products have been recovered and identified. Watanabe (11), working with the reaction products resulting from the hydrolysis of a 0.5% thiamine solution heated at 140° for 12 hours at approximately pH 3.5, the pH resulting from a solution of the salt itself, was able to isolate and identify the degradation products and proposed the following reaction

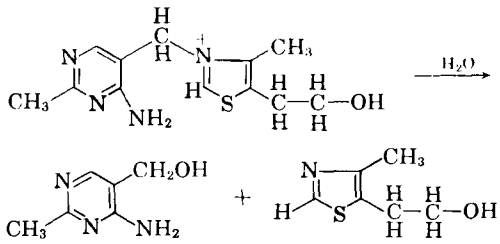
Kinetics of Thiamine Hydrolysis

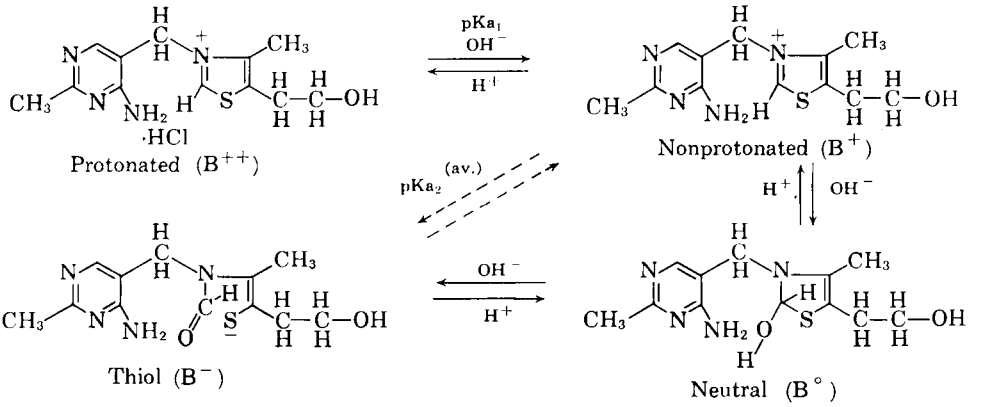


By JOHN J. WINDHEUSER and TAKERU HIGUCHI

The pH-rate profile of the hydrolytic cleavage of thiamine determined from kinetics measurements has been found to be unusually complex. Under essentially buffer-free conditions, the overall behavior suggests existence of at least four separate reactions: (*a*) acid catalyzed mechanism leading to the formation of oxythiamine at pH below 1; (*b*) water cleavage of protonated thiamine yielding a pyrimidine and a thiazole fraction between pH 1–6; (*c*) at pH 2–6.5, hydroxyl ion catalysis of protonated thiamine producing the same products found in reaction (*b*); (*d*) above pH 6.5, water cleavage of thiol thiamine to yield a pyrimidine diamine and other undetermined products. The ionic strength and temperature dependency of the reaction has also been determined. Contrary to earlier works, the hydrolytic reaction appears not to be subject to major negative or positive catalysis by amino acid species. The rate, however, is pronouncedly influenced by what appears to be general base catalysis by several buffer species.

ALTHOUGH hydrolytic cleavage of thiamine, an important pharmaceutical product, represents the major mode of anaerobic degradation of the vitamin, the kinetic dependency of this reaction on pH has not previously been reported in terms of the reactive species present. The present contribution is concerned with the results of an investigation designed to establish the pH profile of this important reaction, to reconfirm the degradation products under the conditions of the experiments and to correlate them with the kinetic observations, to determine whether agents other than hydroxyl and hydrogen ions can accelerate or inhibit the cleavage, and to establish its dependency on other kinetic variables.

Some doubt has been expressed previously on the question of whether the cleavage followed a strictly first-order kinetic expression with respect to the vitamin (1–3), although it appears generally agreed that the rate of hydrolysis was enhanced by increasing pH and the temperature (4–8). Others (9, 10) have also noted that buffers increased the rate of the reaction, although no attempts were made to evaluate the specific effects. McIntire and Frost (2), studying the effects of various compounds on the hydrolytic rate, claimed to have found inhibitory and catalytic effects but did not establish mechanisms for the observed results.



Several cleavage products have been recovered and identified. Watanabe (11), working with the reaction products resulting from the hydrolysis of a 0.5% thiamine solution heated at 140° for 12 hours at approximately pH 3.5, the pH resulting from a solution of the salt itself, was able to isolate and identify the degradation products and proposed the following reaction

Received April 3, 1961, from the School of Pharmacy, University of Wisconsin, Madison.
Accepted for publication June 9, 1961.
This study was supported in part by a grant (A-3437) from the National Institutes of Health, Bethesda, Md., and from Parke Davis and Co., Detroit, Mich.

In a recent publication, Watanabe (12), reviewing the physical chemical properties of thiamine, indicated that in alkaline solution the products of the degradation became more complex and differed from those found in the acidic region. Under strongly acidic conditions the products of the degradation again change. Rydon (13) was able to prepare and isolate oxythiamine by refluxing thiamine in 6 *N* hydrochloric acid for 6 hours. This compound appeared to be formed by the hydrolysis of the 4-amino group on the pyrimidine ring.

Any detailed kinetic analysis of the hydrolytic rate must take into account the existence of different thiamine species in solution. The vitamin undergoes several transformations under conditions of increasing pH. Williams (14) found, when titrating thiamine chloride hydrochloride with base, that after one mole equivalent of base, the pH did not continue to rise rapidly on further addition. The addition of two more mole equivalents of base were required for complete neutralization. He further observed that the last two moles of base reacted at a finite rate, indicating an internal rearrangement, which he postulated as follows

Back titration with acid showed the reaction to be reversible. As it was not possible to determine the concentration of the neutral intermediate, it was necessary to calculate an average equilibrium constant for the conversion of the nonprotonated thiamine to the thiol form, rather than the constants for the individual steps. This constant was designated as the average second dissociation constant. From his data, Williams calculated pKa_1 to be 4.8 and pKa_2 to be 9.0 at 25°. These values are in good agreement with those found by later workers (15, 16).

RESULTS AND DISCUSSION

Reaction Order with Respect to Thiamine.—The results of the present investigation clearly indicate that the hydrolytic reaction proceeds at rates directly proportional to the thiamine concentration in accord with the recent suggestion of Watanabe (12) and in contrast to his earlier work (1) and that of Farrer (3) and McIntire and Frost (2). A plot of the logarithm of the residual thiamine concentration *vs.* reaction time yielded a straight line in each case. The calculated first-order rate constants were found to be identical within experimental limitations. The observed half-lives of the reaction at varying thiamine concentrations are shown in Table I. For our studies, solutions were prepared at constant ionic strength, constant buffer concentration, constant pH, but with varying amounts of thiamine.

TABLE I.—EFFECT OF INITIAL THIAMINE CONCENTRATION ON THE OBSERVED HALF-LIFE OF THE REACTION AT pH 6.37 IN SOLUTIONS DEGRADED AT 96.4°

Initial Thiamine, mg./100 ml.	$t_{1/2}$, hr.
200.0	5.4
100.0	5.5
50.0	5.4
25.0	5.4
12.5	5.5
5.0	5.4
1.0	5.4
0.5	5.5

The previously reported changes of the reaction order might be attributed to changes of pH and also variations of ionic strength of the system. At some pH ranges, the ionic strength apparently has a marked influence on the rate of the reaction.

Dissociation Constants of Thiamine.—As previously stated, the evaluation of the reactions of thiamine requires a detailed knowledge of the species present in the system. For this purpose the dissociation constants were determined at varying temperatures and ionic strength such as to permit species analysis under the conditions of the kinetic runs. From spectrophotometric measurements, based on the method of Flexer (17), pKa_1 was estimated to be 4.0 at 96.4° and pKa_2 (av.) to be 7.8. These values were actually obtained by extrapolation of data determined at lower temperatures from Arrhenius-type plots as shown in Fig. 1 since the instability of the compound precluded deter-

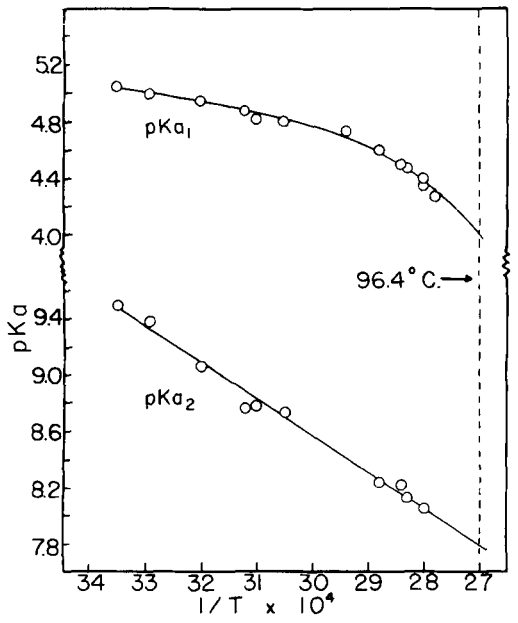


Fig. 1.—Effect of temperature on spectrophotometrically determined pKa_1 and pKa_2 of thiamine at ionic strength 0.5.

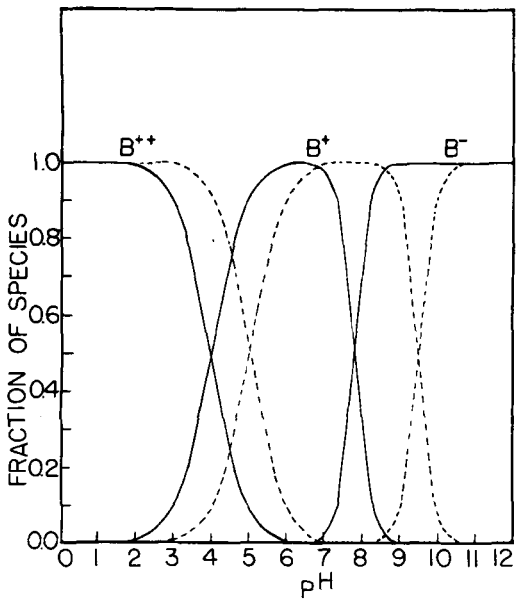

Fig. 2.—Fraction of thiamine species present in solution as functions of pH at 96.4° (—), and 25.0° (---) as calculated from the experimentally determined pKa_1 and pKa_2. B^{++} represents protonated thiamine, B^+ nonprotonated thiamine, and B^- thiol thiamine.

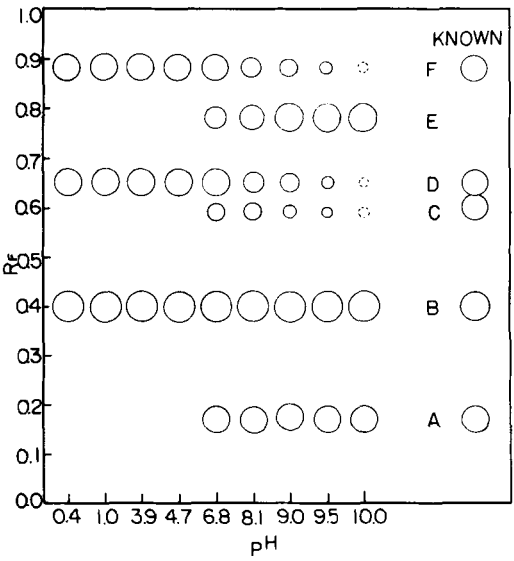
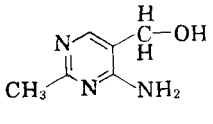
mination at the higher temperature. Figure 2 shows the variations of the thiamine species as a function of pH at 25 and 96.4°. The symbols B^{++} to denote protonated thiamine, B^+ for nonprotonated thiamine, and B^- for the thiol form will be used throughout this presentation.

Identification of the Cleavage Products.—Based on the present findings, and those of others cited, three hydrolytic reactions appear to be responsible for degradation under nonoxidative conditions, the relative importance of each being dependent on the pH of the solution. (*a*) In strongly acid solutions, thiamine apparently degrades by replacement of the primary amino group on the pyrimidine ring by a hydroxyl group to yield oxythiamine. (*b*) The singly protonated and nonprotonated forms which exist in the weakly acid to neutral range seem to undergo simple hydrolytic cleavage at the methylene bridge between the pyrimidine and thiazole groups. (*c*) Under alkaline conditions, where thiamine is present as the thiol form, the end products suggest multiple pathways of degradation. One mechanism resulted in the formation of a pyrimidine diamine and the others resulted in products which have not yet been clearly identified.

To establish the identities of the degradation products over a broad pH range, solutions sealed in ampuls under nitrogen were subjected to hydrolysis at pH values varying from 0.4 to 10.0. The products were separated by a modification of the paper chromatographic technique reported by Lhoest, *et al.* (18). Figure 3 is a composite representation of the chromtographs obtained from the degraded samples along with spots from known compounds. The spots are shown at the average R_f value for each compound and are represented by circles for illustrative purposes.

The results in neutral and acidic media confirmed those of Watanabe (11), in that the end products in this range were 2-methyl-4-amino-5-hydroxymethyl pyrimidine (D) and 4-methyl-5β-hydroxyethyl thiazole (F).





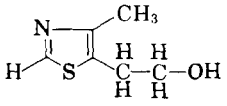


Fig. 3.—Composite representation of paper chromatograms from solutions degraded at 96.4° at various pH's. The spots represent the following compounds: A, 2-methyl-4-amino-5-aminomethyl pyrimidine; B, thiamine; C, thiochrome; D, 2-methyl-4-amino-5-hydroxymethyl pyrimidine; E, unidentified; and F, 4-methyl-5β-hydroxyethyl thiazole. The circles are representative of the size and position of the spots found, not the shape.

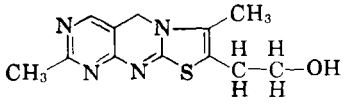
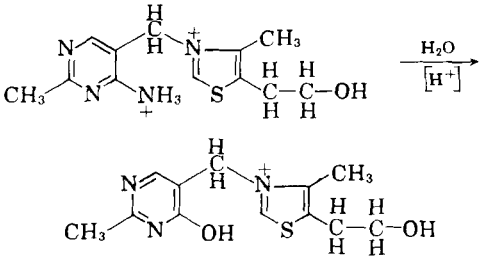


2-Methyl-4-amino-5-hydroxymethyl pyrimidine (D)



4-Methyl-5β-hydroxyethyl thiazole (F)

These compounds were apparently formed as a result of the hydrolytic cleavage of thiamine at the methylene bridge. Although traces of thiochrome (C) were found on some of the chromatograms, electrofluorometric measurements indicated that the amount formed was negligible. This compound, which is an oxidation product of thiamine may have been produced when the ampuls were opened for removal of sample. At high pH the thiochrome production probably ceased due to the inability of the thiol form of thiamine to yield this compound (15).

Thiochrome

In systems of acid concentration higher than 1 *N* acid, a different route of degradation appeared to become dominant. Rydon (13) found that after refluxing thiamine in 6 *N* hydrochloric acid for 6 hours, a new compound was formed in which the primary amine on the pyrimidine ring was replaced by a hydroxyl group according to the following reaction
