

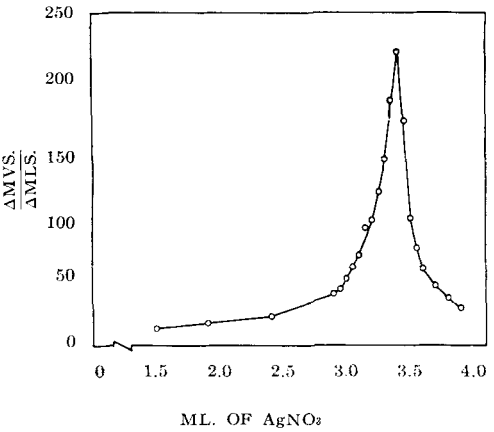

Fig. 1.—A typical first derivative titration curve for barbital titrated with silver nitrate.

tion of free silver ion concentration by measuring the potential using a silver electrode and calomel electrode system

$$p\mathrm{Ag} = \frac{0.7991 - E_s - E_c}{0.0591}$$

Where E_c is the E.M.F. of the calomel electrode which is 0.2444 v. when the electrode contains a saturated solution of potassium chloride at 25° (8). E_s is the measured E.M.F. of the system.

The concentration of anionic complex and free barbiturate was determined by the procedure described by Perelman (4, 5). Molar concentration of the free barbiturate was calculated by the equation

$$C_{\mathrm{molar}} = \frac{(c - a) \cdot N}{a + b}$$

The molar concentration of the anionic complex was calculated in a similar manner, by the equation

$$C_{\mathrm{molar}} = \frac{a \cdot N}{a + b}$$

Where a is the number of milliliters of titrant added; N is the normality of titrant (silver nitrate); b designates the number of milliliters in the original sample solution; and c is the number of milliliters of titrant at the end point, determined by the maximum Δ mv./Δ ml. In all calculations, molar concentrations were used, since the silver ion concentration was so low it was assumed that the activity coefficients were unity.

Results.—The data presented in Table I were obtained from the potentiometric titration procedure. The per cent recovery (titration efficiency) and stability constant data are the average values from a series of determinations plus the standard deviations from the mean.

Perelman (4, 5) calculated the instability constants for diallylbarbituric acid, $K_{\mathrm{ins}} = 1.1 \times 10^{-7}$ ($K_s = 9.1 \times 10^6$) and barbital, $K_{\mathrm{ins}} = 4.7 \times 10^{-8}$ ($K_s = 2.1 \times 10^7$). Poethke and Furst (6) have reported the instability constants for barbital and phenobarbital respectively, $K_{\mathrm{ins}} = 4.0 \times 10^{-7}$ ($K_s = 2.6 \times 10^6$) and 2.7×10^{-7} ($K_s = 3.7 \times 10^6$). The data presented in Table I agree with the limited number of values given by Poethke and Furst.

A general trend is noted between the stability constants of these anionic complexes and the pKa values of the parent acids. Due to the relatively narrow range which the pKa values span for the barbituric acids, it would be expected that the stability constants would be of similar magnitude. The stability of the complexes are of the same magnitude and slightly increase with the decrease in the pKa of the parent acid.

Effect of Silver Ion on the Molar Absorptivity of Barbital.—Danielsson (2) reported that the molar absorptivity of the silver-barbital anion at the pH of 10.9 appears to be 18,820 when determined at 238 mμ. Previously, the molar absorptivity of barbital, at 239 mμ and the pH 10.9, has been shown to be 10.2×10^3 (9). In order to assay barbital in the presence of silver ion and silver-barbital complex, the absorbances of these various species were determined.

The absorbances of 3.89×10^{-5} M solutions of barbital (total) were measured by a Beckman DU spectrophotometer at 239 mμ. The solutions contained varying amounts of silver ions and were buffered at pH 10.9. The data are presented in Table II.

The average molar absorptivity of the complex is 10.10×10^3, which correlated within 99.0% of the

TABLE II.—EFFECT OF SILVER ION ON THE ABSORBANCE OF BARBITAL

Sample	Barbital, $M \times 10^5$	Silver Complex, $M \times 10^5$	Free Barbital, $M \times 10^5$	A_{obs}
1	3.89	0	3.89	0.398
2	3.89	0	3.89	0.397
3	3.89	0.841	3.05	0.400
4	3.89	0.841	3.05	0.395
5	3.89	1.680	2.21	0.394
6	3.89	1.680	2.21	0.395
7	3.89	2.520	1.37	0.395
8	3.89	2.520	1.37	0.394
9	3.89	3.360	0.53	0.398
10	3.89	3.360	0.53	0.388

literature value (9) for the molar absorptivity of barbital. Thus, it appears that the spectrophotometric assay is efficient for determining the total amount of barbital in the system.

Effect of Silver Anionic Complex on the Stability of Barbital.—The decomposition of aliphatic substituted ureides in alkali has been shown to be retarded when intermolecular hydrogen bonding is present. Werner (10) described this as chelate formation. Since barbiturates are cyclic ureides which hydrolyze in alkaline solution, silver ions are believed to form a silver-barbiturate anionic complex which resists hydrolysis.

A 0.2 *M* solution of sodium carbonate (pH 11.0) was employed as the alkaline medium. Barbital solutions were prepared of approximately 4.0×10^{-3} *M* and varying amounts of silver nitrate. Samples were sealed in 2-ml. Neutraglas ampuls and placed in an oil bath at 42.5°. At various time intervals, samples were removed from the constant temperature bath and immediately frozen in a chloroform-dry ice mixture. The samples were assayed spectrophotometrically as previously described.

The degradation rate (apparent) is defined by the following equation

$$k_{app} = N_{barb}\, k_{barb} + N_{barbAg}\, k_{barbAg}$$

Where N_{barb} is the mole fraction of free barbital, N_{barbAg} the mole fraction of silver-barbital complex (silver mole fraction), k_{barb} the pseudo first-order degradation rate of free barbital, and k_{barbAg} the pseudo first-order degradation rate of the complex.

The results are presented in Table III, and Fig. 2 illustrates the relationship between the pseudo first-order reaction rate and the concentration of anionic silver-barbital complex. The comparison of the reaction rate constants between the control samples and the samples containing known amounts of silver ion concentration agrees within 97.7% of the calculated rate of hydrolysis (assuming that only the free barbital degrades). Calculated data (solid line) had a slope -5.43×10^{-5} and the experimental data (broken line) had a slope -5.56×10^{-5}, determined by the method of least squares.

TABLE III.—EFFECT OF SILVER ION ON THE DEGRADATION OF BARBITAL

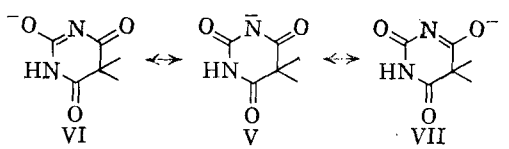
DISCUSSION AND RESULTS

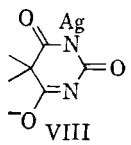
Perelman (4) has described the reaction sequence for the formation of the silver complexes of barbiturates. In an alkaline solution, barbiturates react with silver ions in a step-wise fashion which is shown by the following formulas

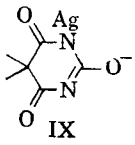


Gautier, *et al.* (3), have followed the released protons of these reactions in pyridine. They have shown that titration of the free barbituric acid liberated two protons and that one proton is liberated when the sodium salts are employed.

Poethke and Furst (6) represent the following formulas as the anionic complex (III) and the water-insoluble disilver barbiturate (IV) as chelate compounds

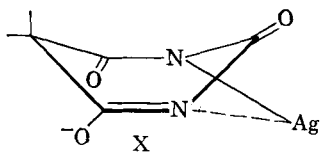
Goyan, *et al.* (11), have written the resonance forms of the anionic species in the following manner





Spectral data have supported the view that species V is not the resonance form which is attacked by the silver ion. The enol forms which are present in alkaline solution are the species responsible for the increase in absorbance and are represented by structures VI and VII. We have shown that the silver-barbital anionic complex does not appear to alter the absorptivity of the barbiturate. Thus, the

silver ion does not change the electron distribution in the enolized form.



Goyan, *et al.* (11), have suggested that barbital degradation in ammonia buffer is similar to ammonolysis of an ester and that hydrolysis of the ionized species would probably be at the 4 (or 6) position. By virtue of infrared spectra of the *p*-nitrobenzyl derivatives of a series of barbiturates, Chatten and Levi (12) have proposed that the mechanism of the reaction involves enolization of the carbonyl at position 4 (or 6).

The silver-barbiturate anionic complex has been shown to be stable in alkaline solution. The silver ion, when attacking the barbiturate anion, liberates a proton, thus the nitrogen atom which is not involved in the enolization appears to be the position of the silver ion, as shown by structures VIII and IX

VIII

IX

These formulas do not appear to explain the stability of the complex to alkaline hydrolysis, especially if the 4 (or 6) carbonyl group is the position vulnerable to hydroxyl ion attack.

X

Barbiturates which have substituents on a nitrogen atom, i.e., a methyl group, are known to hydrolyze in the same way as the unsubstituted compounds. The mono silver anionic complexes are believed to be stabilized by the formation of a chelate structure involving both the 1 and 3 nitrogen atoms. This compound was previously described by Poethke and Furst (6) and is represented by structure X.

SUMMARY

1. Stability constants for the anionic silver complexes for a series of nine barbituric acid derivatives were determined potentiometrically.

2. The per cent recovery or titration efficiency was determined.

3. The molar absorptivity of the silver anionic complex of barbital was shown to be the same as that of barbital in alkaline solution.

4. The effect of silver ion on the stability of barbital in a sodium carbonate solution was described.

5. A structure for the anionic silver complex was proposed.

static and fungicidal activity of fatty acid salts and found that fungicidal activity was acquired as the fatty acid chain was lengthened. Gooding (4) and Geigy (5) reported that certain α,β-unsaturated fatty acids and their derivatives, respectively, possessed fungistatic activity. Peck and Rosenfeld (6) found that olefinic acids possessed antifungal activity to a greater degree than their aliphatic homologs.

Sorbic acid, which is intermediate in the fatty acid series in respect to carbon chain length and is unsaturated at the α,β and γ,δ-positions, and its derivatives have been studied for their antifungal activity. Puls, Lindgren, and Cosgrove (7) reported that sorbic acid was superior to benzoic acid as a fungistatic agent. Recently some derivatives of sorbic acid were reported by Cronk, Zopf, and Jones (8) which have shown the potentialities of sorbic acid derivatives as antifungal agents. This investigation was undertaken to study the effects of some sorbic acid derivatives on certain pathogenic fungi which produce dermatoses in man.

EXPERIMENTAL PART I

Sorbyl Chloride.—To 160 Gm. (1.43 moles) of sorbic acid[1] in a 1-L. round-bottom flask was gradually added 328 Gm. (2.75 moles) of thionyl chloride. After addition of the thionyl chloride, the mixture was stirred for one and one-half hours and then heated to 80° for one-half hour. The product was purified by vacuum distillation using potassium hydroxide and a mixture of dry ice and acetone as traps. The fraction distilling at 95–99° (20 mm. Hg) was collected as a nearly colorless liquid. The yield was 135 Gm. or 72% of the theoretical.

Method I.—The substituted amides of sorbic acid were prepared by reaction of sorbyl chloride with the appropriate amine as illustrated by the following process.

N-Benzylsorbamide.—In a 500-ml. round-bottom flask was placed 6.5 Gm. (0.05 mole) of sorbyl chloride dissolved in 200 ml. of ether. A solution of 10.7 Gm. (0.1 mole) of benzylamine in 50 ml. of ether was added, dropwise. An immediate reaction took place with formation of a precipitate of the amine hydrochloride. The mixture was stirred for 30 minutes at room temperature; the resulting mixture was treated with water and the ether layer separated. The ether layer was washed with 5% hydrochloric acid, 4% sodium carbonate, and water. Evaporation of the ether layer gave the sorbamide which was purified by recrystallization from ethanol. The yield was 8.5 Gm. (84% of theoretical) of white crystals which melted at 129–131°.

Method II.—The amine salts of sorbic acid were prepared by reaction of sorbic acid with the appropriate amine as illustrated by the following process.

N-Cyclohexylamine Sorbate.—In a 500-ml. round-bottom flask was placed 5.6 Gm. (0.05 mole) of sorbic acid dissolved in 200 ml. of ether. A solution of 6.94 Gm. (0.07 mole) of cyclohexylamine, in 50 ml. of ether was added, dropwise. The mixture was stirred for one and one-half hours at room temperature and the resulting precipitate filtered and dried. The salt was purified by recrystallization from ethyl acetate. The yield was 9.6 Gm. (91% of theoretical) of white crystals which melted at 150–153°.

The recrystallization solvents, yields, melting points, and analyses are given in Table I.

EXPERIMENTAL PART II

The antifungal activity of the compounds prepared in this investigation was determined by the paper disk technique. The fungi used were: *Microsporum canis* (ATCC10214), *Microsporum gypseum* (ATCC10215), *Microsporum audouini* (ATCC10216), and *Trichophyton rubrum* (ATCC-10218). Aqueous suspensions of spores of the test organisms were prepared from 14-day agar slants which had been incubated at 28 ± 2°. The suspensions were prepared by aseptically transferring pure colony growths from the slants to a sterile 4-oz. wide-mouth glass bottle. One-half-inch sections of glass rod and 40 ml. of sterile distilled water were added to the bottle, then agitated vigorously to pulverize the colony growth into a homogeneous suspension.

The culture plates were prepared using Difco Sabouraud's dextrose agar dehydrated, 65 Gm./L., pH 5.6. Exactly 20 ml. of the dissolved agar was pipetted into test tubes and autoclaved for 15 minutes at 15 pounds pressure (121°). The media from each test tube was poured into sterile, flat bottom Petri dishes (15 × 100 mm.) and allowed to solidify. The plates were then inoculated with 0.5 ml. of the spore suspensions.

The test compounds, with the exception of cyclohexylamine sorbate, phenylethylamine sorbate, and *n*-hexylamine sorbate were dissolved in acetone in 5% w/v concentrations. The above salts were dissolved in water in the same concentration.

The testing procedure consisted of immersing the sterile paper disks[2] in the test solution of each compound and draining off the excess liquid by touching the disk to the wall of the container. One disk was placed in the center of each culture plate, running triplicate plates for each compound. The plates were then incubated at 28 ± 2° for 14 days. The zones of inhibition were recorded at the end of 7 and 14 days. The zones of inhibition were measured as the minimum distance from the periphery of the paper disk to the edge of the colony growth. The *in vitro* results of the test compounds and controls employed are given in Table II.

DISCUSSION

During the course of this investigation other derivatives were prepared in addition to those reported in Table I, namely N-piperidylsorbamide, N-(*n*-butyl)-sorbamide, N-(*sec*-butyl)-sorbamide, N-(2-aminopyridyl)-sorbamide, and 1-methyl-4-sorbyl-

piperazine. Other salts prepared were benzylamine sorbate, piperidine sorbate, 1-methylpiperazine sorbate, 2-methylpiperidine sorbate, *n*-butylamine sorbate, *sec*-butylamine sorbate, and 2-aminopyridine sorbate.

It was found that many of the sorbamides and amine salts were unstable with respect to light and/or room temperature and decomposed with the formation of light tan to dark brown solids or resinous products. The unstable nature of amine salts and derivatives is well known. A technical bulletin from Union Carbide Corp. (9), in referring to amine soaps (salts), states that the color becomes somewhat darker on standing and that this color formation varies with both the amine component and the oxidizing tendencies of the fatty acid being used, but that the color change does not impair the effectiveness of the compounds. According to a treatise on sorbic acid (2,4-hexadienoic acid) (10), the acid, its esters, and salts are subject to oxidative reactions at the olefinic bonds and that autoxidation results in peroxide formation followed by a degradative and polymerization process. This ease of oxidation apparently accounts for some of the decomposition noted in the compounds prepared during this study.

In preparing the solutions for antifungal testing it was found that compounds No. 2, 3, 6, and 7 (Table I) had a maximum solubility of less than 5% w/v in acetone. This factor may have contributed to the little or no antifungal properties shown for these compounds (Table II). The fact that some solutions were made with acetone and some with water did not exhibit any discernible degree of difference in diffusion rates when the paper disks were placed on the agar media.

It should be noted that although the readings were taken on the 7th and 14th days, that in the case of *M. gypseum*, compounds No. 8, 9, and 10, (Table I), as well as the control, sorbic acid, were effective up to 5 days. After this time growth resumed, until at the end of 2 weeks, no zones of inhibition were perceived.

Compounds No. 4, 5, 8, 9, and 10 (Table I) showed the greatest degree of antifungal activity against all pathogens tested (Table II). With the exception of the test with *M. audouini*, N-(2-methylpiperidyl)-sorbamide appeared to be a more effective antifungal agent than was sorbic acid after 2 weeks of culture growth.

X-ray and Crystallographic Applications in Pharmaceutical Research I

Trace Element Determinations by X-ray Emission

By JOHN W. SHELL†

A standard procedure generally applicable on a routine basis to the determination of any heavy element in a solid organic matrix is described, using an improved method for the determination of selenium in steroids as an example. The general method is applicable for both high and low concentrations including, as is illustrated, trace quantities. An exception to the general application occurs with mercury, due to interferences from primary radiation, and an alternate procedure is described for this element. Extension of the method to lighter elements is illustrated by procedures for the determination of chromium and manganese, and a critical comparison of alternate procedures for these two elements is made. A statistical study of common errors showing optimum conditions for lighter elements is also presented.

X-RAY and crystallographic methods are well known in some fields, but wide usage in the organic, particularly the pharmaceutical field, has not yet occurred. These methods as applied to a wide variety of pharmaceutical problems are valuable and extremely versatile.

A series of papers, of which this is the first, will describe the use of these methods as they have been found to apply to typical pharmaceutical problems. Subsequent papers of the series will be concerned with modified molecular weight determination procedures, quantitative and qualitative diffraction analyses, crystal habit quantitation, low angle scattering applications, and crystal phase transitions.

X-ray emission analysis (also called X-ray fluorescence analysis) has expanded rapidly in recent years. Two excellent books on the method (1, 2) have recently been published, and cover the fundamentals. A review in 1960 (3) listed 223 papers on applications of X-ray absorption and emission, but very few of these were related to organic systems.

Several advantages of the X-ray emission method make it especially adaptable for pharmaceutical problems. Due to the low atomic number of carbon, hydrogen, and oxygen constituting organic systems, matrix component interferences, encountered in many X-ray emission applications, are absent. Moreover, the method is applicable directly on samples, either liquid or solid, and usually without need for separations, permitting assays on final product formulations. Further advantages are speed, specificity, the nondestructive nature of the method, and the inherent simplicity of X-ray spectra. The nonapplicability to low atomic numbered elements is a disadvantage when considering X-ray emission as a general method, but is a decided advantage when the method is used for the determination of heavy elements in a light (organic) matrix.

A method for the simultaneous determination of traces of selenium and mercury in pharmaceuticals was previously reported from these laboratories (4). This method has been greatly improved, particularly in speed and sample handling conveniences, and developed into a standard procedure generally applicable on a routine basis to the determination of any heavy element in a solid organic matrix. This paper describes the general method as applied to trace quantities of elements, such as residual toxic catalysts, and treats special problems encountered in determinations of low concentrations. The same general method and procedures as described are readily applied to the determination of elements at higher concentrations, making it ideally useful for the determination of mineral ingredients in multivitamin products and other preparations.

DISCUSSION

Principle of the Method.—Several processes can be expected to occur when matter is bombarded by intense radiant energy. One of these is a quantum process wherein atomic electrons are displaced, and the vacancies caused are then filled by electrons from an outer shell. Such a process must be accompanied by a release of energy, and it is significant that this energy is in the form of X-rays. As there are several energy levels associated with the various electron shells, quantum theory predicts a number of

Received October 26, 1961, from the Pharmacy Research Section, Product Research and Development Unit, The Upjohn Co., Kalamazoo, Mich.
Accepted for publication November 16, 1961.
Presented to the First Annual Conference on Pharmaceutical Analysis, Land O'Lakes, Wis., September 1961.
It is a pleasure to acknowledge the technical assistance of Dr. J. I. Northam, The Upjohn Co., who provided aid in the statistical analyses, and Mr. Karl Zipple, also of The Upjohn Co., who prepared some of the standard samples and collected a portion of the counting data used in this work.
† Present address: Allergan Pharmaceuticals, Inc., Santa Ana, Calif.

possible transitions, some more likely than others. Thus, an element when bombarded by sufficiently intense radiant energy will emit several X-ray "lines," each at a specific wavelength, characteristic of the element. This is the qualitative aspect of analysis. The intensity of any selected line is proportional to, among other factors, the number of emitting atoms. This, following independent calibration, is the quantitative aspect of emission analysis.

In practice, the radiant energy is supplied by an X-ray tube. The determination of wavelength of the emitted X-ray is accomplished by diffraction, using an analyzing crystal of known orientation and known interplanar spacing; the wavelength is then given by solution of the Bragg equation. The intensity of the diffracted beam is measured by an electronic counter and scaler circuit. The commercially available spectrometers automatically plot this intensity against the Bragg angle, 2θ, which is readily converted to wavelength by the use of tables for a given analyzing crystal. For highly accurate quantitative work, the spectrometer is set for a given wavelength (2θ value), and the counter allowed to accumulate either a fixed number of counts, or to count for a fixed period of time, from which intensity, in counts-per-second, is determined. The procedure generally requires independent standardization, using standards of known concentration.

Sample Preparation.—In preparing samples for analysis it has been found that solid organic compounds are most conveniently handled by briquetting. In this study, 0.5-Gm. samples were compressed in a Perkin-Elmer potassium bromide die at 6000 lb. pressure, without evacuation. This produced pellets of 0.5 in. diam. and, for steroids, about $^1/_8$ in. thick. These samples do not possess "infinite thickness" with respect to the X-ray beam, but since the sample weight, diameter and pressure used are constant, the total mass irradiated remains essentially constant for wide variations in matrix density.

Instrumentation.—A General Electric XRD-5 spectrometer, equipped with a lithium fluoride analyzing crystal, was used for all measurements. Most of the experimental work was completed using a tungsten target X-ray tube (Machlett AEG-50T) operated at 50 kvp and 45 ma. The platinum target tube used for one experiment was also operated at these settings. The scintillation counter used was operated at a plateau voltage of 1.275 kv, and the flow proportional counter (G.E. No. 4SPG) was operated at 2.0 kv, except when these counters were used in connection with a reverter circuit. In instances where a reverter was used, the particular peak voltages employed are listed in the individual sections which follow. The standard mask of the XRD-5 sample drawer was replaced with an aluminum plate, milled with a recession into which the half-inch sample briquettes were placed for analysis.

EXPERIMENTAL

General Illustrative Example. The Determination of Selenium.—Through use of selenium as a catalyst in some organic syntheses, this toxic element can appear in final pharmaceutical products. The determination of selenium in the parts-per-million range is a good example to illustrate application of the general method, as selenium represents an element whose atomic number ($Z = 34$) is high enough so that it may be readily determined. Elements of higher atomic number are determined with even less difficulty.

Selenium standards were prepared by adding aqueous solutions of selenium dioxide, representing several concentrations of selenium, to beakers containing in each 0.5 Gm. steroidal material in acetone solution. After mixing, the solutions were allowed to evaporate to dryness. No heat or vacuum was used, due to the volatility of selenium. The solution step assured homogeneity of selenium dispersions, and relatively little selenium was lost on the beaker surfaces due to the relatively greater adsorbing surface presented by the precipitating steroid crystals. Mixed residues of each beaker were then quantitatively transferred to the die and compressed as described above in the section on sample preparation. The standard briquettes were placed directly into the depression milled into the sample drawer plate.

For this study the XRD-5 spectrometer was equipped with a tungsten target X-ray tube and lithium fluoride analyzing crystal. A scintillation counter fed impulses through a reverter, used to discriminate electronically against undesired wavelengths, to a simultaneously operating decade scaler and timer. The spectrometer was set for $2\theta = 31.89°$, the proper position to measure the Kα emission line of selenium. Following insertion of a high selenium-bearing sample in the sample drawer, the analyzing crystal position was carefully "tuned" to produce maximum counting rate. Adjustments of the crystal position were followed by an automatic slow scan (0.2 degrees per minute) with the recorder, which plotted counting rate *vs.* degrees 2θ, until the maximum rate occurred at exactly 31.89°. A counter voltage of 1.175 kv was found to give maximum counting rate with the reverter for selenium Kα radiation.

The detector was set to record the time required for the accumulation of 200,000 counts, and this time was measured for each of the standard selenium samples while the instrument was set for $2\theta = 31.89°$, the selenium line, and at $2\theta = 34.89°$, a convenient setting for background determination. The peak to background ratio, P/B, was computed for each standard sample.

$$P/B = \frac{\text{selenium, counts-per-second}}{\text{background, counts-per-second}} = \frac{\text{time at background for 200,000 counts}}{\text{time at selenium line for 200,000 counts}}$$

The values for P/B were plotted *vs.* concentration of selenium to give the straight line shown in Fig. 1.

Repeated determinations of the standard curve shown in Fig. 1 from the same samples have shown good reproduction of both the direction and the magnitude of the scatter of each sample value from the line. The method appears to be limited most by lack of complete homogeneity of standard samples, a fact not surprising in low part-per-million concentrations.

Typical times recorded for the required count accumulation range from 167 sec. for the 0 p.p.m.

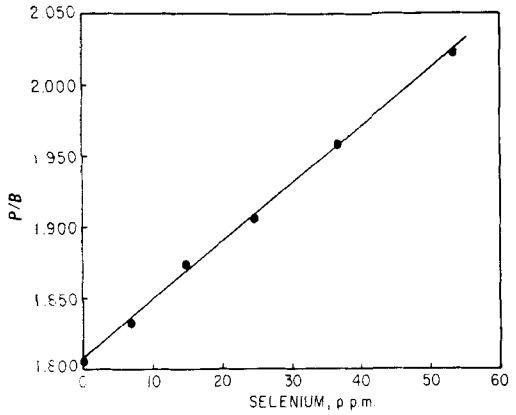

Fig. 1.—Selenium, peak to background ratio *vs.* concentration.

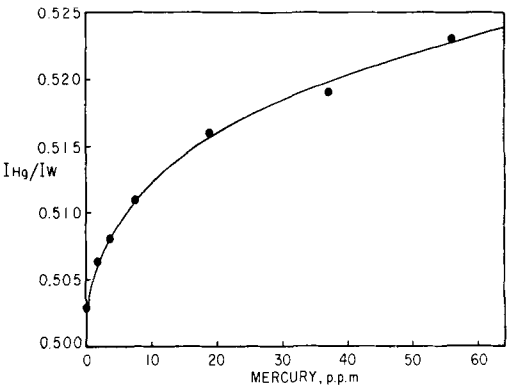

Fig. 2.—Mercury, intensity ratio *vs.* concentration.

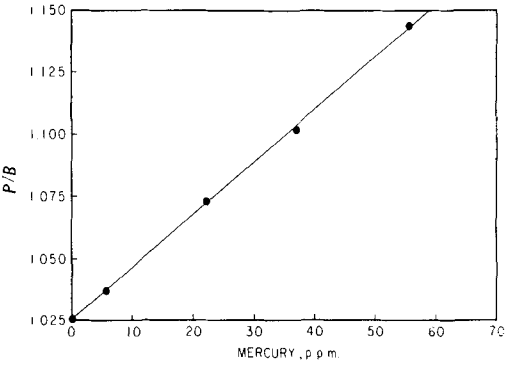

Fig. 3.—Mercury, peak to background ratio *vs.* concentration.

sample to 152.8 sec. for the 35.6 p.p.m. sample. Following standardization, the briquetted unknown samples require only a few minutes to assay.

An Instance Requiring Solution of Interference from the Primary Radiation. The Determination of Mercury.—As noted above, X-ray emission analysis of heavy elements in organic systems is virtually free from interferences from matrix components. The procedure described above for the determination of selenium can be routinely adopted for any heavy element in organic systems, with the exception of one instance. This exception occurs when the analytical emission line to be measured is coincident with, or nearly coincident with, a strong line produced by primary radiation from the X-ray tube. For instance, in the determination of mercury the analytical line of choice, Lα, is found (with a lithium fluoride crystal) at 2 θ = 35.90°. The sample scatters all radiation from the tube, and if a tungsten target tube is used a very strong line, representing tungsten Lβ, will occur at 2 θ = 37.40°. The tungsten line is so strong that even with the high resolution produced by a 0.01-in. detector slit, interference with the mercury line occurs. In fact, the mercury line is found on the steep slope of one side of the tungsten line. A determination for trace amounts of mercury under such conditions produces a standard curve with a major curvature in the low concentration region, as seen in Fig. 2. At higher concentrations of mercury, the tungsten line becomes less dominating, and the standard curve becomes more linear and therefore more useful. But for routine use at low mercury concentrations the curvature is not reproducible from day-to-day.

The best solution found to the interference problem from tungsten was replacement of the tungsten tube with one of different target material. A platinum target tube was used, and the results were a linear relationship in the standard curve for mercury, as seen in Fig. 3. This curve was found to be reproducible from day-to-day. Moreover, counting times were much less for the mercury samples with the platinum target procedure. Each point on the curve for Fig. 3 represents two countings of 40,000 counts each, and the points on the curve for Fig. 2 represent duplicate countings of one million counts each, required for comparable precision. Samples for Fig. 2 were rectilinear compressions of 200 mg. of material, and for Fig. 3 were prepared as described in the standard procedure for selenium, above.

The ratio value plotted in Fig. 2 represents the ratio of the intensity of the mercury Lα line to the intensity of a tungsten scatter line; the value P/B in Fig. 3 represents the ratio of the Lα mercury line intensity to the intensity of the background at the base of the peak. Neither of these selections for background reference appears to have an advantage over the other.

Lower Atomic Numbered Elements. A Critical Study of Alternative Methods for the Determination of Chromium and Manganese.—The applicability of X-ray emission analysis to an element in any matrix depends to a large extent upon the atomic number of the element. This is particularly true for trace analysis, even in organic matrices.

A fundamental relationship states that the reciprocal of the emission wavelength is proportional to the square of the atomic number, where the proportionality constant depends upon the emission series. Thus, lower atomic-numbered elements emit rays of longer wavelength, and these are nonpenetrating, even to air. Further, the "fluorescent yield" of an atom is much less with decreasing atomic number, due to the increasing probability of the Auger effect. A third limitation on emission from elements of low atomic number stems from the lack

of suitability of analyzing crystals with sufficiently large interplanar spacings.

From a practical standpoint, it is generally recognized that elements of atomic numbers 1 through 11 cannot be detected by present day X-ray emission equipment; that elements of atomic numbers 12 through 22 are measured only under special conditions (vacuum or helium atmosphere, and flow-proportional counter), and elements of atomic numbers 23 and higher are measured readily with no special requirements other than that listed in previous sections above for selenium and mercury.

A number of elements of pharmaceutical interest are in the lighter element region. Two such elements, of interest because of their use as catalyst in organic syntheses, are chromium ($Z = 24$), and manganese ($Z = 25$). These elements fall on a very steep portion of the "S-shaped" curve which results from a plot of fluorescent yield *vs.* atomic number (5). They also lie close to the division line for nonfeasibility of determination except under special conditions. A critical study of the effects of the special conditions on each of these two adjacent elements in this particular range was undertaken not only to observe the effects but to gain some idea of the rate of change of feasibility with increasing atomic number in this range, and under the conditions of the standard procedures employed.

Solid pellet standards for manganese and chromium were prepared by the procedure described for selenium, following evaporation of appropriate solutions of manganese dioxide and potassium dichromate. A tungsten target tube was used, and 2θ settings employed were 69.35° for the Kα line of chromium and 62.97° for the Kα line of manganese. All countings were for a fixed time of 100 sec. and no reverter circuit was employed.

Since critical comparisons were to be made in this particular study, net peak height determinations, rather than peak-to-background ratios were measured as a function of concentration, and least squares lines, as well as standard deviations of the net peak heights about the least squares lines were computed.

In this study two methods are compared. Method 1 consisted of procedures as previously described for selenium and mercury; the measurements were carried out in air, using a scintillation counter. Method 2 refers to the use of a helium atmosphere, under positive pressure, which excludes all air from the X-ray beam path, and a gas flow proportional counter in place of the scintillation counter. The gas used to flush this counter continuously was a mixture of 90% argon and 10% methane.

Graphical representation of the results of the use of methods 1 and 2 for the trace determination of both chromium and manganese is shown in Figs. 4 and 5.

The standard deviation of an estimated concentration in parts-per-million is given approximately by

$$\frac{s}{b}\sqrt{\frac{1}{m}+\frac{1}{n}}$$

where b = slope of least squares line, net peak height (c.p.s.) *vs.* concentration (p.p.m.); s = standard deviation of net peak height (c.p.s.) about the least squares line; n = number of determinations used

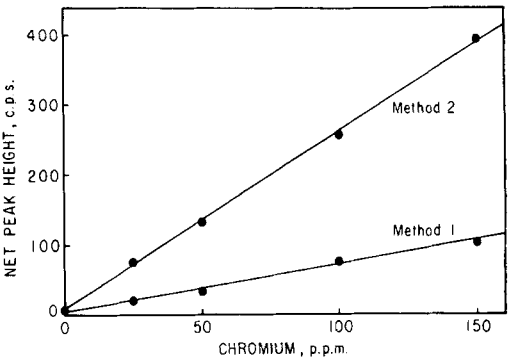

Fig. 4.—Chromium, net peak height *vs.* concentration.

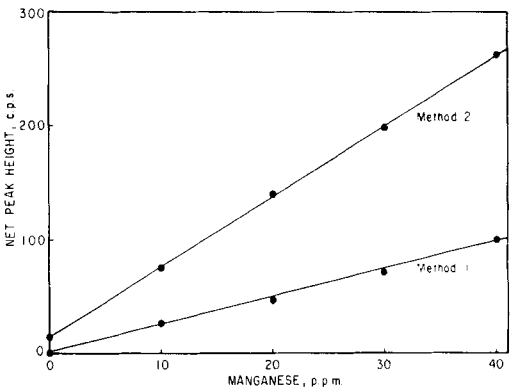

Fig. 5.—Manganese, net peak height *vs.* concentration.

in the standard curve; and m = number of determinations used in measuring the unknowns.

The value $\lambda = s/b$ is an excellent criterion for comparing alternative methods. Smaller values for λ indicate greater inherent precision of the method. Table I lists s, b, and λ values computed for methods 1 and 2 for the determination of chromium and manganese. The ratio of λ values for chromium, 6.22/1.84 = 3.38, indicates that method 2 has 3.38 times the precision of method 1 for estimating the concentration of chromium in p.p.m. Similarly, the value 1.03/0.263 = 3.92 indicates that method 2 for manganese has 3.92 times the precision of method 1. This clearly illustrates the very significant gain in precision made by use of the helium atmosphere and a flow counter for elements in this atomic number range. The λ values also show the rapid gain in feasibility as the atomic number of the element increases slightly in this range.

TABLE I.—STATISTICAL COMPARISON OF METHODS 1 AND 2 FOR THE DETERMINATION OF TRACE AMOUNTS OF CHROMIUM AND MANGANESE

	Method	s	b	λ
Chromium	1	4.216	0.67762	6.22
	2	4.685	2.5475	1.84
Manganese	1	2.544	2.470	1.03
	2	1.628	6.190	0.263

TABLE II.—COMPARISON OF ERRORS IN THE MEASUREMENTS OF A 50 P.P.M. CHROMIUM SAMPLE UNDER VARIOUS INSTRUMENTAL CONDITIONS

Conditions, 10 Determinations Each	Ratio Peak to Background	Net Peak Height, c.p.s.	Counting Error— % P.E.[a]	Counting Error— s_c[b]	Observed Error, s_o[c]	Calculated Extraneous Error, s_e[d]
1. In air, scintillation counter, no reverter	1.334	31.8	3.16	1.49	1.89	1.16
2. In air, scintillation counter, with reverter	2.082	30.9	2.06	0.94	1.79	1.52

4. In helium, flow counter, no reverter	4.412	142.4	0.71	1.50	1.17[e]	0
5. In helium, flow counter, with reverter	5.084	138.0	0.70	1.43	2.40	1.93

[a] % P.E. = Per cent probable error in net peak height = $67.5/(R-1)\sqrt{[R(R+1)]/N_t}$ where R = ratio of peak height to background rates, N_t = total number of counts at peak top, including background. [b] s_c = Net peak height standard deviation, c.p.s. = % P.E. × net peak height, c.p.s./67.5. [c] s_o = Net peak height standard deviation, c.p.s. = $\sqrt{[\Sigma(X_i - \bar{X})^2]/N - 1}$. [d] $s_e = \sqrt{s_o^2 - s_c^2}$. [e] Lower than what is anticipated from pure counting errors, but not by a statistically significant amount.

Common Errors and Optimum Conditions for the Determination of Lighter Elements. A Statistical Study.—The following study was designed to show the relative contributions to precision of the use of helium atmosphere, the flow counter, and the reverter, when considered individually as applied to low concentrations of a light element. In general, these are three major considerations for sources of aid to precision in any prospective procedure. This study was also designed to show the relative sizes of the various types of error, and their contributions under the experimental conditions employed.

Errors in X-ray emission analysis are conveniently divided into two groups. One group consists entirely of counting errors, which stem from the randomness observed when X-ray emission quanta are measured. A second group comprises all sources of error other than counting errors, such as poor reproducibility in resetting the goniometer (2θ setting), sample positioning, etc.

Counting errors can be controlled. The per cent standard counting error, for instance, approximates the reciprocal of the square root of the total number of counts involved. Thus, at a sacrifice of time, a counting rate based on more counts decreases this error by any desired amount.

For a truly critical comparison of instrumental conditions for a given determination, it is necessary to separate these errors and consider the "extraneous error," or that calculated quantity which remains after all counting errors are reduced to zero.

The results of such a procedure are shown in Table II. All measurements were made on a compressed sample of steroidal material containing 50 p.p.m. chromium. Tungsten radiation and the fixed counting time of 100 sec. were used. Five instrumental conditions, derived from combinations of three major variables which strongly affect emission measurements, were statistically evaluated by making 10 determinations for each.

The five conditions of Table II are arranged in increasing order of peak-to-background ratios. These ratios have often been reported as being useful as a rough measure of method precision. The present study belies this usage.

Comparison of the values for the calculated extraneous errors indicates condition 4 to be the one of choice, and further indicates the use of the flow counter to be the single most effective variable in gaining precision under the experimental conditions.

The reverter, often used to good advantage to discriminate against undesired wavelengths when interfering elements are present, was found to be of no advantage in the present study except in connection with the scintillation counter. Even though an increase in peak-to-background ratio was significant, Table II shows large reverter contribution to the extraneous error.

Comparative Cardio-Inhibitory Effects of Substituted Cyclohexanols

By HAROLD H. SMOOKLER and JOHN J. DEFEO

Cyclohexanol and its derivatives 2-(*o*-tolyl), 2-(*m*-tolyl), 2-(*p*-tolyl), 2-(*o*-chlorophenyl), 2-(*m*-chlorophenyl), and 2-(*p*-chlorophenyl) were tested for cardioplegic effects on intact anesthetized rats, isolated guinea pig hearts, and isolated rabbit atria. Most of the compounds produced inhibitory effects varying from a slight depression to complete arrest. Evaluation of potency was based on the ability to produce arrest and the duration of arrest. In both series of substitutions it appears that the *trans*-2-*o*-derivatives are most potent with the *cis*-2-*o*-derivatives least potent. The 2-*m*- and 2-(*p*-chlorophenyl) compounds appear to be toxic to the myocardium as the hearts do not return to their normal level of activity. Mechanism studies indicate an antagonistic effect between these compounds and calcium.

CARDIOPLEGIC AGENTS have become of interest in the past several years with the advances made in "open heart" surgery techniques employing extracorporeal circulation. Such agents would be of great help in securing a motionless field for surgical repair of various complicated cardiac defects.

Elective cardiac arrest has been attempted with such substances as potassium citrate and acetylcholine (1–4). Opinions on the use of cardioplegic agents vary from skepticism to acceptance for routine use.

Although cyclohexanol has never been reported as having cardioplegic properties, it is evident from various reports that certain derivatives bring about such an effect.

In 1957 (5) it was reported that 2-(*o*-methyl phenyl)-cyclohexanol [actually 2-(*o*-tolyl) cyclohexanol] had been able to arrest the heart of a dog but recovery was unsuccessful.

Huitric (6) and his co-workers published a note concerning the production of mechanical cardiac arrest with 2-(*o*-tolyl)-cyclohexanol. During the course of his work, Huitric had synthesized a series of substituted cyclohexanols (Fig. 1) which were used for this study of the comparative effects of the various substitutions on their ability to produce cardiac arrest.

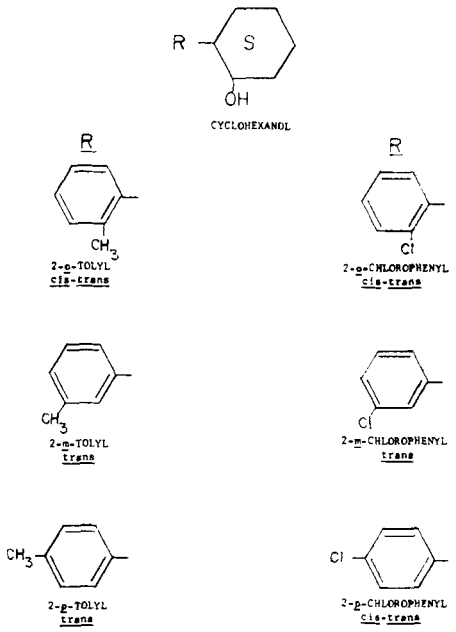

Fig. 1.—Cyclohexanol and its derivatives.

METHODS

The compounds whose structures appear in Fig. 1 have a very low solubility in water. In the tolyl series the *trans*-2-(*p*-tolyl) compound was the only solid, while others were liquid. In the chlorophenyl series, all were solid except the *cis*-2-(*o*-chlorophenyl) compound which was a liquid.

The solid materials were dissolved in 10–50% propylene glycol-water mixtures. An aliquot was measured and diluted to a standard concentration and volume. The liquid forms were mixed with water in order to obtain saturated solutions. A portion of the saturated solution was filtered and the filtrate was employed for testing.

The solubilities of the liquid substances were determined and are listed in Table I. Cyclohexanol was dissolved in water in varying concentrations.

Blood Pressure Studies.—The experiments were conducted in albino rats of both sexes. They were anesthetized with an intraperitoneal injection of 1.2 Gm./Kg. of urethan. The effects were recorded by direct cannulation of the carotid artery through a mercury manometer connected by plastic tubing filled with 7.5% sodium citrate solution. The compounds were administered intravenously. These studies were employed only to determine the rapidity

Abstracted from a thesis submitted by H. H. Smookler in partial fulfillment of the requirements for the M.S. degree, 1961.
Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.

TABLE I.—WATER SOLUBILITY OF CYCLOHEXANOL AND ITS LIQUID 2-ARYL SUBSTITUTION PRODUCTS

Compound	Physical State	Water Solubility, mg./ml.
Cyclohexanol	liquid	5.67 at 15°[a]
trans-2-(*o*-Tolyl)cyclohexanol	liquid	0.8[b]
cis-2-(*o*-Tolyl)cyclohexanol	liquid	0.5
trans-2-(*m*-Tolyl)cyclohexanol	liquid	1.0
cis-2-(*o*-Chlorophenyl)cyclohexanol	liquid	0.2

[a] Handbook of Chemistry and Physics, 35th ed. (1953–1954). [b] Value reported by Huitric, *et al.* (6).

of effect in the intact animal. Those compounds dissolved in the propylene glycol could not be tested, as the solvent has a pronounced hypotensive effect and thus would mask the effect of the compounds.

Guinea Pig Heart Perfusion.—Guinea pigs of either sex were sacrified with a blow to the head. The heart was removed rapidly and flushed with the perfusing solution. It was then suspended in an Anderson-Craver perfusion apparatus by tying a glass cannula into the aorta. Chenoweth's solution (7) modified by replacing magnesium chloride with an equivalent amount of magnesium sulfate at 37.5°, and saturated with a steady flow of a 95% oxygen, 5% carbon dioxide mixture was employed as the perfusing fluid. The total volume of fluid containing the test compound injected into the heart was kept constant at 2 ml. This placed a limit on the upper level of dosage for the liquid compounds because of their poor solubility. An equivalent mixture of propylene glycol and water was used as a control prior to each injection of the compounds dissolved in this material in order to determine its effects.

The magnitude of effect, the duration of the effect, and the time for recovery to 50% of the normal amplitude was determined following each injection of the test compounds.

Isolated Rabbit Atria.—Rabbits were sacrificed and their hearts removed rapidly. The atria were resected intact and suspended in a (70 ml.) tissue bath containing the same nutrient solution as used in the perfusion experiments. The temperature was maintained at 32° in order to reduce the rate and to increase the amplitude of contractions (8).

A 4.0% solution of calcium chloride was used to determine possible interactions with *trans*-2-(*o*-tolyl)-cyclohexanol, which was selected because it appeared to be the most effective of the compounds tested. All drugs were allowed to act for exactly 3-minute periods before adding other agents or washing.

trans-2-(*o*-Tolyl)-cyclohexanol produced an effect lasting indefinitely when not washed. Calcium chloride produced an effect that lasted for at least 30 minutes if not washed.

The experiments were conducted so that the effects of the experimental compounds were recorded well within the above periods in order to assure ourselves that the effects were due to the drugs alone.

RESULTS

Cyclohexanol in doses of 5 mg./Kg. to 100 mg./Kg. produced a drop in mean blood pressure ranging from 20 to 90% of the normal.

trans-2-(*o*-Tolyl)-cyclohexanol in doses of 0.5 to 4.0 mg./Kg. produced a drop in mean blood pressure of 38 to 83%.

cis-2-(*o*-Tolyl)-cyclohexanol in doses of 1.0 to 3.0 mg./Kg. produced a drop in mean blood pressure of 27 to 74%.

trans-2-(*m*-Tolyl)-cyclohexanol in doses of 1.0 to 6.0 mg./Kg. produced a drop in mean blood pressure of 18 to 99%.

cis-2-(*o*-Chlorophenyl) in doses of 0.5 to 1.5 mg./Kg. produced a drop in mean blood pressure of 37 to 91%.

In all of the above experiments death occurred at the highest dose when this quantity was readministered in the same animal. At the conclusion of all of the tests, urine was aspirated from the bladder and hematuria was found in every case.

The results obtained in the guinea pig heart perfusion studies are shown in Table II. It should be noted that a normal heart will contract from 2 to 3 hours in the apparatus before signs of failure appear. In all of the experiments the compounds acted within 1 minute.

Recovery was allowed to occur spontaneously in order to compare the rates of recovery from the effects of the various compounds. Recovery to a 50% level of the original amplitude was variable, ranging from 3 to 29 seconds for cyclohexanol to 34 to 430 seconds for *trans*-2-(*o*-tolyl)-cyclohexanol.

TABLE II.—COMPARATIVE EFFECTS OF CYCLOHEXANOL AND ITS DERIVATIVES ON THE ISOLATED GUINEA PIG HEART

Compound	Minimum[a] Effective Dose, mg.	Cardiac Arrest Arrests/ Trials	Duration of Arrest Mean and Range, sec.	Mean % Depression ± S.D. (if no arrest)

cis-2-*p*-Chlorophenylcyclohexanol	2.0	3/6	262(148–324)	71 ± 18–100(1)[d]
trans-2-*p*-Chlorophenylcyclohexanol	2.0[e]	4/4	442(182–645)	...

[a] Minimum dose which will produce cardiac arrest. [b] Maximum allowable dose injected but not the minimum effective dose. [c] Stimulation occurred in 4 of 12 doses with a mean of 93%. [d] Stimulation occurred in 1 of 6 doses. [e] Toxic dose.

There is an indication of toxicity produced by the *trans*-2-(chlorophenyl) compounds since many of the hearts did not return to normal following the arrest periods.

cis-2-(*o*-Chlorophenyl)-cyclohexanol acted in a manner differing from the other compounds in that it produced a stimulating effect up to 93% of the normal in some hearts. In other cases it was only slightly depressant.

trans-2-(*o*-Tolyl)-cyclohexanol was selected for preliminary mechanism studies due to its reproducible action. A dose of 0.6 mg. was found to be immediately effective in reducing the amplitude of the atrial contractions by 50% without apparently affecting the rate.

It was noted that 4 mg. of calcium chloride in the 70-ml. bath was sufficient to increase the amplitude of the atrial contractions by 100%. When *trans*-2-(*o*-tolyl)-cyclohexanol (0.6 mg.) had reduced the amplitude of contractions by 50% it was found that it required three successive doses of 8 mg. each of calcium chloride over 9 minutes in order to restore the amplitude of contraction, stepwise, to a normal level. When a total of the above amounts (24 mg.) was administered at one time there was a continuous recovery within 3 minutes.

In other tests, when *trans*-2-(*o*-tolyl)-cyclohexanol (0.6 mg.) followed calcium chloride (4 mg.) it was observed that the onset of action was delayed several minutes and the inhibitory effect which followed only overcame the effect of the calcium, thus restoring the amplitude of contractions to a normal or slightly below normal level.

DISCUSSION

The *trans* isomers of these compounds are those in which both the substituted groups and the hydroxyl group occupy equatorial positions on the cyclohexane ring. The *cis* isomers are those where the substituted groups are equatorial and the hydroxyl group is axial to the cyclohexane ring (9).

It is evident that cyclohexanol and its liquid 2-aryl derivatives can produce an immediate drop in blood pressure. The magnitude of the effect is somewhat proportional to the dose. The substitution of a tolyl or chlorophenyl moiety in the number 2 position of the cyclohexanol ring increases the hypotensive activity from 6 to 40 times. This is no doubt due to the inhibitory effect of these substitutions on the myocardium as was shown in the isolated heart tests.

At the dose levels employed in these tests it appears that substitutions at the 2 position on the cyclohexanol structure increase the cardio-inhibitory effect from 4 to 20 times (see Table II). The *trans*-2-(*o*-tolyl) substitution is apparently the most effective in producing arrest at the lowest dose followed by a good recovery. The *cis* isomers of both the (*o*-tolyl) and (*o*-chlorophenyl) compounds are the least depressant, while the *trans* isomers of these compounds are the most effective in their respective series. In both series it appears that the inhibitory effect is enhanced by shifting the methyl on the tolyl and the chlorine on the chlorophenyl from *para* to *meta* to *ortho* positions, respectively.

Tentative conclusions indicate that the tolyl derivatives are less toxic than the chlorophenyl derivatives as evidenced by the failure of most hearts to recover from the effects of the latter compounds.

These facts indicate the importance of the spatial configuration of these compounds in producing their cardio-inhibitory actions.

The antagonism between the calcium ion and *trans*-2-(*o*-tolyl)-cyclohexanol is apparently of a physiological type. The 2-(*o*-tolyl)-cyclohexanol action appears to be the most potent as the same amount of this compound was able to counteract the effect of various amounts of calcium. However, when enough calcium was added to the bath following the depressant effect, it was able to restore the contractions of the atria to a normal level. The major effect of calcium was to increase the latent period of 2-(*o*-tolyl)-cyclohexanol.

SUMMARY

1. Tolyl and chlorophenyl substitutions at the 2 position of the cyclohexanol structure enhance the cardio-inhibitory effect of this compound.

2. The *cis* isomers of the (*o*-tolyl) and (*o*-chlorophenyl) compounds are least effective, whereas the *trans* isomers of these compounds are the most effective in producing cardio-inhibitory effects. The inhibitory effect increases with the position of the methyl and chlorine from *para* to *meta* to *ortho*.

3. The chlorophenyl substituted derivatives appear to exhibit a greater cardio-toxicity than the tolyl derivatives.

4. Calcium delays the onset of action of 2-(*o*-tolyl)-cyclohexanol and antagonizes its effect when administered after the depressant action of the compound has occurred.

Effects of β-Diethylaminoethyl Diphenylpropylacetate Hydrochloride on Three Convulsants and on Propallylonal

By HARALD G. O. HOLCK, GALE E. DEMAREE†, and HIDEKO KATAYAMA KAJI‡

β-Diethylaminoethyl diphenylpropylacetate hydrochloride (SKF 525-A) increased the LD_{50}s of nikethamide, pentylenetetrazol, and picrotoxin in albino mice when given intraperitoneally 1 hour earlier. The maximum action of picrotoxin in mice subcutaneously pretreated with SKF 525-A developed in about 4 hours; action was still marked at 8, but largely absent at 16 hours. SKF 525-A induced full effect when given intraperitoneally immediately before picrotoxin. It also markedly increased the potency of picrotoxin in normal and in barbitalized rats, using a multiple injection technique. However, SKF 525-A did not influence the toxicity of pentylenetetrazol in normal or barbitalized rats employing this technique. Barbital greatly increased the LD_{50}s of pentylenetetrazol and picrotoxin in rats, as shown by the multiple injection method. SKF 525-A markedly prolonged the hypnotic effect of propallylonal without increasing the number of delayed deaths. Its use is recommended for biotransformation studies of the four substances used.

BETA-diethylaminoethyl diphenylpropylacetate hydrochloride, hereafter referred to as compound SKF 525-A, has been shown to potentiate or prolong the action of a great variety of drugs. Cook, *et al.* (1, 2), in mice and rats, demonstrated that it prolonged the action of secobarbital, pentobarbital, hexobarbital, amobarbital, butethal, hexothal, phenobarbital, and chloral hydrate; however, barbital and thiopental depression in mice was not altered. On the other hand, Achor and Geiling (3), administering SKF 525-A intraperitoneally rather than orally, obtained prolongation of thiopental hypnotic action using similar and higher dosage of SKF 525-A. Macko, *et al.* (4), reported that this compound increased the central nervous system stimulation of *d*-amphetamine and strychnine and greatly increased the toxicity of the latter. Loewe (5) noted that the CNS-stimulating properties of yohimbine upon the butallylonal-yohimbine ejaculatory effect in mice was augmented by SKF 525-A. Axelrod and co-workers (6) and Cooper, *et al.* (7), reported that much of the effect of SKF 525-A is due to its ability to inhibit the biotransformation of the drugs in question. It becomes widely localized in rat organ tissues, especially fat, is present in the body after 24 hours, and is practically all metabolized *in vivo* (6). Swinyard and collaborators (8) have shown potentiation of the action of a series of antiepileptic drugs by SKF 525-A; however, the potentiation was not considered due entirely to inhibition of biotransformation of these drugs inasmuch as SKF 525-A possesses some anticonvulsant activity of its own in high dosage.

SKF 525-A is effective *in vivo* when administered up to 20 hours prior to the drugs whose effects are capable of being influenced; also, prolongation of hexobarbital depression could be demonstrated by administering SKF 525-A during hexobarbital hypnosis, but not after recovery (1, 2). It is equally potent when administered orally, intraperitoneally or intravenously (2). A suitable intraperitoneal and oral dose for mice and rats is given as 50 mg./Kg., and the optimum pretreatment time as 40 to 60 minutes prior to the administration of the drug under study (1).

The present series of experiments was designed to obtain information concerning the effects of SKF 525-A upon the median lethal doses of nikethamide, pentylenetetrazol, and picrotoxin in mice. Special attention was given to methods of administration, time interval for pretreatment, and duration of action with picrotoxin. Tests were also conducted in rats to note what influence barbital anesthesia might have upon the effect of SKF 525-A upon pentylenetetrazol and picrotoxin toxicity. Finally, the effect of SKF 525-A upon the duration of depression, incidence of delayed death, and sex variation with propallylonal in rats was studied.

Received October 9, 1961, from the Department of Pharmacology, College of Pharmacy, University of Nebraska, Lincoln.

Accepted for publication December 15, 1961.

Presented in part to the Scientific Section, A.PH.A., Miami Beach meeting, May 1955.

The major portions of this paper are taken from the Master's thesis of Gale E. Demaree.

We are indebted to the Smith Kline & French Research Laboratories for donating SKF 525-A; to Eli Lilly and Co. for picrotoxin; to Bilhuber-Knoll Corp. for Metrazol (pentylenetetrazol); to Ciba Pharmaceutical Products for Cardiazol (nikethamide); and to Miles-Ames Research Division for Nostal (propallylonal). We also wish to thank Messrs. David Sjogren and Loren Braun for aid in conducting some of the experiments and to Deans J. B. Burt and R. D. Gibson for constructive criticism of the manuscript.

† Present address: University of North Carolina, Chapel Hill.

EXPERIMENTAL

General.—Male mice of Swiss albino stock, weighing 16–26 Gm. and randomized according to weight within each suitably sized group, were used in the niketharnide and picrotoxin experiments. With pentylenetetrazol, six males and six females were used in each group. All mice were kept for at least 1 week in temperature-controlled animal quarters on a diet of Purina Laboratory Chow and water *ad libitum* until the time of experimentation. After injection the mice were kept in individual large glass beakers and the room temperature maintained at 25 ± 0.5°. SKF 525-A was administered as a 1.0% solution in distilled water. A 3% solution of niketharnide, a 1% solution of pentylenetetrazol, or a 0.05% solution of picrotoxin was employed; distilled water served as the diluent. Suitable logarithmic dosages were utilized and the median convulsive and lethal doses (CD_{50}s and LD_{50}s) were determined by the Reed-Muench and Pizzi methods, using logarithms (10, 11). An equivalent volume of 0.9% sodium chloride solution was injected into the control groups. Whenever an interval of 3 hours or longer occurred between the injection of SKF 525-A and the picrotoxin, the mice were returned to the stock cages immediately after the administration of SKF 525-A and allowed food and water until 1 hour prior to the scheduled administration of the pictrotoxin. They were then reweighed, placed in individual containers, and the picrotoxin dose calculated from the final weights. In a few cases, when a very large number of mice were under study, it was impractical to complete a series in one day so the series was continued on a later day. All intraperitoneal injections were made in the upper left quadrant of the abdomen, while all subcutaneous injections were made under the loose skin of the lower back.

In the further studies of the effects of SKF 525-A upon pentylenetetrazol and picrotoxin, Holtzman male rats in groups of 10 were employed to determine the CD_{50}s and LD_{50}s in normal and barbitalized animals. Each analeptic was injected subcutaneously every 10 minutes, using ten different sites in rotation according to the technique previously developed by Holck (12). In case of pentylenetetrazol, 200 mg./Kg. of barbital sodium (10% solution) or 2 ml./Kg. of saline were injected intramuscularly 10 minutes prior to injecting 50 mg./Kg. (5% solution) of SKF 525-A or 1 ml./Kg. of saline intraperitoneally. Sixty minutes later an initial dose of 9 mg./Kg. (0.9% solution) of pentylenetetrazol was administered to the nonbarbitalized rats and 25 mg./Kg. (5% solution) to the barbitalized rats and their controls. Barbital was chosen as the hypnotic agent because its action is not prolonged by pretreatment with SKF 525-A (2); it also has more recently been shown that SKF 525-A does not alter its induction time (13). The age of the first two groups of rats was about 5 months, and of the last three groups about 10 months.

In the picrotoxin tests, the barbital sodium dose was 225 mg./Kg. (11.25% solution); the dose of picrotoxin per injection was 0.7 mg./Kg. (0.07% solution) for nonbarbitalized rats and 1 mg./Kg. (0.1% solution) for barbitalized rats. It was necessary to increase the dose of picrotoxin because tolerance developed to the lower dose. The ages of the animals in the two sets of tests were 3 and nearly 5 months, respectively. All rats were kept under conditions similar to those previously described for the mice.

In the studies with propallylonal, this drug was converted to its sodium salt by the addition of an appropriate amount of 0.2 *N* sodium hydroxide solution and diluted to the desired volume with freshly boiled, triple distilled water. Holtzman rats of both sexes were used, because female rats in previous studies usually have proven more sensitive to propallylonal than the males. Rats, 4–6 months old, were used in the first experiment in which 30 mg./Kg. (3% solution) of propallylonal were injected subcutaneously as a single dose. In the experiment using a 50 mg./Kg. dose, a 4% solution was employed and injected intraperitoneally; these rats were 4 months old. In both tests the rats were fasted overnight but allowed water. Intraperitoneal administration of 50 mg./Kg. (2.5% solution in the first, 5% in the second test) of SKF 525-A, or of an equal volume of saline, was made 1 hour prior to the barbiturate medication. The animals were observed during 6 days following propallylonal administration for incidence of delayed death.

RESULTS

Concomitant with administering the analeptics to mice it was ascertained that the stock used had a resistance to SKF 525-A quite similar to that for intraperitoneal administration reported by Cook, *et al.* (1). Thus, with a 1% solution, a temperature of 25° and 10 male mice per group, none died with 100, 5 with 141, and all with 200 mg./Kg. However, with subcutaneous injection the resistance was much higher in that 10 mice survived 100, 200, and 400 mg./Kg., respectively; a 2% solution was used. The results of the experiments with the analeptics in mice and rats are presented in Tables I and II.

Following subcutaneous administration of 30 mg./Kg. of propallylonal, only $^3/_{24}$ rats pretreated with SKF 525-A lost the righting reflex compared with none of the controls. No delayed deaths occurred in either group. With 50 mg./Kg. of propallylonal given intraperitoneally, the righting reflex was recovered in 5 control females in 186 ± 36 and in 5 pretreated ones in 345 ± 15 minutes; $P < 0.01$. In the males the minutes were 73 ± 6.3 for 4 out of 5 controls and 238 ± 24 for 5 pretreated animals; $P < 0.01$. P was about 0.03 for the sex variation in the controls and 0.02 in the pretreated rats. Although the depression time was significantly prolonged by SKF 525-A, the number of delayed deaths was not increased, being $^2/_5$ in the control and pretreated females, respectively, and $^1/_5$ in similar male groups.

DISCUSSION

An outstanding finding of our studies upon albino mice was that the ratio of the LD_{50} of the controls over that of those pretreated with SKF 525-A was smaller for pentylenetetrazol and for niketharnide than for picrotoxin. It was 1.24 for pentylenetetrazol and 1.32 for niketharnide, as compared with 2.63 and 2.81, respectively, in two tests with picrotoxin. The last ratios are in good agreement with the 2.6 reported by Macko, *et al.* (4), for strychnine.

[a] There was evidence of development of tolerance in a few of the rats. [b] No convulsions occurred in either group after 12 injections (300 mg./Kg.), hence the dose per injection was raised to 50 mg./Kg. [c] Only one rat convulsed and none died after 20 injections (20 mg./Kg.). All 10 rats made uneventful recoveries and were alive 5 days later. The average doses producing recovery of the righting reflex were 6.0 ± 0.45 mg./Kg. for the controls and 6.5 ± 0.27 mg./Kg. for the SKF 525-A premedicated rats; $P < 0.3$.

The results with picrotoxin agree with those of Cook, *et al.* (1), in that the action occurred almost immediately after intraperitoneal administration of SKF 525-A and was fully developed in 1 hour; it lasted more than 16 hours after subcutaneous administration. Although marked action was noted after 1 hour, maximum action with subcutaneous pretreatment with SKF 525-A did not occur until several hours later, indicating a slower absorption of SKF 525-A after this method of injection. The much more gradual absorption is also indicated by the mentioned much higher fatal dose of SKF 525-A with subcutaneous compared with intraperitoneal administration. The results with albino rats also agree in principle with those of Cook, *et al.* (2), in that the increase in duration of hypnotic action after propallylonal occurred without increasing the number of delayed deaths; however, the prolongation of depression was much less marked than in case of hexobarbital. Tolerance to pentylenetet-

razol occurred with and without SKF 525-A pretreatment in all of the barbitalized rats and in some of the normals, using a multiple injection technique. Cook, *et al.* (9), have reported a similar absence of interference with development of tolerance to morphine by SKF 525-A; it did not change its LD_{50}.

On the other hand, pretreatment with SKF 525-A markedly lowered the fatal dose of picrotoxin in barbitalized rats and significantly decreased the convulsive and fatal doses in normal rats. The results with barbitalized rats, pretreated with SKF 525-A, were unusually uniform in that the standard errors were less than 1.8% of the CD_{50}s and LD_{50}s of picrotoxin, compared with 3.5% and 3.1% in normal, pretreated rats.

The major factor of SKF 525-A effect is due to the inhibition of biotransformation of substances susceptible to its influence. The extensive review by Brodie (14) involving, in part, numerous *in vivo* and *in vitro* studies by his own staff, indicates that a similar inhibitory effect by SKF 525-A may be exerted on a variety of metabolic pathways or, as stated by Cooper, *et al.* (7), it inhibits a factor or factors possessed in common by a diversity of drug enzyme systems. Depression of bioacetylation and of acetylcholinesterase activity has since been reported by Kuriaki and Marumo (15). The mechanism involved in the case of the three analeptic drugs tested by us remains to be determined. With propallylonal, SKF 525-A may prevent the replacement of Br by an OH group and subsequent molecular rearrangement of the ketone form to give an acetonyl group, which leads to formation of a barbiturate that is much weaker and slower in action than the β-bromallyl derivative (16, 17).

Temperature-Induced Rheological Variability in an Emulsion System

By JAMES C. BOYLAN, H. GEORGE DeKAY, and GILBERT S. BANKER

A study has been made on the effect of emulsification temperature and cooling rate on certain physical properties of a beeswax-mineral oil emulsion. The emulsion, which was prepared at five temperatures and cooled at three rates, was evaluated for plastic viscosity, thixotropy, yield value, water separation rate, and initial average particle size. It was shown that both the emulsification temperature and cooling rate significantly altered these properties.

IN THE PAST few decades, emulsions have been studied from many viewpoints. Despite this, the formulation, preparation, and stability of most emulsion products remains, to a large extent, an empirical art. Investigations to date have failed to pinpoint the rheological characteristics of many emulsions.

It is generally agreed that an increase in temperature facilitates emulsification (1–3). One author (4) contends in rather vague and general terms that an emulsification temperature should be chosen which will give the optimum dispersion to the materials being emulsified. Spalton (5) specifies that a freshly prepared wax emulsion should be allowed to cool slowly since rapid cooling may result in a granular product. Wellman (6) found that the solubility of the soap, as controlled by temperature, is an important factor in emulsion formation. Several studies have been conducted attempting to relate viscosity of emulsions to temperature (7–9).

In the area of particle size and its effect on viscosity, Sherman (10) states that there is a frequent increase in viscosity when an emulsion is homogenized. He feels that this increase in viscosity is due to a decrease in particle size,

razol occurred with and without SKF 525-A pretreatment in all of the barbitalized rats and in some of the normals, using a multiple injection technique. Cook, *et al.* (9), have reported a similar absence of interference with development of tolerance to morphine by SKF 525-A; it did not change its LD_{50}.

On the other hand, pretreatment with SKF 525-A markedly lowered the fatal dose of picrotoxin in barbitalized rats and significantly decreased the convulsive and fatal doses in normal rats. The results with barbitalized rats, pretreated with SKF 525-A, were unusually uniform in that the standard errors were less than 1.8% of the CD_{50}s and LD_{50}s of picrotoxin, compared with 3.5% and 3.1% in normal, pretreated rats.

The major factor of SKF 525-A effect is due to the inhibition of biotransformation of substances susceptible to its influence. The extensive review by Brodie (14) involving, in part, numerous *in vivo* and *in vitro* studies by his own staff, indicates that a similar inhibitory effect by SKF 525-A may be exerted on a variety of metabolic pathways or, as stated by Cooper, *et al.* (7), it inhibits a factor or factors possessed in common by a diversity of drug enzyme systems. Depression of bioacetylation and of acetylcholinesterase activity has since been reported by Kuriaki and Marumo (15). The mechanism involved in the case of the three analeptic drugs tested by us remains to be determined. With propallylonal, SKF 525-A may prevent the replacement of Br by an OH group and subsequent molecular rearrangement of the ketone form to give an acetonyl group, which leads to formation of a barbiturate that is much weaker and slower in action than the β-bromallyl derivative (16, 17).

Temperature-Induced Rheological Variability in an Emulsion System

By JAMES C. BOYLAN, H. GEORGE DeKAY, and GILBERT S. BANKER

A study has been made on the effect of emulsification temperature and cooling rate on certain physical properties of a beeswax-mineral oil emulsion. The emulsion, which was prepared at five temperatures and cooled at three rates, was evaluated for plastic viscosity, thixotropy, yield value, water separation rate, and initial average particle size. It was shown that both the emulsification temperature and cooling rate significantly altered these properties.

IN THE PAST few decades, emulsions have been studied from many viewpoints. Despite this, the formulation, preparation, and stability of most emulsion products remains, to a large extent, an empirical art. Investigations to date have failed to pinpoint the rheological characteristics of many emulsions.

It is generally agreed that an increase in temperature facilitates emulsification (1–3). One author (4) contends in rather vague and general terms that an emulsification temperature should be chosen which will give the optimum dispersion to the materials being emulsified. Spalton (5) specifies that a freshly prepared wax emulsion should be allowed to cool slowly since rapid cooling may result in a granular product. Wellman (6) found that the solubility of the soap, as controlled by temperature, is an important factor in emulsion formation. Several studies have been conducted attempting to relate viscosity of emulsions to temperature (7–9).

In the area of particle size and its effect on viscosity, Sherman (10) states that there is a frequent increase in viscosity when an emulsion is homogenized. He feels that this increase in viscosity is due to a decrease in particle size,

which leads to increased interfacial area and interaction among the globules.

The objective of this study was to determine the following effects of various emulsification temperatures and rates of cooling on a wax-containing emulsion: (*a*) the rheological properties (i.e., viscosity, yield value, and thixotropy), (*b*) the rate of creaming and/or separation of the phases, and (*c*) the particle size of the dispersed phase.

EXPERIMENTAL

Emulsion Formulation and Preparation.—A beeswax emulsion of the following composition was used throughout this study

	Amount, Gm.
White wax	80.0
Liquid petrolatum (heavy)	250.0
Sodium borate	11.0
Purified water	659.0
to make	1000.0

The emulsion formula was chosen on the basis of its simplicity and the wide cosmetic and pharmaceutical use of its ingredients.

The wax and liquid petrolatum were placed in a 2000-ml. stainless steel beaker (inside height 16.5 cm., inside diameter 12.5 cm.). The sodium borate and the water were placed in a 1000-ml. glass beaker. The aqueous phase was brought to the desired temperature by means of a bunsen burner. The temperature of the oil phase was controlled by means of a heating mantle,[1] regulated by a variac. When the desired temperature of both phases was reached, the aqueous phase was slowly added to the oil phase (which was still encased in the heating mantle). A model V-7 "lightin" mixer[2] was immediately started at 1875 r.p.m. and allowed to run for 15 seconds to achieve initial emulsification. The emulsion was then removed from the heating mantle and placed in a specially constructed air bath (see Fig. 1) which had been preset to cool the emulsion at one of the prescribed rates. A second "lightin" mixer within the air bath was started and run at 1800 ± 100 r.p.m. until the emulsion cooled. All emulsions were cooled in the air bath to 30°. With practice, the procedure and time required for enclosing the emulsion in the air bath became nearly constant.

Both mixers utilized a three-blade marine-type propeller, the length of each blade being 1.6 cm. The propeller was mounted on a 26.9-cm. shaft. In each case, the propeller was placed off center in the same quadrant and one-third of the distance from the bottom of the beaker relative to the height of the liquid, with the mixer shaft at an angle of about 25° from the perpendicular. A Stobatac[3] was used to standardize the mixer speeds. A small oscillating fan inside the air bath maintained air circulation and a 12-inch evaporating dish filled with distilled water minimized fluctuations in relative humidity during the experiment.

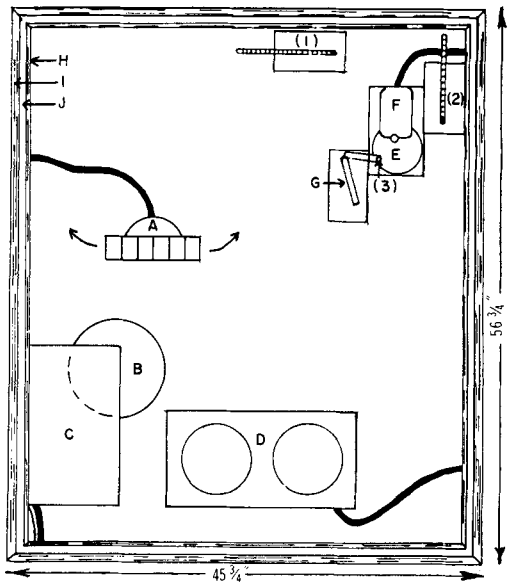

Fig. 1.—Top view of the air bath. The materials are: 3/4 and 3/8 inch plywood, glass wool (insulator), and double glass window above the mixer area. The inside of the roof and the sides are lined with aluminum foil. Thermometers, supported on ring-stands, are at points 1, 2, and 3. A, rotating fan; B, evaporating dish; C, refrigeration unit; D, hot plate; E, emulsion; F, mixer; G, magnifying mirror; H, 3/8 inch plywood; I, 3/4 inch plywood; J, 3/4 inch glass wool.

The emulsions were prepared at five temperatures and cooled at three rates (see Table I). When a sample was to be cooled slowly, the air bath was preset at 25 ± 0.5°. Since the heat lost by the emulsion upon cooling remained in the hermetically sealed air bath, the temperature inside the bath rose to 29–30°. If the emulsion was to be cooled at a moderate rate, the air bath was preset at 11 ± 1°. The temperature within the bath then rose to 14–16°. In the case of rapidly cooled products, the stainless steel beaker containing the emulsion was placed in a 10-inch water bath containing crushed ice. This was then introduced into the precooled air bath (11 ± 1°).

Rheological Evaluation.—The viscometer chosen for this study was a Stormer viscometer provided with the modified cup and bob as suggested by Fischer (11). A weight hanger with various slotted weights provided the shearing stress. A constant temperature water bath maintained the sample temperature at 25 ± 0.1°. A calibration curve for the cup and bob was prepared using seven N.B.S. standard viscosity oils. The emulsion sample was placed in the cup and deaerated by gentle suction. The cup was carefully raised into position, taking care not to entrap air under the bob. The system was then conditioned for 2 hours before beginning a run. The rheogram was obtained by adding successively increasing weights to the hanger. A point on the curve was obtained by noting the

[a] See Table I for the relationship between the emulsion notation and the method of manufacture. [b] The first rheograms were prepared immediately after manufacture and cooling of the emulsion samples. [c] Plastic viscosity in centipoises. [d] Thixotropic area in square inches. [e] Yield value in dynes/cm.^{2}. [g] Rheological data for emulsion samples 2-F to 5-F could not be obtained due to the wax aggregates present.

time required for a given weight to drive the bob through 100 revolutions. This value was then converted to r.p.m. When a maximum of 380 to 410 r.p.m. was reached, the weight on the hanger was reduced in increments. An interval of 60 seconds was observed between each point on the curve. The calculations necessary to obtain the instrumental constants, plastic viscosity, and yield value were identical to those of Fischer (11). The thixotropic area was measured directly in square inches with a compensating planimeter.[4] At least two samples of each emulsion were run immediately after manufacture, and after 1, 3, 5, 6, and 10 weeks, the samples being stored at room temperatures which ranged from 22 to 29°.

Separation Rate Evaluation.—Preliminary work showed that water separation was the only visible change to occur in the emulsion. Consequently, a 100.0-ml. fraction of each emulsion sample was placed in a rubber stoppered Pyrex glass tube as outlined by Peck (12). Water separation was measured at frequent intervals for 180 days.

Particle Size Determination.—Immediately after manufacture, each sample was viewed with a standard optical microscope equipped with a 10× eyepiece and 43× objective. Emulsion samples were "mixed" prior to sampling by gently tumbling them in the sample container by hand. The sample was prepared by diluting one drop of emulsion as delivered by a standard U.S.P. medicine dropper with 5.0 ml. of distilled water. One drop of this dilution was then placed on a glass slide, a cover slip carefully put in place, and the sample viewed. The longest regular dimension of each particle was measured using a micrometer in the eyepiece.

The method of Harris, Horvitz, and Moon (13) was applied to preliminary particle size data obtained from two different emulsion samples to determine the number of particles required for a statistically valid sampling. With the test a maximum confidence interval of 0.5 μ, 99% confidence coefficient, 95% probability, with 99 degrees of freedom, a sample size of 300 to 400 particles was indicated. Subsequently, 400 particles were counted from each emulsion sample in the determination of particle size parameters.

RESULTS AND DISCUSSION

Rheology.—The temperature of emulsification and rate of cooling altered specific rheological properties of this emulsion system. All samples demonstrated plastic viscosity and thixotropy (Table II and Figs. 2–5). As shown by Table II, thixotropy increased greatly with age in all samples. The rate of cooling determined, to a large extent, the amount of thixotropy of the emulsion both initially and on aging.

[4] Keuffel and Essel Co., Model #4242.

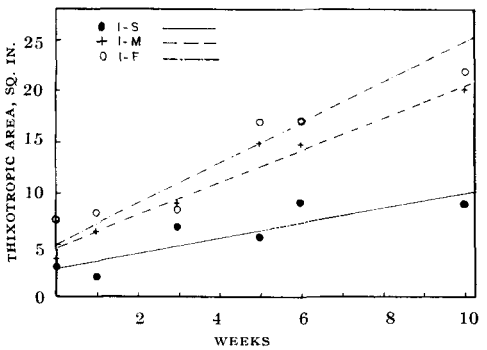

Fig. 3.—The effect of cooling rate and sample age on the thixotropy of a wax emulsion.

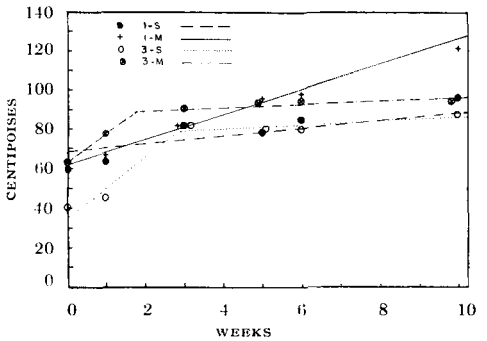

Fig. 4.—The effect of emulsification temperature, cooling rate, and sample age on the plastic viscosity of a wax emulsion.

The more rapid the cooling rate, the greater the thixotropy of the emulsion samples.

Emulsions made at different temperatures and cooled slowly showed, without exception, that the lower the temperature of emulsification, the greater the plastic viscosity, thixotropic area, and yield value of the freshly prepared samples (Tables I and II). After 10 weeks this was still true for the yield values. Compared with emulsions cooled at the fast and medium rates, the slowly cooled emulsions demonstrated the lowest values for plastic viscosity and thixotropic area (Table II).

As illustrated by Table II, emulsions prepared at different temperatures and cooled at a medium rate initially had only about a 10% difference in plastic viscosity. After 10 weeks there was a variance of about 40%. Similarly, the products cooled at a medium rate initially possessed nearly equal thixotropic areas; however, after 70 days there was a great percentage variance in the areas (Table II). Initially, the yield value of emulsion 1-M was greater than emulsions 2-M and 3-M (2-M and 3-M being nearly equal to each other). After 10 weeks there were only small differences in the yield values in emulsions 1-M, 2-M, and 3-M.

The results indicate that the rapidly cooled products possessed the greatest thixotropy and yield value of all emulsions.

Despite the frequently published statement that the separate emulsion phases should not be prepared at widely differing temperatures, with this emulsion it seemed to make little difference in any property measured whether the phase temperatures varied by as much as 20° or not.

TABLE III.—PARTICLE SIZE DATA

Emulsion	Diameter, μ (Arithmetic Mean)	Emulsion	Diameter, μ (Arithmetic Mean)
1-S	6.1	3-F	4.9[a]
1-M	5.3	4-S	5.7
1-F	5.0	4-M	5.0

Error	8	0.6	0.075	..	..	
Total	14	9.5				

Figure 5 shows that rheological replication was possible with this emulsion system. Emulsions 4-S and 4-S' were made, on separate days, at the same temperature and cooled at the same rate.

Separation Rate.—All samples showed water separation. Fast cooled emulsions, with the exception of emulsion 1-F which was prepared at a temperature just above the melting point of white wax (70° both phases), showed rapid pronounced water separation (Fig. 6). After 180 days, 27 to 32 ml. of water had separated from the fast cooled emulsions; however, only 13 ml. of water had separated from emulsion 1-F during this period. Water separation in the samples cooled at the slow and moderate rates varied from 10 to 14 ml. after 180 days. This difference was apparently due to the fact that in the fast cooled emulsions the phases had considerably less time for complete emulsification and mixing (Table I). Emulsion samples cooled at a medium rate consistently showed the least water separation over the test period.

Particle Size.—The study of the particles and their relative sizes under the microscope was quite revealing (Table III). The average particle size was definitely related to the rate of cooling and temperature of emulsification. In the emulsion samples, the average particle size varied from 3.9 μ in emulsion 5-F to 7.0 μ in emulsion 2-S. Without exception, smaller particles resulted as the rate of cooling was increased. However, fast cooled samples also contained large (35 to 50 μ) aggregates in addition to the small individual particles. This was probably due to incomplete emulsification of the sample. It is important to point out that only a few isolated oil globules were seen under the microscope. The mineral oil and the white wax apparently merged, forming needle-like crystals. De Navarre (14) states that when reacting sodium

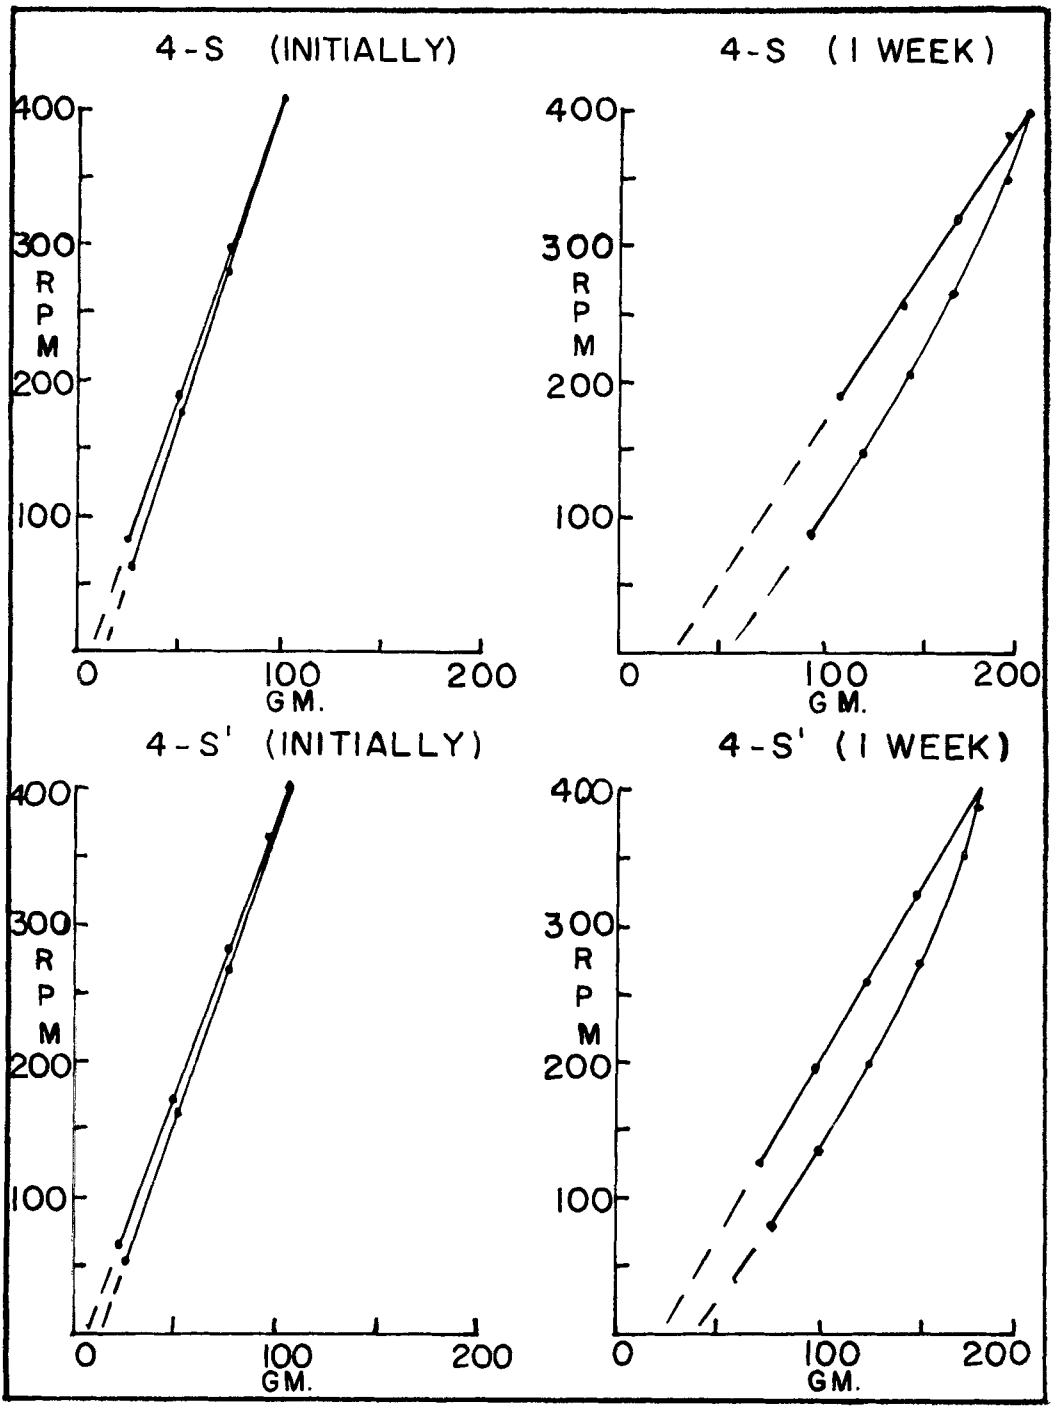

Fig. 5.—Rheological replication of emulsion 4-S.

borate with white wax to form a cold cream, sodium cerotate and several other minor soaps are formed which emulsify the oil and the waxes in the water. To determine if the oil and the wax would combine without the aid of an emulsifier, 80 Gm. of white wax and 250 Gm. of mineral oil were heated together, with mixing, to 80° and maintained at that temperature until all the wax melted. The mixture was then slowly cooled to room temperature. A uniform, semisolid, one-phase product resulted.

A two-way analysis of variance (15) revealed that both the rate of cooling and the temperature of emulsification produced significant changes in the average particle size (Table IV).

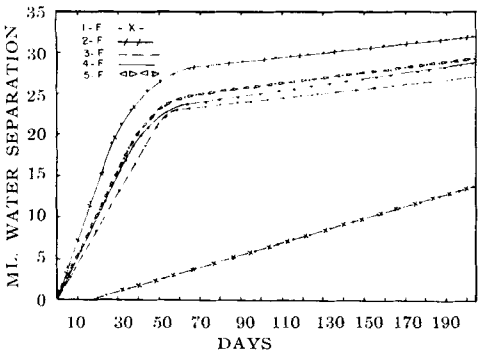

Fig. 6.—Water separation from fast cooled emulsions.

SUMMARY AND CONCLUSIONS

All the samples studied demonstrated plastic viscosity and thixotropy and possessed a yield value. However, the temperature of emulsification and rate of cooling definitely altered these and other physical properties of the emulsion. The rate of cooling was the main variable factor which determined the degree of thixotropy in the sample; the faster the cooling rate, the greater the thixotropy. As a general rule, plastic viscosity and thixotropy increased with age. Emulsions cooled at a medium rate showed more variance in their rheological values and trends than did the slowly cooled products.

Upon cooling, the wax and the mineral oil in the emulsion combined, forming needle-like crystals. Both the cooling rate and the emulsification temperature significantly changed the size of the emulsion particles; without exception, smaller particles resulted as the rate of cooling was increased. However, fast cooled emulsions formed wax-oil aggregates as well as individual particles.

All fast cooled emulsions, with the exception of the one prepared at 70° (both phases), showed rapid water separation over a 180-day interval. All other emulsions showed only slight water separation in the 180 day test period. Fast cooling is not recommended when preparing this emulsion.

Despite the frequently published statement that the separate emulsion phases should not be prepared at widely differing temperatures, with this emulsion it appeared to make little difference visually, microscopically, or rheologically whether the phase temperatures were the same or not.

Direct Acidimetric Analysis of Papaverine in Concentrated Lithium Chloride Solution

By JAMES L. SPAHR, MODEST PERNAROWSKI, and ADELBERT M. KNEVEL

Hydrochloric acid was used as the titrant for papaverine base in two different media: (*a*) 18.5% ethanol and 81.5% 8 *M* lithium chloride solution, and (*b*) 10% tetrahydrofuran, 5% ethanol, and 85% 8 *M* lithium chloride solution. Per cents were calculated on a weight to weight basis. All of the titrations were carried out potentiometrically and the end points were determined by the first derivative method. It was found that bromophenol blue indicator could also be used to determine end points in medium *a*. The mean per cent recovery for the titrations in medium *a*, with the end points determined by the first derivative method, was 98.85 with a standard deviation of 0.69. In the same medium, using bromophenol blue for end point determination, the recovery was 99.48 with a standard deviation of 0.96. In medium *b*, the recovery was 100.02 with a standard deviation of 1.27.

CRITCHFIELD and Johnson (1) have found that the potentiometric break in the titration of a weak base with aqueous hydrochloric acid is greatly enhanced if a concentrated aqueous solution of a neutral salt is used as the titration medium. (Neutral salts, for the purpose of this work, are defined as those derived from strong monobasic inorganic acids and strong mono- or diacidic inorganic bases.) Aniline, for example, with an ionization constant of 3×10^{-10}, is too weak to be titrated satisfactorily in water. By titrating the same compound in 7 *M* sodium iodide solution, a potentiometric break is obtained which is satisfactory for precise analytical measurements.

The present study was undertaken with the purpose of investigating the possibility of analyzing certain pharmaceuticals by the above method. Many pharmaceutical compounds contain tertiary amine structures and can be classed as weak bases. It would appear, therefore, that they might lend themselves to this type of analysis.

Papaverine, which is representative of the type of compound to which this method of analysis may be applied, was selected as the base for this investigation. First, the compound had to have an ionization constant between 1×10^{-8} and 1×10^{-11} (1). It has been observed that compounds with ionization constants greater than 1×10^{-8} can be acidimetrically titrated very satisfactorily in water either by a direct or an indirect method. Compounds with ionization constants smaller than 1×10^{-11} cannot be titrated satisfactorily even in concentrated salt solutions.

Received May 23, 1961, from the School of Pharmacy, Purdue University, Lafayette, Ind.
Accepted for publication October 27, 1961.

Another reason for the selection of papaverine was that it was desired to choose a compound for which this method of analysis might be compared to the official procedure. The U.S.P. XVI method of analysis of papaverine hydrochloride preparations is a gravimetric one.

Lithium chloride was selected as the salt to be used in the titration medium because of its high heat of solution and because it has been successfully employed in titrations of this kind (1). Critchfield and Johnson have attempted to correlate the heat of solution of a salt with its effect on an acid solution. Their experimental data indicate that salts with high heats of solution exhibit the most pronounced effect of increasing the acidity of aqueous mineral acids. They have suggested that these salts have strong affinities for water and, therefore, compete with the hydronium ion for water of hydration (2). This, in effect, decreases the hydration of the hydronium ion and causes it to be more active.

The object of this investigation was to devise a direct acidimetric method of analysis of papaverine. The experimental work required to meet this objective was carried out in three main steps. The first was finding a cosolvent which would solubilize the papaverine in concentrated lithium chloride solution and not interfere with end point detection. The second step was establishing the accuracy and precision which could be obtained by this direct titration procedure. This was done by titrating known samples of papaverine and calculating per cent recovery. The third step was comparing the accuracy of the titration and the gravimetric methods. This was done by analyzing several official papaverine preparations by both methods and comparing the results.

EXPERIMENTAL

General Titration Procedure

All titrations were carried out potentiometrically using a Leeds and Northrup line-operated pH meter[1] equipped with glass and calomel electrodes. The titrant was added from a 5-ml. buret and the titration mixture was stirred throughout the process with Sargent magnetic stirrer.[2] The applicability of the potentiometric curves to end point determination was judged intuitively. Unless otherwise indicated, end points were determined by the first derivative method. That is, the volume at which the greatest value of dpH/dV occurred was taken as the end point.

Reagents

Hydrochloric acid, at a normality near 0.05, was used as the titrant. This acid was standardized against a 0.1 N sodium hydroxide solution which was standardarized using potassium acid phthalate. The lithium chloride was a Baker analyzed reagent.[3]

Preparation of Samples

Ion Exchange.—Papaverine hydrochloride was converted to the free base by means of an ion exchange resin. The procedure proposed by Levi and Farmilo (3) was used with the following alterations: Dowex 1-X4[4] resin was substituted for Amberlite IR-4B[5] and the sample size was reduced from 75 mg. to 65 mg. Individual samples were prepared by dissolving 0.6500 Gm. of papaverine hydrochloride in 100 ml. of the solution in a 100-ml. volumetric flask and pipetting 10-ml. aliquots. The solvent used in this step consisted of two parts by volume of chloroform and one part by volume of ethanol. The aliquots were introduced onto the ion exchange column and a solution of the free papaverine base was eluted. The solvent was removed by evaporation on a water bath, and the sample was then ready to be dissolved in the appropriate solvent and titrated with acid.

The columns were checked for completeness of recovery by processing a sample in the above manner, collecting the eluted papaverine solution in ten 10-ml. fractions, and testing these fractions for papaverine by the U.S.P. XVI identification test (4). Recovery was found to be essentially complete. Samples prepared in this way are referred to as column samples.

Extraction.—Papaverine was extracted from papaverine hydrochloride according to the method described in U.S.P. XVI under the assay of papaverine hydrochloride injection. Individual samples were prepared by weighing portions of the dried free base. Samples prepared in this way are referred to as extracted samples.

Solubilization of Papaverine in 8 *M* Lithium Chloride

The very low solubility of papaverine in water requires the use of cosolvents to produce a homogeneous system in 8 *M* lithium chloride solution.

Tetrahydrofuran-Ethanol (Alcohol U.S.P. XVI).—Tetrahydrofuran (THF) is a good solvent for papaverine. However, it is immiscible with 8 *M* lithium chloride and hence a third solvent, ethanol, is required to solubilize certain concentrations of THF in 8 *M* lithium chloride. These three comprise a typical ternary system, the compositions of which can be described graphically by means of a triangular plot. This plot was constructed by the following procedure: a series of seven solutions was prepared containing known amounts of ethanol and 8 *M* lithium chloride, and these were titrated with THF. The end point was taken as the first perceptible cloudiness. A second series of seven solutions was prepared containing known amounts of ethanol and THF. These were titrated to cloudiness with 8 *M* lithium chloride. The per cent composition of each sample at the end point was calculated on a weight basis and these compositions were plotted on triangular graph paper. This plot is shown in Fig. 1. At any point above the curved line, the system is homogeneous. At any point below the line, the system consists of two phases.

From the triangular plot, different compositions were selected with the objective of keeping the THF and ethanol concentration at the lowest possible value which would solubilize the papaverine and produce a satisfactory titration curve. The combination which gave the best results with respect to solubility and per cent recovery was 10% THF, 5% ethanol, and 85% 8 *M* lithium chloride solutions. A convenient volume was chosen to be 5.6 ml. of THF, 3.2 ml. of ethanol, and 36 ml. of 8 *M* lithium chloride. Ten column samples were analyzed using this system.

It was observed that when column samples were dissolved in this medium, the solution was slightly turbid. This cloudiness was caused by a small amount of insoluble residue eluted from the ion exchange resin.

It was found that ethanol alone would solubilize a column sample of papaverine. This solution also had a slightly turbid appearance which was again attributed to the presence of an insoluble residue eluted from the resin. However, when the first

increment of acid was added, a small amount of precipitate formed. This did not occur when the three-component system was used as the titration medium. The precipitate was slight and did not interfere with the end point determination. It was not identified.

Ethanol.—Ethanol also proved to be a good co-solvent for extracted samples. A system consisting of 18.5% (12 ml.) of ethanol and 81.5% (36 ml.) of 8 *M* lithium chloride solution gave good results with 5 samples. Volumes of ethanol less than 12 ml. failed to keep the papaverine in solution. Volumes greater than 15 ml. tended to flatten the curve and cause erratic pH meter response.

Figure 2 shows curves obtained in the titration of extracted samples. Curve 1 is the titration in the ethanol-8 *M* lithium chloride system and curve 2 is the titration with the same amount of ethanol but with the 8 *M* lithium chloride solution replaced by water.

It was found that bromophenol blue indicator gave satisfactory end points in this system. The color change is from blue to faint yellow.

For the solubilization of a column sample, 15 ml. of ethanol was required. The need for this increased volume might possibly have been due to the presence of the insoluble column residue. At this concentration of ethanol, the potentiometric curve was leveled somewhat and the end point was not as clearly indicated. Therefore, the tertiary mixture was used as the titration medium of choice for column samples. It was observed, when calculating the per cent recovery of a series of samples, that the results were consistently high. This suggested that the medium was contributing a certain amount of basicity. A series of titrations performed on the components of the system indicated that the lithium chloride was the source of error and demanded that a blank value be determined. This blank value was not strictly reproducible by direct titration of the lithium chloride solution with acid so a back titration procedure was tried. Standard acid was added to the lithium chloride solution and the excess was titrated with sodium hydroxide. The milliequivalents of acid equivalent to the basicity of 36 ml. of 8 *M* lithium chloride solution was calculated. Reproducible results were obtained by this procedure and it was accepted as a satisfactory method for the determination of the blank value. A certain amount of variation can be observed in the blank values recorded in Tables I, II, and III. This is accounted for by the fact that the 8 *M* lithium chloride solution was only approximate and, therefore, a new blank value had to be determined for each batch of solution which was prepared. Another reason for the variation is that all the lithium chloride used did not come from the same lot.

Assay of Some Official Papaverine Preparations

Papaverine hydrochloride injection[6] (0.032 Gm./ml.) and papaverine hydrochloride tablets[6] (0.0324 Gm./tab.) were assayed according to the U.S.P. XVI procedures. After the samples were dried and weighed, they were dissolved in 20 ml. (18.5% w/w) of ethanol and 60 ml. (81.5% w/w) of 8 *M* lithium chloride solution and titrated with 0.1 *N* hydrochloric acid. Either titration medium previously outlined could have been used. The ethanol-THF combination will solubilize a greater amount of papaverine per unit volume than will ethanol alone. However, the preparation of the three-component medium requires one additional volume measurement, i.e., THF. Since both systems give satisfactory curves with extracted samples, the ethanol-8 *M* lithium chloride medium was selected because of its relative ease of preparation.

RESULTS

Table I lists the per cent recovery for 10 column samples of papaverine titrated in 10% THF, 5% ethanol, and 85% 8 *M* lithium chloride solution. End points were determined by the first derivative method. The mean per cent recovery indicates good accuracy. The deviation of 1.27% represents about 0.05 ml. of 0.05 *N* acid, about 0.002 meq., and about 0.7 mg. of papaverine.

Table II lists the per cent recovery obtained from the five extracted samples titrated in 18.5% ethanol and 81.5% 8 *M* lithium chloride solution. In this table the end points were determined by the first derivative method. Table III lists the recovery of the same five samples, but the end points were determined with bromophenol blue indicator. The alkaline form of bromophenol blue is bluish-purple in this system. The end point occurred at pH 2.8–3.5 and the color changed to an easily perceptible faint bluish-yellow. The change is abrupt enough to be used in routine analysis.

[6] Eli Lilly and Co., Indianapolis, Ind.

Tables IV and V list the per cent recovery obtained in the assay of two official preparations. End points for the titrimetric data were determined by the first derivative method. These same end points were also determined using bromophenol blue and the results obtained were essentially equivalent to those by the first derivative. Since the exact amount of papaverine in the samples is unknown, the mean per cent recovery is not as significant as that of the known samples. The standard deviation is, however, a valid measure of precision.

CONCLUSIONS

The data obtained in this investigation indicate that this method of analysis is suitable for the quantitative determination of papaverine and other alkaloids or pharmaceuticals whose properties are similar to those of papaverine.

The problem of solubilizing the free base was overcome by using cosolvents in either a binary or ternary system. The optimum volume of the cosolvent was that volume which would hold the papaverine in solution in 8 *M* lithium chloride and not cause excessive dilution. This investigation indicates that 8 *M* lithium chloride solution can be diluted 33% with cosolvent and still sufficiently enhance the potentiometric break when titrating papaverine.

Chlorpromazine Hyperthermia in Young Albino Mice

By WALTER J. BAGDON and DAVID E. MANN, Jr.

The intraperitoneal administration of chlorpromazine hydrochloride to albino mice, ranging in age from 10 to 38 days, caused hyperthermia in the younger and hypothermia in the older animals. No significant difference due to sex was observed in the effect of the drug at different ages.

THE BODY temperature of the homoiothermic vertebrate, contrary to the poikilothermic animal, is controlled within narrow limits by hypothalamic coordinating centers which maintain a delicate balance between heat production and dissipation, and function independently of environmental thermal changes (1). In 1951, during the preliminary pharmacologic investigations of the phenothiazine tranquilizers, it was observed by Courvoisier and her co-workers (2) that chlorpromazine could temporarily transform an homoiotherm into a poikilotherm, an effect later denied by Decourt, *et al.* (3). Later that year, despite this controversy, Laborit and Huguenard (4) introduced chlorpromazine into clinical medicine as a preoperative drug in conjunction with promethazine and meperidine (the lytic cocktail), a combination that caused a fall in body temperature with the attainment of a state of "artificial hibernation," presumably conducive to the prevention of postoperative shock. The hypothermic action of chlorpromazine in a wide variety of mature animals, including mice (1, 5–7), is now well established, and many factors have been found which affect this response (6, 8–13), yet a paucity of information exists in the literature with regard to the effect of this agent on the normal body temperature of immature animals. Therefore, it was the purpose of this study to observe the effects of chlorpromazine when administered to young mice of various ages.

EXPERIMENTAL

Albino mice (1321) (Huntingdon Farms, Inc., HTF strain) were divided into nine groups, each containing from 116 to 238 animals, according to age as follows: 10, 15, 20, 25, 27, 30, 31, 35, and 38 days old. The variation in age of mice within a group did not vary more than 15 hours. With the exception of the youngest age groups (10 and 15 days), each group was equally divided as to sex. Food was withdrawn 15 minutes and water 1 hour before experimentation to provide for nutritional constancy. Temperature recordings, to the nearest 0.1°, were determined orally immediately prior to and 30 minutes after each injection with a model 43 Tele-Thermometer equipped with a No. 402 probe.[1] During testing, each animal was confined in a 100-ml. glass beaker with a screen top, and kept at a constant environmental temperature of 38° 15 minutes before injection and throughout the 30-minute observation period. Freshly prepared aqueous solutions of chlorpromazine hydrochloride[2] were administered at a dosage level of 1 mg./Kg., a dose known to produce hypothermia in mature mice (5, 7), to one-half of a group (equally divided as to sex), while the remaining mice received distilled water and served as controls. All injections were given intraperitoneally at a fixed volume of 0.1 ml.

RESULTS AND DISCUSSION

The effect of chlorpromazine hydrochloride, administered intraperitoneally at a dosage level of 1 mg./Kg., on the body temperature of young albino mice was shown to be influenced by age as recorded in Table I. From the data obtained from 1321 animals, the differences between "before" and "after" temperatures and means for each group were calculated. The significance of differences between means was estimated by use of the *t* test and results are shown in Table II. Only probability levels of 5% or below are indicated. It can be seen that the differences between drug and control groups are significant at extremes of age only, and that there is no evidence that the differences at ages of 20 through 30 days could not have occurred by chance.

Differences between male and female groups at every age are small, and it could be similarly shown that they do not reach levels of statistical significance.

Even if the male and female groups are combined for ages 20 through 31 days, as in Table III, only the 30 and 31-day-old groups reach the 5% level of probability; thus, there is no evidence of either hyperthermia or hypothermia at the ages of 20, 25, or 27 days.

In order to test the significance of the drug × age interaction, the male and female groups were combined and tables of random numbers were used to discard three cases from the 25-day-control group, two from the 27-day-control group, two from the 30-day-drug group, and two from the 38-day-control group, leaving numbers in groups as shown in Table IV. An analysis of variance was then performed as shown in Table V.

[a] No significance.

It is seen (Table V) that the drug × age interaction is significant; i.e., the effect of the drug is different as age increases, and by inspecting the table of differences (Table II), it is seen that this effect is to increase temperature in the lower age groups and to reduce it in the higher age groups.

The significant main effect of age shown in Table V is of much less interest; by inspection of Table II

TABLE III.—SIGNIFICANCE OF DIFFERENCES BETWEEN MEANS FOR COMBINED GROUPS, ESTIMATED BY THE *t* TEST

we can interpret this as reflecting the increasing hypothermia with age shown in the control groups as well as in the chlorpromazine groups.

To test for the presence of a significant drug × age × sex interaction, the two lowest age groups, undifferentiated as to sex, were discarded, and, as before, cases were discarded from the remaining groups using a table of random numbers, leaving numbers in groups as shown in Table VI. An analysis of variance was then performed which showed no significant age × sex × drug interaction, no significant sex × drug or sex × age interaction, or main effect of sex (*F* values, respectively, 0.29, 1.41, 0.17, and 0.24). Thus, there is no evidence that the change in effect of drug with age is different as between males and females.

SUMMARY

1. The data show that the effect of chlorpromazine on body temperature is influenced by age, the drug causing significant hyperthermia in 10 and 15-day-old mice and hypothermia in 35 and 38-day-old mice.

2. There is no significant evidence of a difference in the effect of chlorpromazine at various ages due to sex.

Identification and Evaluation of Botanical Extracts by Paper Chromatography

By WILLIAM A. MEER†, ROLF S. WESTBY‡, and WALTER SIRGO†

The problem of identification of botanical drug extracts is enormous in view of the large variety of botanical species as well as other factors affecting the biosynthesis of plant constituents. This is particularly true for those drugs which do not have a pharmacologically active ingredient or chemical component which can be assayed for in a routine manner. A rapid method is proposed which utilizes an ascending paper chromatographic technique with slight modification, ultraviolet light for observation, and the use of appropriate chromogenic spray reagents. This procedure produces a chromatogram consisting of base, stem, cone, and solvent front regions. The resulting characteristic picture, when viewed as a whole in comparison with a standard or control sample, can then be used for the identification and evaluation of the drug extract.

THE IDENTIFICATION of botanical drugs is accomplished by a variety of analytical and biochemical methods. Generally speaking, these have been based on both macroscopic and microscopic pharmacognostical descriptions, color reactions, assay procedures for the determination of chemical constituents as well as specific physiological responses observed through biological assay techniques.

Due to the complexity of most drugs, these procedures are generally lengthy and rather intricate so that identification often is based solely on physical characteristics. In the case of extracts of these drugs, so often indistinguishable in such a form, identification poses an even greater problem. As many extracts, fluidextracts, tinctures, and similar preparations are daily analyzed in our laboratories, our concern was more immediate and led us to devise a rapid identification method. The natural choice was paper chromatography. The method described using this technique has met with good success and is now being used as a routine control procedure.

Accounts of the history of chromatography dating to about 1903 have been adequately covered by Lederer and Lederer (1), by Consden, Gordon, and Martin (2), and others.

Many techniques and adaptations of methods have widely increased the scope of chromatography. The use of ultraviolet light, suggested by the Portuguese scientist Konig in 1935 (3) to help detect or locate fluorescent substances, has been of great value. In a recent study by Kokoski, *et al.* (4), 133 powdered crude drugs were examined under ultraviolet light and the color of the fluorescence proposed for identification. A disadvantage noted was that there was some variation in color reported for the same crude drug by different observers.

Work supported jointly by the Vanilla Bean Association and the Flavoring Extract Manufacturers Association resulted in the development of a paper chromatographic method for the evaluation of vanilla extracts and the detection of foreign materials used for adulteration (5). An important and interesting result of this work has also been the development of a method whereby fluorescent chromatograms can be photographed in their true colors (6).

At present, the N.F. XI utilizes paper chromatography in the chemical identification test appearing in the monograph on *Rauwolfia serpentina* (7). The alkaloidal content of the sample is compared to a reference standard.

The problem of positive identification of botanical drug extracts is enormous in view of the large variety of botanical species as well as factors affecting the biosynthesis of plant constituents. This is particularly true for those drugs which do not have a pharmacologically active ingredient or chemical component which can be assayed for in a routine manner.

With all of these problems in mind, a rapid method is proposed which uses an ascending paper chromatographic technique with slight modification, ultraviolet light for observation, and, in some cases, the use of appropriate chromogenic spray reagents. This procedure allows for the examination of the drug extract as a whole. The amount of the extract used represents a very small amount of whole crude drug so that identification can be made with only a limited amount of material, the same amount of which may prove difficult or impossible by

microscopic examination. The resulting chromatogram will produce a characteristic picture and, when compared to a standard or control sample, can then be used for identification.

EXPERIMENTAL

Materials.—Fluid extracts (1 ml. = 1 Gm. crude drug). Tinctures must be concentrated from 0.1–0.2:1 strength to 1:1 ratio. Powdered extracts are reconstituted with the appropriate hydroalcoholic menstruum and filtered or centrifuged to remove insoluble solids (starch, marc, etc.). Solid or pilular extracts are appropriately reconstituted with menstruum to a 1:1 ratio.

Apparatus and Reagents.—A chromatographic chamber whose size will vary with the number of strips run; this may be a box constructed from cardboard, wood, or glass with a removable front and no top; this chamber helps to maintain an atmosphere somewhat saturated with the solvent while protecting the strips from air currents. Crystallizing dishes, 70 mm. in diameter and 50 mm. in depth. Graduated cylinders. Pipet to deliver 0.02 ml. Metal or glass rods and framework to support paper strips. Ventilating hood or similar exhaust system. Ultraviolet lamp with filter passing only long rays (3600–3700 Å.). Filter paper, Whatman No. 4, chromatographic grade, strips cut 2 × 11 in. with the paper fibers running lengthwise. Solvents: *n*-butyl alcohol, glacial acetic acid, distilled water (4:1:5). Chromogenic reagents to be sprayed on the developed and dried chromatographic strip.

Filter Paper Chromatographic Strip.—The paper strip is developed by ascending chromatography. Normal development time, useful for routine identification, requires 2 hours. Longer periods of time did not give improved resolution. Spots A and B represent points of application of the extract. Spot B is a reference spot and is useful to compare the concentration of one extract with another. After development of spot A, the chromatographic picture consists of the base, stem, cone, and solvent front regions. An area above the solvent front region sometimes becomes visible after the chromatogram is treated with an appropriate chromogenic reagent. A drawing representing a typical developed paper strip is shown in Fig. 1.

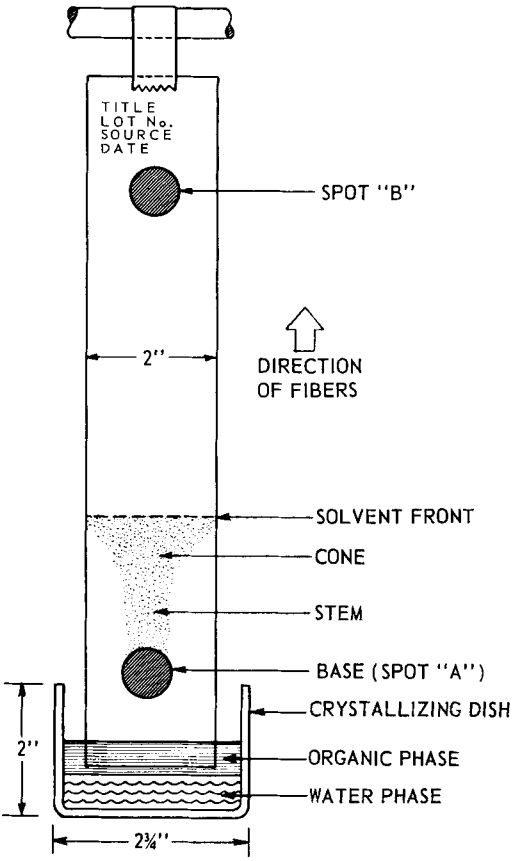

Fig. 1.—A drawing representing a typical developed paper strip.

Procedure.—Prepare the filter paper strip with the title of the extract, lot number, source, date, etc. With a pin and using a guide, mark the exact spots to apply the extract. Spot A centered 1 in. from the bottom edge of the strip and spot B centered 2 in. from the top edge of the strip. Place exactly 0.02 ml. of the extract on spot A and B and allow to dry, about 5 minutes. The extract should be applied slowly to keep the spots as small as possible. Use fluid extract strength (1 ml. = 1 Gm. crude drug). Prepare the solvent consisting of *n*-butyl alcohol, glacial acetic acid, distilled water (40:10:50), and shake vigorously in a separator (stopcock free from grease) for at least 1 minute to saturate before transferring the entire mixture to a crystallizing dish. The solvent is ready to use when the two layers are clear. The solvents should be freshly prepared and of the highest chromatographic grade. Immerse the paper strip in the organic phase so that the bottom edge of the strip is 2–3 mm. above the aqueous layer. Fasten the strips with scotch tape or clamps to a support rod about 12 in. above the bench top. Keep the temperature as constant as possible in the range of 20–25°. For checking reproducibility and comparison, run a reference standard or control and the unknown simultaneously. Each extract should be run in triplicate, not only to gain experience and to confirm reproducibility within each set, but to have additional strips for reagent treatment. Allow the chromatograms to develop for 2 hours with controllable ventilation. It is important to prevent drafts over the paper. Figure 2 shows three sets of chromatograms at the end of a 2-hour developing period. Dry the developed strips in a ventilated hood for 1 hour. The chromatograms should be viewed and evaluated soon after drying because some colors may change or disappear.

Results.—The developed and dried chromatograms are first viewed under visual and then ultraviolet light and the samples compared with the control or standard. Spot B should not show a variation of more than approximately ±10% in intensity. If the intensity varies greatly between the sample and the control, then the extract in question should be either diluted or concentrated to match more nearly the reference standard for identification purposes. Differences in intensity of spot B provide further information in the evaluation

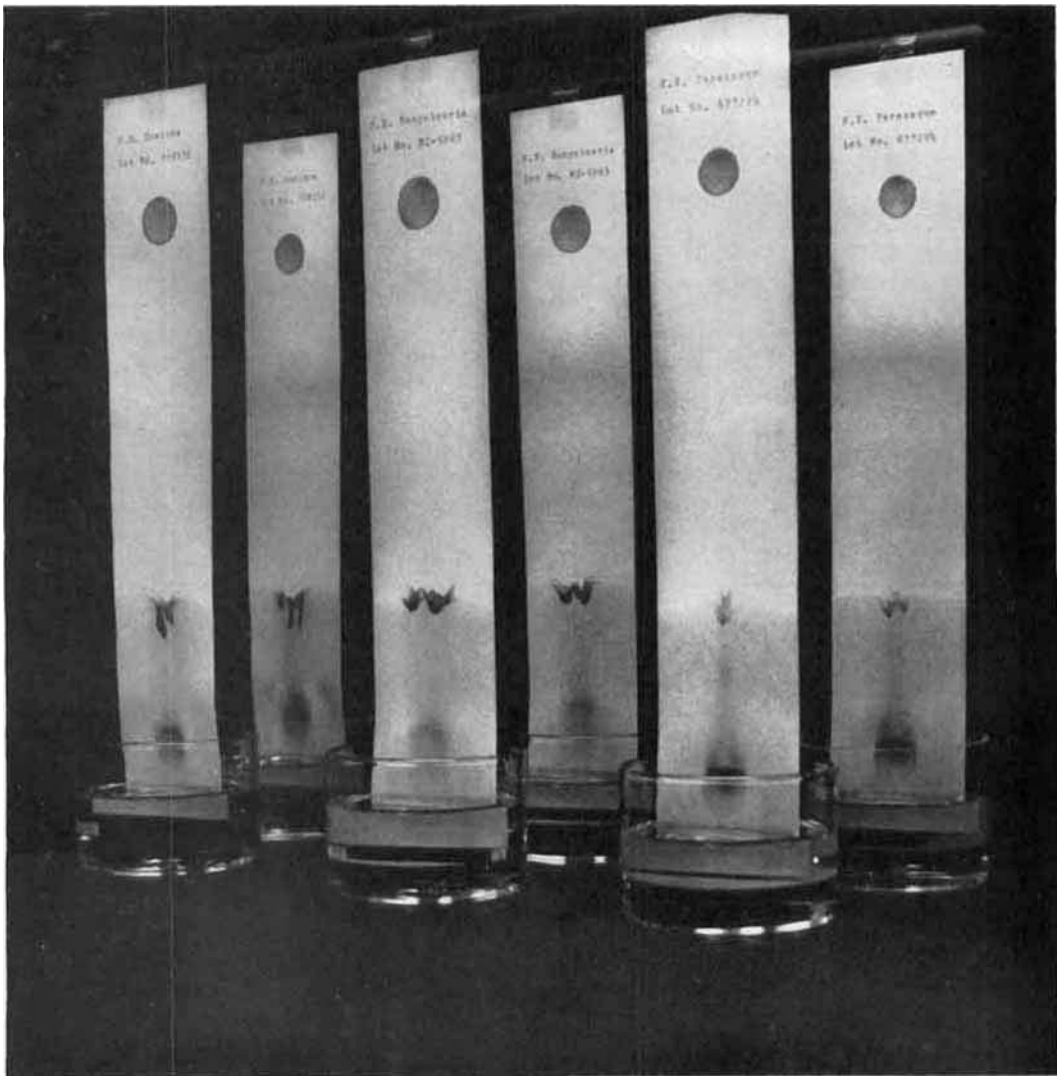

Fig. 2.—Three sets of chromatograms at the end of a 2-hour developing period. For this photograph, the protective side has been removed.

of the sample. A spot of lesser intensity generally indicates a lower concentration of soluble solids in the extract. Spot A has now traveled to form the base, stem, cone, and solvent front regions. Color comparisons should be made of these areas. Shade and intensity should be noted both under visible and ultraviolet light. The degree of travel, distribution, fluorescence, and relative position of the solute must also be observed.

Results have shown that a characteristic picture is produced for each extract tested (Fig. 2). A sample will therefore be positively identified when its developed chromatogram corresponds to that of the control after it has been subjected to the requirements described in the above procedure.

SUMMARY

This technique has proved to be a rapid analytical tool in the routine control, identification, and evaluation of botanical extracts. It produces a chromatogram consisting of base, stem, cone, and solvent front regions. By observing the chromatographic picture as a whole, an unknown can be determined when it matches a control or known sample by producing a total effect similar in distribution, intensity, coloring, and fluorescence. It must be remembered, however, that the variation in details may be due to the natural variation of botanical constituents.

If similar results are obtained with original chromatograms of extracts of different botanicals, further treatment with a chromogenic reagent may provide distinguishing characteristics. Preliminary work has indicated that it is difficult to ascertain the best chemical for use, especially due to the variety of compounds occurring in a

single extract. Effective use has been made of several reagents, however, such as: (*a*) a 0.1 *M* solution of cerium sulfate in water, (*b*) saturated methanol solution of aluminum sulfate, and (*c*) saturated water solution of sodium borate.

The common alkaloidal, sugar, and protein color producing reagents may also be employed. Work is in progress on the tabulation of extracts with corresponding spray reagents and will be described in a subsequent communication.

Effects of Buffered and Unbuffered Acetylsalicylic Acid upon the Gastric Acidity of Normal Human Subjects

By CLARKE DAVISON, BENJAMIN W. SMITH, and PAUL K. SMITH†

Acetylsalicylic acid in tablet form, in buffered tablets, and effervescent buffered solution, has been compared with regard to the effect upon gastric acidity and pH. Aspirin and buffered aspirin have little or no effect as compared to controls, whereas the effervescent preparation reduces free acidity and raises gastric pH significantly for 30 minutes. This elevation of gastric pH correlates well with the more rapid absorption and reduced gastric irritation which has been reported for various soluble and buffered forms of salicylates.

DISADVANTAGES of acetylsalicylic acid as an analgetic and antipyretic agent are low solubility, which delays absorption (1), and gastric irritation and bleeding which may result from the erosive action of the crystals of the drug (2), or possibly from its acidity (3), as well as a neurohumoral action (4). It has been shown by Alvarez and Summerskill (5) that there is a causal relationship between salicylate consumption and massive gastrointestinal hemorrhage associated with peptic ulcer. For these reasons, there are a number of proprietary preparations of acetylsalicylate available which are buffered so as to minimize these problems. Several investigators have noted that such buffered preparations are more rapidly absorbed (6, 7). There are also scattered reports that soluble preparations of acetylsalicylic acid or salicylic acid are less irritating and less prone to produce gastric hemorrhage (8, 9). The present investigations were designed to compare the effects of such buffered preparations upon free and total gastric acidity and gastric pH, as compared to unbuffered aspirin.

† Deceased October 1960.

PROCEDURE

For the initial experiments, subjects were selected at random from available laboratory personnel and included six male and one female subject. They were fasted for 12 hours prior to the experiment and then given a test meal consisting of 50 ml. of cold 45% alcohol, to stimulate gastric secretion. Fifteen minutes after the test meal each subject swallowed a stomach tube, and 5 minutes later withdrew a zero-hour sample of 10 ml. of fluid. Immediately after removal of this control sample the drugs were administered. Over a period of 2 weeks each subject received each drug and performed one experiment where only water was administered (control). Effervescent aspirin[1] was administered dissolved in water, two tablets in 250 ml. of water; buffered aspirin[2] and aspirin[3] were taken whole, two tablets followed by 250 ml. of water. All doses were equivalent to 650 mg. of acetylsalicylic acid. Controls received 250 ml. of water only.

Ten-milliliter samples of gastric juice were removed 10, 20, 30, and 40 minutes after administration of the drugs. All samples were tested for pH using pHydrion paper; for free acid by titration with 0.01 *N* sodium hydroxide to a change in color with Töpfers reagent (pH 3.5); and for total acidity by titration to the end point of phenolphthalein (pH 8.4). Free and total acidity are reported in clinical units (milliliters of 0.1 *N* sodium hydroxide required to neutralize 100 ml. of gastric juice).

[1] Marketed as Alka-Seltzer by Miles Laboratories.
[2] Marketed as Bufferin by Bristol-Myers Co.
[3] Bayer Aspirin.

In view of the wide variability observed in these subjects' results, the experiments using aspirin and effervescent aspirin were repeated under more carefully controlled conditions and with more accurate procedures for measurement of pH and free and total acidity.

Some of the subjects in the first series of experiments had experienced a great deal of difficulty in swallowing the stomach tube. In order to eliminate the possibility of such trauma affecting the response to the test meal, 35 prospective subjects were tested as to their ability to swallow the stomach tube without difficulty. Twelve were selected as having little or no difficulty and were used in this series of experiments; these included ten male and two female subjects. The test meal was changed to one designed to give better stimulation and consisted of 50 ml. of 14% ethanol to which was added one-half teaspoonful of dry Cream of Wheat to provide mechanical stimulation. The general procedure used was the same except that the drugs were administered with only 150 ml. of water. The pH was measured using the Beckman Zeromatic pH meter. Free and total acidity were measured by titration with 0.01 *N* sodium hydroxide to pH of 3.5 and 8.4, respectively, as measured by the pH meter.

RESULTS

The subjects exhibited a widely varying and generally poor response to the test meal used. In spite of this, marked differences were obtained with the drugs tested (Table I). Effervescent aspirin caused an immediate elevation in gastric pH which reached a maximum of 2.2 pH units above the water control at 20 minutes, and decreased thereafter. A statistical analysis revealed that the gastric pH with the effervescent preparation was significantly higher at 10 and 20 minutes ($P < 0.05$ and < 0.001, respectively) than with the other three preparations. After 20 minutes no differences were seen. The other two salicylate preparations do not affect the pH significantly at any time, nor do they alter free acidity, as compared to the water control. The free acidity drops sharply after the administration of the effervescent drug, the difference being highly significant ($P < 0.01$) at 10, 20, and 30 minutes, and probably significant at 40 minutes ($P = 0.05$). Total acid levels were also compared by the analysis of variance technique, and no differences were found among the drugs.

The second series of experiments, employing a test meal of greater stimulatory capacity and selected subjects, was much more uniform. Effervescent aspirin again produced a marked elevation in pH as compared to aspirin (Table II, Fig. 1) and a marked drop in free acidity (Table II, Fig. 2). An analysis of variance was again performed, followed by comparisons at the individual times by the technique of Scheffe (10). The pH differences were highly significant through 30 minutes ($P < 0.001$) and probably significant at 40 minutes. Differences in free acidity were also significant at 10, 20, and 30 minutes ($P < 0.01$). Total acidities differed only at the 40-minute measurement at a low level of significance ($P < 0.05$).

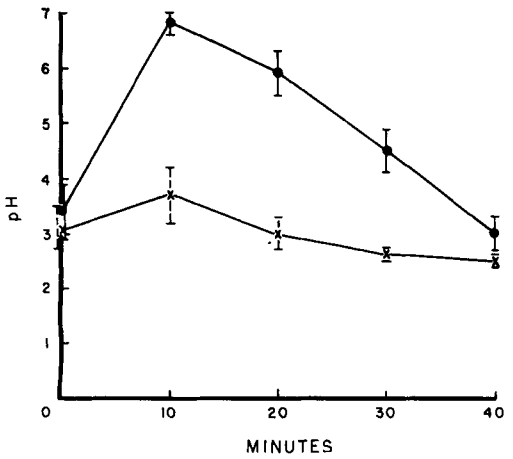

Fig. 1.—Comparison of the effects of 650 mg. of aspirin or effervescent aspirin upon the gastric pH of 12 normal subjects after a standard test meal. Vertical bars represent the standard error of the mean. ●, Effervescent aspirin; ×, aspirin.

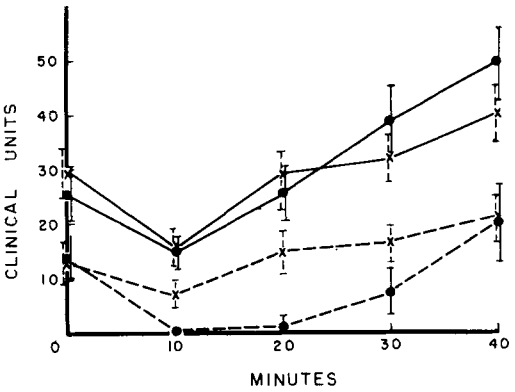

Fig. 2.—Comparison of the effects of 650 mg. of aspirin or effervescent aspirin upon the free and total gastric acidities of 12 normal subjects after a standard test meal. Vertical bars represent the standard error of the mean. ●, Effervescent aspirin; ×, aspirin; — total acidity; - -, free acidity.

DISCUSSION

The results as presented in the tables and figures indicate clearly that effervescent aspirin decreases the free gastric acidity and increases the pH for at least 30 minutes. In contrast, acetylsalicylic acid tablets and buffered aspirin increase the pH only slightly, and depress the acidity to a small degree. This latter effect is presumably due only to dilution of the gastric contents with the ingested water, since these effects did not differ from the controls. Rubin, Pelikan, and Kensler (11) measured intragastric pH levels after the administration of placebos, acetylsalicylic acid, and buffered aspirin, and noted an increase of 0.24 to 0.29 pH units in all cases, these differences not being statistically significant. It will be noted that the pH of those subjects ingesting acetylsalicylic acid tablets or buffered tablets never exceeded 3.7, falling to 2.6 by 40 minutes. This might be expected since at this dosage the buffered aspirin had a neutralization equivalent of only 5 meq. of hydrochloric acid (50 ml. of 0.1 *N* hydrochloric acid). Since the pKa of acetylsalicylate is

3.49, this means that a large proportion of the drug is unionized and of relatively low solubility throughout the period of measurement. The solubility of the drug is about 6.6 Gm./L. at 37° at pH 3 in dilute hydrochloric acid, so that all of the 650 mg. could be in solution in the volume of water used. However, the local pH at the mucosal wall and the diffusion constants of solid acetylsalicylic acid as it goes into solution would modify the rate of solution. Edwards (1) made theoretical calculations concerning such factors, and Nelson and Schaldemose (12) confirmed these experimentally by showing that acetylsalicylic acid in aqueous solution was much more rapidly absorbed than a comparable amount in tablet form. In contrast, after the administration of effervescent aspirin, the pH remained above 4.5 up to 30 minutes so that the drug would be more than 90% in the ionized form throughout this period. The effervescent preparation contains about 10 times more buffer, equivalent to 48 meq. It will also be noted that this large amount is not reflected in the total acid titrations; in the second experiment at 40 minutes, the increase was only 0.9 meq./100 ml. of gastric juice. This must result from the relatively rapid passage of a large proportion of the buffered gastric juice into the intestine. Moreover, Bolton (13) has demonstrated that citrate enhances solubility of acetylsalicylic acid, so that in pH 4.5 sodium citrate, acetylsalicylate is soluble to the extent of 32.4 Gm./L. at 30°. Obviously, solubility is not a problem with this buffered preparation and probably accounts for its more rapid absorption, reaching a peak at 30 to 45 minutes (6, 7). The enhanced solubility may very well reduce the gastric irritation associated with plain aspirin. In a group of 103 patients, Alvarez and Summerskill (5) incriminated salicylates in over 40% of cases admitted for hematemesis and melena connected with peptic ulcer. Stubbe (8), in studying patients with rheumatoid arthritis, observed that about 70% of these patients and a control population gave positive benzidine tests for occult blood in the stool regardless of the amounts of aspirin ingested. Enteric coated aspirin gave positive results also, but when positive patients (on aspirin) were changed to sodium salicylate, the benzidine tests became negative. In recent work, Stubbe (14, unpublished) has shown that positive benzidine tests for occult blood occurring when patients were on aspirin became negative when the medication was changed to effervescent aspirin. Pierson, *et al.* (9), employing chromium-tagged red cells, made similar observations with calcium aspirin complex and choline salicylate. Muir and Cossar (2) have seen crystals of acetylsalicylate for as long as several hours after tablet administration. Davison and Guy (unpublished) observed more occult blood produced in pyloric pouch dogs at acid pH values after the administration of acetylsalicylate as opposed to neutral pH. It would appear, therefore, that the erosive properties of the crystalline form of acetylsalicylic acid may account for at least a part of its hemorrhagic properties.

Hurley (15, unpublished), using gastroscopic observations in dogs and substantiated by photographs, has evaluated the local effects of aspirin and soluble effervescent aspirin on the gastric mucosa over a 2-week period. Aspirin produced initial characteristic erosions of the mucosa with hemorrhage, which cleared after 5 days and remained so for the balance of the dosage period. Administration of soluble effervescent aspirin over the same period had no effect on the mucosa. If aspirin is administered following a previous period of effervescent aspirin, the characteristic erosion and hemorrhage occur which clears up after 1 week.

Winkelman (16) suggests that while aspirin and associated salicylates are incriminated in bleeding, with or without peptic ulcer, no proved effect has been demonstrated, but proposed that factors responsible for ulcer production, such as impaired mucosal resistance or increased acid-pepsin secretion, may enhance the development of acute ulceration from salicylate-induced gastritis in some patients.

As Brodie and Hogben (17) have pointed out, it is apparently the unionized form of the drug which is absorbed, and Davison and Guy (unpublished) have confirmed this in dogs with pyloric pouches. Consequently, the buffered forms of acetylsalicylic acid should be absorbed more slowly on the ionic basis but, apparently, the enhanced solubility and consequent distribution over the entire stomach wall, as well as the more rapid penetration into the intestine, overcome this deficiency. Acetylsalicylic acid can even be absorbed within the intestine despite apparently unfavorable pH since, according to Brodie and Hogben (17), the pH of the intestinal wall can be as low as 5.3.

Selection, Evaluation, and Control of the Assay of the Pharmaceutical Product II

Effect of Sampling and Bulk Mix Heterogeneity on Tablet Variation

By EDWARD R. GARRETT† and EDWARD C. OLSON‡

The coulometric bromine oxidation procedure for *o*-methoxy-α-methylphenethylhydrazine has been applied to the analysis of two experimental tablet preparations and one lot of bulk drug. The results show that the variation from tablet to tablet is significantly greater than the error in the assay, that random sampling of bulk drug should be rigidly controlled, that the micro-heterogeneity of a tablet mix may exceed the variability among tablets. The present investigation points out the need for statistically designed studies to determine the uniformity of the drug content.

One of the major production and control interests in the pharmaceutical industry is the preparation of reproducible dosage forms. The variables encountered are the degree of homogeneity of the bulk drug and the pharmaceutical mixture of the drug and excipient, the reproducibility of the dose per unit dosage form, and the relation of these factors to the error in the assay of bulk drug, formulation mix, and final dosage form.

This paper considers the detailed design and statistical evaluation of data obtained on an exploratory batch of tablets to delineate completely the above stated problems.

A coulometric titration procedure with electrolytically generated bromine had been devised to assay the pharmacologically active drug, *o*-methoxy-α-methylphenethylhydrazine in acetic acid-water-methanol and is reported in the literature (1).

The statistical methods are as given in standard texts (2) and the prior paper in this series (3).

EXPERIMENTAL

The coulometric titration with electrolytically generated bromine of *o*-methoxy-α-methylphenethylhydrazine, I, has been published by Olson (1) and the procedures used in these studies were identical with those described. For single tablet assay, the tablet was thoroughly ground, and weighed portions of this mix were analyzed. Analysis of I without excipients and with the excipients of tablet preparations A and B shows no interference with the assay procedure (Table I). The consistent positive error in these assays has been shown to be due to slight hydrazine contamination.

The details of the statistical designs for the studies

$\sigma_D^2 = 0.659$; $\sigma_D = 0.81$

$\sigma_t^2 = \sigma^2 + \sigma_s^2 + \sigma_D^2 = 3.532$; $\sigma_t = 1.88$

[a] Duplicate assays among and within days.

on the homogeneity of the bulk drug and tablets with the evaluation of assay errors are given in the next section.

RESULTS AND DISCUSSION

Evaluation of Variability among Assays and Days of Assay of the Bulk Drug.—The coulometric assay of *o*-methoxy-α-methylphenethylhydrazine in 25 samples of the bulk drug, lot A, are given in Table II. The high results (>100%) have been shown to be due to hydrazine contaminants (1). The request was made that this lot of bulk drug be randomly sampled. Each of the 25 samples was homogenized and micronized, and two assays were run on each sample. As received, 5 samples were run in duplicate on each of five days.

The Table III analysis of variance of the data of Table II demonstrated that the variation among the samples run on the same day is not significantly greater than the variations between duplicates. However, the variation among days is significantly greater than the variation among the daily samples. This implies a daily variation in the assay or a bias in the samples assigned to be assayed on a given day.

TABLE IV.—ASSAY DATA OF DRUG IN TABLETS OF PREPARATION A

Tablet No.	Tablet Wt., mg.	Replicate Assays mg. Drug/100 mg. of Tablets

σ	0.419
S. D.: % of Mean	9.1

This latter could have been the case since no specific instructions as to how to sample randomly were given. For example, samples run on the first day may have been from the top fraction of the bulk drug, on the second day may have been from a second layer, etc. Future designs should be fully cognizant of this source of possible bias.

The estimated error in (standard deviation) per cent of the mean among samples within days is 1.64%. The variation ascribed among days is 0.81%. The standard deviation of any one sample (pooled among days and assays) may be estimated as 1.88%.

Evaluation of Variability among Tablets from Two Different Preparations, A and B.—Two tablet preparations were studied. The data are given in Tables IV and V and consist of the weight of 10 individual tablets and two replicate assays of these tablets. The tablets were halved and the halves randomized so that the operator had no knowledge of whether he was assaying the same or another tablet.

In addition, a sample of the bulk mix obtained prior to the tableting was strewn along the table top and at equal linear intervals, five samples were obtained and assayed.

TABLE VI.—ANALYSIS OF VARIANCE OF TABLE IV, PREPARATION A

Source of Variation	SS	DF	MS	Components of Variance	*F* Test
Among tablets	0.91408825	9	0.1015654	$2\sigma_1^2 + \sigma^2$	$F = 27.9$, significant at 0.001 level
Replicates	0.03774750	10	0.00377475	σ^2	
Total	0.95183575	19			

Estimated variances

$\sigma^2 = 0.0037748 \therefore \sigma = 0.0615$ S. D., % of mean = 1.54

$\sigma_1^2 = 0.0489 \therefore \sigma_1$ 0.221 S. D., % of mean = 5.52

$\sigma_t^2 = \sigma^2 + \sigma_1^2 = 0.0527 \therefore \sigma_1 = 0.230$ S. D., % of mean = 5.60

TABLE VII.—ANALYSIS OF VARIANCE OF TABLE V, PREPARATION B

Source of Variation	SS	DF	MS	Components of variance	*F* Test
Among tablets	0.716431	8	0.089533	$2\sigma_1^2 + \sigma^2$	$F = 12.6$ significant at <0.001 level
Replicates	0.063845	9	0.0070944	σ^2	
Total	0.780276	17			

Estimated variance

$\sigma^2 = 0.0070944 \therefore \sigma = 0.0843$, S. D., % of mean = 2.00

$\sigma_1^2 = 0.04123 \therefore \sigma_1 = 0.203$, S. D., % of mean = 4.80

$\sigma_t^2 = \sigma^2 + \sigma_1^2 = 0.04832 \therefore \sigma_t = 0.220$, S. D., % of mean = 5.21

The analyses of variance for the preparations are given in Tables VI and VII. The variation among tablets for the two preparations, A and B, was similar. The variations in drug assay (as standard deviation, per cent of mean) from tablet to tablet were ±5.5 and 4.8%, respectively. The respective estimates of assay error were 1.54 and 2.00%. These latter values agree well with the 1.64% among assays within days and the 1.88% among assay and days estimated from the previous study on the bulk drug.

The variations in tablet weight are small, ±1 and ±1.3%, respectively, for the two preparations.

It should be pointed out that the tablet-to-tablet variation of drug content is actually larger than that given in Tables IV and V, since the drug assay is given in terms of mg./100 mg. of tablet.

The blend prior to tableting shows an even greater heterogeneity than from tablet to tablet, 12.6 and 9.1%, respectively. This is significantly greater (by *t* test) than the variation among tablets. A valid explanation is that tableting tends to average out some of the inherent microscopic heterogeneity of the pretableting blend.

CONCLUSIONS

The variations in assay of *o*-methoxy-α-methylphenethylhydrazine from tablet to tablet far exceed the error in the assay for the preparations studied. This is highly significant. The drug potency varies 5% from tablet to tablet when considered on a per-unit weight basis Variation between the preparations shows no effect of the excipients. The assay error is only 1.5–2.0%.

The microscopic heterogeneity of the pretableting blend is significantly very much greater than that in the tablets and runs to ±9.1–12.6% in per cent standard deviation. (This includes assay error.)

Assay studies on the bulk drug substantiated the above assay error, 1.64% (per cent standard deviation). Significant variation in assay with days of assay may be attributed to possible bias in the sampling of drug from the bulk lot on the various days. Properly, this portion of the experiment should be repeated to substantiate or negate this possible source of variability.

Studies such as these serve an important function in that they may guide the proper future preparation of tablets to be used in clinical drug evaluation or to be placed on the market.

Selection, Evaluation, and Control of the Assay of the Pharmaceutical Product III

Statistical and Economic Evaluation of the Three-Component Infrared Spectrophotometric Assay of Aspirin Anhydride

By EDWARD R. GARRETT† and JAMES L. JOHNSON

An experimental design of a series of three-component infrared spectrophotometric assays of various preparations of aspirin anhydride is statistically analyzed. Methods are shown for the proper choice of standards and the economical design of assays for a desired statistical confidence. Information as to stability and significance of physicochemical properties, such as melting point, is also obtained.

In previous papers of this series (1, 2), the statistical evaluation of final and bulk drug assays by ultraviolet spectrophotometry (1) and coulometry (2) was considered. The studies on aspirin anhydride (AA) as a possibly superior form for the oral administration of aspirin (3–6) necessitated the preparation of various batches. A three-component infrared spectrophotometric procedure was devised (4) to assay for the aspirin anhydride, aspirin, and salicylic acid in such material.

In general, three-component infrared spectrophotometric assays against synthetic standards are not as precise as the previous types of instrumental analysis discussed. Questions that should be answered concern the precision of such assays, the choice of the proper standard, the economics of replication within and among days of assays.

An experimental design to permit such conclusions is considered in this paper. The validity and reliability of the melting point as an indicator of purity is also considered. The weight loss and initial purity of the preparations are considered in light of the tendencies of the preparations toward instability. The statistical methods used are as discussed in standard texts (7).

EXPERIMENTAL

Four separate lots, A, B, C, and D, of aspirin anhydride which had been stored since preparation were used. They were sampled from the center of 100-Gm. amounts which had been sealed in brown glass bottles. The age of these lots and the analytical data obtained at the time they were originally prepared are given in Table I.

An additional lot, E, in use in Lab A as the assay standard, was included in the study. Ten samples, two of each lot, were submitted to Lab A on each of 5 days with requests for aspirin, salicylic acid, and aspirin anhydride assays of each. The coding of the samples was such (see Table II) that the operator was unaware of the duplication or that the same sample was submitted on sequential days. On each of the days of assay, aspirin anhydride, lot E, aspirin, and salicylic acid were run to serve as standards for the three-component assays on that day. The method of infrared assay was as given in the literature (4). The results of these assays are given in Table II.

Simultaneously with these studies, the lots were submitted on various days for weight loss on drying and melting point. These data are given in Tables III and IV.

RESULTS AND DISCUSSION

The analyses of variance of the anhydride, aspirin, and salicylic acid assays in AA are given in Tables V, VI, and VII. With all three, the assay variation among days exceeds the error among duplicate assays on the same day. Thus, assay duplication on any given day against the same standards may not be warranted if any obtained assay value is to be considered as characteristic of a particular preparation when assayed on any day.

The estimated standard deviations of a single infrared assay, including the error, day by lot interaction, and variation among days are ±0.9% for aspirin anhydride, ±0.4% for aspirin, and ±0.2% for salicylic acid for 87–100% pure anhydride. These standard deviations are given in per cent of the total sample, not in per cent of the component. The 95% confidence limits may be estimated by doubling these values.

Inspection of the data in Table II in comparison with Table I clearly shows that lot A would serve as a better standard than lot E.

In addition, appended to Tables V, VI, and VII are estimates of the components of variance for the data calculated from the standards run on the same day and for the average of the standards over the 5 days. In the cases of salicylic acid and aspirin assays of the AA, it apparently makes no difference whether a separate daily set of standards or the averages are used. However, the variability among days of assays for AA assay vanishes when the average of the standards is used and the total error among assays lessens. Thus, it is recommended that the same absorptivity constants be used in the calculation of all assays at all times. A set of

TABLE III.—WEIGHT LOSS OF ASPIRIN ANHYDRIDE LOTS ON DRYING

Lot	Day Completed[a]	Weight Loss, %
A	8	0.06
	9	0.03
	10	0.04
B	8	0.13
	8	0.22
	10	0.13
C	8	0.24
	10	0.21
	10	0.27
D	9	0.08
	8	0.13
	10	0.20
E	6	0.08
	10	0.02
	10	0.04

[a] The three samples from each lot were respectively submitted on days 3, 5, and 8. The drying was started one day before date of completion.

standards may be run on a given day just to check on being within the control range of the series of standards.

It is interesting to note that lot A has shown no significant degradation for 12 months since its preparation, whereas lots B, C, and D prepared since that time and initially of less purity, have shown some run-down. Lot C has degraded as much as 10%. This confirms the effect of impurities on stability as previously noted (4). Comparison of weight loss values in Table III with the infrared assay (Table II) clearly shows that weight loss, presumably moisture, correlates with instability, as expected from previous studies (4). Melting points correlate with purity as expected. The best preparation, lot A, (Table II) of 99.7% AA has the highest and most reproducible melting point range, 83.4–83.8°, whereas the worst, lot C, of 87.5% AA, has the lowest melting point and the widest range. An individual melting point determination is most valid in the lower limit and least valid in the upper limit (see Table IV).

The estimated component of variance for variation among days of AA assay is $\sigma_D^2 = 0.43$, and for the error among assays on the same day is $\sigma_E^2 = 0.204$. The estimate of variance, σ_{AV}^2 for the average of nk assays could be

$$\sigma_{AV}^2 = \sigma_E^2/nk + \sigma_D^2/k \qquad \text{(Eq. 1)}$$

where n is the number of assays based on one set of standards or run on a given day, and where k is the number of days of assay. The variation among days is assumed to be independent of n. Equation 1 excludes the day × lot variation.

TABLE IV.—MELTING POINTS OF ASPIRIN ANHYDRIDE LOTS

Lot	Day Completed[a]	Melting Point Results, °C.	
A	11	83.4 –83.7	83.5–83.7

		82.0 –82.3	
		82.3 –82.6	
	12	82.2 –96	82.1–96.4
		81.9 –96.8	

[a] The two samples from each lot were respectively submitted on days 3 and 5, each to be run at least in duplicate.

TABLE V.—ANALYSIS OF VARIANCE OF THE INFRARED ASSAY FOR ASPIRIN ANHYDRIDE IN ASPIRIN ANHYDRIDE[a]

Sources of Variation	Sum of Squares	Degrees of Freedom	Mean Square[b]	Quantities Estimated by M.S.
Days (D)[c]	19.12	4	4.78	$10\,\sigma_D^2 + 2\,\sigma_{DL}^2 + \sigma_E^2$
Lots (L)	966.37	4	241.6	$10\,\sigma_L^2 + 2\,\sigma_{DL}^2 + \sigma_E^2$
Days × lots (D × L)[d]	8.38	16	0.524	$2\,\sigma_{DL}^2 + \sigma_E^2$
Error (E)[e]	5.10	25	0.204	σ_E^2
Total	998.96	49	20.39	

[a] Lots among days, 5; lots, 5; and replicates, 2. [b] F test: days × lots: error = 2.57; 5% F = 2.1 ∴ significant at 5% level. Lots: days × lots = 461; 0.1% F = 7.9 ∴ significant at ≪0.1% level. Days: days × lots = 9.13; 0.1% F = 7.9 ∴ significant at 0.1% level. [c] Estimated variance; $\sigma D^2 = 0.43$ ($\sigma D^2 = 0$ if av. of daily standard used). [d] Estimated variance; $\sigma DL^2 = 0.16$ ($\sigma DL^2 = 0.15$ if av. of daily standards used). [e] Estimated variance; $\sigma E^2 = 0.204$ ($\sigma E^2 = 0.212$ if av. of daily standards used). Estimate of variance of a single assay of a given lot = $\sigma^2 = \sigma D^2 + \sigma DL^2 + \sigma E^2 = 0.76$ ∴ $\sigma = 0.89\%$ ($\sigma = 0.60\%$ if av. of daily standards used).

Equation 1 may be combined with a cost function to determine the most economic distribution of assays among and within days. A possible cost function could be

$$C = nkc_1 + kc_2 \qquad \text{(Eq. 2)}$$

where C is the total cost, c_1 is the cost of a replicate assay per day, and c_2 is the cost of setting up the assay on any given day. In general c_2 far exceeds c_1, but for $k = 1$, σ_{AV}^2 must always exceed σ_D^2, no matter the number of replicates.

TABLE VI.—ANALYSIS OF VARIANCE OF THE INFRARED ASSAY FOR ASPIRIN IN ASPIRIN ANHYDRIDE[a]

Sources of Variation	Sum of Squares	Degrees of Freedom	Mean Square[b]	Quantities Estimated by M.S.
Days (D)[c]	3.80	4	0.950	$10\,\sigma_D^2 + 2\,\sigma_{DL}^2 + \sigma_E^2$
Lots (L)	482.62	4	120.65	$10\,\sigma_L^2 + 2\,\sigma_{DL}^2 + \sigma_E^2$
Days × lots (D × L)[d]	1.747	16	0.1092	$2\,\sigma_{DL}^2 + \sigma_E^2$
Error (E)[e]	1.09	25	0.0436	σ_E^2
Total	489.25	49	9.985	

[a] Lots among days, 5; lots, 5; and replicates, 2. [b] F test: days × lots: error = 2.51; 5% F = 2.1 ∴ significant at 5% level. Lots: days × lots = 1.104; 0.1% F = 7.9 ∴ significant at ≪0.1% level. Days: days × lots = 8.70; 0.1% F = 7.9 ∴ significant at 0.1% level. [c] Estimated variance; $\sigma D^2 = 0.084$ ($\sigma D^2 = 0.075$ if av. of daily standards used). [d] Estimated variance; $\sigma DL^2 = 0.033$ ($\sigma DL^2 = 0.029$ if av. of daily standards used). [e] Estimated variance; $\sigma E^2 = 0.044$ ($\sigma E^2 = 0.040$ if av. of daily standards used). Estimate of variance of a single assay of a given lot = $\sigma^2 = \sigma D^2 + \sigma DL^2 + \sigma E^2 = 0.131$; $\sigma = 0.36\%$ ($\sigma = 0.38\%$ if av. of daily standards used).

TABLE VII.—ANALYSIS OF VARIANCE OF THE INFRARED ASSAY FOR SALICYLIC ACID IN ASPIRIN ANHYDRIDE[a]

Sources of Variation	Sum of Squares	Degrees of Freedom	Mean Square[b]	Quantities Estimated by M.S
Days (D)[c]	1.077	4	0.2692	$10\,\sigma_D^2 + 2\,\sigma_{DL}^2 + \sigma_E^2$
Lots (L)	0.433	4	0.1082	$10\,\sigma_L^2 + 2\,\sigma_{DL}^2 + \sigma_E^2$
Days × lots (D × L)[d]	0.3852	16	0.0241	$2\,\sigma_{DL}^2 + \sigma_E^2$
Error (E)[e]	0.2150	25	0.0086	σ_E^2
Total	2.1100	49	0.0431	

[a] Lots among days, 5; lots, 5 and replicates, 2. [b] F test: days × lots: error = 2.80; 5% F = 2.1 ∴ significant at 5% level. Lots: days × lots = 4.50; 5% F = 3.0 ∴ significant at 5% level. Days: days × lots = 11.2; 0.1% F = 7.9 ∴ significant at 0.1% level. [c] Estimated variance; $\sigma D^2 = 0.0245$ ($\sigma D^2 = 0.046$ if av. of daily standards used) [d] Estimated variance; $\sigma DL^2 = 0.0078$ ($\sigma DL^2 = 0.011$ if av. of daily standards used). [e] Estimated variance; $\sigma E^2 = 0.0086$ ($\sigma E^2 = 0.0078$ if av. of daily standards used). Estimate of variance of a single assay of a given lot = $\sigma^2 = \sigma D^2 + \sigma DL^2 + \sigma E^2 = 0.0409$ ∴ $\sigma = 0.204$ ($\sigma = 0.254$ if av. of daily standards used).

As was developed in an analogous situation (8), the condition,

$$n = \sqrt{c_2/c_1}\,(\sigma_E/\sigma_D) \qquad \text{(Eq. 3)}$$

specifies the number of replicates per day for the minimum standard error, σ_{AV}, of the assay at a specified total cost C, where the value of n from Eq. 3 substituted into a rearranged Eq. 2 determines the number of days, k, of n assays.

The condition of Eq. 3 also specifies the value of n for a specifically desired σ_{AV} at minimum cost where this value of n substituted into a rearranged Eq. 1 determines the number of days, k, of n assays.

CONCLUSIONS

The reliability of the infrared assay for aspirin anhydride, salicylic acid, and aspirin is obtained from the studies, and statistical evaluations are

given. The estimated standard deviations of a single infrared assay of aspirin anhydride are AA, ±0.9%; aspirin ±0.4%; and salicylic acid, ±0.2%; in terms of per cent of the total sample. The 95% confidence limits may be estimated by doubling these values. This is based on a new set of standards run on each day. This information demonstrates the foolishness of reporting apparent values by tenths of per cent. For example, if the obtained numerical value of salicylic acid and aspirin in one assay ranges from 0.0 to 0.4%, the amounts present are actually immeasurable and may be considered absent by the sensitivity of the assay.

The greatest assay variation is among days of assay rather than among replicates on a given day. If a routine control procedure is put into effect, assay duplication on the same day is an unnecessary expense. If the most precise assay estimate is desired at minimum cost, special consideration must be given to assaying the sample for several days.

The use of one set of standards or an average value for standards gives less total variability in the AA assay, ±0.6%, and no apparent variation among days. The variability in the aspirin and salicylic acid assays is not significantly changed by the use of either daily or averaged standards.

A comparative study such as this permits the choice of the better standard. For example, lot A should be preferred to lot E. Lot A, the oldest of the lots but of the highest initial purity, has shown no significant degradation for over a year's time. Less initial purity results in greater degradation. It is also shown that low per cent weight loss (considered as low moisture content) correlates with the higher stability.

The correlation of melting point with purity permits the establishment of a desired m.p. and expected error. The lower limit for good AA should be 81.8 ± 0.2°.

The insignificance of salicylic acid in these AA lots of varied purity show that little definition is lost on ignoring it. In fact, a statistical evaluation of data assayed by a two-component assay, for aspirin and AA only, gave less error of estimation.

Antibacterial Activity of Mixtures of Quaternary Ammonium Compounds and Hexachlorophene

By G. R. WALTER and W. S. GUMP

Hexachlorophene and several quaternary ammonium compounds in admixture were evaluated for antibacterial activity by *in vitro* techniques commonly employed for the evaluation of lotions, creams, and ointments. It was observed that a maximum decrease in activity occurred as the components of the mixture approached equimolar ratios. The formation of a water-insoluble complex tends to diminish the antibacterial activity of mixtures when tested by broth dilution or agar plate techniques.

Numerous examples of the inactivation of bactericidal cationic substances may be found in the literature and several have been reviewed by Lawrence (1).

The anionic nature of hexachlorophene would also suggest a lesser antibacterial action in the presence of quaternary ammonium compounds. The problem of ascertaining the extent of inactivation, if any, was undertaken because of the possible usage of both hexachlorophene and quaternary ammonium compounds in items such as lotions, powders, and creams. The methods selected for bacteriological evaluation were those commonly associated with the *in vitro* evaluation

Antibacterial Activity of Mixtures of Quaternary Ammonium Compounds and Hexachlorophene

By G. R. WALTER and W. S. GUMP

Hexachlorophene and several quaternary ammonium compounds in admixture were evaluated for antibacterial activity by *in vitro* techniques commonly employed for the evaluation of lotions, creams, and ointments. It was observed that a maximum decrease in activity occurred as the components of the mixture approached equimolar ratios. The formation of a water-insoluble complex tends to diminish the antibacterial activity of mixtures when tested by broth dilution or agar plate techniques.

Numerous examples of the inactivation of bactericidal cationic substances may be found in the literature and several have been reviewed by Lawrence (1).

The anionic nature of hexachlorophene would also suggest a lesser antibacterial action in the presence of quaternary ammonium compounds. The problem of ascertaining the extent of inactivation, if any, was undertaken because of the possible usage of both hexachlorophene and quaternary ammonium compounds in items such as lotions, powders, and creams. The methods selected for bacteriological evaluation were those commonly associated with the *in vitro* evaluation

of these materials; namely, the zone of inhibition type of test and the broth tube serial dilution technique.

EXPERIMENTAL

Alcoholic stock solutions of benzalkonium chloride (alkylbenzyldimethylammonium chloride) and of hexachlorophene were mixed to give varying ratios of the active materials. In addition to these mixtures, equimolar amounts of hexachlorophene and benzalkonium chloride were brought to reaction in the following manner: To a solution of 8.1 Gm. of hexachlorophene in 100 ml. of acetone was added 15 Gm. of benzalkonium chloride (50% aqueous solution). The mixture was refluxed for 1 hour, the acetone distilled, and the solid removed by filtration, followed by drying at 50° in a 4-mm. vacuum. A slightly sticky material (15.5 Gm.) was obtained. The alkyl group in benzalkonium chloride represents a mixture of the alkyls C_8H_{17} to $C_{18}H_{37}$, the average being about $C_{13}H_{27}$, therefore the molecular weight of benzalkonium chloride approximates 354. The complex obtained from benzalkonium chloride and hexachlorophene would be about 724 (one mole of hydrogen chloride being removed) and its chlorine content 29.4%. The analysis of the product described above gave 29.5% chlorine.

For the bacteriological evaluation, aliquots of the alcoholic mixtures were added to tryptic soy broth (Difco) followed by twofold serial dilution in additional broth. Broth tubes were inoculated with one drop of a 1:100 water dilution of a 24-hour A.O.A.C. broth culture of *Staphylococcus aureus* A.T.C.C. 6538 (2). Tubes were incubated at 34° and growth was recorded by turbidity after 4 days. A slight haze was observed to form when alcoholic aliquots were added to the first tube of the serial dilution series. It was thought that this haze formation might lead to excess variation in the test and obscure any small differences in end points that might occur. For this reason, determinations were replicated seven times, each test being performed on a different day. The log means were analyzed for a significant difference from that of the hexachlorophene mean. It may be noted from Table I that, while both components of the mixture were highly bacteriostatic *per se*, a maximum loss in activity was approached as the ratio of components approached one to one.

An alternate approach for demonstrating the observed loss in activity was performed with the aid of 13-mm. filter paper disks (Schleicher & Schuell No. 740-E) which were impregnated with 0.07 ml. of alcoholic solutions of varying levels of hexachlorophene and benzalkonium chloride. The disks were dried at room temperature to remove solvent and then placed on seeded *S. aureus* plates. Replicate disks were prepared for each solution and placed on assay plates in a random manner. The plates were prepared such that each plate (100 mm. diameter) contained a 20-ml. base layer and a 6-ml. seed layer of agar. Dextrose tryptone extract agar (Difco) was employed for both the base layer and the seed layer. The inoculum consisted of a 1% (v/v) 24-hour A.O.A.C. broth culture of *S. aureus* in agar used for the seed layer. Sharp, well-defined inhibition zones were obtained for both hexachlorophene and benzalkonium chloride by this technique. The loss of zone production by mixtures of the active materials may be noted in Fig. 1. It may be observed that maximum loss of activity was

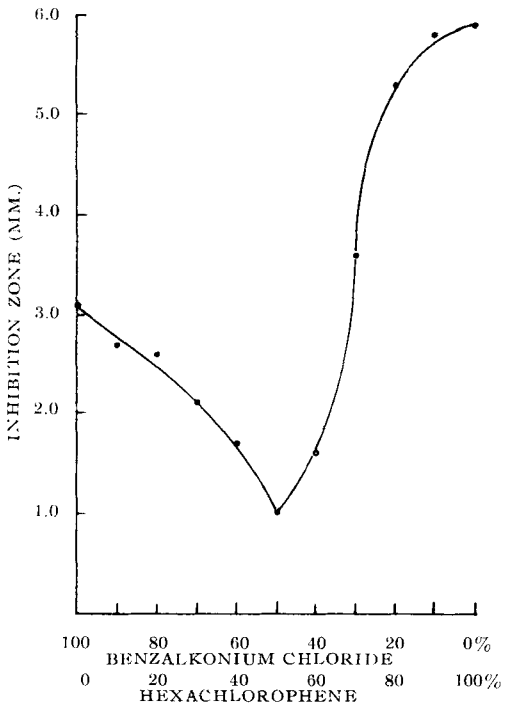

Fig. 1.—Effect of varying ratios of hexachlorophene and benzalkonium chloride on the inhibition zone produced against *S. aureus*. Each point is the mean of three determinations. Solutions were 0.1% with respect to total mixture present.

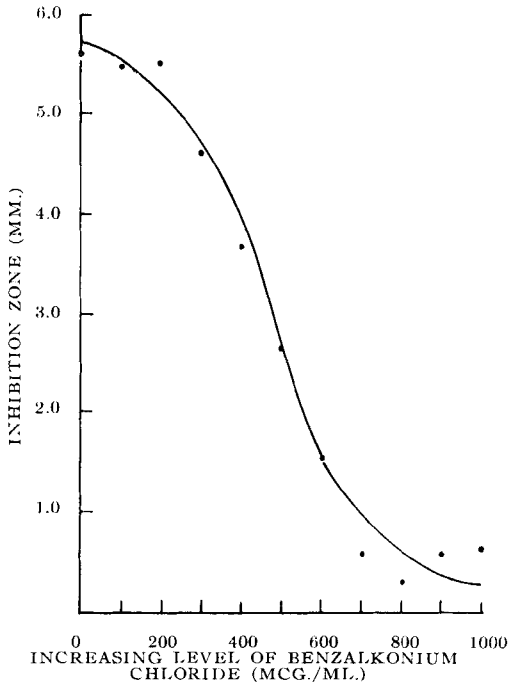

Fig. 2.—Diminishing zone production of a 1000 mcg./ml. hexachlorophene solution with increasing levels of benzalkonium chloride.

found at approximately a 1:1 ratio. Alcoholic mixtures of hexachlorophene and benzalkonium chloride, examined by the plate technique, in which the hexachlorophene level was held constant may be seen in Fig. 2. A loss of activity as the mixture approached a 1:1 ratio was observed.

Several quaternary ammonium compounds structurally dissimilar to benzalkonium chloride were examined in equimolar mixtures with hexachlorophene by the plate technique. As may be seen in Table II, zones produced by these mixtures were also considerably smaller than those of the active materials *per se*.

DISCUSSION AND SUMMARY

Bacteriological examination of mixtures of quaternary ammonium compounds and hexachlorophene demonstrated an antagonistic relationship when evaluated by tube dilution and agar plate techniques. The maximum loss of activity was observed at an approximate equimolar concentration of each component of the mixture. The loss of activity by broth dilution was less dramatic than on agar plates. The haze observed in the broth tubes during the conduct of the tests indicates the formation of an insoluble reaction product. This loss of activity was greatly magnified in the plate technique which relies on the ability of materials to diffuse through agar.

Mixtures of hexachlorophene and quaternary ammonium compounds produce a relatively insoluble complex which is less active than the components, *per se*, of the mixture. The activity loss is greatest at an equimolar ratio, and it must be assumed that one is determining the activity of the uncombined excess of one or the other component when ratios other than equimolar are examined.

Thioacetamide I

Substitute for Hydrogen Sulfide in Medicinal Chemicals for Identity and Purity

By JACK JUE and C. LEE HUYCK†

Identification tests and tests for heavy metals in inorganic chemicals using thioacetamide solution and hydrogen sulfide solution gave identical results. Difficulty was encountered only when solutions of organic drugs in volatile flammable solvents interfered with the hydrolysis of thioacetamide. In this case, the length of time for the completion of the test was increased in order to insure complete hydrolysis of the thioacetamide. In testing acetylsalicylic acid, methenamine, and salicylic acid contaminated with the minimum amount of solution of lead salt sensitive to hydrogen sulfide test solution, the color of the precipitate was brown instead of black.

THE PURPOSE of this study is to review the previous work done on the use of thioacetamide test solution as a substitute for hydrogen sulfide test solution in identifying salts of heavy metals, to detect heavy metal impurities in chemicals, and to investigate the possibility of using thioacetamide test solution as a substitute for hydrogen sulfide test solution.

Hydrogen sulfide from generators or compressed hydrogen sulfide is troublesome compared with aqueous solutions of a solid compound such as thioacetamide as a source of the gas. An added disadvantage of hydrogen sulfide is unpleasant odor, with both systemic and local toxicity.

Thioacetamide (1) is available in the form of white crystals. It is soluble in water, alcohol, benzene, and sparingly soluble in ether. Its aqueous solution is neutral and stable at room temperature. A slight sediment may develop upon standing, but the liquid still has precipitating power. In solution, thioacetamide is a mixture of the amide and its enol form in equilibrium

$$CH_3CSNH_2 \leftrightarrows CH_3C(SH)=(NH)$$

Hydrolysis occurs in both alkaline and acid solutions. Both acids and bases catalyze the hydrolysis. The equations for the reactions are as follows

with acids: $CH_3CSNH_2 + 2H_2O \rightarrow CH_3COONH_4 + H_2S$

with bases: $CH_3CSNH_2 + 3OH^- \rightarrow CH_3COO^- + NH_3 + S^{2-}$

The hydrolysis reaction may be expressed as follows

$$CH_3CSNH_2 + H_2O \rightarrow H_2S + CH_3CONH_2$$

Thioacetamide hydrolyzes slowly in the cold but more rapidly at elevated temperature; therefore, the rate of hydrolysis can be controlled by regulating the temperature. The thioacetamide is introduced into the solution to be analyzed and is heated to approximately 80° on a water bath to cause hydrolysis. Hydrogen sulfide is liberated, causing metal sulfides to be precipitated. The precipitates formed with thioacetamide are coarser and more easily separated by centrifuging or filtering than those formed with hydrogen sulfide. The cations are precipitated in nearly stoichiometric amounts and very little of the hydrogen sulfide ever escapes into the air. There is no need for delivery tubes, safety traps, or hoods. The thioacetamide is usually used in the form of a 10% aqueous solution, the most common being 1*M* or 7.5% w/v concentration.

Vavilov (2) showed that bismuth can be detected in the presence of metals of group IV with thioacetamide. When a drop of bismuth solution is treated with an alcoholic solution of thioacetamide, a yellow coloration is produced. It is probable that $(BiO).SCNHCH_3$ is formed as a result of the reaction between the univalent BiO and the thioacetamide. Cations of group III and copper show evidence of behaving similarly.

Barber and Grzeshowiak (3) used thioacetamide in place of gaseous hydrogen sulfide for precipitation of insoluble sulfides. Thioacetamide was sucessfully used in place of gaseous hydrogen sulfide in the development of new methods of qualitative analysis of group II and group III. A water solution of thioacetamide was added directly to the solution of cations. No great ex-

† Present address: Eaton Laboratories Division of The Norwich Pharmacal Co., Norwich, N. Y.

cess of thioacetamide was required. Nearly equivalent amounts of the organic sulfide and the cation brought about complete precipitation of the insoluble sulfide. The hydrolysis of thioacetamide gave a relatively low concentration of the sulfide ions favoring the rapid coagulation and filtration of the insoluble sulfides. The time required for complete precipitation of the insoluble sulfides by thioactamide was less than the overall time required when gaseous hydrogen sulfide was used. The advantages of thioacetamide solution are tolerable odor, good stability, low cost, and a high degree of solubility in water.

Fales and Kenny (4) gave alternative thioacetamide precipitation procedures which have been used for the last 3 years in our classes.

Bloemendal and Veerkamp (5) found that thioacetamide can fully replace hydrogen sulfide and ammonium sulfide in the qualitative test for heavy metals. A simple analysis procedure was given. They also found that other sulfide compounds like thioformamide are less stable, but usable. Thiourea, thioglycollate, thioacetate, thiosalicylate, and thiophosphate, however, are useless as a replacement for hydrogen sulfide.

Flaschka (6) and Flaschka and Abdine (7) made a study of the use of thioacetamide. Qualitative procedures using thioacetamide were fundamentally identical with those using hydrogen sulfide and differ only in manipulative details. Some precipitation and separation procedures were outlined.

Flaschka and Abdine (7) were among the first to study thioacetamide in quantitative analysis. They found that since thioacetamide formed coarser precipitates, the precipitates are less contaminated by foreign ions, easier to filter, and therefore more suitable for gravimetric analysis than those formed by hydrogen sulfide.

Flaschka and Abdine (7, 8) studied some thioacetamide separations in the presence of ethylenediaminetetraacetic acid (EDTA). The EDTA prevented the precipitation of some metals as their sulfides through chelation. Equilibrium of the metal-EDTA-thioacetamide system resulted by the addition of the calcium ion. Metals were separated as sulfides by precipitating some with thioacetamide in EDTA solution and separating the remainder by the addition of a large amount of calcium ions.

Amin (9) used thioacetamide with EDTA titrations in complexometric analysis of different ores and alloys. Also thioacetamide was used with ion-exchange resins in the analysis of various ores.

Swift and Butler (10) do not agree that thioacetamide solutions can be substituted for hydrogen sulfide without modification of procedure. Rate of reaction measurements have shown that the hydrolysis of thioacetamide to hydrogen sulfide and acetamide is a first-order reaction with respect to both thioacetamide and hydrogen ion concentration, and only a small fraction of the acetamide formed is hydrolyzed to acetic acid and ammonia. In solutions having pH values of less than 3, the precipitation of lead sulfide by thioacetamide is preceded by hydrolysis and the rate of precipitation equaled the rate of hydrolysis. In solutions having pH values from 3.5 to 5.1, the precipitation is first order with respect to both thioacetamide and lead ion concentration. At pH 5, the rate of precipitation of lead sulfide with hydrogen sulfide was found to be 1000 times greater than the formation of lead sulfide by hydrolysis of thioacetamide.

Monte Bovi (11) who first suggested the use of thioacetamide in the testing of pharmaceuticals found it to be a satisfactory replacement for hydrogen sulfide in certain tests used to establish the identity of mercury, bismuth, zinc, and manganese salts, and to detect the presence of such impurities as mercury (II) in merbromin and nitromersol, mercuric iodide in yellow mercurous iodide, copper or zinc in methylene blue, iron in zinc oxide, and heavy metals in sodium chloride and potassium nitrate. Monte Bovi concluded "there is need for more fundamental studies, especially on a quantitative basis, to establish the sensitivity of thioacetamide and the mechanism of reaction, before it can be adopted as a direct replacement for hydrogen sulfide in all pharmaceutical testing. Until then, the indiscriminate use of thioacetamide as a replacement for hydrogen sulfide is not justified."

EXPERIMENTAL

Every identification test for heavy metal salts and every test for heavy metal impurities in chemicals of the U.S.P. (12) was performed with both hydrogen sulfide test solution and thioacetamide aqueous solution. The hydrogen sulfide test solution was made by passing an excess of hydrogen sulfide into cold distilled water. The solution was stored in a small, dark amber-colored bottle filled nearly to the top and kept in a cool dark place. It was not used unless it possessed a strong odor of hydrogen sulfide and unless it produced a copious precipitate with an equal volume of ferric chloride test solution.

The thioacetamide was 1 *M* or 7.5% w/v. The commercial reagent grade thioacetamide was used. The solution was stored in a dark amber-colored bottle similar to the bottle used to store the hydrogen sulfide test solution. An equal volume of this solution, previously heated on a water bath to approximately 80° for a minimum of 5 minutes (in order to hasten the hydrolysis of the thioacetamide) was

used along with the hydrogen sulfide solution in all the tests for comparative purposes.

In the tests for identification, the procedure of the U.S.P. was followed with both solutions. In testing for heavy metals, contamination was accomplished by addition of 0.001 mg. lead in the form of a water-soluble salt dissolved in 1 ml. distilled water. This amount of lead is the minimum amount that gives a color with hydrogen sulfide test solution and was the standard of comparison for the thioacetamide solution.

Where applicable, official tests for identification were conducted as directed in the U.S.P. with the two solutions, and no difference in color or appearance could be detected. See Table I.

TABLE I.—CHEMICALS WHICH YIELDED EQUALLY POSITIVE IDENTIFICATION TESTS WITH HYDROGEN SULFIDE AND THIOACETAMIDE TEST SOLUTIONS

Antimony potassium tartrate	Mercuric chloride
Antimony sodium thioglycolate	Yellow mercuric oxide
Bismuth potassium tartrate	Mersalyl
Bismuth subcarbonate	Zinc peroxide
Bismuth subsalicylate	Zinc stearate
Carbarsone	Zinc sulfate

Tests for heavy metals impurities were conducted as directed with the two solutions, after contaminating them with lead as directed above. Differences were noted with acetylsalicylic acid, methenamine, and salicylic acid. Solutions of these chemicals required a slight amount of heat in addition to the heat supplied by the reagent. After warming slightly on a water bath, instead of a black precipitate, a brown precipitate was observed. No differences in color or appearance could be detected when the two solutions were used in testing the chemicals contaminated with heavy metals. See Table II.

TABLE II.—CHEMICALS CONTAMINATED WITH HEAVY METALS WHICH YIELDED EQUALLY POSITIVE TESTS WITH HYDROGEN SULFIDE AND THIOACETAMIDE TEST SOLUTIONS

Aluminum sulfate	Magnesium oxide, heavy
Ammonium carbonate	Magnesium sulfate
Ammonium chloride	Magnesium trisilicate
Barium sulfate	Potassium bicarbonate
Boric acid	Potassium bromide
Calcium carbonate	Potassium chloride
Calcium chloride	Potassium hydroxide
Calcium gluconate	Potassium iodide
Calcium hydroxide	Potassium nitrate
Calcium lactate	Sodium bicarbonate
Calcium mandelate	Sodium biphosphate
Dibasic calcium phosphate	Sodium bisulfate
Ferrous sulfate	Sodium borate
Diluted hydriodic acid	Sodium bromide
Hydrochloric acid	Sodium chloride
Diluted hydrochloric acid	Sodium citrate
Hydrogen peroxide solution	Sodium iodide
	Sodium phosphate
Magnesium carbonate	Sodium salicylate
Magnesium oxide	Sodium sulfate

Likewise, U.S.P. organic chemicals examined for heavy metals were contaminated with a lead solution as previously described and tested with the two solutions as directed. No difference in color or appearance could be detected. See Table III.

TABLE III.—ORGANIC CHEMICALS CONTAMINATED WITH HEAVY METALS WHICH YIELDED EQUALLY POSITIVE TESTS WITH HYDROGEN SULFIDE AND THIOACETAMIDE TEST SOLUTIONS

Amylene hydrate	*p*-Aminobenzoic acid
Barbital sodium	Pentobarbital sodium
Carbachol	Phenobarbital sodium
Citric acid	Phenolphthalein
Dextrose	Propylene glycol
Ethyl aminobenzoate	Saccharin
Gelatin	Sodium saccharin
Glucose	Sucrose
Glycerin	Tartaric acid
Iodoalphionic acid	Theobromine calcium salicylate
Lactic acid	
Lactose	Thiopental sodium
Methyl salicylate	Urea
Nicotinamide	Urethane
Nicotinic acid	

In addition, the official pharmaceuticals and their preparations were contaminated with lead solution and tested for heavy metals by the two solutions as previously described. No difference in color or appearance could be detected. Pharmaceuticals and preparations tested are given in Table IV.

TABLE IV.—PHARMACEUTICALS CONTAMINATED WITH HEAVY METALS WHICH YIELDED EQUALLY POSITIVE TESTS WITH HYDROGEN SULFIDE AND THIOACETAMIDE TEST SOLUTIONS

Aluminum acetate solution	Ammoniated mercury ointment
Aluminum hydroxide gel	Orange flower water
Aluminum phosphate gel	Orange oil
Diluted ammonia solution	Ringer's solution
Caffeine and sodium benzoate	Lactated Ringer's solution
Cinnamon oil	Stronger rose water
Clove oil	Sassafras oil
Dextrose injection	Isotonic sodium chloride solution
Milk of magnesia	Distilled water
Zinc peroxide	

DISCUSSION OF RESULTS

Identification tests for heavy metals showed that thioacetamide test solution and hydrogen sulfide test solution, with few exceptions, gave identical results. Difficulty was encountered in testing water-insoluble organic salts for heavy metals because the volatile flammable solvents used had to be heated. In this case, the length of time of standing on a hot water bath could be increased in order to insure the complete hydrolysis of thioacetamide.

Plans are made to compare thioacetamide with hydrogen sulfide in the identification and detection of heavy metals in chemicals and pharmaceuticals

of the National Formulary. Comparative quantitative analyses with thioacetamide and hydrogen sulfide are also planned for chemicals of both the United States Pharmacopeia and the National Formulary where hydrogen sulfide is directed as the quantitative precipitating reagent.

Kinetics of Reaction between Molecular Oxygen and 2,3-Dimercapto-1-propanol in Aqueous Solution

By EDWARD G. RIPPIE† and TAKERU HIGUCHI

Autoxidation of BAL is shown to take place in the absence of metallic catalysts. Although the iodometric sulfhydryl concentration in this system was found to decrease linearly with time, the reaction was found to approach true zero order only at higher initial BAL concentration. The observed rate of oxidation was found to decrease with increased hydrogen ion concentration and to be of a mixed order with respect to oxygen tension.

BARRON, *et al.* (1), have suggested that the observed reaction in aqueous solution between 2,3-dimercapto-1-propanol, BAL, and molecular oxygen in absence of added catalyst could be entirely attributed to trace quantities of catalytic copper. In this communication, experimental evidence which supports the existence of the uncatalyzed reaction and kinetic dependencies of this oxidative reaction on pH, oxygen tension, and initial substrate concentration are presented.

EXPERIMENTAL

Reagents and apparatus employed in the work were the same as those reported in previous work on the copper catalyzed oxidation of BAL (2). The procedure used was also essentially the same except that potassium cyanide was added to all reaction solutions at a concentration of $1 \times 10^{-3} M$. While catalase is known to be inhibited by cyanide (3), sufficient catalase was found to remain to destroy satisfactorily any peroxide which may have been formed. The reacting systems were sufficiently stirred (2) so that the solutions were always kept in equilibrium with the gas phase.

RESULTS AND DISCUSSION

Evidence for Uncatalyzed Reaction.—There appears to be ample evidence which points to reaction in the absence of copper between molecular oxygen and BAL in aqueous solution. As has already been shown (2), significant copper concentration, *ca.* $2 \times 10^{-6} M$, is apparently necessary to account for the observed rate. If such high concentrations of the metal were introduced by chance contamination, it would be expected that variation in sources of buffer salts, water, and substrate would produce significant changes in the observed rates of oxidation. This was not the case. Quite reproducible rates were observed for different lots of buffer salts, BAL, and water.

Further evidence supporting the existence of uncatalyzed reaction is presented in Fig. 1. These plots show the residual sulfhydryl concentration of aqueous solutions of BAL as a function of time when exposed to oxygen at 1 atm. The uppermost curve shows the kinetic dependency for a system free of copper and cyanide as far as was possible experimentally. The second line shows essentially the same system but with $1 \times 10^{-3} M$ potassium cyanide added. It is evident that these two functions are quite similar, both qualitatively and quantitatively. The third and fourth curves show the effects of addition of copper, 2×10^{-6} and $5 \times 10^{-6} M$, respectively, on the initial system. The kinetic behavior of these last two runs is obviously quite different from those of the preceding two. Although the data are not shown, addition of $1 \times 10^{-3} M$ cyanide to the latter two systems yielded rate curves identical with the first two.

of the National Formulary. Comparative quantitative analyses with thioacetamide and hydrogen sulfide are also planned for chemicals of both the United States Pharmacopeia and the National Formulary where hydrogen sulfide is directed as the quantitative precipitating reagent.

RESULTS AND DISCUSSION

Evidence for Uncatalyzed Reaction.—There appears to be ample evidence which points to reaction in the absence of copper between molecular oxygen and BAL in aqueous solution. As has already been shown (2), significant copper concentration, *ca.* $2 \times 10^{-6} M$, is apparently necessary to account for the observed rate. If such high concentrations of the metal were introduced by chance contamination, it would be expected that variation in sources of buffer salts, water, and substrate would produce significant changes in the observed rates of oxidation. This was not the case. Quite reproducible rates were observed for different lots of buffer salts, BAL, and water.

Further evidence supporting the existence of uncatalyzed reaction is presented in Fig. 1. These plots show the residual sulfhydryl concentration of aqueous solutions of BAL as a function of time when exposed to oxygen at 1 atm. The uppermost curve shows the kinetic dependency for a system free of copper and cyanide as far as was possible experimentally. The second line shows essentially the same system but with $1 \times 10^{-3} M$ potassium cyanide added. It is evident that these two functions are quite similar, both qualitatively and quantitatively. The third and fourth curves show the effects of addition of copper, 2×10^{-6} and $5 \times 10^{-6} M$, respectively, on the initial system. The kinetic behavior of these last two runs is obviously quite different from those of the preceding two. Although the data are not shown, addition of $1 \times 10^{-3} M$ cyanide to the latter two systems yielded rate curves identical with the first two.

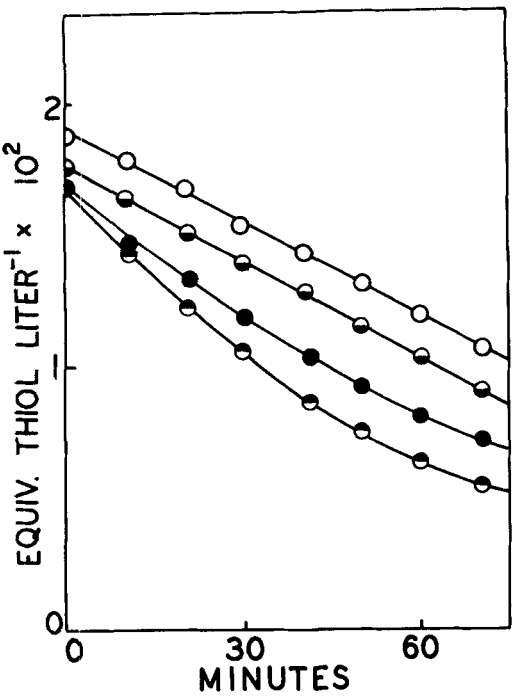

Fig. 1.—Plots contrasting BAL dependency of the oxidation with and without copper. ○, essentially copper free; ◒, previous system plus 0.001 *M* cyanide; ●, initial system plus 2 × 10^{-6} *M* copper; ◓, initial system plus 5 × 10^{-6} *M* copper; temp., 20°; pH, 6.66; 0.25 *M* phosphate buffer.

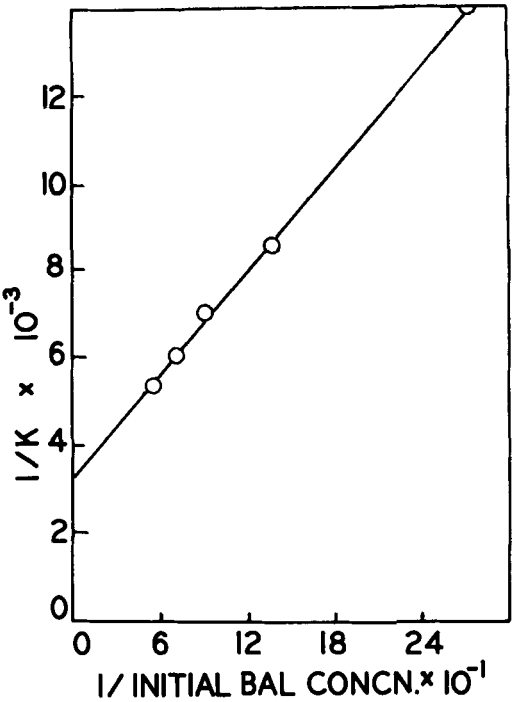

Fig. 2.—Reciprocal zero-order rate constants plotted against the reciprocal initial BAL concentration. The extrapolated value of the limiting rate is 3.06 × 10^{-4} equiv. per L. per min.; temp., 20°; pH, 6.66; 0.25 *M* phosphate buffer; 1 atm. oxygen.

These facts strongly suggest that BAL can undergo oxidation by molecular oxygen in the absence of copper or any other metallic catalyst. Any catalytic contribution from trace copper appears to be removed effectively by addition of cyanide. Although the part played by the uncatalyzed reaction would be relatively small in the presence of certain metallic ions, it would appear that for simple aqueous systems this would be the important kinetic route of oxidation of the sulfhydryl compound.

Order of the Reaction with Respect to BAL.—The behavior of BAL concentration with respect to time as shown in the upper two plots of Fig. 1 is typical of the uncatalyzed reaction. Essentially straight-line decrease is experienced although the absence of a short initial lag time could not be unequivocally established since readings were difficult to obtain during the first few minutes. Determinations of apparent zero-order rate constants were made over a temperature range of 0 to 24.5° at pH values from 6.50 to 7.14. Individual runs were made with initial molar BAL concentrations of 0.0037, 0.0074, 0.0111, 0.0148, and 0.0185. The apparent zero-order disappearance which was observed through approximately 75 per cent of the reaction suggests a rather complex dependency on the dithiol.

Although individual runs followed apparent zero-order kinetics, marked differences in the rates were found when varying initial concentrations were employed. When the reciprocals of these apparent zero-order rate constants were plotted against the reciprocals of the initial BAL concentrations, a

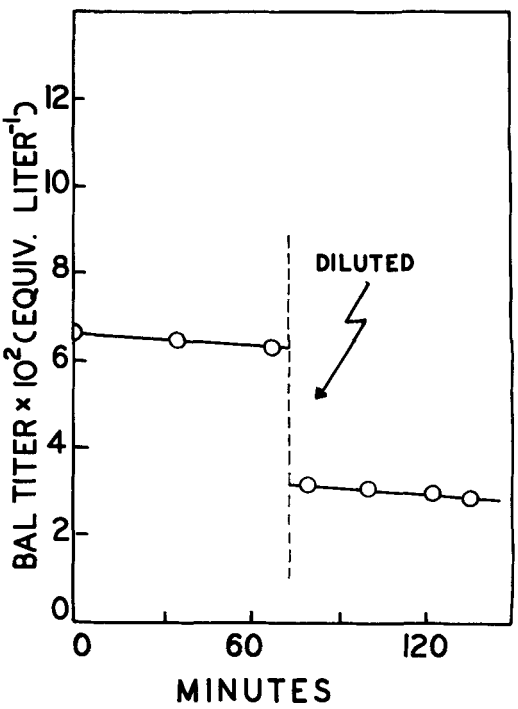

Fig. 3.—Plot of BAL concentration against time showing the effect of dilution of the reaction mixture at a time indicated by the dotted line. Temperature, 0°; 2 atm. oxygen; pH, 6.66; 0.25 *M* phosphate buffer.

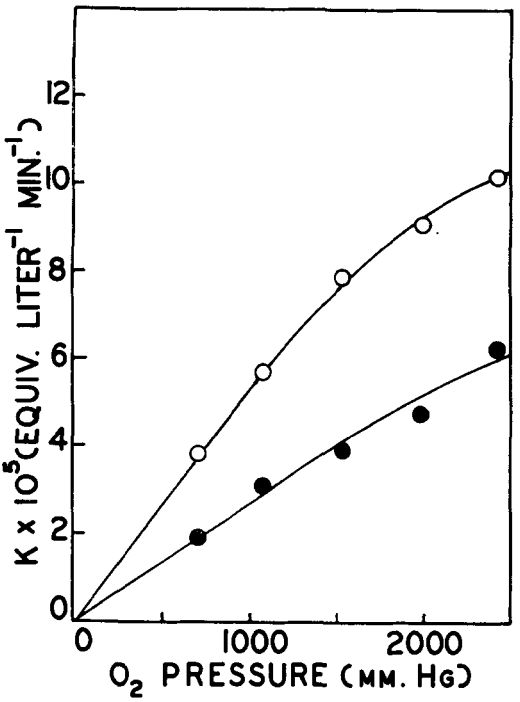

Fig. 4.—Plots of zero-order rate constants of BAL oxidation against oxygen pressure. Initial BAL concentrations: ○, 0.0370; ●, 0.0185; temp., 0°; pH, 6.66; 0.25 *M* phosphate buffer.

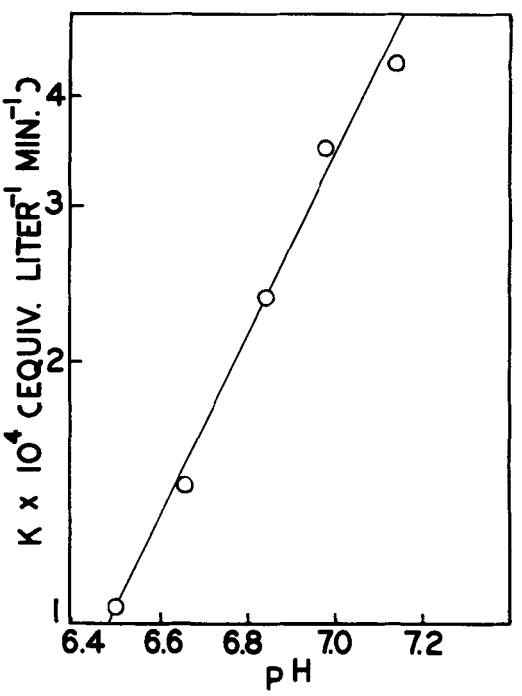

Fig. 6.—Semilog plot of zero-order rate constant against pH determined at 20°. Slope of the line is 1.0; 1 atm. oxygen; 0.25 *M* phosphate buffer.

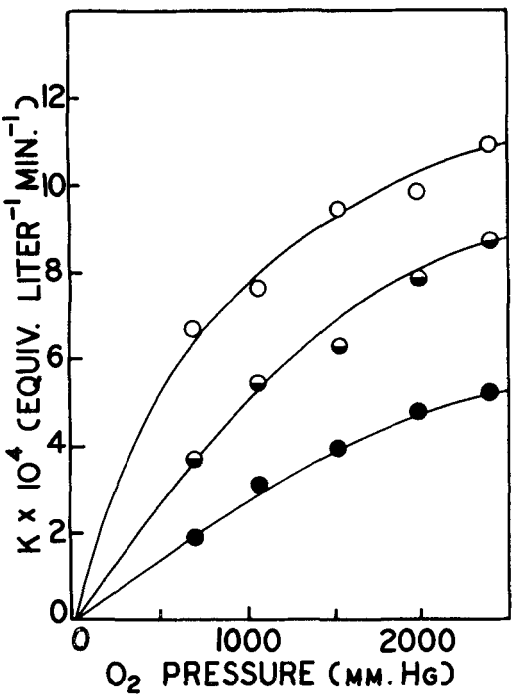

Fig. 5.—Plots of zero-order rate constants of BAL oxidation against oxygen pressure. Initial BAL concentrations; ○, 0.0370; ◒, 0.0185; ●, 0.0093; temp., 24.5°; pH, 6.66; 0.25 *M* phosphate buffer.

straight line plot was obtained, as shown in Fig. 2. The intersection of this line with the vertical axis above the origin appears to indicate a finite limiting rate of 3.06×10^{-4} equiv. per L. per min. at theoretically infinite BAL concentration.

Runs were made in which the reaction was allowed to proceed for several minutes, after which the reaction mixture was diluted with an equal volume of solvent solution. A typical run plotted in Fig. 3 shows a change in oxidation rate upon dilution. The rate of oxidation after dilution corresponds to the expected rate, had the reaction been started at half the initial BAL concentration. These observations serve to show that the reaction is truly zero order with respect to BAL only at very high concentrations. Apparent zero-order kinetic behavior at lower concentrations suggests that a rather complex situation exists.

Oxygen Dependency.—Determination of oxygen dependency was carried out at a pH of 6.66, showing oxidation rate as a function of oxygen tension at 0 and 24.5°. Oxygen pressures ranged from 1 to 3 atm. and rate constants are given for initial BAL concentrations of from 0.0093 to 0.0370 *M*. The results of these determinations are plotted in Figs. 4 and 5. Although the oxidation rate appears to be first order with respect to oxygen tension at low oxygen pressures, the dependency at higher oxygen pressures appears to decrease. The rate, however, does not appear to approach a finite limiting value at high oxygen pressures.

***Effect of* Hydrogen Ion Concentration.**—The effect of pH on the rate of BAL autoxidation was determined between pH 6.4 and 7.2 at an initial BAL concentration of 0.0111 *M*. In Fig. 6 the logarithm of the rate in equivalents per L. per min.

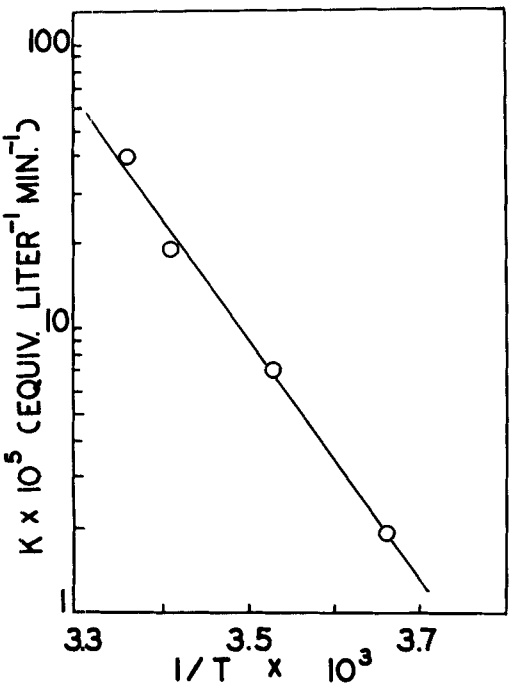

Fig. 7.—Arrhenius plot of zero-order rate constants against reciprocal absolute temperature. Determinations made at pH 6.66 and a pressure of 1 atm. oxygen; 0.25 *M* phosphate buffer.

has been plotted against the pH of solutions buffered by 0.25 *M* potassium phosphate. The isotherm has a positive slope of 1.0, showing more rapid oxidation at the higher pH.

Temperature Dependence.—A semilog plot of apparent zero-order rate constants determined at 0, 10, 20, and 24.5° *vs.* reciprocal absolute temperature is shown in Fig. 7. The heat of activation, ΔHa, as calculated from the slope, was 20.1 Kcal. per mole. Since the effect of temperature on oxygen solubility or on the degree of ionization of BAL was not taken into account, the heat of activation given is the apparent heat of activation. This can be corrected by subtracting the heat of solution of oxygen in water (−3.6 Kcal. per mole) to give a corrected ΔHa of 23.7 Kcal. per mole. The heat of ionization of BAL, however, was not known and no correction has been made for its presumably small effect. The ΔHa found here was considerably larger than that found for the copper catalyzed oxidation (16.2 Kcal. per mole).

Consideration of the Overall Reaction.—It is evident from the dependency on BAL and oxygen that the reaction mechanism encountered here is probably quite complex. It was suggested by Harrison (4) that the disulfide linkage is essential in the autoxidation of sulfhydryl compounds. Highly reactive cyclic disulfide may possibly play an important role in BAL oxidation, acting as a source of the radical. The 23.7 Kcal. per mole activation energy found for the overall process is of the magnitude which might be expected for the homolytic cleavage of the disulfide bond (5) of the oxidized BAL monomer. The possibility of heterogeneous catalysis by the glass wall of the reaction vessel was investigated and ruled out.

The overall mechanism which fits the observed facts can be formulated in any number of ways. The apparent linear decrease of sulfhydryl concentration with time may be rationalized, for example, on the basis that a significant buildup of reactive cyclic disulfide may occur. Another rationalization may be based on the assumption that two BAL molecules linked by a disulfide bond may undergo autoxidation more readily than BAL itself. The obvious zero-order character of the reaction with respect to BAL at high BAL concentration appears to suggest, on the other hand, that the dithiol itself may act as an efficient chain stopper at higher concentrations. Such information as is presently available appears to be insufficient to resolve the question.

The following series of reactions may possibly play a part in the oxidative breakdown of BAL in the absence of copper

$$B(SH)S^- + BS_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} B(SH)S\cdot +$$

$$BS_2^{-}\cdot \overset{H^+}{\rightleftharpoons} 2\ B(SH)S\cdot$$

$$B(SH)S\cdot + O_2 \xrightarrow{k_2} BS_2 + HO_2\cdot$$

$$HO_2\cdot + B(SH)S^- \xrightarrow{k_3} HO_2^- + B(SH)S\cdot$$

$$BS_2 \xrightarrow{k_4} (BS_2)_x \text{ polymer}$$

It offers an explanation of the dilution effect noted previously and the fact that the rate depends upon the initial BAL concentration. Other reactions no doubt take place (6) since this series of equations does not predict mixed-order kinetics with respect to oxygen at higher pressures. It should be emphasized that the chemical reactions suggested here are presented as those which may occur. Because of the apparent complexity of the findings, the overall process in reality may consist of many interacting pathways.

Barbiturate Glucosides

By GLENN A. PORTMANN† and LOYD E. HARRIS

Nitrogen barbiturate glucosides of barbital, phenobarbital, amobarbital, secobarbital, and pentothal were prepared from acetobromoglucose and the potassium barbiturate. Proof of the nitrogen glucosidic linkages was obtained by direct condensation of sym-di-(tetra-O-acetyl-β-D-glucopyranosyl)urea with diethylmalonyldichloride. The lack of hypnotic activity of the barbiturate glucosides was demonstrated with intraperitoneal injections of 6 to 25 times the hypnotic dose of the corresponding barbiturate salt.

IT IS WELL KNOWN that many glycosides have very pronounced and widely varied pharmacological effects. The type of pharmacological response always depends on the specific structure of the aglycone but the sugar moiety contributes important absorption and distribution characteristics. However, a survey of the literature pertaining to glucosides of pharmacologically active compounds showed no consistent change in the varied responses of the compounds studied.

Many investigators have studied the effect of glucose and its metabolic products on barbiturate anesthesia. Lamson and his co-workers (1) were the first to publish their observations made when glucose was injected into dogs which recovered from pentobarbital anesthesia. They found that the dogs returned to anesthesia and remained in this state for an average time of 1 hour. Upon subsequent injections of glucose, the duration of anesthesia decreased until eventually further anesthesia could not be produced. Some other substances which will also cause this return to barbiturate anesthesia are products of glycolysis and the Krebs cycle, vitamins, malonic acid, glycerin, and epinephrine (2–5). Bester and Nelson (6) found that normal blood glucose levels did not affect pentobarbital anesthesia and proposed a competitive inhibition mechanism to explain the significant increase in sleeping time when glucose was injected with pentobarbital. Further evidence supporting an oxidative inhibitory mechanism is animal protective studies with cytochrome C injected with pentothal (7) and the need for greater quantities of pentothal to produce anesthesia in insulin-treated animals (8).

The present study was undertaken in order to determine whether glucose would have a potentiating effect if chemically combined with barbiturates. Furthermore, stable water-soluble barbiturate glucosides would be advantageous for liquid pharmaceutical dosage forms.

Only three barbiturate glycosides are reported in the literature. The mono-glucoside of barbital was prepared by reacting diethylmalonyldichloride with tetra-O-acetylglucose-urea (9). Bodendorf (10) prepared 5,5-diethyl-1,3-di-(tetra-O-acetyl-β-D-glucopyranosyl)barbituric acid from tetra-O-acetyl-α-D-glucopyranosylbromide and potassium barbital with subsequent deacetylation by sodium methoxide. Only one enolic barbiturate glucoside has been prepared utilizing the enolizing influence of silver oxide. Snyder and Link (11) prepared 5,5-diethyl-4-(tetra-O-acetyl-β-D-glucopyranosyloxy)-2,6-pyrimidinedione in 2.6% yield from 5,5-diethylbarbituric acid and tetra-O-acetyl-α-D-glucopyranosylbromide in the presence of silver oxide and a catalytic amount of quinoline.

EXPERIMENTAL[1]

Tetra-O-acetyl-α-D-glucopyranosylbromide.—Tetra-O-acetyl-α-D-glucopyranosylbromide, commonly known as acetobromoglucose, was prepared by a combination of two known methods (12, 13). Two hundred grams of β-D-glucose pentaacetate prepared by a standard procedure (14) was mixed with 350 ml. of 30% hydrogen bromide in glacial acetic acid and kept at room temperature for 4 hours. Hydrogen bromide was removed under reduced pressure at 40–50°, passing dry nitrogen through the capillary. Excess acetic acid was distilled at the bath temperature of 55–60° and 15 mm. Hg. The dark brown residue was crystallized twice from dry ether giving white needles; yield 127 Gm. (60%), m.p. 89–90°.

Glucosides of Barbital, Phenobarbital, Amobarbital, and Secobarbital.—These four nitrogen glucosides were prepared by following general procedure. Fifteen milliliters of 2 *N* potassium hydroxide was added to 50 ml. of an acetone solution containing acetobromoglucose (0.030 mole) and the barbiturate (0.015 mole). After 4 days reaction time, the absence of acetobromoglucose was shown by a negative silver nitrate test. The acetone was then evaporated and the resulting syrup was dissolved in 50

[1] Melting points were taken with a Fisher-Johns melting point apparatus and are uncorrected. Analyses were performed by Galbraith Microanalytical Laboratories, Knoxville, Tenn.

ml. benzene and extracted with three 50-ml. portions of 20% sodium hydroxide, followed by water extraction until all the base was removed. After drying the benzene solution over anhydrous sodium sulfate, the solvent was evaporated giving hard, white, glassy products. Yields and physical constants are listed in Table I. Only the acetylated glucoside of barbital was crystallizable. Two crystallizations from absolute ethanol gave 1.8 Gm. (14%) of fine needles. None of the four acetylated nitrogen glucosides reduced hot Benedict's reagent.

Elemental analyses shown in Table I indicate that a di-glucoside was formed in every case except with amobarbital. Infrared spectra support this by the presence of imino group absorption at 3.1 μ with the acetylated amobarbital glucoside and the absence of this absorption in the spectra of phenobarbital, secobarbital, and barbital acetyl glucosides.

Deacetylations were done by partially dissolving the acetylated glucoside (0.002 mole) in 100 ml. of absolute ethanol, adding 6 ml. of sodium methoxide solution (1 mg. sodium per ml. of methanol) and distilling the methylacetate and alcohols. After decolorizing with charcoal, white hard amorphous compounds were obtained which were very water soluble but were not crystallizable. After acid hydrolysis, they reduced hot Benedict's reagent. Deacetylation of the crystalline barbital glucoside was also accomplished with ammonia in absolute methanol. The acetylated compound (0.0015 mole) was partially dissolved in 60 ml. of absolute methanol and saturated with dry ammonia gas at 5°. After 1 day, the ammonia and methanol were evaporated and the acetamide was removed from the white residue with 10 ml. of chloroform. The yield was 0.50 Gm. (0.0010 mole) of a white, brittle, amorphous solid.

Anal.—Calcd. for $C_{20}H_{32}N_2O_{13}$: N, 5.51. Found: N, 5.12.

5-Ethyl-5-(1-methylbutyl)-1,3-di-β-D-glucopyranosyl-2-thiobarbituric Acid.—Acetobromoglucose (8.2 Gm., 0.02 mole) was added to 60 ml. of a dry acetone solution containing 6.0 Gm. (0.02 mole) of sodium pentothal. After 1 day at room temperature, the sodium bromide was filtered out and the acetone evaporated. The resulting yellow syrup was dissolved in 30 ml. of benzene and extracted with three 10-ml. portions of 2% sodium hydroxide solution, followed by extraction with water until the base was removed. After drying over anhydrous sodium sulfate, the benzene was evaporated, giving 7.8 Gm. (87%) of a hard yellow amorphous powder. Analytical data shown in Table I and the absence of imino group absorption at 3.1μ in the infrared spectrum indicate the formation of a di-glucoside. Deacetylation was accomplished by the standard sodium methoxide method resulting in a yellow amorphous solid which was very water soluble but noncrystallizable.

SYNTHETIC PROOF OF NITROGEN GLUCOSIDE BOND

It is obvious that the glucoside bonds could be either through the nitrogen or enolic oxygen atoms of the barbiturate. Therefore, the acetylated di-nitrogen glucoside of barbital was synthesized in an unambiguous manner. The physical properties of this compound are identical to those of the glucoside synthesized from acetobromoglucose and barbital, indicating that a di-nitrogen glucoside was actually formed. The synthetic approach which was chosen involves the following steps: (*a*) synthesis of sym-di-(tetra-O-acetyl-β-D-glucopyranosyl)-urea, and (*b*) condensation of the acetylated di-glucose-urea derivative with diethylmalonyldichloride.

(*a*) **Sym-di-(tetra-O-acetyl-β-D-glucopyranosyl)-urea.**—A mixture of urea (0.60 Gm., 0.01 mole), powdered Drierite (10 Gm.), silver oxide (2.32 Gm., 0.01 mole), and acetobromoglucose (8.22 Gm., 0.02 mole) in 10 ml. of dimethylsulfoxide (DMS) was

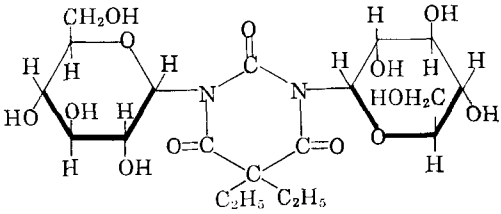
TABLE II.—PHARMACOLOGICAL RESULTS

Barbiturate	Anesthetic Dose of Sodium Barbiturate,[a] mg.	Type of Glucoside	Dose of Barbiturate Glucoside,[a] mg.	Results
Barbital	200	Di-nitrogen	1500	Inactive
Barbital	200	Mono-enolic tetraacetate[a]	1200	Inactive
Phenobarbital	100	Di-nitrogen	1000	Inactive
Secobarbital	40	Di-nitrogen	1000	Inactive, painful
Amobarbital	200	Mono-nitrogen	2000	Inactive
Thiopental	40	Di-nitrogen	500	Inactive



[a] All were intraperitoneal injections of aqueous solutions except the mono-enolic glucoside tetraacetate of barbital which was in the form of a 1% acacia aqueous suspension. The doses are in mg. of compound per Kg. of rat.

stirred for 12 hours (reaction of all acetobromoglucose was indicated by negative test with silver nitrate T.S.). After filtering and washing with dry ether, the DMS was distilled (58°, 5 mm.) resulting in an opaque syrup. It was not possible to crystallize the syrup which was used in the following reaction with diethylmalonyldichloride.

(*b*) **Condensation of Sym-di-(tetra-O-acetyl-β-D-glucopyranosyl)-urea with Diethylmalonyldichloride.**—Diethyldiethylmalonate was prepared from 0.5 mole of diethylmalonate according to the procedure of Vogel (15), but was not isolated. The alcoholic filtrate containing diethyldiethylmalonate was then saponified with 2.5 moles of sodium hydroxide and the alcohol distilled. After extraction with ether and crystallization from chloroform, the yield of diethylmalonic acid was 15.1 Gm. (19%), m.p. 124–125°.

Diethylmalonyldichloride was prepared from 8.0 Gm. of diethylmalonic acid and 20.8 Gm. of phosphorus pentachloride according to standard procedure. The acid chloride was distilled at 85–89° (14 mm.); yield 9.1 Gm. (92%), b.p. 199°.

Diethylmalonyldichloride, 1.37 Gm. (0.007 mole) was added to 50 ml. of an ether solution containing 3.5 Gm. of the syrup obtained in (*a*) and 1.2 Gm. (0.015 mole) of pyridine. After 20 hours reaction time at room temperature, the mixture was filtered and residue washed with dry ether. The ether filtrate was then extracted with two 50-ml. portions of 5% sodium carbonate solution and two 50-ml. portions of water. After drying the ether solution with anhydrous sodium sulfate, the solvent was removed *in vacuo*. Crystallization occurred very slowly after 2 days from alcohol-water, after seeding with the acetylated barbital diglucoside which was obtained by the Bodendorf procedure. The crystals were filtered after 10 days and washed with 10 ml. water. After recrystallization from absolute methanol, the yield of fine needles was 480 mg.; m.p. 174–175°. A mixed melting point with the acetylated barbital diglucoside obtained by direct condensation of acetobromoglucose and barbital showed no depression. This unambiguous synthesis indicated that the structure of the barbital di-nitrogen glucoside is that shown below

PHARMACOLOGICAL TESTING

A comparison was made between the barbiturate glucosides and the corresponding sodium barbiturate salts for hypnotic activity in albino rats. The lack of hypnotic activity of the barbiturate glucosides was demonstrated with intraperitoneal injections of 6 to 25 times the hypnotic dose of the corresponding barbiturate salt. Both the enolic tetraacetate and nitrogen-type glucosides were inactive. The results are summarized in Table II.

Comparative Activities and Toxicities IV

Dinitro- and Dichloronitro- Phenylamino Acids and Esters

By WILLIAM O. FOYE and DAVID B. MORTENSON

N-2,4-Dinitrophenyl- and N-4,5-dichloro-2-nitrophenyl-α-amino acids and esters have been synthesized in an attempt to remove the toxic effects of the nitro and dichloronitro benzene nucleus to the host without removing antimicrobial activity. The esters were more effective than the free amino acids in reducing acute toxicity to mice. Some antibacterial and antifungal activity was retained in these derivatives, particularly the N-4,5-dichloro-2-nitrophenyl α-amino acids.

BELLENGHI and Wittgens (1) have reviewed the antimycotic and antibacterial effects of nitrovinyl derivatives in the benzene, thiophene, and furan series and shown that the presence of the nitro group in these compounds generally enhanced these activities. Other nitro-containing furans (2), quinolines (3), and phenols (4–6) have been tested for antibacterial action, and the introduction of the nitro group has generally enhanced the effectiveness of the compounds against bacteria. Serious toxic effects may be observed from the use of nitro-containing compounds, however, such as Tien, *et al.* (7), found in a series of N-arylglycines that showed good antitubercular activity *in vitro*.

Previously, in this laboratory, successful use was made of D-glucamine as a detoxifying agent for nitro-containing and halogenated benzene derivatives (8), but with the exception of the 2-nitro-4,5-dichlorophenyl residue, antibacterial activity was also removed by introduction of the glucamine moiety. Introduction of the glycine and glycine ethyl ester residues into the nitro benzenes did not cause such a striking detoxication effect, but neither was the antibacterial spectrum diminished so drastically. Since then, a series of N-2,4-dinitrophenyl and N-2-nitro-4,5-dichlorophenyl derivatives of several representative α-amino acids and their ethyl esters have been prepared, and we now can report the effects these amino acids and esters have on the toxicities and antibacterial spectra of the dinitro and dichloronitro benzene residues. The physical properties of the compounds prepared are listed in Table I.

Received October 20, 1961, from the Department of Chemistry, Massachusetts College of Pharmacy, Boston.

Accepted for publication November 29, 1961.

Abstracted from a thesis submitted by D. B. Mortenson in partial fulfillment of the requirements for the degree of Master of Science, 1959.

This project was supported in part by a grant (A-1914) awarded by the National Institute of Arthritis and Metabolic Diseases of the National Institutes of Health.

The authors acknowledge with appreciation the cooperation of Drs. K. K. Chen and E. Rohrmann, and W. S. Boniece, M. Clarkson, D. Fleming, and C. L. Rose in carrying out the toxicity and antimicrobial tests and making the results available for publication.

The relative detoxifying effects of the various amino acids and esters may be seen in Table II, where the acute i.p. toxicities in mice are recorded. With the exception of the serine derivative, the N-2,4-dinitrophenyl amino acids were found to be lethal to mice within the dose range of 400–800 mg./Kg. A greater range of toxicities, and generally greater toxicity, was found with the N-4,5-dichloro-2-nitrophenyl amino acids, the glycine and serine derivatives conferring the largest detoxifying effects. The amino acid esters showed a more dramatic detoxifying effect, on the 2-nitro-4,5-dichlorophenyl residue, the lethal doses to mice exceeding 800 mg./Kg. The leucine ester was not obtained in crystalline form for comparison.

Antibacterial screening of the compounds prepared (with the exception of the glycine ester derivative) was carried out by using a small quantity of the dry, powdered material placed on an agar plate. These tests (Table III) showed that in approximately two-thirds of the cases (10 organisms were used) growth inhibition resulted, although the success of this method is dependent upon the ability of the compounds to diffuse through agar. Lack of solubility of the compounds in suitable solvents prevented the use of more customary procedures.

Antimicrobial testing against a larger number of bacteria and several fungal plant pathogens was carried out at the Lilly Research Laboratories with some of the compounds, using the agar dilution technique (see Table IV). N-(2,4-Dinitrophenyl)-methionine, N-(2,4-dinitrophenyl)-leucine, and N-(2,4-dinitrophenyl)-phenylalanine showed no growth inhibition of the organisms tested below a concentration of 200 mcg./ml., but the results obtained with the other compounds tested are shown in Table IV. The 2,4-dinitrophenyl amino acids, the most consistent inhibitors on the agar plate, were found to be without antibacterial activity at the dilutions employed. The 4,5-dichloro-2-nitrophenyl

		800	5/5	Died, 3–4 hr.
14	N-(4,5-Dichloro-2-nitrophenyl)-DL-serine ethyl ester	400	0/5	
		800	0/5	None

[a] Determined at the Lilly Research Laboratories by C. L. Rose. [b] Observations were made for 1 week after single injections of compound.

amino acids in general showed some antibacterial activity, although none approached the breadth of spectrum previously found for N-(4,5-dichloro-2-nitrophenyl)-D-glucamine (8). Only two of the esters were tested, the glycine and phenylalanine derivatives. The former showed no activity while the latter showed some activity, particularly against the fungal plant pathogens. N-(2,4-Dinitrophenyl)-glycine was also tested in mice against two types of virus, *Streptococcus pyogenes*, *Proteus vulgaris*, and typhoid organisms, but was found ineffective.

TABLE III.—ANTIBACTERIAL SCREENING[a]

Test Organism	Compound Number 1	2	4	5	6	7	8	9	10	11	12	13	14
Staphylococcus aureus	−	−	−	−	+	−	−	−	−	+	−	−	+

[a] Carried out at the Lilly Research Laboratories by M. Clarkson and D. Fleming. [b] The agar dilution technique was used, the bacteria being observed for 48 hours and the fungal plant pathogens for 72 hours. [c] Test organism did not grow sufficiently well to establish an end point; where no inhibitory concentration is reported, the organism was not inhibited by 200 mcg./ml. of compound.

It may be concluded from these comparisons that the introduction of the α-amino acid residue into the *m*-dinitrobenzene molecule shows a small but definite detoxifying effect (*m*-dinitrobenzene killed four of five mice used at 400 mg./Kg., and 2,4-dinitroaniline killed all of five mice at 400 mg./Kg.). The amino acid esters, however, showed a greater ability to detoxify, when attached to the 4,5-dichloro-2-nitrophenyl nucleus. Again, as in our previous study (8), loss of toxicity to mice generally paralleled loss of toxicity to microorganisms, although use of the amino acid ester derivatives holds some promise that a selective detoxifying effect without corresponding loss of antimicrobial ability may be achieved.

EXPERIMENTAL

The melting points were taken on a Fisher-Johns block and are uncorrected. Analyses were done either by Weiler and Strauss, Oxford, England, or by Carol K. Fitz, Needham, Mass.

N-2,4-Dinitrophenylamino Acids.—These compounds were prepared either by the method of Abderhalden and Blumberg (9) or Sanger (10). A representative synthesis follows. DL-Phenylalanine (2.0 Gm., 0.012 mole) and sodium bicarbonate (4.0 Gm., 0.048 mole) were dissolved in 50 ml. of water, and 2.5 ml. (0.220 mole) of 2,4-dinitrofluorobenzene in 100 ml. of ethanol was added. The mixture was shaken at room temperature for 2 hours, and the ethanol was then removed by evaporation. The resulting mass was dissolved in water, shaken three times with ether, and the aqueous solution was acidified. The yellow precipitate was collected, washed with ice water, and dissolved in acetone. The acetone solution was shaken with anhydrous sodium sulfate, filtered, and evaporated to a small volume. An equal volume of benzene was added, followed by petroleum ether until the product precipitated. The compound was dried in air, dissolved in ether, and reprecipitated with petroleum ether. This precipitation procedure was repeated several times until well-formed crystals were obtained. The yield was 0.78 Gm. (19%) of yellow crystalline compound, m.p. 217.5–219° [lit. (10) m.p. 204–206°].

N-4,5-Dichloro-2-nitrophenylamino Acids.—A typical procedure follows. Glycine (0.75 Gm., 0.01 mole) and sodium bicarbonate (1.68 Gm., 0.20 mole) were dissolved in 50 ml. of warm water and 50 ml. of warm ethanol was added. 1,2-Dinitro-4,5-dichlorobenzene (2.37 Gm., 0.01 mole) [prepared by the procedure of Hartley and Cohen (11)] was dissolved in 100 ml. of warm aqueous ethanol (50:50). The two solutions were mixed and boiled until no odor of ethanol could be detected. The solution was cooled and filtered, and the residue was dissolved in warm water. The aqueous solution was acidified,

and the yellow product was filtered and recrystallized from aqueous ethanol. The yield was 0.83 Gm. (31%); m.p. 198–199°.

N-4,5-Dichloro-2-nitrophenylamino Acid Ethyl Esters.—The following procedure is representative. N-4,5-Dichloro-2-nitrophenyl-DL-serine (3.0 Gm., 0.008 mole) was dissolved in 100 ml. of absolute ethanol. The solution was heated to 70°, and dry hydrogen chloride was introduced, with stirring, for a period of 2 hours. The resulting solution was evaporated to a small volume and cooled. Water was added until the ester precipitated, and the precipitate was collected. This precipitation from ethanol was repeated, and the product was dried over calcium chloride. The yield was 0.60 Gm. (19%); m.p. 127–128°.

Phytochemical Investigation of *Amphipterygium adstringens*

By EDWARD E. GONZALEZ† and JAIME N. DELGADO

A general phytochemical investigation was conducted on *Amphipterygium adstringens*, Schlecht. Numerous qualitative studies were conducted and several conventional techniques were employed in the detection, isolation, purification, and chemical characterization of constituents. Qualitative chemical tests showed the presence of phytosterols, glycosides, and tannins, and the absence of alkaloids and phloroglucides. An organic acid and a steroidal saponin were isolated from the diethyl ether and *n*-butanol extracts, respectively. The *p*-nitrobenzyl and *p*-phenylphenacyl derivatives of the carboxylic acid were prepared. The neutralization equivalent and infrared spectrum of the isolated acid were established. Chromatographic and infrared studies of the saponin have been reported.

THIS PHYTOCHEMICAL study was initiated primarily because preliminary screening tests indicated that *Amphipterygium adstringens*, Schlecht (Fam. *Julianiaceae*) possessed a certain degree of anticancer activity (1). This observation, together with a survey of the available literature which revealed no apparent report on the exact chemistry of this botanical species, stimulated interest and prompted this investigation. Furthermore, since Martinez (2) briefly makes note of *Amphipterygium adstringens* in the second part of his book which deals only with medicinal plants lacking scientific investigation, it was felt that the project was worthy of exploration.

A survey of botanical literature revealed disagreements in the scientific nomenclature of *Amphipterygium adstringens*, Schlecht. Some of the early reports refer to the species as *Hypopterygium adstringens*. In the more recent literature the generic name is given as *Juliania*, family *Julianiaceae*. *Amphipterygium adstringens*, commonly known as "Cuachalalate," is a small tree indigenous to Mexico, growing from Michoacán to Morelos and Puebla to Oaxaca. The assumed medicinal effects of the bark are briefly described by Martinez (2). Concoctions of the bark are used extensively for alleviating numerous conditions, including malaria, intermittent fever, ulcers, and cancer of the gastrointestinal tract.

and the yellow product was filtered and recrystallized from aqueous ethanol. The yield was 0.83 Gm. (31%); m.p. 198–199°.

N-4,5-Dichloro-2-nitrophenylamino Acid Ethyl Esters.—The following procedure is representative. N-4,5-Dichloro-2-nitrophenyl-DL-serine (3.0 Gm., 0.008 mole) was dissolved in 100 ml. of absolute ethanol. The solution was heated to 70°, and dry hydrogen chloride was introduced, with stirring, for a period of 2 hours. The resulting solution was evaporated to a small volume and cooled. Water was added until the ester precipitated, and the precipitate was collected. This precipitation from ethanol was repeated, and the product was dried over calcium chloride. The yield was 0.60 Gm. (19%); m.p. 127–128°.

Phytochemical Investigation of *Amphipterygium adstringens*

By EDWARD E. GONZALEZ† and JAIME N. DELGADO

A general phytochemical investigation was conducted on *Amphipterygium adstringens*, Schlecht. Numerous qualitative studies were conducted and several conventional techniques were employed in the detection, isolation, purification, and chemical characterization of constituents. Qualitative chemical tests showed the presence of phytosterols, glycosides, and tannins, and the absence of alkaloids and phloroglucides. An organic acid and a steroidal saponin were isolated from the diethyl ether and *n*-butanol extracts, respectively. The *p*-nitrobenzyl and *p*-phenylphenacyl derivatives of the carboxylic acid were prepared. The neutralization equivalent and infrared spectrum of the isolated acid were established. Chromatographic and infrared studies of the saponin have been reported.

THIS PHYTOCHEMICAL study was initiated primarily because preliminary screening tests indicated that *Amphipterygium adstringens*, Schlecht (Fam. *Julianiaceae*) possessed a certain degree of anticancer activity (1). This observation, together with a survey of the available literature which revealed no apparent report on the exact chemistry of this botanical species, stimulated interest and prompted this investigation. Furthermore, since Martinez (2) briefly makes note of *Amphipterygium adstringens* in the second part of his book which deals only with medicinal plants lacking scientific investigation, it was felt that the project was worthy of exploration.

A survey of botanical literature revealed disagreements in the scientific nomenclature of *Amphipterygium adstringens*, Schlecht. Some of the early reports refer to the species as *Hypopterygium adstringens*. In the more recent literature the generic name is given as *Juliania*, family *Julianiaceae*. *Amphipterygium adstringens*, commonly known as "Cuachalalate," is a small tree indigenous to Mexico, growing from Michoacán to Morelos and Puebla to Oaxaca. The assumed medicinal effects of the bark are briefly described by Martinez (2). Concoctions of the bark are used extensively for alleviating numerous conditions, including malaria, intermittent fever, ulcers, and cancer of the gastrointestinal tract.

EXPERIMENTAL

Source and Preparation of the Plant Material.—The chemical studies were conducted on authenticated samples.[1] The plant material used in this study consisted of the outer, dried bark of *Amphipterygium adstringens*, free of adulteration and adhering foreign matter. The hard, bulky pieces of bark were first reduced in size with a Wiley grinding laboratory mill, and then pulverized to a No. 20 mesh size in a W. J. Fitzpatrick, model D, comminuting machine. The ground material was then stored in tight metal containers to avoid contamination and possible deterioration.

Extraction Studies.—Suitable, accurately weighed samples of powdered material were extracted successively with a series of solvents in a Soxhlet continuous extraction apparatus by the Rosenthaler method (3). The solvents were used in the order of increasing polarity, and the extraction with a given solvent was continued until an aliquot of the colorless percolate left no residue when evaporated to dryness. The percentage of extractives were as follows: petroleum ether (b.p. range 30–60°), 6.11%; anhydrous ether, 4.62%; chloroform U.S.P., 0.82%; anhydrous ethanol, 9.61%; 70% ethanol, 4.07%.

Phytosterols.—In an attempt to determine the presence of phytosterols, effective application was made of the digitonin reaction according to the method described by Fieser and Fieser (4). The nonsaponifiable fraction of the petroleum ether[2] extract gave a positive reaction with digitonin, forming a white crystalline substance which melted at 139–143°. In order to substantiate fully the results of the digitonin reaction, other more general and classical qualitative tests were applied to fractions of the nonsaponifiable material. Positive results were obtained with Hesse's, Moleschott's, Liebermann's, and Hirschsohn's reactions.

Phloroglucides.—The Coward-Harris (5) procedure was employed as the basis for the qualitative analysis for phloroglucides. No precipitation was observed indicating their absence.

Alkaloids.—The chloroform extract of the whole drug (200 Gm.) was examined for alkaloids by the proximate assay method for alkaloids (6). Since the resulting extract gave a negative test with Mayer's reagent but produced slight opalescence with gold chloride T.S. and tannic acid T.S., an attempt to isolate alkaloids was made on a larger portion of crude drug following the procedure of Kleber and Gisvold (7). Negative results were obtained with Mayer's reagent, Lugol's solution, gold chloride T.S., picric acid T.S., and phosphomolybdic acid T.S., conclusively indicating the absence of alkaloidal substances in the plant material.

Glycosides.—A modified procedure of the Stas-Otto method was employed in the qualitative determination for glycosides. A mixture of plant material (300 Gm.) and ethanol containing tartaric acid (2%) was refluxed for approximately 12 hours. After the solvent was recovered by filtration, the marc was washed several times with hot ethanol and then pressed as free as possible of solvent. These filtrates were combined and evaporated to dryness in a Rinco rotatory evaporator under reduced pressure using steam as the source of heat. The residue was washed with hot distilled water (four 50-ml. portions) and the aqueous solution was extracted with diethyl ether (four 50-ml. portions) in a separator. The combined ethereal extracts were evaporated to dryness and the residue dissolved in ethanol. Aliquots of this solution were tested with Molisch reagent. Positive results were obtained, indicating the presence of carbohydrate substances and/or glycosides.

Tannins.—A hydroalcoholic (50% ethanol) extract of the plant material was prepared and aliquots of the solution were checked for tannins with various test solutions. A positive reaction was obtained with potassium dichromate, gelatin, ferric chloride, and uranyl acetate reagents. The tannins were isolated by the Feist and Bestehorn method (3) and an attempt was made to classify the tannins according to their specific chemical reactions with various reagents (8). In order to prevent one intense color from obscuring or masking another, several tannin solutions of ranging concentration were prepared. Positive results were obtained with fresh bromine water and ferric chloride T.S., while negative results were obtained with vanillin-hydrochloride and ammonium molybdate.

The production of a green color with ferric chloride T.S. indicated a catechol nucleus (two adjacent free phenolic groups) in the molecule, rather than a pyrogallol nucleus (three adjacent free phenolic) groups). The fact that the tannins were precipitated with bromine water reveals that they are of the nonhydrolyzable type since the hydrolyzable tannins do not react in this manner. Negative results obtained with ammonium molybdate and vanillin-hydrochloride indicate the absence of gallic acid and phloroglucin tannins, respectively.

Examination of Diethyl Ether Fraction.—The marc which had been previously exhausted with petroleum ether was extracted with diethyl ether by cold percolation. The ethereal extract was concentrated under reduced pressure to 50% of its original volume and placed in the deep freezer at −10° for several days. A substantial amount of pyramidal shaped crystals precipitated from the ethereal solution. The yellowish crystals which formed were removed by filtration and washed several times with cold acetone and methanol. These washings removed most of the colored impurities. The crude crystalline substance was recrystallized from ethanol and dried, *in vacuo*, at 80° with potassium hydroxide in an Abderhalden drying pistol. The crystalline material melted at 165–166° and was acidic to both litmus paper and phenolphthalein T.S. The crystals proved to be insoluble in water, methanol, acetone, concentrated hydrochloric acid, and sulfuric acid; sparingly soluble in hot methanol, cold ethanol, chloroform, and carbon tetrachloride. On the other hand, the substance exhibited a high degree of solubility in hot ethanol, sodium hydroxide solution, alcoholic potassium hydroxide, and sodium bicarbonate solution. Some of the qualitative tests that were applied for the classification and partial chemical characterization are summarized as follows: (*a*) ferric chloride test for phenols, negative; (*b*) Molisch test for carbohydrates, negative; (*c*) ceric ammonium nitrate test for alcohols, negative; (*d*)

[1] Kindly furnished by Dr. H. R. Schmidt, research pharmacognosist, Department of Research, S. B. Penick and Co., New York, N. Y.

[2] Unless otherwise specified, petroleum ether refers to technical grade petroleum benzin, boiling range 30–60°.

Liebermann-Burchard test for sterols, negative; (*e*) Fuchsin-aldehyde test, negative; (*f*) lead acetate test, positive; (*g*) picric acid test, negative; (*h*) cupric sulfate test, positive; (*i*) iodine test, negative; (*j*) potassium permanganate test, positive (ppt.); (*k*) sodium fusion test for nitrogen, phosphorus, and sulfur, negative. The preceding data eliminated several possibilities and indicated that the isolated substance was possibly an organic acid.

Anal.—Found: C, 78.26; H, 10.99. The neutralization equivalent of the acidic crystalline substance was determined according to the standard analytical method described by Niederl and Niederl (9). The average neutralization equivalent was determined to be 550.20.

Esterification.—The *p*-nitrobenzyl and *p*-phenylphenacyl derivatives of the organic acid were prepared from the corresponding bromides according to the procedures of Kelly (10) and Drake (11), respectively. These two particular derivatives were chosen because there is usually a considerable difference in the melting point of the *p*-nitrobenzyl and *p*-phenylphenacyl ester of any one acid. During the esterification process, it was essential to maintain the reaction mixture slightly acidic since alkalies could hydrolyze the parent halides to the corresponding alcohols. The prepared *p*-nitrobenzyl ester melted at 72–73° and the *p*-phenylphenacyl ester at 127–128°.

The neutralization equivalent value and the melting points of the prepared derivatives did not compare with any values reported in the literature.

Infrared Analysis.—A potassium bromide wafer of the crystalline substance was prepared for the infrared spectrum analysis since it was not sufficiently soluble in chloroform. The infrared spectrum was determined in an infrared recording spectrophotometer, model 4-55, Baird Associates, Inc. The absorption spectrum of the isolated acid is shown in Fig. 1.

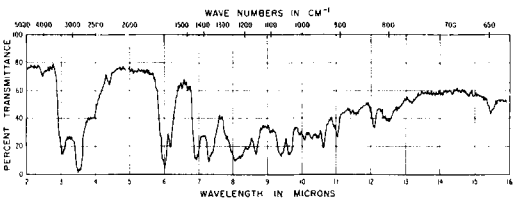

Fig. 1.—Infrared spectrum of the unknown acid in potassium bromide wafer.

The broad absorption bands between 3.0 and 3.6 μ (3310–2860 cm.$^{-1}$) fall within a frequency range which is normally assigned to carboxylic acids; however, the specific band observed under 3.5 μ (2850–2860 cm.$^{-1}$) may be conferred also by —CH_2— vibrations (12). Inspection of the spectrum for the carboxyl function disclosed a stretching band with a shoulder near 6.0 μ (1700–1650 cm.$^{-1}$). The absorption band at 6.9 μ (1465–1400 cm.$^{-1}$) could be manifested by the covalent carbon-oxygen bond of the carboxyl group. Some indications of the presence of an isopropyl group is found in the absorption band observed in the 7.3–7.4 μ (1370–1350 cm.$^{-1}$) region (12). Furthermore, the bands appearing near 8.1 μ (1250 cm.$^{-1}$) and 8.7 μ (1150 cm.$^{-1}$) give reason to suspect its presence. The other weak peaks noted above 9.0 μ may possibly be deformation frequencies associated with either propyl or carboxyl group vibrations.

Examination of Aqueous Fraction.—During the preliminary chemical studies, it was noted that the aqueous extract produced vigorous foaming when agitated. This observation, and the fact that the Stas-Otto test for glycosides was positive, suggested the possibility of existing saponins. In order to provide more convincing evidence, the aqueous extract of the plant material was extracted with hot *n*-butanol by means of a separator and the residue obtained after evaporation of the butanol was tested with antimony trichloride T.S. (13). A positive reaction was observed with the production of a yellow color.

In order to isolate an adequate amount of saponin, 10 Kg. of powdered bark were extracted by means of cold percolation in a large metal percolator (36 in. high and 14 in. inside diameter). The percolation was continued at a moderate rate over a period of several days until 15 gallons of liquid were collected. Extreme care was exercised to avoid fermentation during the long period of slow maceration and percolation. The aqueous percolate was lyophilized to dryness in a F. J. Stokes Lyophilyzer, model 2004L X 3, and the combined residues washed and refluxed in *n*-butanol.[3]

After filtration, the *n*-butanol extract was concentrated by distillation, *in vacuo*, at 55–60° to a small volume. Cold anhydrous acetone (200 ml.) was added to the contents of the flask causing the precipitation of a light amorphous substance. A total of 13.4 Gm. of crude saponin was recovered by the aforementioned process. The solid amorphous substance was hygroscopic and soluble in water, with considerable foaming and opalescence. It was soluble in methanol and ethanol, insoluble in petroleum ether, diethyl ether, chloroform, and acetone. Some of the basic qualitative tests that were applied for the chemical classification are summarized as follows: (*a*) Molisch test, positive; (*b*) ferric chloride test, negative; (*c*) Liebermann-Burchard test, negative; (*d*) Seliwanoff test, negative; (*e*) antimony trichloride test, positive; (*f*) basic lead acetate test, positive; (*g*) the addition of ether to an aqueous solution caused the formation of a gelatinous precipitate; (*h*) the addition of sulfuric acid (1 ml.) to a concentrated aqueous solution produced a crimson color. The preceding chemical data substantiated that the amorphous substance under consideration was a saponin.

Hydrolysis of Saponin.—Hydrolysis of the above described glycosidal compound was accomplished by means of strong mineral acid in alcohol and water mixtures. A saponin sample (4 Gm.) was dissolved in a hydroalcoholic mixture composed of distilled water (50 ml.) and ethanol (25 ml.), to which was added concentrated sulfuric acid (8.6 ml.). The acidic mixture was refluxed vigorously on a steam bath for 6.5 hours. The foaming that occurred on heating was controlled by the addition of *n*-amyl alcohol (5 ml.). The reaction mixture was allowed to cool and the contents poured into a separator and extracted with warm chloroform (three 50-ml. portions). The combined chloroform extracts were con-

[3] Grateful acknowledgment is made to Dr. F. P. Cosgrove for his technical assistance in this phase of our study.

TABLE I.—SOLVENT SYSTEMS AND R_f VALUES FOR UNKNOWN AND REFERENCE SAPOGENINS[a]

Solvent System	a	b	c	d	e
Petroleum ether, ml.	400	400	200	100	0
Toluene, ml.	0	50	100	200	400
Ethanol, ml.	10	10	10	30	10
Water, ml.	90	90	90	70	90
Chlorogenin	...	...	...	0.310	0.290
Gitogenin	...	...	...	0.522	0.496
Hecogenin	...	0.227	0.430	0.851	0.878
Tigogenin	0.396	0.641	0.778	0.911	0.960
Diosgenin	0.433	0.645	0.832	0.956	0.988
Sarsasapogenin	0.701	0.862	0.755	1.000	1.000
Smilagenin	0.728	0.859	0.931	1.000	1.000
Unknown genin	0.698	0.865	0.750	1.000	1.000
Unknown genin plus sarsasapogenin	0.695	0.864	0.755	1.000	1.000

[a] Chemically pure (A.R.) reagents were employed in preparing all solvent systems used for chromatographic studies.

centrated to a small volume under reduced pressure in a Rinco rotatory evaporator; the sapogenin was then precipitated by the addition of methanol A.C.S. (10 ml.). The crude genin was recrystallized from methanol and used for chromatographic and infrared studies.

Paper Chromatographic Analysis of Sapogenins.—The apparatus and technique used for the chromatographic analysis of the sapogenins was essentially that described by Heftmann and Hayden (14). Whatman No. 1 filter paper was employed throughout the chromatographic studies and all chromatographic work was carried out in an air-conditioned room at 23°. After resolution was complete, the sapogenin chromatograms were sprayed with a freshly prepared solution of trichloroacetic acid in chloroform (25%) in the manner of Svendsen and Jensen (15). The sheets were heated in a chromatography oven at 90–100° for approximately 15 minutes and, thereafter, the sapogenins were detected by their varying fluorescence under ultraviolet light.

The R_f values of the unknown genin and reference compounds which were chromatographed individually and as mixtures with themselves and with the unknown sample are listed in Table I.

Reference Sapogenins.—Pure authenticated sapogenin samples for experimental study were kindly supplied by Dr. O. Mancera, Syntex Laboratories, Mexico City; and Dr. E. Heftmann, National Institutes of Health, Bethesda, Md. Comparative chromatographic and infrared studies of the unknown genin and reference sapogenins were made. All of the sapogenins were used in a concentration of 1 mg. per ml. of chloroform U.S.P.

Identification of Sugar Moieties of the Saponin.—After removal of the aglycon from the hydrolyzed mixture, the filtrate was neutralized with barium carbonate and filtered. The filtrate was concentrated to a syrupy consistency, dissolved in ethanol, and filtered to give a yellow solution. All of the solutions that were prepared were stored in the refrigerator and warmed to room temperature before using for chromatographic analysis.

Two different solvent systems were employed for the chromatographic resolution of the carbohydrates. One solvent system (S-1) was composed of *n*-butanol (4 parts), distilled water (5 parts), and glacial acetic acid (1 part) (16). The other solvent system (S-2) consisted of 2,6-lutidine (13 parts), and distilled water (7 parts) (17). Because solvent system S-1 was subject to esterification, it was always freshly prepared and used only once. Solvent system S-2 never was used more than twice in the experiments.

An ascending chromatographic technique was used for the separation and identification of the sugar residues. The chromatograms were developed with the mobile phase for approximately 16 hours. After resolution was complete, the dried chromatograms were sprayed with a solution of aniline acid phthalate in water-saturated *n*-butanol and dried for 5 minutes in a chromatography oven at 100°. On sheets developed with this reagent, aldopentoses appeared as red spots and hexoses as green to brown spots. Extreme care was exercised to prevent any destruction of the paper when heating.

Several known sugars of analytical purity were chromatographed individually, and as mixtures with themselves and with the unknown sample. The R_f values obtained with the two different solvent systems are given in Table II.

TABLE II.—SUMMARY OF R_f VALUES FOR CARBOHYDRATES

Compound	R_f Values S-1	R_f Values S-2
D-Xylose	0.353	0.554
D-Glucose	0.295	0.534
D-Galactose	0.306	0.496
D-Rhamnose	0.526	0.641
Unknown sugar mixture	0.297 0.523	0.536 0.644

Infrared Spectra as Proof of Identity.—Since the unknown genin behaved chromatographically like sarsasapogenin, application of infrared spectra was made as a further check in establishing its identity. Chloroform solutions (30%) of the unknown genin and sarsasapogenin were prepared for infrared analysis. The infrared absorption spectrum of each sample was determined in an infrared Beckman spectrophotometer, model IR-5, using 0.059 mm. sodium chloride cells. Chloroform U.S.P. was used as the standard reference sample. The infrared absorption spectra of the isolated sapogenin and sarsasapogenin are shown in Figs. 2 and 3, respectively.

It will be noted that the infrared spectrum of the unknown sapogenin bears great resemblance to that of sarsasapogenin. Each of the two steroidal compounds produced curves with distinctive bands in the

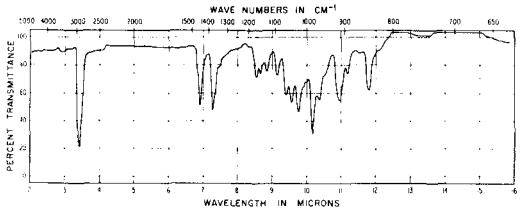

Fig. 2.—Infrared spectrum of the unknown sapogenin in chloroform U.S.P.

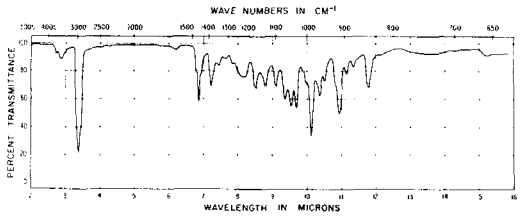

Fig. 3.—Infrared spectrum of sarsasapogenin in chloroform U.S.P.

"finger-print region" which is characteristic of sapogenins. Between 850 and 1350 cm.$^{-1}$ intense absorption bands conferred by the spiroketal side chain are observed (18). The bands of maximum absorption in this highly specific region are located near 987 and 908 cm.$^{-1}$. Those absorption bands observed in the region between 1350 and 1500 cm.$^{-1}$ seem to be associated with vibrations localized in the methyl groups (19). The notable peak located near 2940 cm.$^{-1}$ could be assigned to the —CH_2— vibrations of the molecule. Inspection of the spectra for the 3-hydroxyl group disclosed two bands of medium intensity between 1000 and 1050 cm.$^{-1}$ (20). The absorption bands below 850 and above 1800 cm.$^{-1}$ have not been extensively studied since these regions do not show any prominent features of reasonable consistency.

SUMMARY

A general phytochemical investigation was conducted on *Amphipterygium adstringens*, primarily on the basis of its promising anticancer activity. Numerous chemical qualitative studies were conducted and several conventional techniques were employed in the detection, isolation, purification, and characterization of constituents.

The results of this phytochemical study may be summarized as follows:

1. The qualitative tests for the presence of phytosterols were positive.

2. The determinations for the presence of phloroglucides and alkaloids were negative.

3. The tannins were found to be members of the nonhydrolyzable group containing a catechol type of nucleus.

4. A crystalline substance (m.p. 165–166°) was isolated from the diethyl ether extract of the marc previously exhausted with petroleum ether.

5. On the basis of chemical qualitative tests, solubility properties, and infrared studies, the crystalline substance was characterized as an organic acid. The prepared *p*-nitrobenzyl ester melted at 72–73°, and the *p*-phenylphenacyl ester at 127–128°.

6. The Stas-Otto analysis for the presence of glycosides was positive.

7. A steroidal saponin was isolated from the *n*-butanol extract of the aqueous fraction.

8. Paper chromatographic and infrared analysis of the isolated sapogenin showed that its physical-chemical properties were similar and in direct agreement with those of sarsasapogenin.

9. Hydrolysis of the saponin and subsequent paper chromatographic analysis of the carbohydrate residues showed the presence of D-glucose and D-rhamnose.

Some Antiarrhythmic Actions of Primaquine, Amodiaquin, and Quinidine

By E. L. HOLLAND and R. S. McCUTCHEON

This study concerns (*a*) the antiarrhythmic properties of amodiaquin and primaquine in comparison with those of quinidine and (*b*) the ionic fluxes caused by acetylcholine and the depression of these fluxes by the antiarrhythmic drugs used. Under (*a*) it was found that both amodiaquin and primaquine are as effective as quinidine in halting atrial fibrillation induced by the injection of acetylcholine after pretreatment with neostigmine. Under (*b*) no ion fluxes were demonstrated after the injection of acetylcholine under the conditions of the experiment.

QUINIDINE is an established drug in the treatment of cardiac disorders. It is the dextroisomer of quinine and is the most active of the cinchona alkaloids in antiarrhythmic activity (1). Quinidine has been reported by Lewis (2) to have the following effects on heart muscle: it depresses excitability, slows conduction, slows the rate, increases the refractory period, and causes a decrease in vagal tone. It has no effect on the contractility of the heart in normal doses.

A search of the literature revealed two synthetic antimalarials that had been studied only a very little for their antiarrhythmic activity. In the few studies that have been done on these drugs it was shown that they are more effective than quinidine in halting atrial fibrillation; these two drugs are amodiaquin and primaquine (3–5).

Arora, *et al.* (3), have shown that amodiaquin is more effective than quinidine in reversing aconitine-induced auricular fibrillation in cats. In another report, Arora, *et al.* (4), have shown that amodiaquin possesses a quinidine-like action on the refractory period of isolated rabbit atria and has a stronger antifibrillatory action on acetylcholine-induced atrial fibrillation in dogs than quinidine. Arora (4) has also reported that amodiaquin differs from quinidine in not protecting against epinephrine-induced ventricular arrhythmias and causing a greater slowing of conduction rate and less prolongation of the refractory period.

Primaquine has been reported by Arora, *et al.* (5), to be more effective than quinidine in protecting dogs against atrial fibrillation induced by the topical application of aconitine and atrial flutter caused by crush stimulation of the atria, but did not show protective action against epinephrine-hydrocarbon-induced ventricular arrhythmias. It has been shown (5) by the electrocardiograph that primaquine increases the refractory period and conduction time of the heart more than did quinidine.

Several authors have also shown that acetylcholine stimulates the efflux of potassium and the influx of sodium in myocardial tissue (6–12). It has also been reported that quinidine depresses this ionic flux (8–10).

EXPERIMENTAL

Antiarrhythmic Study.—One object of these studies was to compare the action of amodiaquin and primaquine with quinidine as to relative effectiveness in halting atrial fibrillation induced by the injection of acetylcholine after the animal had been pretreated with neostigmine.

Five mongrel dogs weighing from 15 to 24 Kg. were used in these studies. Each animal was anesthetized with pentobarbital sodium solution, 35 mg./Kg. intraperitoneally. The anesthetic was supplemented, if necessary, by pentobarbital sodium solution intravenously.

Control electrocardiograms were taken on all animals to determine if any cardiac abnormalities were present. If the animal exhibited any it was rejected.

All electrocardiograms were taken on a Sanborn model 150 four-channel recorder and monitored visually at all times with a Sanborn Visoscope oscilloscope. Standard limb lead II was used and the lead wires were connected to the animal by means of subcutaneous electrode needles.

All injections were made through an indwelling 21-gauge needle placed in either the right or left saphenous vein. To keep the needle from plugging, a very slow (3 to 5 drops/minute) infusion of isotonic sodium chloride was allowed to infuse. The animals were placed in the prone position with the posterior elevated to facilitate the drainage of the copious salivary secretions caused by the acetylcholine.

A method of initiating atrial fibrillation of sufficient duration and predictability to determine the effectiveness of the three drugs was adapted from the following. Leveque (13) produced atrial fibrillation averaging about 25 seconds in dogs by thyroid administration and acetylcholine injection. Loomis and Krop (14) reported that atrial fibrillation could be induced in dogs by the injection of acetylcholine

after the animal had been pretreated with an anticholinesterase agent.

The latter method was found to be the most reliable for inducing atrial fibrillation of extended duration. The cholinesterase agent chosen was neostigmine bromide which was given in a dose of 0.05 mg./Kg. A dose of 0.15 mg./Kg. of acetylcholine 30 minutes after neostigmine was found to produce an atrial fibrillation of long duration with nonfatal respiratory embarrassment.

To summarize, the atrial fibrillation was induced four times by the injection of acetylcholine, after pretreatment with prostigmine, for each treatment with each drug. The average time of the first and second fibrillation served as the control time, and the average time of the third and fourth fibrillation served as the treatment time. Each animal was used three times at random intervals and was treated with each of the antiarrhythmic drugs, fibrillation being produced 12 different times in each.

Drugs and dosages used in the antiarrhythmic study were as follows

Drug[1]	Dose, mg./Kg.
Neostigmine bromide	0.05
Acetylcholine chloride	0.15
Quinidine gluconate	5.00
Amodiaquin hydrochloride	4.00
Primaquine dihydrochloride	4.00

Ion Studies.—The purpose of these studies was to determine the extent to which acetylcholine causes a sodium and potassium flux and to determine whether the three antiarrhythmic drugs studied would depress it.

Serum sodium and potassium were determined using a Beckman model DU spectrophotometer with a flame attachment according to the method of Hawk, *et al.* (15).

All blood samples were drawn from either the right or left saphenous vein or the right or left radial vein in the following order: control (no drug administered except the anesthetic), 20 minutes after prostigmine, immediately after acetylcholine, and shortly after the antiarrhythmic drug. The 5-ml. samples of blood were allowed to coagulate in a refrigerator and then were centrifuged and the clear supernatant serum was drawn off. The serum was diluted 1:250 for the determination of sodium and 1:100 for the determination of potassium. This method is described in Hawk, *et al.* (15).

In this series each dog was used three times as in the antiarrhythmic studies. Blood samples were taken in the order indicated each time the dog was used in the antiarrhythmic study and analyzed for sodium and potassium.

RESULTS AND DISCUSSION

Antiarrhythmic Study.—Each figure of Table I expresses time as minutes:seconds, and is the average of two determinations, showing the average duration of an atrial fibrillation.

The columns labeled "before" show the duration of control fibrillations and the columns labeled "after" are the fibrillatory periods after treatment with the antiarrhythmic drug.

[1] These drugs were kindly furnished by the respective manufacturers: neostigmine bromide, Roche Laboratories; acetylcholine chloride, Merck & Co.; quinidine gluconate, Eli Lilly and Co.; amodiaquin HCl, Parke Davis; primaquine diHCl, Winthrop Laboratories.

It can be seen from Table I that all of the drugs are effective in shortening the duration of the acetylcholine-induced atrial fibrillation. To determine if the three drugs are equally effective, a statistical analysis of the results was done. This is a randomized block experiment with three treatments (drugs) and five replications (dogs).

The difference between the control (before) times and the treatment (after) times was used in the statistical analysis. These differences appear in Table II, the differences being expressed as seconds.

The statistical analysis shows that the three drugs are effective in shortening the duration of the acetylcholine-induced atrial fibrillation, $F = 86.19$.

It also indicates that the dogs are not a variable in this experiment, $F = 0.556$.

And finally the statistical analysis shows that the three drugs in the doses used are equally effective in shortening the duration of the acetylcholine-induced atrial fibrillation. These results do not support those of Arora, *et al.* (3–5), who state that both amodiaquin and primaquine at a dosage level of 4 mg./Kg. are more effective than quinidine at a dosage level of 5 mg./Kg. Our work shows an equal effect of the three drugs at a dosage of 4 mg./Kg. for amodiaquin and primaquine compared to 5 mg./Kg. for quinidine, thus indicating a stronger effect for the two experimental drugs. This difference in results can probably be explained by the different experimental techniques. In their work the heart was exposed and the atrial fibrillation was induced by the direct application of acetylcholine or aconitine. This extensive surgical manipulation may have caused a general weakening of the animal or an altered ionic concentration and have affected their results.

Ion Studies.—At no point in these studies is there any indication of a statistically significant ion flux. The ranges for the ion values obtained are presented in Table III.

These findings do not agree with those of the authors cited previously (6–12), however the methods used are probably not comparable.

Most work done previously was done on an isolated perfused preparation. Holland used an isolated perfused amphibian heart. The differences in experimental techniques and the differences between an isolated perfused amphibian heart and an intact mammalian heart are probably responsible for the differences between this work and his. Conn and Wood (8) used a dog's heart as an isolated perfused preparation. Again wide variations in experimental techniques are probably responsible for the difference in results.

There is a strong possibility that these ionic fluxes occur so rapidly that it is difficult to collect a blood sample at the exact peak of the flux. There is also a possibility that these ion changes are of such magnitude that the instrument used in this study would not be sensitive to them. Still another possibility for the discrepancy in these results and those of other workers is that the red blood cells may play a role in adjusting these fluxes. As the blood is coagulating, the red blood cells may tend to adjust the ionic imbalances back toward normal. Still another possibility for the inability to demonstrate these fluxes is that the kidney may make a rapid readjustment.

Primaquine	4.4	6.5

SUMMARY AND CONCLUSIONS

An investigation of the antiarrhythmic properties of amodiaquin and primaquine has shown them to be as effective as quinidine in shortening the duration of experimentally induced atrial fibrillation but of stronger antiarrhythmic activity. The atrial fibrillation was induced by the injection of acetylcholine after the animal had been pretreated with the anticholinesterase agent, prostigmine.

This study has attempted to show the ionic changes caused by acetylcholine. Further, this study has attempted to show that these ionic fluxes are depressed by the antiarrhythmic drugs studied. No ionic fluxes are demonstrated at any point in this study so it could not be said that quinidine or related drugs had any demonstrable effect on the ionic concentration or ionic fluxes of the myocardial tissue.

Stability Assays of Pharmaceutical Preparations by Quantitative Paper Chromatography

Steroid Hormones in Oil

By HENRY R. ROBERTS and KLAUS FLOREY

A quantitative paper chromatographic method has been developed which is routinely used as a stability assay for steroid esters having a 4-dehydro-3-keto configuration. The method involves: (*a*) a separation between the parent steroid ester and the free steroid, (*b*) the quantitative elution of the steroid ester from the chromatogram using an acidified methanolic solution of isonicotinic acid hydrazide, and (*c*) a spectrophotometric analysis of the eluate. Recoveries in excess of 95% are obtained by simultaneously chromatographing replicates of standard and sample solutions on the same chromatogram. A detailed account of the procedure is presented using, as examples, the assay of 17-α-hydroxyprogesterone caproate and testosterone enanthate in oil formulations.

WHEN DEVELOPING analytical procedures for the determination of active ingredients in pharmaceutical preparations, it is necessary to make a distinction between content and stability assays. For a content assay, any characteristic property of the molecule amenable to convenient quantitation can be used. A stability assay, on the other hand, has to show whether or not the amount originally put into a formulation has undergone changes which, with time, will alter its pharmacological potency. A stability assay must, therefore, measure either the intact active ingredient or its breakdown products.

In cases where breakdown products are either difficult to measure chemically because they closely resemble the active ingredient or are altogether unknown, we have found it convenient to follow the stability of formulations by measuring the active ingredients by quantitative paper chromatography. In quite a number of cases, this method reduces the need for elaborate extraction procedures, especially when two or more similar components have to be separated. It also eliminates the cumbersome task of preparing, for comparison, blank formulations which contain all the ingredients except the active one.

Previous workers (1–3) have described the application of quantitative paper chromatography for the assay of various pharmaceuticals. We have adapted quantitative paper chromatography specifically to measure product stability of a great variety of pharmaceutical preparations. In this paper we wish to report on techniques which permit the quantitation of 4-dehydro-3-keto steroids with isonicotinic acid hydrazide (4). The examples chosen are the quantitative determination of two steroid hormones, testosterone enanthate and 17α-hydroxyprogesterone caproate in oil formulations.

Received October 20, 1961, from the Squibb Institute for Medical Research, New Brunswick, N. J.
Accepted for publication January 12, 1962.

EXPERIMENTAL

The paper chromatographic procedure involves, essentially, two steps: (*a*) the separation of the active component from its hydrolytic product and (*b*) the elution of the parent compound from the chromatogram followed by a quantitative spectrophotometric analysis of the eluate.

Preparation of Standards.—The reference standard solution should contain 1 mg. of the steroid hormone per ml. of solution. In a tared volumetric flask, the appropriate amount of steroid is dissolved in the smallest volume of N,N-dimethylformamide. Then methyl isobutyl ketone is added to the mark. The reference standard material should be from the same lot as the formulation undergoing analysis.

Preparation of Sample.—The amount of sample which will yield, based on theory, 1 mg. of the hormone per ml. of solution is weighed into a tared volumetric flask, dissolved, and diluted to the mark with methyl isobutyl ketone.

Filter Paper.—Whatman No. 1, $5^3/_4$ in. × 18 in., shape ERS, with 5 cut-outs. Prior to spotting, the papers are immersed for a minimum of 30 minutes in each of two 95% ethanol washes in order to minimize the concentration of ultraviolet light absorbing impurities in the paper. A large Pyrex baking dish can be used satisfactorily to wash 20 folded sheets at one time. The strips are folded but not creased. Following the second alcohol wash, the strips are air dried.

Solder is used to mark the strips with two lines prior to the spotting step. The origin line is $3^1/_4$ in. from the top.

The second line, $2^1/_4$ inches from the top, serves as a folding guide, providing the strip with a $2^1/_4$-inch tab which is inserted into the solvent trough.

Developing Solvent.—Methylcyclohexane saturated with diethylene glycol monoethyl ether[1] (DGME) (5).

[1] 2-(2-Ethoxyethoxy)ethanol, marketed as a Carbitol by Carbide and Carbon Chemical Co.

Chromatographic Chamber.—Any conventional chamber used for descending paper chromatography is suitable.

Eluting Solution.—A 1-Gm. quantity of isonicotinic acid hydrazide is dissolved in 1 L. of absolute methyl alcohol containing 1.25 ml. of concentrated hydrochloric acid.

Paper Chromatographic Procedure.—Two chromatograms are run per sample. The filter paper contains six 3/4-inch strips which are spotted as illustrated in Fig. 1.

Blow-out pipets, 0.1 ml. capacity, graduated in 0.01 ml., are used to apply the standards and the sample to the paper. The solutions are applied in aliquots of approximately 0.005 ml. so that the area of application remains small. A stream of warm air is directed on the spot after each aliquot is applied. The air is warmed by passing it through heated coiled copper tubing.

TABLE I.—PAPER CHROMATOGRAPHIC CONDITIONS FOR ASSAY OF SEX HORMONES[a]

Compound	Time, hr.
Testosterone enanthate	2 1/2
17α-Hydroxyprogesterone caproate	4

[a] Paper impregnating solution, 30% DGME in chloroform; developing solvent, methylcyclohexane saturated with DGME.

A spotting board, Fig. 2,[2] while not absolutely essential, offers a distinct advantage. It not only provides a support for the paper but it also holds the paper, by vacuum, in a fixed position. This permits spotting with one hand while the other hand is free to dry the spot after each application.

The spotted strips are impregnated with DGME by dipping them into the appropriate solution of DGME in chloroform, see Table I. The short end of the strip (3 1/4 inches from the origin) is dipped first, just up to the origin, and blotted lightly. The remainder of the strip is then passed through the impregnating solution with a rapid pass over the origin. In this manner, the entire strip, including the spotted origin, becomes impregnated with DGME. Since the extent of DGME impregnation will influence the mobility of the steroid being assayed, it is important that the DGME in chloroform solution be prepared accurately. Also, since evaporation of chloroform will alter the concentration of DGME, it is best if approximately 100 ml. of dipping solution is used to impregnate two to three chromatograms.

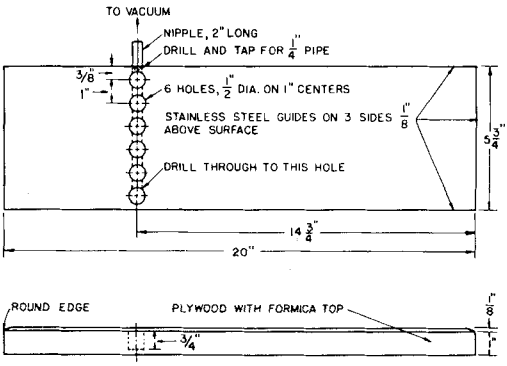

Fig. 2.—Board for spotting filter paper strips.

The impregnated strips are hung in a hood until the odor of chloroform can no longer be detected, and then they are placed in the chamber, the bottom of which is covered with DGME saturated with methylcyclohexane. The tab ends of the strips are placed into the troughs which contain the developing solvent, methylcyclohexane saturated with DGME. Following solvent development, Table I, the strips are removed from the chamber and dried in a mechanical convection oven for 20 minutes at 90°.

The positions of the steroids on the chromatograms are located by examining the strips through a fluorescent paddle over an ultraviolet light source.[3]

[2] The board shown here is a modification of the original design for which we are indebted to John M. West of these laboratories.

[3] The simple and efficient U.V. light source and paddle described here are a modification of the original design of Drake, *et al.* (6). We are indebted to R. W. Thoma and J. R. Gerke of these laboratories for these modifications.

The locations of the steroids are seen as black areas since they absorb the U.V. radiation and block the fluorescence. The source of ultraviolet radiation is a wooden box (8 in. × 8 in. × 21 in.) containing a 15-watt germicidal lamp (General Electric, 17 inch, No. G 1578) in the bottom and covered on top with three $6^1/_2$ in. sq. pieces of red-purple Corex A filters (No. 9863, Corning Glass Works, Corning, N. Y.).

The paddle is made from $^1/_8$ in. clear plexiglas and measures 7 in. square with a $1^1/_2 \times 4$ in. handle. It is coated with a thin layer of green fluorescing zinc silicate as follows: 6 ml. of collodion is measured into a 50-ml. glass-stoppered graduated cylinder and diluted to 22 ml. with acetone. To this is added 2 Gm. of zinc silicate phosphor (No. 609, E. I. DuPont de Nemours and Co., Towanda, Pa.). The mixture is shaken thoroughly and poured onto the paddle. The paddle is tipped in all directions so that the whole surface is evenly covered with a thin layer. Excess material is dripped off the paddle in the process of distributing it evenly.

The areas of the strips containing the steroids are marked with a solder pencil, cut out and folded, and placed in 50-ml. Erlenmeyer flasks. A paper blank, equal in area to the standard and sample segments, is included for each chromatogram (see Fig. 1). A piece of plywood mounted with 48 flask clamps (No. XCO050, New Brunswick Scientific Co., Inc., New Brunswick, N. J.) holds the flasks during the elution step. A 10-ml. quantity of the isonicotinic acid hydrazide solution is added to each flask, the flasks covered with aluminum foil to prevent the evaporation of the methanol, and then shaken for 60 minutes on a reciprocating shaker (130 strokes per min.). A variable reciprocating laboratory shaker manufactured by Eberbach (No. G-21827, Emil Greiner Co.) is ideal for this step. The 60-minute shaking period is necessary for (*a*) the elution of the steroid and (*b*) the reaction, at room temperature (*ca.* 22°), between the eluted 4-dehydro-3-keto steroid and the isonicotinic acid hydrazide reagent to form a yellow hydrazone.

The solution is then decanted into a 1-cm. Corex cell and the absorbance is read at 415 mμ, using a Beckman DU spectrophotometer. Absolute methanol is used as the reference solution. The standard and sample readings are corrected for cell readings and for the paper blank.

Calculations.—The absorbance readings are recorded on a data sheet which contains all the information necessary to calculate the concentration of steroid in the sample. Table II gives the data obtained in a typical analysis.

For each of the two chromatograms, absorbance readings are obtained for the standard at two levels and for the sample at one level, in triplicate. The absorbance readings of the two standards for each of the chromatograms are converted to the equivalent absorbance for the 0.1 ml. standard concentration and averaged. The three absorbance readings of the sample are converted to 0.1 ml. readings and averaged.

The concentration of the steroid in the sample is calculated from the following equation

$$\text{mg. of steroid per ml. formulation} = \frac{A \times B \times C \times D}{E \times F \times G}$$

where A = average absorbance of 10 ml. eluate of 0.1 ml. chromatographed sample, B = weight in mg. of 0.1 ml. chromatographed standard, C = volume in ml. of sample dilution, D = specific gravity of formulation, E = average absorbance of 10 ml. eluate of 0.1 ml. chromatographed standard, F = weight in Gm. of sample, and G = volume (0.1 ml.) of chromatographed sample.

The final concentration of the steroid in the sample is obtained by averaging the values obtained for each of the two chromatograms.

Sample Calculation.—Table II, chromatogram No. 1

$$\text{mg. testosterone enanthate per ml.} = \frac{0.119 \times 0.1048 \times 100 \times 1.0127}{0.180 \times 0.1752 \times 0.1} = 400$$

RESULTS AND DISCUSSION

Recoveries in excess of 95% must be obtained if any analytical method is to serve as an effective stability assay. The accuracy and precision of the method were established by determining the 17α-hydroxyprogesterone caproate content of a Delalutin 2X preparation. Ten aliquots were weighed and diluted; two chromatograms were run per aliquot. The average value of 253 mg./ml. obtained from 10 individual assays (Table III) differed from the theoretical value by 1.2%. In every instance, no individual assay differed from the theoretical value by more than 3.2%, well below the 5% maximum limit placed on the assay. The standard deviation, 3.74 mg./ml., indicates that the assay can be repeated with good precision.

Accuracies of this magnitude are obtained since the standards and sample are run on the same chromatogram in replicate and both are exposed simultaneously to the same chromatographic and assay conditions. Table IV contains additional data indicating that assays with recoveries in excess of 95% are obtained consistantly.

The hormone preparations described here are dissolved in sesame or castor oil. They contain, in addition, some combination of benzyl alcohol, benzyl benzoate, and chlorobutanol.

Not only does the paper chromatographic procedure separate the active ingredient from its hydrolytic product but it achieves this without the need of any elaborate extraction procedure. A simple dilution prior to spotting is all the sample preparation required.

A marked separation is achieved on the chromatogram between the parent steroid esters and the free steroids. Testosterone and 17α-hydroxyprogesterone remain near the origin while the esters migrate down the strip. While the intact ester is measured, the procedure also permits a visual identification and, if necessary, quantitative measurement of the hydrolytic product. However, the stabilities of the steroid esters in the oil formulations described here are excellent and no breakdowns have been observed upon prolonged storage at elevated temperatures, Table V.

The other components in the formulation do not interfere. The only possible interference originated with the benzyl benzoate. This compound is a U.V. absorber which has a chromatographic mobility similar to the steroids being assayed. While a clear

separation between the steroid and benzyl benzoate is not obtained, its presence is negated by reacting the steroid with isonicotinic acid hydrazide.

The use of acidified alcoholic isonicotinic acid hydrazide solution as a colorimetric reagent and as a paper chromatographic spray reagent for the detection of 4-dehydro-3-keto steroids have been described by a number of investigators (4, 7, 8). The manner in which it is utilized as a simultaneous eluant and colorimetric reagent as reported here has not, to the authors' knowledge, been described previously.

The absorption spectra of the isonicotinyl hydrazones of testosterone enanthate and 17α-hydroxyprogesterone caproate are similar to the spectrum given by Umberger (4) for the hydrazone of testosterone with a maximum at 380 mμ. The absorbances of the eluates can be measured in two different ways, both giving equally reliable results (Table VI). Absorbances of the eluates can be read at 380 mμ using the hydrazide reagent as a reference solution. At this wavelength the paper blank readings are extremely low. However, due to evaporation of the solvent, the concentration of the reference solution changes very rapidly and has to be replaced after every three readings. This becomes tedious and time consuming when the absorbances of a large number of eluates have to be read. There-

[a] Read against the isonicotinic acid hydrazide reagent; fresh reagent blank for every three eluate readings. [b] Read against absolute methanol; same blank for all eluate readings. [c] Theoretical value, 400 mg./ml.

fore, as described in the experimental part, the absorbances of the eluates are read at 415 mμ against methanol as the reference solution. At this wavelength, lower paper blank readings ($A \backsim 0.050$) are obtained than at 380 mμ ($A \backsim 0.200$). The high paper blank at 380 mμ is primarily due to the absorbance of excess hydrazide in the eluates (4).

The generally accepted procedure when working with Zaffaroni-type chromatographic systems is to impregnate the paper with the stationary phase prior to spotting the steroidal solution. For quantitation, spotting the paper prior to impregnation is more expeditious since the spotting-dipping sequence provides for better control over the uniformity of the stationary phase. Furthermore, papers can be spotted well in advance of chromatography. No distortion or diffusion of the zones has been noted when the impregnation of the spotted origin is done rapidly, as described.

The use of slotted sheets of filter paper offers a number of apparent advantages. The steroids corresponding to the standard and sample applications are confined in their solvent migration to their own 3/4-in. wide strips. Lateral diffusion is suppressed and contamination from adjacent spots can never occur. Also, the area of each of the strips containing the steroid, as well as the paper blank segment, are at all times equal since only the north-south boundaries have to be ascertained.

The design of the fluorescent screen as a paddle makes for easy marking of the steroid segments. The edges of the paddle are used as guides while, at the same time, assuring that all the absorption is confined to the outlined zones.

SUMMARY

1. A quantitative paper chromatographic assay has been developed for the assay of 4-dehydro-3-keto steroids using an acidified methanolic solution of isonicotinic acid hydrazide.

2. The procedure is used routinely to measure the stability of a number of sex hormones in oil preparations. The assay of 17α-hydroxyprogesterone caproate and testosterone enanthate are described in detail.

3. The method is simple and accurate and permits the simultaneous visual identification and, if necessary, quantitative measurement of any hydrolytic product.

4. No extraction of the sex hormone is required. A simple dilution prior to chromatography is the only sample preparation required.

5. Accuracies in excess of 95% are obtained by simultaneously chromatographing replicates of standard and sample solutions on the same chromatogram.

Preparation and Pharmacological Properties of Some Benzyl Derivatives of Diphenylacetic Acid

By U. E. JOHNSEN, C. R. JACOBSON†, R. A. LaFORGE‡, and CALVIN HANNA§

Benzyl derivatives of diphenylacetic acid were prepared from the starting material 2-chlorodiphenylacetyl chloride. The compounds synthesized were the N-benzyl derivatives of 2-chloro-, 2-hydroxy-, 2-acetoxy-, 2-dimethylaminoethoxy-, and 2-benzylaminodiphenylacetamide; N-benzyl-N-methyl derivatives of 2-chloro- and 2-hydroxy-diphenylacetamide; O-benzyl derivatives of 2-chloro- and 2-hydroxy-diphenylacetamide; and the compound 2-benzylaminodiphenylacetamide. The compounds have limited aqueous solubility so the full extent of the possible pharmacologic actions could not be studied. These agents orally in doses of 1 Gm./Kg. produced no toxic symptoms but the N-benzyl-N-methyl-2-chloro- and the N-benzyl-2-hydroxy-diphenylacetamides inhibited the passage of a charcoal meal, indicating antispasmodic activity similar in potency to that of atropine. Intravenously, the compounds were without cardiovascular or respiratory effects. Intraperitoneally, N-benzyl-2-hydroxy and N-benzyl-2-acetoxy diphenylacetamides showed antipentamethylene tetrazol activity, and one of these also abolished the convulsive actions of electrical shock.

VARIOUS diphenylacetic acid derivatives have long been of interest as antispasmodic agents. The relatively recent literature indicates that certain compounds containing the diphenylacetyl moiety have also been found to possess sedative or anticonvulsant properties. For example, Billman, *et al.* (1, 2), have studied a series of substituted derivatives of 2-aminodiphenylacetamide possessing both anticonvulsant and antispasmodic activity. Among references in the patent literature, N-acetoxy (diphenylacetyl)acetamide (3) is claimed to be an antiepileptic without untoward effects and having extremely low toxicity in animals.

Also apparent from the recent literature is the frequency with which the benzyl group is found, usually as an amide or ester, in compounds with notable properties as sedatives or anticonvulsants. Kushner, *et al.* (4), also observed that many compounds containing a benzylamide moiety possessed pronounced anticonvulsant activity and their study of a variety of such substances resulted in the development of N-benzyl-β-chloropropionamide. N-Benzylmandelamide has

[a] Melting points are not corrected. [b] Previously described by Lespagnol and Ponthieu (6) who report a melting point of 86°. [c] Previously described by Klinger and Standke (7), m.p. 75–76°.

been reported (5) to be an effective anticonvulsant against electroshock or pentylenetetrazol shock in rats.

These observations suggested the possibility that benzyl amides or esters of substituted diphenylacetic acids might well be active sedative or anticonvulsant agents and, further, might still retain some of the antispasmodic properties more commonly associated with derivatives of these acids.

The compounds of this series, together with pertinent chemical data, are listed in Table I. They were all prepared from 2-chlorodiphenylacetyl chloride which was synthesized from benzilic acid (1). Treatment of this acid chloride with ammonia, benzylamine, or N-benzylmethylamine gave 2-chlorodiphenylacetamide and the substituted 2-chlorodiphenylacetamides (I and II), while reaction with benzyl alcohol produced the benzyl ester (III). The 2-chloro derivatives (I, II, and III), were smoothly converted to the benzilamides (IV and V) or the benzilic acid ester (VI) by warming with aqueous acetone. N-Benzyl-2-chlorodiphenylacetamide (I) reacted with fused sodium acetate in glacial acetic acid to give N-benzyl-2-acetoxydiphenylacetamide (VII), while reaction with sodium 2-dimethylaminoethanolate gave N-benzyl-2-dimethylaminoethoxydiphenylacetamide (VIII). Treatment of 2-chlorodiphenylacetamide and the 2-chloroamide (I) with benzylamine gave the corresponding 2-benzylamino amides (IX and X).

EXPERIMENTAL

2-Chlorodiphenylacetyl Chloride.—This material was prepared by the improved procedure of Billman and Hidy (1) in yields of 70–80%, m.p. 49–50°.

N-Benzyl-2-chlorodiphenylacetamide (I).—Following the procedure of Billman, Ward, and Hidy (2), reaction of 2-chlorodiphenylacetyl chloride with benzylamine in anhydrous ether solution provided an 87% yield of pure N-benzyl-2-chlorodiphenylacetamide.

N-Benzyl-N-methyl-2-chlorodiphenylacetamide (II).—Substitution of N-benzyl-methylamine and dry benzene for benzylamine and anhydrous ether in the above procedure gave a 42% yield of the pure N-benzyl-N-methylamide.

Benzyl 2-chlorodiphenylacetate (III).—Addition of an ether solution of 2-chlorodiphenylacetyl chloride to a chilled ether solution of an equimolar quantity of benzyl alcohol, followed by stirring at room temperature for 24 hours, gave a 45% yield of the benzyl ester after concentration of the reaction solution and crystallization of the oily residue from ligroin.

Benzilic Acid Amides and Ester.—The 2-chlorodiphenylacetamides, (I and II), and the benzyl ester (III), were transformed into the corresponding benzilic acid amides and ester (IV, V, and VI) in 84, 75, and 68% yields, respectively, by refluxing the chloro compounds for 8–12 hours in a 1:3 acetone-water mixture. The products were isolated by concentration of the reaction mixtures and recrystallization of the solid residues from appropriate solvents.

N-Benzyl-2-acetoxydiphenylacetamide (VII).—This compound was prepared by reacting N-benzyl-2-chlorodiphenylacetamide with fused sodium acetate in glacial acetic acid according to the procedure of Emerson, *et al.* (8). The product was isolated in 48% yield by pouring the reaction mixture over ice and recrystallizing the precipitated solid several times from isopropanol.

N-Benzyl-2-dimethylaminoethoxydiphenylacetamide (VIII).—Dropwise addition of a solution of N-benzyl-2-chlorodiphenylacetamide in dry benzene to a benzene suspension of an equimolar quantity of sodium dimethylaminoethanolate, prepared from sodium and dimethylaminoethanol, was followed by refluxing of the reaction mixture for 12 hours. After filtering off the precipitated sodium chloride, the benzene solution was extracted with dilute

hydrochloric acid and the crude product was precipitated by addition of sodium hydroxide solution to the combined acidic extracts. Several recrystallizations from isopropanol afforded a 39% yield of the pure basic ether. The hydrochloride salt of the product decomposes at 192° after recrystallization from a mixture of methanol, isopropanol, and ether. It is not appreciably soluble in water.

2-Chlorodiphenylacetamide.—Addition of gaseous ammonia to a chilled ether solution of 2-chlorodiphenylacetyl chloride, following the method of Bickel (9), gave a pure product, melting at 118–119°, in 90% yield after recrystallization from toluene.

2-Benzylaminodiphenylacetamide (IX).—Benzylamine was reacted with 2-chlorodiphenylacetamide in benzene solution according to the procedure of Billman, Ward, and Hidy (2) to afford a 38% yield of pure product after several recrystallizations from isopropanol.

N-Benzyl-2-benzylaminodiphenylacetamide (X).—This compound was prepared by the above procedure from N-benzyl-2-chlorodiphenylacetamide and benzylamine in 45% yield.

PHARMACOLOGY

Pharmacologic studies were carried out on these compounds using dogs, cats, hamsters, and rats. The full extent of the possible actions of these chemicals could not be determined due to their restricted solubility in aqueous solutions. None of the agents were soluble to the extent of 1% in water or in 25% aqueous dimethylacetamide, and only compounds I and IV appeared to be soluble to the extent of 1% in ethylene glycol at 35°. Wherever possible, the compounds were suspended in water with gum acacia. Toxicity in rats could not be determined.

Doses of 1 Gm./Kg. given orally to rats produced no toxic symptoms. The influence of these agents on the intestinal motility of the small intestine was measured as the inhibition of passage of a charcoal meal, using the method of Macht and Gose. Each compound was suspended in an aqueous solution of 10% charcoal and 10% gum acacia. One milliliter of this suspension was given by stomach tube, and 1 hour later the rats were sacrificed, the intestines removed, and the distance traversed by the charcoal and the length of the intestines were measured. The ten controls averaged 69% with a standard deviation of ±6%. Atropine sulfate in doses of 0.1, 1.0, 2.0, and 3.0 mg./Kg. in 5 animals each was used as a standard of reference, giving the means and standard deviations as follows: 67±5, 62±5, 52±4, 50±4%, respectively. A dose of atropine *vs.* the percentage of the total distance the charcoal meal traversed curve was plotted. The effectiveness of the compounds tested was given in terms of equivalent effective doses of atropine. The test compounds were given in doses up to 0.75 Gm./Kg., and compounds II and VI influenced the intestinal motility. At this dose level, the activity of II and VI were equivalent to that of 1.0 and 0.2 mg./Kg. of atropine, respectively. At a dose level of 1.0 Gm./Kg. with these two agents, the activity of II was equivalent to 3.0 mg./Kg. of atropine and that of VI was equal to 2.0 mg./Kg. of atropine.

Blood pressure studies were made on the pentobarbitalized dog and cat following intravenous injections of 2.0 mg./Kg. of the chemicals in 25% ethanol in isotonic saline. There was only a minimal effect of these compounds on the mean arterial blood pressure; an equivalent amount of 25% ethanol in isotonic saline was used as a control and was found to be without effect on the blood pressure.

These compounds do not appear to be well absorbed orally because of lack of solubility and toxicity, so the intraperitoneal route of injection was used for the anticonvulsant testing. The agents were dissolved in hot 50% ethanol and cooled to 40° just before injection, and the animals in groups of 10 were tested 1 hour later. Control animals given 50% ethanol in saline in the volumes used in the experiments did not show central nervous system effects nor did they differ in convulsant thresholds when compared to saline-treated animals. Anticonvulsant studies were carried out first by the rat subcutaneous pentylenetetrazol test. This demonstrated the activity of the compound being tested to block the convulsions produced by 100 mg./Kg. pentylenetetrazol given subcutaneously. Phenobarbital sodium was used as the standard of comparison.

Due to limited solubility, compounds IV and VII were injected in doses of 100 mg./Kg., while the rest of the compounds were administered in doses of 40 mg./Kg. Only compounds IV and VII showed antipentylenetetrazol activity in doses of 40 mg./Kg. In doses of 100 mg./Kg., compound VII exhibited a minimal activity, while compound IV elicited an effectiveness similar to hypnotic doses of phenobarbital. The second method used was the supramaximal electrical shock test. This showed the ability of the compounds to abolish the hind limb extensor reflex produced by a current of 150 ma. delivered for 0.3 sec. to the brain via the ear electrodes, using the rat. Only compound IV, in doses of 100 mg./Kg., was effective in this respect by abolishing the hind limb extensor reflex in 4 out of the 10 animals.

The "wild" hamster is useful in determining sedative and tranquilizer effects, since the actions of the barbiturates and reserpine are easily differentiated when this animal is hungry and made angry by being picked up by the tail. Intraperitoneal injections of 40 mg./Kg. of these compounds had no effect on this animal.

Analysis of Data on the Medicament Release from Ointments

By W. I. HIGUCHI

An analysis of some recently published data on the sodium radioiodide release from hydrophilic ointment bases is presented and discussed. The release dependence on time and the value for the effective diffusion coefficient are compared with theoretical predictions. The generally good agreement between theory and data demonstrates the potential usefulness of the theoretical relationships in both experimental design and data evaluation. The simplicity of some of the theoretical equations is indicated.

RECENT THEORETICAL investigations (1, 2) of drug release from ointments resulted in equations which were expected to be useful in describing ointment release rates. Because of the lack of availability of suitable data at the time, the applicability of these mathematical relationships to real situations was not experimentally demonstrated. Recently, however, Patel, Banker, and DeKay reported (3) results of some studies on sodium radioiodide release from hydrophilic ointment bases. Because an examination of their data with the appropriate theoretical relationships appeared to add to the better basic understanding of ointment behavior, this report was prepared for presentation at this time.

Higuchi deduced (1) the following equation for the amount of drug released from (one side of) a layer of ointment in which the drug is initially uniformly dissolved

$$Q = hC_0 \left[1 - \frac{8}{\pi^2} \sum_{m=0}^{\infty} \frac{1}{(2m+1)^2} \exp \left(- \frac{D(2m+1)^2 \pi^2 t}{4h^2} \right) \right] \quad \text{(Eq. 1)}$$

where Q = amount of drug released per unit area of application, h = thickness of layer, C_0 = initial concentration of drug in ointment, D = diffusion coefficient of drug in the ointment, t = time after application, m = integer, as indicated, goes from 0 to ∞.

The per cent released, R, is then simply

$$R = \frac{100Q}{hC_0} = 100 \left[1 - \frac{8}{\pi^2} \sum_{m=0}^{\infty} \frac{1}{(2m+1)^2} \exp \left(- \frac{D(2m+1)^2 \pi^2 t}{4h^2} \right) \right] \quad \text{(Eq. 2)}$$

Equation 1 is a solution to Fick's law of diffusion which is extensively described in a number of textbooks (4, 5). The main assumptions involved in Eq. 1, in practical language, are (*a*) that only a single drug species is important in the ointment, (*b*) that D must be constant with respect to both time and position in the ointment layer, (*c*) that only the drug is able to diffuse out of the layer, i. e., components of the vehicle cannot diffuse out (or evaporate), and finally (*d*) that the drug reaching the receptor side of the ointment layer is removed rapidly (means the same as the boundary condition: concentration of drug = 0 at receptor-ointment boundary for $t > 0$).

The experimental method described by Patel, Banker, and DeKay appears to conform approximately to all of the above requirements for the applicability of Eq. 1. Thus, a direct comparison of their data with Eq. 1 would seem to be justified. The difficulty with the idea of attempting a direct quantitative test is that the value of D is difficult to estimate for such complex systems as those studied by Patel, Banker, and DeKay. Therefore, the most profitable approach would be to consider first only the time-dependent part of the equation by selecting a value for D which gives the best overall fit for each set of data. Thus for each set of data one must choose the best single D value, which when placed into Eq. 2, will give the best agreement between the particular set of data and Eq. 2. This means effectively forcing a fit between data and theory at one point for each set of data. The agreement of the rest of the data for a particular set would constitute a test of the time-dependent portion of the theory. Then these chosen D values could be examined independently in light of the expected structure of the vehicle and with the mathematical relationships for D in heterogeneous systems (2).

TIME DEPENDENCE

In Fig. 1 representative sets of data taken from the work of Patel, Banker, and DeKay are given (circles). The different sets of data refer to sodium radioiodide release from bases[1] containing different surfactants or different amounts as indicated in the figure. The curves represent values predicted by Eq. 2 with a single value of D for each set of data.

The agreement of the time-dependent portion of Eq. 2 with the data is highly satisfactory indicating that the idealized conditions had been well approximated by the experimental method. These results support the assumptions (under assumption *d* above) that the Visking membrane in these experiments contributed negligibly to the release resistance and that stirring in the solution on the other side of the membrane was rapid enough to prevent buildup of a liquid diffusion layer of any

The author is grateful to Professor DeKay for helpful correspondence.

[1] The reader is referred to the original work (3) for complete description of ointment bases. Except for the surfactant used, each base contained essentially the same ingredients and the same amounts of them as those in the official hydrophilic ointment U.S. P. XVI.

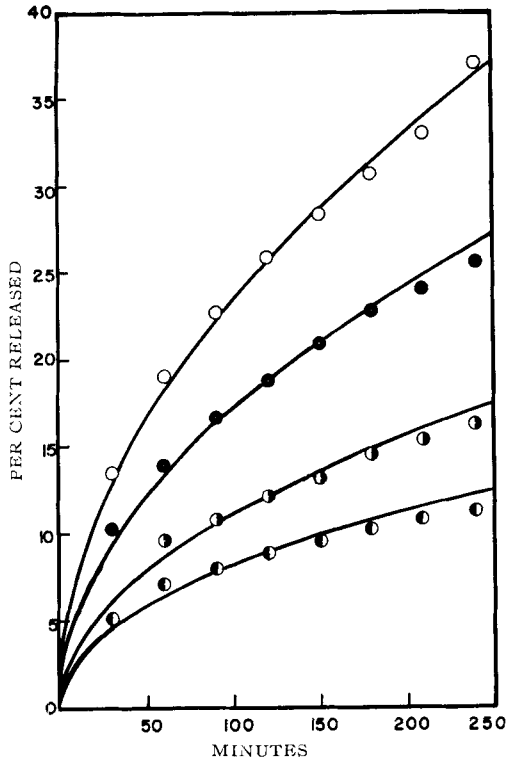

Fig. 1.—Comparison of data with theory for release from ointment base. Circles give data of Patel, Banker, and DeKay. Smooth curves obtained from Eq. 2 and a single adjustable parameter. ○, Sipon ES, 1%; ●, Sipon ES, 2%; ◑, Maprofix TLS, 3%; ◐, Catanac SN, 3%.

importance. If such were not the case, there would have been deviations of the data in the direction of less curvature than theory. Actually, the small deviations present are consistently in the opposite direction. The good agreement also supports the expected constancy of D (assumption b). This is reasonable in view of the diluteness of the sodium radioiodide in the vehicle.

It is worth while to point out at this time that for most practical applications of Eqs. 1 and 2, simplified forms of these equations may be used. When the per cent released, R, is not too large, i. e., for $R \lesssim 30\%$, it can be easily shown that

$$Q = 2\,C_0 \left(\frac{Dt}{\pi}\right)^{1/2} \qquad \text{(Eq. 3)}$$

and

$$R = 200 \left(\frac{Dt}{\pi h^2}\right)^{1/2} \qquad \text{(Eq. 4)}$$

These "square root" approximations should hold rather well for most studies of practical importance. The simplicity of Eqs. 3 and 4 makes the use of the theory very convenient.

EFFECTIVE OINTMENT DIFFUSION COEFFICIENTS

The values for the effective experimental diffusion coefficients derived from the data-theory fitting process described above are given in Table I.

Let us now see how these D values compare with the expected value based on our scanty knowledge

TABLE I.—EFFECTIVE DIFFUSION COEFFICIENTS OF SODIUM RADIOIODIDE IN OINTMENT BASES DETERMINED[a] FROM RELEASE DATA AT 37°

Base Designation	D (cm.^{2} sec.$^{-1}$)
Sipon ES, 1%	3.6×10^{-6}
Sipon ES, 2%	2.0×10^{-6}
Maprofix TLS, 3%	0.80×10^{-6}
Catanac SN, 3%	0.43×10^{-6}

[a] The value $h = 0.7$ cm. (3) was employed in these calculations.

of the detailed structure of these ointment bases. Since these hydrophilic bases are oil-in-water emulsions, the external phase is aqueous and presumably should represent about 40 to 50% of the total volume [corresponding to the 37% water and 12% propylene glycol by weight used (3)]. On the basis of what we know we could make both an upper limit estimate and a less exact "probable value" estimate of the effective diffusion coefficient.

For the upper limit estimate we assume that (a) sodium radioiodide is distributed only in the aqueous phase, that (b) it is able to diffuse only in the aqueous phase (i. e., zero diffusion coefficient in the internal phase), and that (c) the diffusion coefficient in the aqueous phase is the same as that in pure water. Note that assumption c makes this estimate an upper limit one. We may then write a relationship (2) for the effective diffusion coefficient in heterogeneous system where the internal phase may be considered to be impenetrable spheres

$$D_e = \frac{1.61 D_1}{3 - 1.39 V_1} \qquad \text{(Eq. 5)}$$

where D_e is the effective diffusion coefficient, D_1 is the diffusion coefficient in the external phase, and V_1 is the volume fraction of the external phase. Equation 5 appears to be a relatively good relationship for diffusion data (2) on suspensions of glass spheres, powders, sand, etc. For our calculation, if we take $V_1 \approx 0.45$, Eq. 5 gives $D_e \approx 0.7 D_1$. Now the literature value (6) for the diffusion coefficient of sodium iodide in water at 25° is 1.5×10^{-5} cm.^{2} sec.$^{-1}$. At 37° the value would be[2] about 1.9×10^{-5} cm.^{2} sec.$^{-1}$. Therefore, at 37°, $D_e \approx 1.3 \times 10^{-5}$ cm.^{2} sec.$^{-1}$, which is only about 3.6 times greater than the largest D value in Table I.

Now a "probable value" estimate can be made if it is permissible to assume that essentially all of the propylene glycol is in the aqueous phase. This consideration will make D_e smaller by about a factor of two[3] or so (with an uncertainty, say, about one-half of this).

The above analysis, although crude, clearly supports the expected mechanism of release. Sipon ES, 1%, represents a base with just about the maximum rate of release, i. e., further changes in surfactant or surfactant concentration should not increase the per cent release rate by a great deal. More independent information on these systems is needed before the dependence of D on surfactant type and surfactant concentration (see Table I) can be logically explained.

[2] Both Stokes-Einstein equation and data on similar systems predict this.

[3] Stokes-Einstein equation prediction (inverse proportionality with viscosity). Viscosity estimates inferred from other systems.

CONCLUSIONS

The analyses of the data of Patel, Banker, and DeKay by means of theory demonstrates the possible usefulness of the quantitative theory in future studies. Simple relations could be employed to help evaluate the proposed mechanisms. It would be of interest to investigate experimentally other types of ointments, e. g., the water-in-oil type, suspension type, bound drug type, etc., and compare results with appropriate theoretical relationships (1, 2).

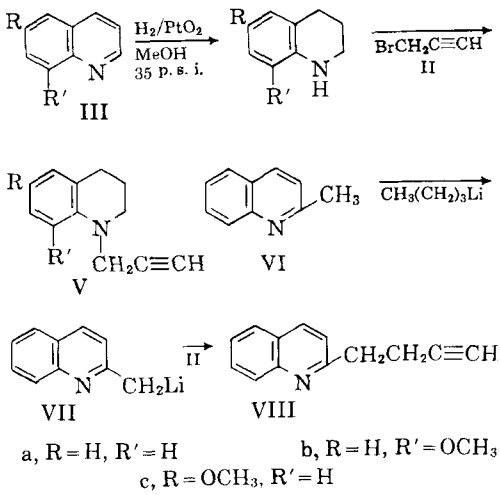
Synthesis of Some Monoamino Alkynes

By JOHN L. NEUMEYER† and JOSEPH G. CANNON‡

The preparation of a series of monoamino alkynes has been undertaken. A method of reduction of the substituted and unsubstituted quinolines to their corresponding tetrahydro derivatives is presented. Some of the monoamino alkynes showed weak fungicidal activity against *T. mentagrophytes*.



DURING THE COURSE of the investigation of a series of unsymmetrically alkylated acetylenic bis-quaternary ammonium compounds, it was necessary to prepare a series of monoamino alkynes (I)

$$RCH_2C{\equiv}CH$$
I

R = Pyrrolidino, diethylamino, 1,2,3,4-tetrahydroquinolino, 6-methoxy-1,2,3,4-tetrahydroquinolino, 8-methoxy - 1,2,3,4 - tetrahydroquinolino, 2 - quinolyl methyl

The structural similarity of certain of these intermediates to a series of 8-hydroxy-2-quinoline acrylic acids, prepared by Vaidya and Cannon (1), exhibiting fungicidal activity, prompted us to screen these compounds as potential fungicides. Preliminary screening against *T. mentagrophytes*, and *C. albicans* revealed that some of these compounds showed fungicidal activity against *T. mentagrophytes* at concentrations of 100–500 mcg./ml.

Propargyl bromide (II) was employed as the alkylating agent for the preparation of these compounds by the following routes.

a, R = H, R′ = H b, R = H, R′ = OCH_3

c, R = OCH_3, R′ = H

The catalytic reduction of quinoline and of the 6- and 8-methoxy-quinolines (III a, b, and c) was based on a method of Skita and Meyer (2) who reduced quinoline to decahydro- and tetrahydroquinoline with platinum chloride in glacial acetic acid. Employing platinum oxide (Adams) in methanol at 35 p.s.i., we successfully reduced the quinolines III a, b, and c to their respective tetrahydro derivatives in 80–96% yields. Propargyl bromide (II) was then treated with a 1-molar excess of the appropriate tetrahydroquinoline in isopropyl alcohol. The formation of quaternary propargyl halide salts was prevented by adding the propargyl bromide slowly to the amine. The alkynyl amines could be readily purified by fractional distillation

at reduced pressure. A 2-quinolyl derivative was prepared by treating *n*-butyl lithium with quinaldine (VI); the resulting 2-(lithio methyl) quinoline (VII) was condensed with an equimolar quantity of propargyl bromide, to yield 2-(3-butynyl) quinoline (VIII).

EXPERIMENTAL

All melting points were obtained in a Hershberg-type, silicone filled melting point apparatus equipped with Anschutz immersion thermometers. The samples were placed in the circulating silicone bath 10° below the melting points and heated at the rate of 1–2° per minute. Elemental analyses were performed by Drs. Weiler and Strauss, Oxford, England, and Huffman Microanalytical Laboratories, Wheatridge, Colo. Infrared spectra were determined on a Beckman IR-5 double-beam infrared recording spectrophotometer.

A. Substituted 1,2,3,4-tetrahydroquinolines

8 - Methoxy - 1,2,3,4 - tetrahydroquinoline.—8-Hydroxyquinoline was converted to 8-methoxyquinoline with dimethyl sulfate in 53% yield by the method of Vogel (3) m.p. 45–46° [Kaufman and Rothlin (4) reported 46–47°]. Eight grams (0.05 mole) of 8-methoxyquinoline in 100 ml. of methanol was hydrogenated in a Parr hydrogenation apparatus using 0.4 Gm. of platinum oxide as the catalyst; the calculated amount of hydrogen was absorbed in 50 minutes. The product was isolated by removing the catalyst by filtration, evaporating the solvent under reduced pressure, and fractionally distilling the residue, b.p. 94–98° (0.75 mm.), yield 7 Gm. (87%); n_D^{26} 1.5846.

Anal.—Calcd. for $C_{10}H_{13}NO$: C, 73.60; H, 7.98; N, 8.60. Found: C, 73.82; H, 7.83; N, 9.02.

The benzenesulfonamide of this secondary amine was prepared by shaking 0.5 Gm. of the amine in 25 ml. of 5% solution of sodium hydroxide and 1 Gm. of benzenesulfonyl chloride. An oil separated which, after standing for several days, crystallized. The yellow needles were recrystallized several times from 95% ethanol to yield a white crystalline product, m.p. 91.8–92.4°.

Anal.—Calcd. for $C_{16}H_{17}NO_3S$: C, 63.29; H, 5.65; N, 4.62. Found: C, 63.07; H, 5.30; N, 4.90.

6-Methoxy-1,2,3,4-tetrahydroquinoline (Thalline).—Twenty-five grams (0.157 mole) of 6-methoxyquinoline (Eastman white label) in 100 ml. of methanol was hydrogenated in a Parr hydrogenation apparatus using 0.4 Gm. of platinum oxide as the catalyst. The calculated amount of hydrogen was absorbed in 19 hours. The product was purified by vacuum distillation to give 24 Gm. (96% yield) of a pale yellow oil b.p. 84–85° (0.01 mm.). The oil solidified on cooling and the compound was recrystallized from 95% ethanol, m.p. 40–42°. [Cromwell (5) using a copper chromite catalyst under a pressure of 1800 lbs./sq. in. at 180° reported a product with a m.p. 42–43° in 93% yield.]

B. 3-Amino-1-propynes

To 1.0 mole of secondary amine in 150 ml. of anhydrous ethyl ether was added, with stirring,

59.5 Gm. (0.5 mole) of propargyl bromide (Aldrich Chemical Co.). The mixture was stirred at reflux for 12 hours. The ether solution was decanted from the oily amine hydrobromide layer, and the latter was extracted three times with ether. The ether was evaporated from the combined ether extracts and the residue was fractionated at reduced pressure (see Table I). The hydrochloride salts were prepared by passing dry hydrogen chloride through ether solutions of the amines. The precipitated salts were collected on a filter, washed with ether and were recrystallized (see Table I).

C. Aminoalkynyltetrahydroquinolines

To 0.18 mole of a freshly distilled 1,2,3,4-tetrahydroquinoline in 35 ml. of isopropyl alcohol was added 10.7 Gm. (0.09 mole) of propargyl bromide over a period of 30 minutes with stirring. The reaction mixture was refluxed 2 hours, then the mixture was cooled to 4° and was allowed to stand for 12 hours. The precipitate of the 1,2,3,4-tetrahydroquinoline hydrobromide was removed by filtration, and the filtrate was subjected to fractional distillation (see Table I).

The hydrochloride salts were prepared by passing dry hydrogen chloride through an ether solution of the amine. The precipitated salts were collected on a filter, washed with ether, and were recrystallized (see Table I).

D. 2-(3-Butynyl)quinoline

2-(Lithio methyl)-quinoline was synthesized by the method of Cannon (6) for the preparation of 1-(lithio methyl) isoquinoline. To the ethereal solution containing 0.1 mole of 2-(lithio methyl)-quinoline was added, in a slow stream and with stirring, a solution of 11.9 Gm. (0.1 mole) of propargyl bromide in 100 ml. of anhydrous ether. The solution turned a deep purple color and a moderate boiling ensued. As additional organic halide was added the purple color became fainter and finally disappeared. Stirring was continued overnight at room temperature, during which time a brown precipitate formed. Stirring was continued while 100 ml. of distilled water was slowly added. The aqueous layer was removed and discarded and the ethereal solution which also contained a considerable quantity of a brown precipitate was filtered and washed several times with water. After drying with anhydrous magnesium sulfate and filtering, the ether was removed from the filtrate on a steam bath and the brown-black oily residue was distilled under reduced pressure (see Table I). $\lambda_{max.\mu}^{film}$ 3.05 (=CH stretching), m 4.70 (—C≡C— stretching.)

E. Fungicidal Activity

Fungicidal activity was evaluated by a serial dilution procedure, utilizing Sabouraud's medium. The tubes were incubated at 25°; turbidimetric and growth readings were taken after 48 hours.

Some 1,2,3,4-Benzothiatriazine 1,1-Dioxides

By SCOTT J. CHILDRESS

1,2,3,4-Benzothiatriazine 1,1-dioxide analogs of chlorothiazide have been prepared and tested for diuretic activity.

NOVELLO and Sprague (1) in 1957 reported the synthesis and diuretic activity of 6-chloro-7-sulfamyl-1,2,4-benzothiadiazine 1,1-dioxide (chlorothiazide). Since then numerous analogs have been described (2). There are no specific structural requirements for activity except for the presence of a sulfamyl group and even this can be substituted (3). It seemed to be of interest to prepare some substituted 1,2,3,4-benzothiatriazine 1,1-dioxides and examine them for diuretic activity.

Received October 18, 1961, from the Research and Development Division, Wyeth Laboratories, Inc., Radnor, Pa.
Accepted for publication October 25, 1961.

In order to isolate stable compounds, it was necessary to have an alkyl group in the 2-position. For convenience in synthesis, the 7-sulfamyl group was also substituted by an alkyl group. It did not seem that such substitution would destroy any potential activity in the benzothiatriazine 1,1-dioxides, for 5-chloro-2,4-bis-(methylsulfamyl)aniline, an intermediate, is reported to have diuretic properties (4). Also, methyl and isopropyl substituents in sulfamyl groups are removed metabolically in some cases (5).

The desired benzothiatriazine 1,1-dioxides were prepared by treatment of the appropriate 5-chloro-2,4-bis-(alkylsulfamyl)aniline with nitrous acid (6). The intermediates are listed in Table I and the products in Table II. The benzothiatriazine 1,1-dioxides proved to have statistically significant diuretic activity in rats (7).

59.5 Gm. (0.5 mole) of propargyl bromide (Aldrich Chemical Co.). The mixture was stirred at reflux for 12 hours. The ether solution was decanted from the oily amine hydrobromide layer, and the latter was extracted three times with ether. The ether was evaporated from the combined ether extracts and the residue was fractionated at reduced pressure (see Table I). The hydrochloride salts were prepared by passing dry hydrogen chloride through ether solutions of the amines. The precipitated salts were collected on a filter, washed with ether and were recrystallized (see Table I).

C. Aminoalkynyltetrahydroquinolines

To 0.18 mole of a freshly distilled 1,2,3,4-tetrahydroquinoline in 35 ml. of isopropyl alcohol was added 10.7 Gm. (0.09 mole) of propargyl bromide over a period of 30 minutes with stirring. The reaction mixture was refluxed 2 hours, then the mixture was cooled to 4° and was allowed to stand for 12 hours. The precipitate of the 1,2,3,4-tetrahydroquinoline hydrobromide was removed by filtration, and the filtrate was subjected to fractional distillation (see Table I).

The hydrochloride salts were prepared by passing dry hydrogen chloride through an ether solution of the amine. The precipitated salts were collected on a filter, washed with ether, and were recrystallized (see Table I).

D. 2-(3-Butynyl)quinoline

2-(Lithio methyl)-quinoline was synthesized by the method of Cannon (6) for the preparation of 1-(lithio methyl) isoquinoline. To the ethereal solution containing 0.1 mole of 2-(lithio methyl)-quinoline was added, in a slow stream and with stirring, a solution of 11.9 Gm. (0.1 mole) of propargyl bromide in 100 ml. of anhydrous ether. The solution turned a deep purple color and a moderate boiling ensued. As additional organic halide was added the purple color became fainter and finally disappeared. Stirring was continued overnight at room temperature, during which time a brown precipitate formed. Stirring was continued while 100 ml. of distilled water was slowly added. The aqueous layer was removed and discarded and the ethereal solution which also contained a considerable quantity of a brown precipitate was filtered and washed several times with water. After drying with anhydrous magnesium sulfate and filtering, the ether was removed from the filtrate on a steam bath and the brown-black oily residue was distilled under reduced pressure (see Table I). $\lambda_{max.\mu}^{film}$ 3.05 (=CH stretching), m 4.70 (—C≡C— stretching.)

E. Fungicidal Activity

Fungicidal activity was evaluated by a serial dilution procedure, utilizing Sabouraud's medium. The tubes were incubated at 25°; turbidimetric and growth readings were taken after 48 hours.

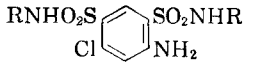
Some 1,2,3,4-Benzothiatriazine 1,1-Dioxides

By SCOTT J. CHILDRESS

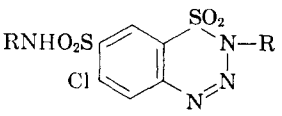
1,2,3,4-Benzothiatriazine 1,1-dioxide analogs of chlorothiazide have been prepared and tested for diuretic activity.



NOVELLO and Sprague (1) in 1957 reported the synthesis and diuretic activity of 6-chloro-7-sulfamyl-1,2,4-benzothiadiazine 1,1-dioxide (chlorothiazide). Since then numerous analogs have been described (2). There are no specific structural requirements for activity except for the presence of a sulfamyl group and even this can be substituted (3). It seemed to be of interest to prepare some substituted 1,2,3,4-benzothiatriazine 1,1-dioxides and examine them for diuretic activity.

Received October 18, 1961, from the Research and Development Division, Wyeth Laboratories, Inc., Radnor, Pa.
Accepted for publication October 25, 1961.

In order to isolate stable compounds, it was necessary to have an alkyl group in the 2-position. For convenience in synthesis, the 7-sulfamyl group was also substituted by an alkyl group. It did not seem that such substitution would destroy any potential activity in the benzothiatriazine 1,1-dioxides, for 5-chloro-2,4-bis-(methylsulfamyl)aniline, an intermediate, is reported to have diuretic properties (4). Also, methyl and isopropyl substituents in sulfamyl groups are removed metabolically in some cases (5).



The desired benzothiatriazine 1,1-dioxides were prepared by treatment of the appropriate 5-chloro-2,4-bis-(alkylsulfamyl)aniline with nitrous acid (6). The intermediates are listed in Table I and the products in Table II. The benzothiatriazine 1,1-dioxides proved to have statistically significant diuretic activity in rats (7).

TABLE I.—INTERMEDIATES FOR BENZOTHIATRIAZINE 1,1-DIOXIDES

EXPERIMENTAL

5-Chloro-2,4-bis-(alkylsulfamyl)anilines.—The required intermediates, 5-chloro-2,4-bis-(alkylsulfamyl)anilines (Table I), were prepared by treating an alcoholic or aqueous solution of 4 equivalents of the appropriate amine with crude 5-chloro-2,4-bis-(chlorosulfonyl)aniline prepared by the method of Novello (8). The products were recrystallized from alcohol.

2-Benzyl-7-benzylsulfamyl-6-chloro-1,2,3,4-benzothiatriazine 1,1-Dioxide.—A suspension of 7.8 Gm. of 5-chloro-2,4-bis-(benzylsulfamyl)aniline in 22 ml. of acetic acid and 1 ml. of water was treated with a solution of 1.2 Gm. of sodium nitrite in 9 ml. of sulfuric acid, keeping the temperature below 20°. The mixture was filtered and the filtrate was diluted with water. The gummy precipitate was washed with alcohol and recrystallized from acetone by addition of water, affording 5.5 Gm. of cream-colored crystals.

The other compounds (Table II) were prepared similarly. They showed positive diazo coupling tests with alkaline β-naphthol. Dumas nitrogen analyses were erratic.

Synthetic Polymers as Potential Enteric and Sustained-Release Coatings

Sir:

We wish to report pharmaceutical applications of various copolymers as potential enteric and sustained-release coatings. These coatings are based on a series of partial esters (ethyl through decyl) of water-soluble copolymers of maleic anhydride with ethylenic compounds, *e.g.*, ethylene or vinyl methyl ether (1). Preliminary results indicate that films of these polymeric derivatives are brilliantly clear, chemically and physically stable, and nontoxic. Variations in ester chain length and degree of esterification effect a gradation in dissolution pH.

An increase in ester chain length for the essentially one-half ester produces a corresponding increase in dissolution pH. This highly significant property permits the design of pharmaceuticals which release their medicament only upon reaching a specific intestinal pH. Thus, specific coatings may be selected in order to obtain maximum therapeutic effect from those drugs which are absorbed in various areas of the intestinal tract. This effect on absorption by the gradation in dissolution pH is illustrated in Table I by the plasma salicylate levels from enteric coated acetylsalicylic acid tablets. Complete physiological availability (relative to a control) was obtained.

TABLE I.—PLASMA SALICYLATE LEVELS[a]

Coating Polymer	2 hr. Level, mcg./ml.	Peak Level, mcg./ml.	Peak Time,[b] hr.
Uncoated	38	38	2
1/2 Ethyl PVM/MA[c]	11	38	4
1/2 Isopropyl PVM/MA[c]	6	34	5
1/2 *n*-Butyl PVM/MA[c]	1	26	8

[a] Following administration of 652 mg. of acetylsalicylic acid to fasting patients. [b] Time of maximum plasma level. [c] Copolymer of vinyl methyl ether and maleic anhydride.

Sustained release may be obtained in two ways for those drugs which are well absorbed throughout the gastrointestinal tract. First, a series of polymer coatings dissolving at different pH may be used to coat small portions of the dose. Second, the rate of solubility of a coating based on a single polymeric ester can be decreased as desired by the addition of suitable extenders. In both instances, initial levels may be obtained by the administration of uncoated drug.

A comprehensive report on the characterization, coating techniques, and clinical evaluation will be forthcoming.

Directory of the American Council of Independent Laboratories, Inc. 8th ed. American Council of Independent Laboratories, 4302 East-West Highway Washington 14, D. C., 1961. xi + 114 pp. 17 × 25.5 cm. Paperbound.

The eighth edition (1961) of the ACIL Directory is available, without charge, to industrial and government executives from the above address. Specific services of the member laboratories are indicated.

Experimental Pharmacognosy. 3rd ed. By VARRO E. TYLER, JR., and ARTHUR E. SCHWARTING. Burgess Publishing Co., 426 South Sixth St., Minneapolis 15, Minn., 1962. v + 104 pp. 21 × 27.5. cm. Paperbound.

Major changes in the 3rd edition of this laboratory teaching guide are included in the section on biochemical processes and are demonstrated in exercises relating to biosyntheses of clavine alkaloids, tetracycline antibiotics, and a heteroglucoside.

A new Dictionary of Chemistry. 3rd. ed. Edited by L. MACKENZIE MIALL. Interscience Division, John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1962. vii + 593 pp. 15.5 × 23 cm. Price $13.75

A useful source of limited information, judiciously selected in many fields of chemistry and related sciences. Concise references to important contributors to the sciences, historically and recent, are helpful and interesting.

Choix de Techniques de Biochimie Clinique. By GUY DEVAUX. Gauthier-Villars & Cie., 55, Quai des Grands-Augustins, Paris, France, 1961. 220 pp. 21 × 27 cm. Price 30 NF.

Selected procedures in clinical biochemistry are described (in French). The text is divided into "explorations" of hydro-mineral, glucidic, lipidic, and protidic metabolisms, biocatalysis, and functional reactions of the organs and fluids. A chart for the determination of Ambard's constant is appended.

Biochemical Mechanisms. By LLOYD L. INGRAHAM. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1962. x + 108 pp. 15 × 23 cm. Price $5.75.

General mechanistic principles of chemistry that are of value in considerations of biochemistry are covered in Part I. Specific biochemical mechanisms in Part II are concerned with solution chemistry, model systems, and comparison of enzymic reaction with model reactions.

The Mechanism of Action of Water-Soluble Vitamins. Edited by A. V. S. DE REUCK and MAEVE O'CONNOR. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. viii + 120 pp. 12.5 × 18.5 cm. Price $2.50.

A compilation of five papers and discussions of a Ciba Foundation study group held April 1962.

Volkstümliche Namen der Arzneimittel, Drogen Heilkräuter und Chemikalien. 15th ed. Edited by JOHANNES ARENDS. Springer-Verlag, Berlin Wilmersdorf, Dept. VI, Heidelberger Platz 3, West Berlin, Germany, 1962. vi + 418 pp. 12.5 × 18.5 cm. Price DM 18.60.

A dictionary of common German names for plant drugs, medicinal compounds and dosage forms, and chemicals. The usual entry gives the equivalent Latin name.

Problems in Communication. Edited by CHARLES WATKINS and BENJAMIN PASAMANICK. The American Psychiatric Association, 1700 Eighteen St., N.W. Washington 9, D. C., 1961. 131 pp. 15 × 23 cm. Paperbound. Price $2.

A compilation of papers and discussions at the Regional Research Conference held January 1960 at New Orleans. Subjects covered are: Signals, signs, and symbols; mythological behavior; Is it true? Or is it so?; Psychomotility; Psychophysiological reactions of "normals" and patients; The first-year medical student: problems in the development of perceptiveness and self-awareness.

Organophosphorus Poisons. By D. F. HEATH. Pergamon Press Ltd., Headington Hill Hall, Oxford, England, 1961. vii + 403 pp. 15 × 23 cm. Price $12.50.

Intended for use mainly as a reference source for researchers, this book covers the fundamental aspects of the chemistry, biochemistry, and pharmacology of organophosphorus compounds which are anticholinesterases or are metabolized *in vivo* to anticholinesterases. An appendix discusses the theory of reaction rates in solution. Chemical and common names are tabulated and a good general index is appended.

Year Book of Drug Therapy. 1961–1962 Series. Edited by HARRY BECKMAN. Year Book Medical Publishers, Inc., 200 East Illinois St., Chicago 11, Ill., 1962. 659 pp. 13 × 19.5 cm. Price $8.50.

Excellent reviews of published medical reports for the year ending September 1961 are given in the author's style. Dr. Beckman's own critical evaluation of the year's new drugs (blue pages) is interesting. Author and subject indexes are appended.

Punch-Card Methods in Research and Documentation. By MARTIN SCHEELE. Interscience Publishers, Inc. 250 Fifth Ave., New York 1, N. Y., 1961. xiv + 274 pp. 16 × 23 cm. Price $9.50.

This book, an English translation of a German text, covers terminology, technology, and methodology. It includes general rules and gives examples. Special emphasis is given to biology throughout the text. This is the second volume in a series on Library Science and Documentation. The first volume was "Tools for Machine Literature Searching."

Directory of the American Council of Independent Laboratories, Inc. 8th ed. American Council of Independent Laboratories, 4302 East-West Highway Washington 14, D. C., 1961. xi + 114 pp. 17 × 25.5 cm. Paperbound.

A compilation of papers and discussions at the Regional Research Conference held January 1960 at New Orleans. Subjects covered are: Signals, signs, and symbols; mythological behavior; Is it true? Or is it so?; Psychomotility; Psychophysiological reactions of "normals" and patients; The first-year medical student: problems in the development of perceptiveness and self-awareness.

Organophosphorus Poisons. By D. F. HEATH. Pergamon Press Ltd., Headington Hill Hall, Oxford, England, 1961. vii + 403 pp. 15 × 23 cm. Price $12.50.

Intended for use mainly as a reference source for researchers, this book covers the fundamental aspects of the chemistry, biochemistry, and pharmacology of organophosphorus compounds which are anticholinesterases or are metabolized *in vivo* to anticholinesterases. An appendix discusses the theory of reaction rates in solution. Chemical and common names are tabulated and a good general index is appended.

Year Book of Drug Therapy. 1961–1962 Series. Edited by HARRY BECKMAN. Year Book Medical Publishers, Inc., 200 East Illinois St., Chicago 11, Ill., 1962. 659 pp. 13 × 19.5 cm. Price $8.50.

Excellent reviews of published medical reports for the year ending September 1961 are given in the author's style. Dr. Beckman's own critical evaluation of the year's new drugs (blue pages) is interesting. Author and subject indexes are appended.

Punch-Card Methods in Research and Documentation. By MARTIN SCHEELE. Interscience Publishers, Inc. 250 Fifth Ave., New York 1, N. Y., 1961. xiv + 274 pp. 16 × 23 cm. Price $9.50.

This book, an English translation of a German text, covers terminology, technology, and methodology. It includes general rules and gives examples. Special emphasis is given to biology throughout the text. This is the second volume in a series on Library Science and Documentation. The first volume was "Tools for Machine Literature Searching."

Directory of the American Council of Independent Laboratories, Inc. 8th ed. American Council of Independent Laboratories, 4302 East-West Highway Washington 14, D. C., 1961. xi + 114 pp. 17 × 25.5 cm. Paperbound.

The eighth edition (1961) of the ACIL Directory is available, without charge, to industrial and government executives from the above address. Specific services of the member laboratories are indicated.

Experimental Pharmacognosy. 3rd ed. By VARRO E. TYLER, JR., and ARTHUR E. SCHWARTING. Burgess Publishing Co., 426 South Sixth St., Minneapolis 15, Minn., 1962. v + 104 pp. 21 × 27.5. cm. Paperbound.

Major changes in the 3rd edition of this laboratory teaching guide are included in the section on biochemical processes and are demonstrated in exercises relating to biosyntheses of clavine alkaloids, tetracycline antibiotics, and a heteroglucoside.

A new Dictionary of Chemistry. 3rd. ed. Edited by L. MACKENZIE MIALL. Interscience Division, John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1962. vii + 593 pp. 15.5 × 23 cm. Price $13.75

A useful source of limited information, judiciously selected in many fields of chemistry and related sciences. Concise references to important contributors to the sciences, historically and recent, are helpful and interesting.

Choix de Techniques de Biochimie Clinique. By GUY DEVAUX. Gauthier-Villars & Cie., 55, Quai des Grands-Augustins, Paris, France, 1961. 220 pp. 21 × 27 cm. Price 30 NF.

Selected procedures in clinical biochemistry are described (in French). The text is divided into "explorations" of hydro-mineral, glucidic, lipidic, and protidic metabolisms, biocatalysis, and functional reactions of the organs and fluids. A chart for the determination of Ambard's constant is appended.

Biochemical Mechanisms. By LLOYD L. INGRAHAM. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1962. x + 108 pp. 15 × 23 cm. Price $5.75.

General mechanistic principles of chemistry that are of value in considerations of biochemistry are covered in Part I. Specific biochemical mechanisms in Part II are concerned with solution chemistry, model systems, and comparison of enzymic reaction with model reactions.

The Mechanism of Action of Water-Soluble Vitamins. Edited by A. V. S. DE REUCK and MAEVE O'CONNOR. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. viii + 120 pp. 12.5 × 18.5 cm. Price $2.50.

A compilation of five papers and discussions of a Ciba Foundation study group held April 1962.

Volkstümliche Namen der Arzneimittel, Drogen Heilkräuter und Chemikalien. 15th ed. Edited by JOHANNES ARENDS. Springer-Verlag, Berlin Wilmersdorf, Dept. VI, Heidelberger Platz 3, West Berlin, Germany, 1962. vi + 418 pp. 12.5 × 18.5 cm. Price DM 18.60.

A dictionary of common German names for plant drugs, medicinal compounds and dosage forms, and chemicals. The usual entry gives the equivalent Latin name.

Problems in Communication. Edited by CHARLES WATKINS and BENJAMIN PASAMANICK. The American Psychiatric Association, 1700 Eighteen St., N.W. Washington 9, D. C., 1961. 131 pp. 15 × 23 cm. Paperbound. Price $2.

A compilation of papers and discussions at the Regional Research Conference held January 1960 at New Orleans. Subjects covered are: Signals, signs, and symbols; mythological behavior; Is it true? Or is it so?; Psychomotility; Psychophysiological reactions of "normals" and patients; The first-year medical student: problems in the development of perceptiveness and self-awareness.

Biochemical Mechanisms. By LLOYD L. INGRAHAM. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1962. x + 108 pp. 15 × 23 cm. Price $5.75.

General mechanistic principles of chemistry that are of value in considerations of biochemistry are covered in Part I. Specific biochemical mechanisms in Part II are concerned with solution chemistry, model systems, and comparison of enzymic reaction with model reactions.

The Mechanism of Action of Water-Soluble Vitamins. Edited by A. V. S. DE REUCK and MAEVE O'CONNOR. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. viii + 120 pp. 12.5 × 18.5 cm. Price $2.50.

A compilation of five papers and discussions of a Ciba Foundation study group held April 1962.

Volkstümliche Namen der Arzneimittel, Drogen Heilkräuter und Chemikalien. 15th ed. Edited by JOHANNES ARENDS. Springer-Verlag, Berlin Wilmersdorf, Dept. VI, Heidelberger Platz 3, West Berlin, Germany, 1962. vi + 418 pp. 12.5 × 18.5 cm. Price DM 18.60.

A dictionary of common German names for plant drugs, medicinal compounds and dosage forms, and chemicals. The usual entry gives the equivalent Latin name.

Problems in Communication. Edited by CHARLES WATKINS and BENJAMIN PASAMANICK. The American Psychiatric Association, 1700 Eighteen St., N.W. Washington 9, D. C., 1961. 131 pp. 15 × 23 cm. Paperbound. Price $2.

A compilation of papers and discussions at the Regional Research Conference held January 1960 at New Orleans. Subjects covered are: Signals, signs, and symbols; mythological behavior; Is it true? Or is it so?; Psychomotility; Psychophysiological reactions of "normals" and patients; The first-year medical student: problems in the development of perceptiveness and self-awareness.

Organophosphorus Poisons. By D. F. HEATH. Pergamon Press Ltd., Headington Hill Hall, Oxford, England, 1961. vii + 403 pp. 15 × 23 cm. Price $12.50.

Intended for use mainly as a reference source for researchers, this book covers the fundamental aspects of the chemistry, biochemistry, and pharmacology of organophosphorus compounds which are anticholinesterases or are metabolized *in vivo* to anticholinesterases. An appendix discusses the theory of reaction rates in solution. Chemical and common names are tabulated and a good general index is appended.

Year Book of Drug Therapy. 1961–1962 Series. Edited by HARRY BECKMAN. Year Book Medical Publishers, Inc., 200 East Illinois St., Chicago 11, Ill., 1962. 659 pp. 13 × 19.5 cm. Price $8.50.

Excellent reviews of published medical reports for the year ending September 1961 are given in the author's style. Dr. Beckman's own critical evaluation of the year's new drugs (blue pages) is interesting. Author and subject indexes are appended.

Punch-Card Methods in Research and Documentation. By MARTIN SCHEELE. Interscience Publishers, Inc. 250 Fifth Ave., New York 1, N. Y., 1961. xiv + 274 pp. 16 × 23 cm. Price $9.50.

This book, an English translation of a German text, covers terminology, technology, and methodology. It includes general rules and gives examples. Special emphasis is given to biology throughout the text. This is the second volume in a series on Library Science and Documentation. The first volume was "Tools for Machine Literature Searching."

Directory of the American Council of Independent Laboratories, Inc. 8th ed. American Council of Independent Laboratories, 4302 East-West Highway Washington 14, D. C., 1961. xi + 114 pp. 17 × 25.5 cm. Paperbound.

The eighth edition (1961) of the ACIL Directory is available, without charge, to industrial and government executives from the above address. Specific services of the member laboratories are indicated.

Experimental Pharmacognosy. 3rd ed. By VARRO E. TYLER, JR., and ARTHUR E. SCHWARTING. Burgess Publishing Co., 426 South Sixth St., Minneapolis 15, Minn., 1962. v + 104 pp. 21 × 27.5. cm. Paperbound.

Major changes in the 3rd edition of this laboratory teaching guide are included in the section on biochemical processes and are demonstrated in exercises relating to biosyntheses of clavine alkaloids, tetracycline antibiotics, and a heteroglucoside.

A new Dictionary of Chemistry. 3rd. ed. Edited by L. MACKENZIE MIALL. Interscience Division, John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1962. vii + 593 pp. 15.5 × 23 cm. Price $13.75

A useful source of limited information, judiciously selected in many fields of chemistry and related sciences. Concise references to important contributors to the sciences, historically and recent, are helpful and interesting.

Choix de Techniques de Biochimie Clinique. By GUY DEVAUX. Gauthier-Villars & Cie., 55, Quai des Grands-Augustins, Paris, France, 1961. 220 pp. 21 × 27 cm. Price 30 NF.

Selected procedures in clinical biochemistry are described (in French). The text is divided into "explorations" of hydro-mineral, glucidic, lipidic, and protidic metabolisms, biocatalysis, and functional reactions of the organs and fluids. A chart for the determination of Ambard's constant is appended.

Biochemical Mechanisms. By LLOYD L. INGRAHAM. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1962. x + 108 pp. 15 × 23 cm. Price $5.75.

This book, an English translation of a German text, covers terminology, technology, and methodology. It includes general rules and gives examples. Special emphasis is given to biology throughout the text. This is the second volume in a series on Library Science and Documentation. The first volume was "Tools for Machine Literature Searching."

Titrimetric Methods. Edited by D. S. JACKSON. Plenum Press, 227 West 17th St., New York 11, N. Y., 1961. 185 pp. 15 × 22.5 cm. Price $7.50.

A compilation of 11 papers presented at a symposium sponsored by the Chemical Institute of Canada, Analytical Subject Division, Cornwall District Section. The major areas of titrimetric analysis considered are electrometric methods, complexometric methods utilizing chelating agents, and nonaqueous titrations.

Methods of Biochemical Analysis. Vol. 9. Edited by DAVID GLICK. John Wiley & Sons, Inc., Interscience Division, 440 Park Ave. South, New York 16, N. Y., 1962. ix + 452 pp. 15 × 23 cm. Price $14.50.

The subjects covered in this volume are: Assay of deoxyribonuclease activity, Characterization of ribonuclease and determination of its activity, Analysis of plant hormones, Analysis of adrenal steroids in blood by counter-current distribution, Some recent developments in column electrophoresis in granular media, Spectrophotometry of opaque biological materials: Reflection methods, and Introduction to magnetic resonance spectroscopy methods and biochemical applications. Author and subject indexes for this volume and cumulative indexes for volumes 1–9 are appended.

Developments in Industrial Microbiology. Vol. 3 Plenum Press, Inc., 227 West 17th St., New York 11, N. Y., 1962. ix + 398 pp. 16.5 × 25 cm. Price $13.50.

Papers and discussions at the August 1961 meeting of the Society for Industrial Microbiology are assembled in this Proceedings volume. Sections are devoted to reports on Microbiological applications in space, Preservation of oil-in-water systems, Water microbiology, Fermentations, and other contributed papers. A cumulative index for volumes 1–3 is appended.

Mises au Point Biologiques. By G. DEYSSON, R. FABRE, A. GERMAN, M. GUILLOT, M. LECLERC, G. LE MOAN, and J. SAVEL. Vigot Frères, 23, rue de l'Ecole de Médecine, Paris VIe, 1962. 286 pp. 15.5 × 24 cm. Price 35 NF.

A textbook (in French) with chapters on serology, techniques in biochemistry, toxicology, mushroom poisoning, and techniques in parasitology.

Manual of Practical Micro and General Procedures in Clinical Chemistry. By SAMUEL MEITES and WILLARD R. FAULKNER. Charles C Thomas, 301–327 East Lawrence Ave., Springfield, Ill., 1962. xvi + 354 pp. 15.5 × 23 cm. Price $11.50.

The text of this very useful book is divided into four sections under the headings: Principles of microchemistry, Routine methods (of clinical testing), Special Procedures, and Appendix of reference information. The methods described have been trial-tested by the authors in their laboratories. This should add to the practical reliability of the book.

Advances in Pharmacology. Vol. 1. Edited by SILVIO GARATTINI and PARKHURST A. SHORE. Academic Press Inc., 111 Fifth Ave., New York 3, N. Y., 1962. xi + 474 pp. 15 × 23 cm. Price $13.

This new serial publication will try to present a balanced view of the entire field for the student and investigator of problems in pharmacology, physiology, biochemistry, pharmaceutical chemistry, and related medical sciences. Volume 1 includes chapters on: A new interpretation of the adrenergic nerve fiber, Factors influencing drug metabolism, Chemotherapeutic approaches to the problem of hyperlipidemia, Antihypertensive Drugs, Pharmacological Aspects of psychiatry, Pharmacological consideration of antithrombotic therapy, The gastrintestinal tract and naturally occurring pharmacologically active amines, and Binding of some biogenic amines in tissues. General author and subject indexes are appended.

Mises au Point Relatives a des Activités Parapharmaceutiques et Biologiques. Vol. 1. By J. COURTOIS, A. DESVIGNES, A. GERMAN, M. GUILLOT, P. LARUELLE, M. PIETTE, and J. VAYSSETTE. Vigot Frères, 23, rue de l'Ecole de Médecine, Paris VIe, France, 1960. 438 pp. 15.5 × 24 cm. Price 55 NF.

A textbook (in French) includes in Part 1 chapters on techniques in hematology, diagnostic serology of syphilis, and techniques in microbiology. Part 2 covers hydrology, and applications of optics and acoustics.

Shock Pathogenesis and Therapy. Edited by K. D. BOCK. Available in the U. S. from Academic Press, 125 East 23rd St., New York 10, N. Y., 1962. vi + 387 pp. 14 × 20.5 cm. Price $13.

The papers and discussions at the June 1961 Ciba-sponsored symposium at Stockholm are compiled in this book. Hemodynamic, metabolic, and renal factors in shock, and adjustments of the central nervous system are covered. A good subject index is appended.

Renal Biopsy. Edited by G. E. W. WOLSTENHOLME and MARGARET P. CAMERON. Little Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. xii + 395 pp. 13.5 ×20.5 cm. Price $10.50.

The papers presented at the Ciba Foundation Symposium of March 14–16, 1961, are compiled in this book. The papers and discussions are related to the clinical and pathological significance of renal biopsy. General author and subject indexes are appended.

Writing Guide for Chemists. By WALTER J. GENSLER and KINERETH D. GENSLER. McGraw-Hill Book Co., Inc., 330 West 42nd St., New York 36, N. Y., 1961. xiii + 149 pp. 13 × 20.5 cm. Price $4.50.

A practical handbook to assist chemists in reporting the results of their work in acceptable and readable form. Its use could improve many technical reports.

Titrimetric Methods. Edited by D. S. JACKSON. Plenum Press, 227 West 17th St., New York 11, N. Y., 1961. 185 pp. 15 × 22.5 cm. Price $7.50.

A compilation of 11 papers presented at a symposium sponsored by the Chemical Institute of Canada, Analytical Subject Division, Cornwall District Section. The major areas of titrimetric analysis considered are electrometric methods, complexometric methods utilizing chelating agents, and nonaqueous titrations.

Methods of Biochemical Analysis. Vol. 9. Edited by DAVID GLICK. John Wiley & Sons, Inc., Interscience Division, 440 Park Ave. South, New York 16, N. Y., 1962. ix + 452 pp. 15 × 23 cm. Price $14.50.

The subjects covered in this volume are: Assay of deoxyribonuclease activity, Characterization of ribonuclease and determination of its activity, Analysis of plant hormones, Analysis of adrenal steroids in blood by counter-current distribution, Some recent developments in column electrophoresis in granular media, Spectrophotometry of opaque biological materials: Reflection methods, and Introduction to magnetic resonance spectroscopy methods and biochemical applications. Author and subject indexes for this volume and cumulative indexes for volumes 1–9 are appended.

Developments in Industrial Microbiology. Vol. 3 Plenum Press, Inc., 227 West 17th St., New York 11, N. Y., 1962. ix + 398 pp. 16.5 × 25 cm. Price $13.50.

Papers and discussions at the August 1961 meeting of the Society for Industrial Microbiology are assembled in this Proceedings volume. Sections are devoted to reports on Microbiological applications in space, Preservation of oil-in-water systems, Water microbiology, Fermentations, and other contributed papers. A cumulative index for volumes 1–3 is appended.

Writing Guide for Chemists. By WALTER J. GENSLER and KINERETH D. GENSLER. McGraw-Hill Book Co., Inc., 330 West 42nd St., New York 36, N. Y., 1961. xiii + 149 pp. 13 × 20.5 cm. Price $4.50.

A practical handbook to assist chemists in reporting the results of their work in acceptable and readable form. Its use could improve many technical reports.

Titrimetric Methods. Edited by D. S. JACKSON. Plenum Press, 227 West 17th St., New York 11, N. Y., 1961. 185 pp. 15 × 22.5 cm. Price $7.50.

A compilation of 11 papers presented at a symposium sponsored by the Chemical Institute of Canada, Analytical Subject Division, Cornwall District Section. The major areas of titrimetric analysis considered are electrometric methods, complexometric methods utilizing chelating agents, and nonaqueous titrations.

Methods of Biochemical Analysis. Vol. 9. Edited by DAVID GLICK. John Wiley & Sons, Inc., Interscience Division, 440 Park Ave. South, New York 16, N. Y., 1962. ix + 452 pp. 15 × 23 cm. Price $14.50.

The subjects covered in this volume are: Assay of deoxyribonuclease activity, Characterization of ribonuclease and determination of its activity, Analysis of plant hormones, Analysis of adrenal steroids in blood by counter-current distribution, Some recent developments in column electrophoresis in granular media, Spectrophotometry of opaque biological materials: Reflection methods, and Introduction to magnetic resonance spectroscopy methods and biochemical applications. Author and subject indexes for this volume and cumulative indexes for volumes 1–9 are appended.

Developments in Industrial Microbiology. Vol. 3 Plenum Press, Inc., 227 West 17th St., New York 11, N. Y., 1962. ix + 398 pp. 16.5 × 25 cm. Price $13.50.

Papers and discussions at the August 1961 meeting of the Society for Industrial Microbiology are assembled in this Proceedings volume. Sections are devoted to reports on Microbiological applications in space, Preservation of oil-in-water systems, Water microbiology, Fermentations, and other contributed papers. A cumulative index for volumes 1–3 is appended.

Mises au Point Biologiques. By G. DEYSSON, R. FABRE, A. GERMAN, M. GUILLOT, M. LECLERC, G. LE MOAN, and J. SAVEL. Vigot Frères, 23, rue de l'Ecole de Médecine, Paris VIe, 1962. 286 pp. 15.5 × 24 cm. Price 35 NF.

A textbook (in French) with chapters on serology, techniques in biochemistry, toxicology, mushroom poisoning, and techniques in parasitology.

Manual of Practical Micro and General Procedures in Clinical Chemistry. By SAMUEL MEITES and WILLARD R. FAULKNER. Charles C Thomas, 301–327 East Lawrence Ave., Springfield, Ill., 1962. xvi + 354 pp. 15.5 × 23 cm. Price $11.50.

The text of this very useful book is divided into four sections under the headings: Principles of microchemistry, Routine methods (of clinical testing), Special Procedures, and Appendix of reference information. The methods described have been trial-tested by the authors in their laboratories. This should add to the practical reliability of the book.

Advances in Pharmacology. Vol. 1. Edited by SILVIO GARATTINI and PARKHURST A. SHORE. Academic Press Inc., 111 Fifth Ave., New York 3, N. Y., 1962. xi + 474 pp. 15 × 23 cm. Price $13.

This new serial publication will try to present a balanced view of the entire field for the student and investigator of problems in pharmacology, physiology, biochemistry, pharmaceutical chemistry, and related medical sciences. Volume 1 includes chapters on: A new interpretation of the adrenergic nerve fiber, Factors influencing drug metabolism, Chemotherapeutic approaches to the problem of hyperlipidemia, Antihypertensive Drugs, Pharmacological Aspects of psychiatry, Pharmacological consideration of antithrombotic therapy, The gastrintestinal tract and naturally occurring pharmacologically active amines, and Binding of some biogenic amines in tissues. General author and subject indexes are appended.

Mises au Point Relatives a des Activités Parapharmaceutiques et Biologiques. Vol. 1. By J. COURTOIS, A. DESVIGNES, A. GERMAN, M. GUILLOT, P. LARUELLE, M. PIETTE, and J. VAYSSETTE. Vigot Frères, 23, rue de l'Ecole de Médecine, Paris VIe, France, 1960. 438 pp. 15.5 × 24 cm. Price 55 NF.

A textbook (in French) includes in Part 1 chapters on techniques in hematology, diagnostic serology of syphilis, and techniques in microbiology. Part 2 covers hydrology, and applications of optics and acoustics.

Shock Pathogenesis and Therapy. Edited by K. D. BOCK. Available in the U. S. from Academic Press, 125 East 23rd St., New York 10, N. Y., 1962. vi + 387 pp. 14 × 20.5 cm. Price $13.

The papers and discussions at the June 1961 Ciba-sponsored symposium at Stockholm are compiled in this book. Hemodynamic, metabolic, and renal factors in shock, and adjustments of the central nervous system are covered. A good subject index is appended.

Renal Biopsy. Edited by G. E. W. WOLSTENHOLME and MARGARET P. CAMERON. Little Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. xii + 395 pp. 13.5 ×20.5 cm. Price $10.50.

The papers presented at the Ciba Foundation Symposium of March 14–16, 1961, are compiled in this book. The papers and discussions are related to the clinical and pathological significance of renal biopsy. General author and subject indexes are appended.

Writing Guide for Chemists. By WALTER J. GENSLER and KINERETH D. GENSLER. McGraw-Hill Book Co., Inc., 330 West 42nd St., New York 36, N. Y., 1961. xiii + 149 pp. 13 × 20.5 cm. Price $4.50.

A practical handbook to assist chemists in reporting the results of their work in acceptable and readable form. Its use could improve many technical reports.

Titrimetric Methods. Edited by D. S. JACKSON. Plenum Press, 227 West 17th St., New York 11, N. Y., 1961. 185 pp. 15 × 22.5 cm. Price $7.50.

A compilation of 11 papers presented at a symposium sponsored by the Chemical Institute of Canada, Analytical Subject Division, Cornwall District Section. The major areas of titrimetric analysis considered are electrometric methods, complexometric methods utilizing chelating agents, and nonaqueous titrations.

Methods of Biochemical Analysis. Vol. 9. Edited by DAVID GLICK. John Wiley & Sons, Inc., Interscience Division, 440 Park Ave. South, New York 16, N. Y., 1962. ix + 452 pp. 15 × 23 cm. Price $14.50.

The subjects covered in this volume are: Assay of deoxyribonuclease activity, Characterization of ribonuclease and determination of its activity, Analysis of plant hormones, Analysis of adrenal steroids in blood by counter-current distribution, Some recent developments in column electrophoresis in granular media, Spectrophotometry of opaque biological materials: Reflection methods, and Introduction to magnetic resonance spectroscopy methods and biochemical applications. Author and subject indexes for this volume and cumulative indexes for volumes 1–9 are appended.

Developments in Industrial Microbiology. Vol. 3 Plenum Press, Inc., 227 West 17th St., New York 11, N. Y., 1962. ix + 398 pp. 16.5 × 25 cm. Price $13.50.

Papers and discussions at the August 1961 meeting of the Society for Industrial Microbiology are assembled in this Proceedings volume. Sections are devoted to reports on Microbiological applications in space, Preservation of oil-in-water systems, Water microbiology, Fermentations, and other contributed papers. A cumulative index for volumes 1–3 is appended.

Mises au Point Biologiques. By G. DEYSSON, R. FABRE, A. GERMAN, M. GUILLOT, M. LECLERC, G. LE MOAN, and J. SAVEL. Vigot Frères, 23, rue de l'Ecole de Médecine, Paris VIe, 1962. 286 pp. 15.5 × 24 cm. Price 35 NF.

A textbook (in French) with chapters on serology, techniques in biochemistry, toxicology, mushroom poisoning, and techniques in parasitology.

Manual of Practical Micro and General Procedures in Clinical Chemistry. By SAMUEL MEITES and WILLARD R. FAULKNER. Charles C Thomas, 301–327 East Lawrence Ave., Springfield, Ill., 1962. xvi + 354 pp. 15.5 × 23 cm. Price $11.50.

The text of this very useful book is divided into four sections under the headings: Principles of microchemistry, Routine methods (of clinical testing), Special Procedures, and Appendix of reference information. The methods described have been trial-tested by the authors in their laboratories. This should add to the practical reliability of the book.

Advances in Pharmacology. Vol. 1. Edited by SILVIO GARATTINI and PARKHURST A. SHORE. Academic Press Inc., 111 Fifth Ave., New York 3, N. Y., 1962. xi + 474 pp. 15 × 23 cm. Price $13.

This new serial publication will try to present a balanced view of the entire field for the student and investigator of problems in pharmacology, physiology, biochemistry, pharmaceutical chemistry, and related medical sciences. Volume 1 includes chapters on: A new interpretation of the adrenergic nerve fiber, Factors influencing drug metabolism, Chemotherapeutic approaches to the problem of hyperlipidemia, Antihypertensive Drugs, Pharmacological Aspects of psychiatry, Pharmacological consideration of antithrombotic therapy, The gastrintestinal tract and naturally occurring pharmacologically active amines, and Binding of some biogenic amines in tissues. Writing Guide for Chemists. By WALTER J. GENSLER and KINERETH D. GENSLER. McGraw-Hill Book Co., Inc., 330 West 42nd St., New York 36, N. Y., 1961. xiii + 149 pp. 13 × 20.5 cm. Price $4.50.

A practical handbook to assist chemists in reporting the results of their work in acceptable and readable form. Its use could improve many technical reports.

Titrimetric Methods. Edited by D. S. JACKSON. Plenum Press, 227 West 17th St., New York 11, N. Y., 1961. 185 pp. 15 × 22.5 cm. Price $7.50.

A compilation of 11 papers presented at a symposium sponsored by the Chemical Institute of Canada, Analytical Subject Division, Cornwall District Section. The major areas of titrimetric analysis considered are electrometric methods, complexometric methods utilizing chelating agents, and nonaqueous titrations.

Methods of Biochemical Analysis. Vol. 9. Edited by DAVID GLICK. John Wiley & Sons, Inc., Interscience Division, 440 Park Ave. South, New York 16, N. Y., 1962. ix + 452 pp. 15 × 23 cm. Price $14.50.

The subjects covered in this volume are: Assay of deoxyribonuclease activity, Characterization of ribonuclease and determination of its activity, Analysis of plant hormones, Analysis of adrenal steroids in blood by counter-current distribution, Some recent developments in column electrophoresis in granular media, Spectrophotometry of opaque biological materials: Reflection methods, and Introduction to magnetic resonance spectroscopy methods and biochemical applications. Author and subject indexes for this volume and cumulative indexes for volumes 1–9 are appended.

Developments in Industrial Microbiology. Vol. 3 Plenum Press, Inc., 227 West 17th St., New York 11, N. Y., 1962. ix + 398 pp. 16.5 × 25 cm. Price $13.50.

Papers and discussions at the August 1961 meeting of the Society for Industrial Microbiology are assembled in this Proceedings volume. Sections are devoted to reports on Microbiological applications in space, Preservation of oil-in-water systems, Water microbiology, Fermentations, and other contributed papers. A cumulative index for volumes 1–3 is appended.

Mises au Point Biologiques. By G. DEYSSON, R. FABRE, A. GERMAN, M. GUILLOT, M. LECLERC, G. LE MOAN, and J. SAVEL. Vigot Frères, 23, rue de l'Ecole de Médecine, Paris VIe, 1962. 286 pp. 15.5 × 24 cm. Price 35 NF.

A textbook (in French) with chapters on serology, techniques in biochemistry, toxicology, mushroom poisoning, and techniques in parasitology.

Manual of Practical Micro and General Procedures in Clinical Chemistry. By SAMUEL MEITES and WILLARD R. FAULKNER. Charles C Thomas, 301–327 East Lawrence Ave., Springfield, Ill., 1962. xvi + 354 pp. 15.5 × 23 cm. Price $11.50.

The text of this very useful book is divided into four sections under the headings: Principles of microchemistry, Routine methods (of clinical testing), Special Procedures, and Appendix of reference information. The methods described have been trial-tested by the authors in their laboratories. This should add to the practical reliability of the book.

Advances in Pharmacology. Vol. 1. Edited by SILVIO GARATTINI and PARKHURST A. SHORE. Academic Press Inc., 111 Fifth Ave., New York 3, N. Y., 1962. xi + 474 pp. 15 × 23 cm. Price $13.

This new serial publication will try to present a balanced view of the entire field for the student and investigator of problems in pharmacology, physiology, biochemistry, pharmaceutical chemistry, and related medical sciences. Volume 1 includes chapters on: A new interpretation of the adrenergic nerve fiber, Factors influencing drug metabolism, Chemotherapeutic approaches to the problem of hyperlipidemia, Antihypertensive Drugs, Pharmacological Aspects of psychiatry, Pharmacological consideration of antithrombotic therapy, The gastrintestinal tract and naturally occurring pharmacologically active amines, and Binding of some biogenic amines in tissues. General author and subject indexes are appended.

Mises au Point Relatives a des Activités Parapharmaceutiques et Biologiques. Vol. 1. By J. COURTOIS, A. DESVIGNES, A. GERMAN, M. GUILLOT, P. LARUELLE, M. PIETTE, and J. VAYSSETTE. Vigot Frères, 23, rue de l'Ecole de Médecine, Paris VIe, France, 1960. 438 pp. 15.5 × 24 cm. Price 55 NF.

A textbook (in French) includes in Part 1 chapters on techniques in hematology, diagnostic serology of syphilis, and techniques in microbiology. Part 2 covers hydrology, and applications of optics and acoustics.

Shock Pathogenesis and Therapy. Edited by K. D. BOCK. Available in the U. S. from Academic Press, 125 East 23rd St., New York 10, N. Y., 1962. vi + 387 pp. 14 × 20.5 cm. Price $13.

The papers and discussions at the June 1961 Ciba-sponsored symposium at Stockholm are compiled in this book. Hemodynamic, metabolic, and renal factors in shock, and adjustments of the central nervous system are covered. A good subject index is appended.

Renal Biopsy. Edited by G. E. W. WOLSTENHOLME and MARGARET P. CAMERON. Little Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. xii + 395 pp. 13.5 ×20.5 cm. Price $10.50.

The papers presented at the Ciba Foundation Symposium of March 14–16, 1961, are compiled in this book. The papers and discussions are related to the clinical and pathological significance of renal biopsy. General author and subject indexes are appended.

Writing Guide for Chemists. By WALTER J. GENSLER and KINERETH D. GENSLER. McGraw-Hill Book Co., Inc., 330 West 42nd St., New York 36, N. Y., 1961. xiii + 149 pp. 13 × 20.5 cm. Price $4.50.

A practical handbook to assist chemists in reporting the results of their work in acceptable and readable form. Its use could improve many technical reports.

Titrimetric Methods. Edited by D. S. JACKSON. Plenum Press, 227 West 17th St., New York 11, N. Y., 1961. 185 pp. 15 × 22.5 cm. Price $7.50.

A compilation of 11 papers presented at a symposium sponsored by the Chemical Institute of Canada, Analytical Subject Division, Cornwall District Section. The major areas of titrimetric analysis considered are electrometric methods, complexometric methods utilizing chelating agents, and nonaqueous titrations.

Methods of Biochemical Analysis. Vol. 9. Edited by DAVID GLICK. John Wiley & Sons, Inc., Interscience Division, 440 Park Ave. South, New York 16, N. Y., 1962. ix + 452 pp. 15 × 23 cm. Price $14.50.

The subjects covered in this volume are: Assay of deoxyribonuclease activity, Characterization of ribonuclease and determination of its activity, Analysis of plant hormones, Analysis of adrenal steroids in blood by counter-current distribution, Some recent developments in column electrophoresis in granular media, Spectrophotometry of opaque biological materials: Reflection methods, and Introduction to magnetic resonance spectroscopy methods and biochemical applications. Author and subject indexes for this volume and cumulative indexes for volumes 1–9 are appended.

Developments in Industrial Microbiology. Vol. 3 Plenum Press, Inc., 227 West 17th St., New York 11, N. Y., 1962. ix + 398 pp. 16.5 × 25 cm. Price $13.50.

Papers and discussions at the August 1961 meeting of the Society for Industrial Microbiology are assembled in this Proceedings volume. Sections are devoted to reports on Microbiological applications in space, Preservation of oil-in-water systems, Water microbiology, Fermentations, and other contributed papers. A cumulative index for volumes 1–3 is appended.

Mises au Point Biologiques. By G. DEYSSON, R. FABRE, A. GERMAN, M. GUILLOT, M. LECLERC, G. LE MOAN, and J. SAVEL. Vigot Frères, 23, rue de l'Ecole de Médecine, Paris VIe, 1962. 286 pp. 15.5 × 24 cm. Price 35 NF.

A textbook (in French) with chapters on serology, techniques in biochemistry, toxicology, mushroom poisoning, and techniques in parasitology.

Manual of Practical Micro and General Procedures in Clinical Chemistry. By SAMUEL MEITES and WILLARD R. FAULKNER. Charles C Thomas, 301–327 East Lawrence Ave., Springfield, Ill., 1962. xvi + 354 pp. 15.5 × 23 cm. Price $11.50.

The text of this very useful book is divided into four sections under the headings: Principles of microchemistry, Routine methods (of clinical testing), Special Procedures, and Appendix of reference information. The methods described have been trial-tested by the authors in their laboratories. This should add to the practical reliability of the book.

Advances in Pharmacology. Vol. 1. Edited by SILVIO GARATTINI and PARKHURST A. SHORE. Academic Press Inc., 111 Fifth Ave., New York 3, N. Y., 1962. xi + 474 pp. 15 × 23 cm. Price $13.

This new serial publication will try to present a balanced view of the entire field for the student and investigator of problems in pharmacology, physiology, biochemistry, pharmaceutical chemistry, and related medical sciences. Volume 1 includes chapters on: A new interpretation of the adrenergic nerve fiber, Factors influencing drug metabolism, Chemotherapeutic approaches to the problem of hyperlipidemia, Antihypertensive Drugs, Pharmacological Aspects of psychiatry, Pharmacological consideration of antithrombotic therapy, The gastrintestinal tract and naturally occurring pharmacologically active amines, and Binding of some biogenic amines in tissues. General author and subject indexes are appended.

Mises au Point Relatives a des Activités Parapharmaceutiques et Biologiques. Vol. 1. By J. COURTOIS, A. DESVIGNES, A. GERMAN, M. GUILLOT, P. LARUELLE, M. PIETTE, and J. VAYSSETTE. Vigot Frères, 23, rue de l'Ecole de Médecine, Paris VIe, France, 1960. 438 pp. 15.5 × 24 cm. Price 55 NF.

Review Article

Prediction of Stability of Drugs and Pharmaceutical Preparations

By EDWARD R. GARRETT

TO PREDICT is "to tell or declare beforehand, foretell or prophesy" (190). In the realms of science, prediction is based on a knowledge of the relations among experimental values under observed experimental conditions. Prediction of the stability of drugs and pharmaceutical preparations depends on quantitative mathematical expressions that permit the calculation of rates of degradation by the substitution of the appropriate values for temperature, concentrations, pressure, time, pH, oxygen content, centrifugal or gravitational stress, light intensities and wavelengths, etc.

These quantitative relations can be obtained from the classical literature of chemistry and physics (83, 169). Judicious experimental design can permit the evaluation of the vital parameters with the minimum expenditure of time and labor. Thus, stability can be predicted for practical circumstances where study, *per se*, is experimentally or economically impractical or unsuitable.

The literature contains many articles on drug incompatibilities or instabilities for which references are cited (18, 134, 158, 192).

However, kinetic and predictive studies of drugs in the pharmaceutical literature are of relatively recent vintage. In fact, *ca.* 1950 can be considered the start of the modern era in the quantitative comprehension and prediction of drug stability.

Received from the College of Pharmacy, University of Florida, Gainesville.

This review will be concerned with those studies on drugs and pharmaceutical formulations where quantitative expressions were obtained to permit prediction of stability. It will consider the basic concepts and the rationales which can be applied to permit prognosis. This review will be practically limited to studies conducted in liquid media involving solvolytic processes and leave the aerobic, bacterial, enzymic, or photolytic degradations to another time or another reviewer. The prediction of stability of the complex systems characterized by colloidal suspensions, emulsions, ointments, and solid formulations will, in general, also be ignored.

The basic concepts of kinetics and their applications to the understanding of the mechanisms of reactions of many simple systems and reactive groups are given in many fine books on these subjects (2, 9, 14, 29, 43, 71, 72, 86, 103, 104, 123, 138). Their reading is recommended.

Predictive Use of the Apparent First-Order Rate Constant.—The chemical action of a solvent and other solutes on the drug in solution is of prime importance. A systematic approach to its understanding and quantification is to consider the rate of degradation of such a drug as proportional to the concentrations of the reactants in the rate-determining step, or proportional to the concentrations of the reactants in the equilibria which precede such a rate-determining step. The rate of drug transformation is given in concentration, c, change per unit of time; (time-unit^{-1}).

In most solvolytic reactions with constant conditions of temperature, pH, buffer kind and concentration, and ionic strength, the rate of change per unit of time is proportional to the first power of the concentration of the drug being transformed

$$dc/dt(M/\text{L./sec.}) = kc^1(\text{sec.}^{-1} \times \text{moles/L.}) \quad \text{(Eq. 1)}$$

The rate is considered as apparent first order since it varies as the first power of the concentration, c, of the substrate. On integration of Eq. 1, the logarithm of the concentration, c, when plotted against time is a straight line of slope $k/2.303$

$$\log c = -kt/2.303 + \log c_0 \quad \text{(Eq. 2)}$$

or the logarithm of the fraction of substrate untransformed when plotted against time is a straight line of the same slope

$$\log c/c_0 = -kt/2.303 \quad \text{(Eq. 3)}$$

where c_0 is the original concentration and k is in reciprocal time units (29, 71). It has been recommended that all rate constants be given in units of seconds for ease of literature comparison (161). Some typical semilogarithmic plots for the degradation of thiamine hydrochloride (47) are given in Fig. 1.

The rate constants, k, are frequently used to compare and estimate rates. An alternative constant to use is the half-life, $t_{1/2}$; the time when a concentration is reduced by half its initial value. For all apparent first-order reactions the $t_{1/2}$ is independent of the magnitude of the initial concentration of the substrate and is related to the first-order rate constant, k, by

$$t_{1/2}(\text{sec.}) = -2.303 \log 0.5/k = 0.693/k \quad \text{(Eq. 4)}$$

from the rearrangement of Eq. 3 where $c/c_0 = {}^1/_2$, $t = t_{1/2}$ and k is in sec.$^{-1}$.

Variations on this theme can be chosen to alculate the time of 5 or 10% loss of substrate, *i.e.*, $t_{0.95}$ or $t_{0.90}$, respectively (117). The half-life is only independent of initial substrate concentrations for first-order reactions. It has been used frequently to describe the stability of a drug and the rate dependencies (35, 95, 98, 130, 132, 193, 198). Nelson (143) provides a convenient table to determine the fractional loss of substrate for n half-lives. However for the purpose of a systematic presentation, the concept of the rate constant will be used in this paper as descriptive of the fraction of substrate remaining on exponential decay

$$c/c_0 = e^{-kt} \quad \text{(Eq. 5)}$$

It is apparent that if the apparent first-order rate constant, k, can be determined as a function of the physical conditions of the solution, the rate of degradation at a given concentration can be determined by substitution of that concentration, c, into Eq. 1; that the half-life under those conditions can be determined by substitution into Eq. 4; that the fraction of substrate remaining at any time, t, can be determined by use of Eq. 5.

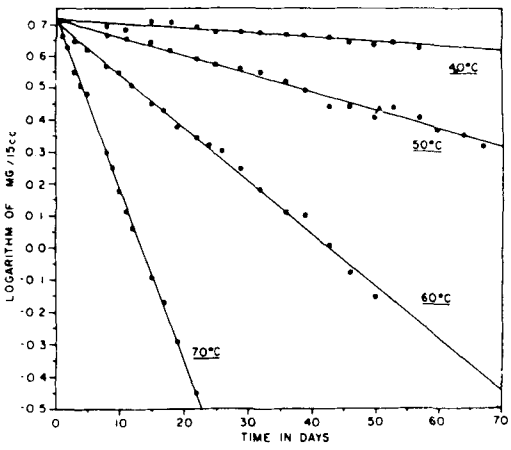

Fig. 1.—First-order plots of the thermal degradation of thiamine hydrochloride in a liquid multivitamin; logarithms of concentration (mg./15 ml.) against time in days. [Figure 1 of Garrett, E. R., This Journal, **45**, 470(1956) (47).]

To transform the half-life or first-order rate constants into other time units such as hours, days, years, etc., the conversions are

$$t_{1/2}(\text{time units}) = t_{1/2}(\text{in sec.})/(\text{seconds/time unit}) \quad \text{(Eq. 6)}$$

$$k(\text{time unit})^{-1} = k(\text{sec.}^{-1}) \times \text{sec./time unit} \quad \text{(Eq. 7)}$$

An appropriate procedure for studies that may be ambiguous is to verify the fact experimentally that the apparent first-order rate constant, k, is independent of substrate concentration. This has been done in many such cases (52, 55, 57, 66, 91, 114, 140, 154, 165, 193). Alternative methods of estimating apparent first-order rate constants are from the slopes of plots of concentration changes against time at the initial concentrations of substrate or by the Guggenheim method (81). Such procedures have been used with steroid hemiester hydrolysis and compared to the k values derived from classical plots (59, 61, 68).

Specific Acid-Base Catalyzed Solvolysis.—The simplest catalysts for solvolysis are hydrogen ions and hydroxyl ions so that the apparent first-order reaction rate constant k would be determined by

$$k = k_1[H^+] + k_6[OH^-] \quad \text{(Eq. 8)}$$

where catalysis by $[H^+]$ and $[OH^-]$ and the respective specific rate constants k_1 and k_6(L./*M*/sec.) are considered specific acid-base catalysis. In general, hydroxyl ion catalysis is negligible when a hydrogen ion catalyzed transformation is operative, and vice versa, so that one method of determining k_1 is to plot the observed rate constant, k, obtained from the slope of the plot of data according to Eq. 2, against the maintained hydrogen ion concentration.

As per Eq. 8 where the contribution of $k_6[OH^-]$ is negligible, the slope of such a plot estimates k_1 in L./*M*/sec. Obviously, k_6 may be similarly obtained by plotting k against $[OH^-]$ when the contribution of k_1 $[H^+]$ is negligible and k_6 in L./*M*/sec. can be estimated. A typical plot in this manner is given in Fig. 2 for the acid hydrolysis of psicofuranine (56). The negative intercept of the plot is due to the fact that the true molarity of hydrochloric acid is the apparent molarity lessened by the amount necessary to neutralize the psicofuranine.

Definition of Hydrogen and Hydroxyl Ion Concentrations and Activities.—The specific bimolecular rate constants are defined in terms of the ratio of the apparent first-order rate constant and the concentration or activity of the catalytic species. The specific rate constants of Eq. 8

$$k_1 = k/[H^+] \text{ when } k_6[OH^-] \sim 0 \quad \text{(Eq.8a)}$$

or

$$k_6 = k/[OH^-] \text{ when } k_1[H^+] \sim 0 \quad \text{(Eq. 8b)}$$

can be defined in terms of the stoichiometric strong acid or strong alkali concentration, *e.g.*, $[H^+]$ = [HCl] or $[OH^-]$ = [NaOH] on the postulate that the hydrogen or hydroxyl ion catalytic contributions are equivalent to the molarity of the strong acid or base. This is not necessarily true, however, as the effective hydrogen (or hydroxyl) ion concentration (activity) of a strong acid (or base) decreases from expectation with increased concentrations of the acid (or base) (89). The high activity of perchloric acid makes it one of the most ideal acids for the study of specific hydrogen ion catalysis (97, 98, 130–132). Ester hydrolysis is most generally catalyzed only by hydrogen and hydroxyl ions (specific acid-base catalysis) (9, 123) but consumes hydroxyl ions, so that if $k_6 = k/[OH^-]$ is to be determined, then the molar concentration of strong alkali should exceed the concentration substrate by at least tenfold, *e.g.*, $[OH^-] > 10c$ when $[OH^-]$ is taken as equivalent to [NaOH]. A specific example is the determination of $k/[OH^-]$ in the hydrolysis of acetylsalicylates (50). When the molar concentration of strong alkali approaches that of the substrate, bimolecular rate expressions must be used to calculate k_6 (9, 43, 104, 123). It is a similar situation for amides when hydrogen ions are taken up by the liberated amines the concentration of strong acid must greatly exceed the substrate concentration for pseudo first-order techniques to be used in the calculation of the apparent bimolecular rate constant k_1 (70).

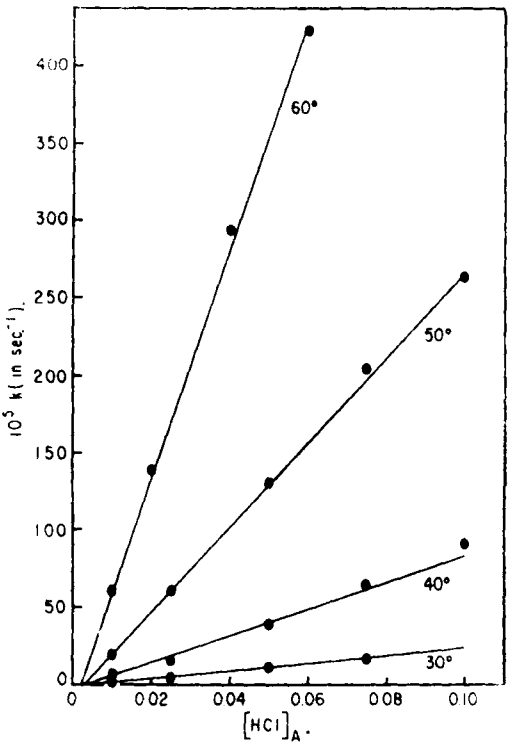

Fig. 2.—Rate constants, k in sec.$^{-1}$, for the apparent first-order degradation of psicofuranine as a function of apparent hydrochloric acid molarity. [Figure 3 of Garrett, E. R., *J. Am. Chem. Soc.*, **82**, 827(1960)(56).]

An alternative method is frequently used to calculate k_1 and k_6 where these values are defined in terms of the activities of hydrogen ions and hydroxyl ions, respectively.

The pH can be experimentally determined and, when k_6 $[OH] \sim 0$, the logarithmic transformation of Eq. 8 yields

$$\log k = \log k_1' - \text{pH} \quad \text{(Eq. 9)}$$

so that the slope of the logarithm of the apparent first-order rate constant against the experimentally determined pH is negative and equal to unity, and the antilog of the intercept yields the bimolecular rate constant k_1'. This k_1' value is related to the specific bimolecular rate constant k_1 by

$$k_1' = f_{H^+} k_1 \quad \text{(Eq. 10)}$$

where f_{H^+} is the activity coefficient (2, 89, 149) for the hydrogen ion and

$$k = k_1' \ 10^{-pH} \text{ when } k_6[OH^-] \sim 0 \quad \text{(Eq. 11)}$$

where the pH is the experimentally determined ($-\log a_{H^+}$), where a_{H^+} is the hydrogen ion activity.

A similar development for k_6' yields

$$\log k = \log k_6' - pOH = \log k_6 - pKw + pH \quad \text{(Eq. 12)}$$

The pK_w for a given temperature and solvent can be obtained from the literature (89, 149) so that k_6 can be calculated from the intercept of the plot of the logarithm of the apparent first-order rate constant against the experimentally determined pH. Thus, Eq. 8 is redefined in terms of pH as

$$k = k_1' \ 10^{-pH} + k_6' \ 10^{-(pKw - pH)} \quad \text{(Eq. 13)}$$

where the k_1' and k_6' values of Eq. 12 will frequently differ slightly from the k_1 and k_6 of Eq. 8 and yet be the desired values for prediction of solvolysis rates in intermediate pH ranges where pH is experimentally determined.

Comparisons of k_1 determined from stoichiometric catalytic concentrations and from pH measurements (*i.e.*, k_1') have been made in the cases of the solvolysis of the antibiotic streptovaricin (53) and the solvolysis of the antibiotic psicofuranine (56). An interesting comparison of measured pH and the pH calculated from kinetic rate constants is given for the solvolysis of acetylsalicylates (50).

It is frequently difficult to determine pH experimentally at high concentrations of hydrogen or hydroxyl ions so as to deduce the bimolecular rate constants k_1 and k_6 as from plots of Eqs. 9 and 12. However, stoichiometric acid concentrations can be converted to pH values corresponding to hydrogen ion and hydroxyl ion activities from the data on electrolytes in the literature (2, 89, 149).

For example, in concentrated hydrochloric acid solutions

$$pH = -\log f_{HCl}[HCl] \quad \text{(Eq. 14)}$$

where the mean activity coefficient of hydrochloric acid, f_{HCl}, is given at various temperatures, solvent mixtures, and HCl concentrations (89, 149). This definition of pH has been used in the study of the acid catalyzed solvolysis of hydrocortisone hemiester in alcohol-water mixtures (59) and of N-acetyl-*p*-aminophenol (114).

In the study of the acid catalyzed solvolysis of the antibiotic streptozotocin (57), the pH calculated from the activity coefficients (89) and the hydrochloric acid concentrations can be compared to the observed pH values of the solutions. Reasonable agreement is obtained above a pH of 1.2 and within 0.15 pH units below that value.

Similarly

$$pH = pKw - pOH = pKw + \log f_{NaOH}[NaOH] \quad \text{(Eq. 15)}$$

where f_{NaOH}, the mean activity coefficient of sodium hydroxide, and pKw are given in the literature for many solvent mixtures, temperatures, and solutes (89, 149). This definition of pOH has been used in the study of the alkaline hydrolysis of the antibiotics psicofuranine (56) and actinospectacin (69), where the k_6 values determined from the calculated hydroxyl ion activities and the stoichiometric [NaOH] have been compared.

Frequently, data exist in the literature to permit prediction of pH of buffer solutions under the conditions of preparation. An example of this procedure is in the study of barbital degradation in an ammonia buffer system (80) where the dissociation constants for the ammonia buffer system (8) and barbital (128) are given in the literature as a function of temperature. By the use of available activity coefficients (89, 115) and discreet approximations (7), the pH at various temperatures was calculated from the equation for the thermodynamic equilibrium constant for the buffer used. It is interesting to compare this approach (80) in the determination of the pH for the dependency of barbital kinetics to that of phenobarbital kinetics where the pH was determined experimentally (88).

Another method of characterizing hydrogen or hydroxyl ion concentrations is by the spectrophotometric determination of the degree of dissociation of a weakly acidic or basic indicator of known pKa where the spectrophotometric absorptivities of the charged and uncharged forms differ (73). The $[OH^-]$ calculated thusly has been used to determine the kinetic dependencies of the solvolysis of homatropine and atropine methyl-bromides (151).

Specific methods of calculating hydrogen and hydroxyl ion concentrations or activities for the prediction of the apparent first-order rate constants for the degradation of various pharmaceuticals are indicated in Table I. Methyl *dl*-α-phenyl-2-piperidylacetate (170) has exhibited specific acid-base catalyzed solvolysis where the log k *vs.* pH profile is given in Fig. 3 and the pH of minimum degradation is *ca.* 3. Specific acid-base catalyzed solvolysis has also been exhibited by the alkyl *dl*-α-(2-piperidyl)-phenyl-

acetates with pH *ca.* 3 of maximum stability (155) and N-acetyl-*p*-aminophenol with a pH 5–6 of maximum stability. The minimum of the catenary as exemplified in Fig. 3 and the pH of minimum overall rate at the isocatalytic point can be calculated from the specific acid-base catalytic constants as demonstrated in the literature (35, 113, 170). Many other examples of such catenaries are given in books on kinetics and mechanisms of reactions (2, 9, 43, 104, 123).

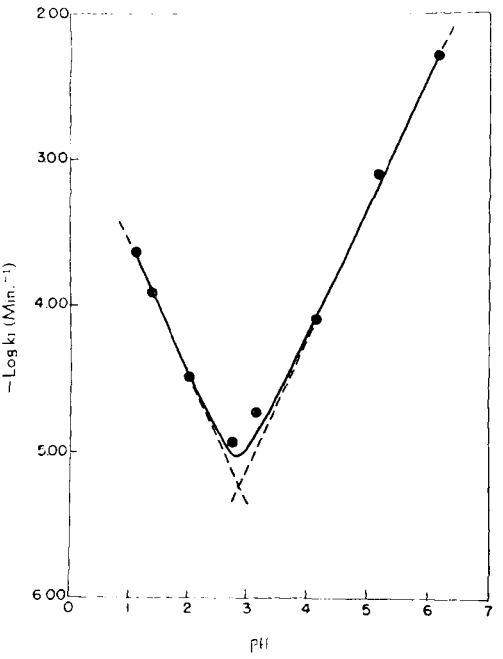

Fig. 3.—pH Dependency of the hydrolysis of methyl DL-α-phenyl-2-piperidylacetate at 80° [Figure 5 of Siegel, S., Lachman, L., and Malspeis, L., THIS JOURNAL, **49**, 431(1959) (170).]

Catalysis by Solvent.—If the apparent first-order rate constants calculated from Eqs. 8 or 13 do not agree with the observed values for intermediate pH ranges, then catalysis by solvent or solutes, intramolecular catalysis, or ionic strength must be considered as contributing to the overall rate.

The simplest modification of Eq. 8 is

$$k = k_1[H^+] + k_6[OH^-] + k_2 \quad \text{(Eq. 16)}$$

When the k plotted against $[H^+]$ has an intercept which cannot be attributed to hydroxyl ion attack, a solvent catalytic effect k_2 is implicated. This is further confirmed when k plotted against $[OH^-]$ has the same intercept or when

$$k = k_2, k_1[H^+] \sim 0 \sim k_6[OH^-] \quad \text{(Eq. 17)}$$

Such solvent attack on a degradable species is frequently apparent from the log k-pH profiles as with thiamine (193), pyridine-2-aldoxime methiodide (35), methyl pyrrolidylacetylsalicylate hydrochloride (51), and streptovaricin (53), which is given in Fig. 4.

General Acid-Base Catalysis.—Not only may hydrogen and hydroxyl ions and solvent alone catalyze the decomposition of drugs in solution, but charged species contributed from excipients or buffers may do so also. A general rule is that if solvent does catalyze, other catalytic species exist which can act as acids or bases with catalytic activity, and

[a] SH^+ represents a protonated substrate in equilibrium with an uncharged substrate, S, with a dissociation constant K_a. The uncharged substrate, S, may lose a proton and may equilibrate with a negatively charged substrate, S^-. The symbol HS represents an acidic, uncharged substrate of a dissociation constant Ka, which may equilibrate with an anionic substrate, S^-. The symbol pH is for the experimentally determined value, $pH' = -\log f[HCl]$ and $pOH = -\log f[MOH]$ where f is the mean activity coefficient (2). The pH'' are values determined or calculated from the literature for the buffers used. Other symbols are $[H^+] = [HCl]$, $[H^+]' = [HClO_4]$, $[OH^-] = [NaOH]$. The $[OH^-]'$ is the hydroxyl ion concentration determined by an indicator method. The hydrogen or hydroxyl ion activity is frequently expressed in the form $a_{H^+} = 10^{-pH}$ or $a_{OH} = 10^{-pOH} = 10^{-(pKw - pH)}$. The general form of the kinetic expressions given is $(k_1[H^+] + k_2 + k_3[OH^-])f_{HS\ (or\ SH^+)} + (k_4[H^+] + k_5 + k_6[OH^-])f_{S^-\ (or\ S)} + (k_8 + k_9)[OH^-]f_{S^=\ (or\ S^-)}$ where $f_{HS\ (or\ SH^+)} = 1/(1 + Ka/[H^+])$ is the fraction of substrate as the acid form (uncharged or positively charged), where $f_{S^=\ (or\ S)} = 1/(1 + [H^+]/Ka_1)$ is the fraction of substrate as the base form (negatively charged or uncharged) and if another proton is removed, then $f_{S^-\ (or\ S^-)} = 1/(1 + Ka_2/[H^+])$ is the fraction of substrate further dissociated as a doubly or singly charged anion. The $[H^+]$ in these definitions of fractions of substrate is usually defined in terms of the measured hydrogen ion activity, *i.e.*, 10^{-pH}. The A_i^- and B_i represent charged and uncharged general bases respectively, whereas the HA_i and H^+B_i represent uncharged and charged general acids, respectively, so that $\Sigma_i k_i A_i^-$, $\Sigma_i k_i B_i$, $\Sigma_i k_i Ha_i$, and $\Sigma_i k_i H^+ B_i$ represent the contribution of solutes to general acid-base catalyzed solvolysis of the substrate. [b] Values at all operating temperatures can be calculated from $k_i = Ae^{-\Delta Ha/RT}$ or $\log k_i = \log A - \Delta Ha/2.303\ RT$ where A and ΔH_a can be derived from values given in the references. [c] Studied at one or two temperatures only. [d] Aqueous solutions. [e] Aqueous alcohols (methanol, ethanol, propylene glycol). [f] Aqueous dioxane or aqueous acetone. [g] Strong acid region. [h] Acetate buffer region. [i] Phosphate buffer region. [j] Mildly alkaline region. [k] Strong alkali region. [l] General acid-base catalysis checked and not observed with acetic acid-acetate buffers. [m] Ionic strength effects checked and not observed in region studied. [n] Oxidative degradation checked and not observed in region studied. [o] General acid-base catalysis checked and not observed with phthalic acid-phthalate buffers. [p] Oxidatively degraded when oxygen present. [q] Dissociation constants, Ka, at all operating temperatures can be calculated from Arrhenius expressions or other data. [r] General acid-base catalysis checked and not observed. [s] Checked at different substrate concentrations for first order with respect to substrate. [t] Rates studied as functions of dielectric constant where D is dielectric constant and m and b are constants. [u] $Z_A$and Z_B are the charges on the reacting ions and $\mu = \frac{1}{2}\Sigma c_i Z_i^2$ is the ionic strength. [v] $Z_A Z_B A$ is negative. [w] $Z_A Z_B A$ is positive. [x] The constant C is positive.

conversely. An example of this is the assignment of intramolecular catalysis to the pH-independent hydrolysis of the aspirin anion (50) rather than general acid-base catalysis by water since variations in acetic acid-acetate buffer concentrations had negligible effect on the hydrolysis (34).

Thus, Eq. 8 which has been extended to become Eq. (16) can be further modified

$$k = k_1[H^+] + k_6[OH^-] + k_2 + \Sigma_i k_i[HA_i] + \Sigma_i k_i[A_i^-] + \Sigma_i k_i[B_i] + \Sigma_i k_i[B_i H^+] \quad \text{(Eq. 18)}$$

where B is a general base and BH^+ its conjugate acid, where HA is a general acid and A^- is its conjugate base according to the treatment of Frost and Pearson (43).

An appropriate method to evaluate general acid-base effects is to determine the apparent first-order rate constant in the buffered vehicle and subtract those rate contributions which can be studied separately, such as k_1 $[H^+]$, k_6 $[OH^-]$, and k_2. The excess in degradation rate can be assigned to general acid-base catalysis provided

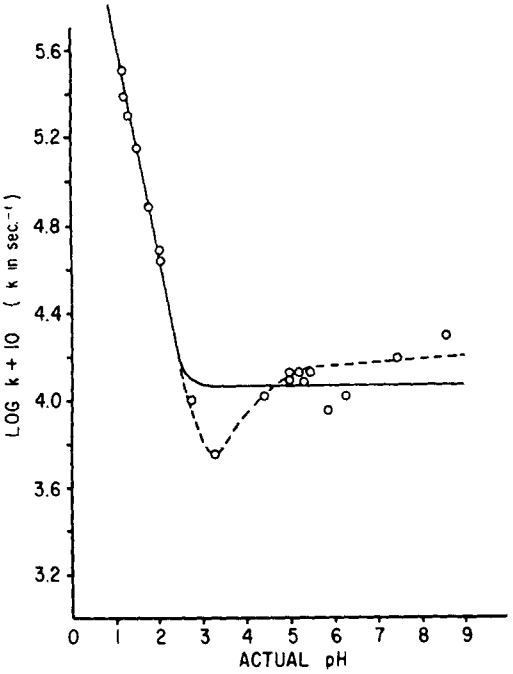

Fig. 4.—The pH profile of the degradation rates of streptovaricin C based on the 432 mμ absorbance disappearance in 25% ethanol at 30.3°. [Figure 3 of Garrett, E. R., THIS JOURNAL, **48**, 169(1959) (53).]

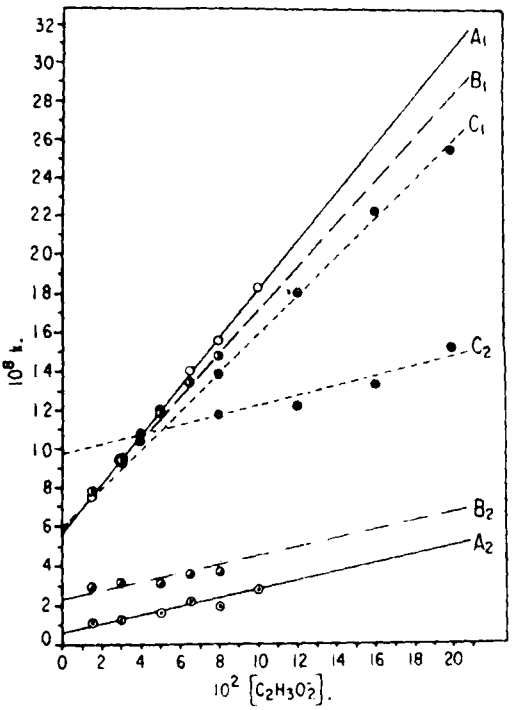

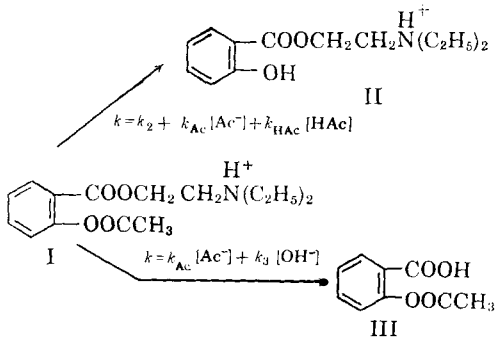

Fig. 5.—Effect of varying acetate ion concentration at constant ionic strength, μ, at several pH values on the simultaneous first-order rate constants of the hydrolyses to diethylaminoethyl salicylate hydrochloride, II, (curves A_1, B_1, C_1) and to aspirin, III, (curves A_2, B_2, C_2) of 10×10^{-4} *M* diethylaminoethyl acetylsalicylate hydrochloride, I, at 30.3°. ○, A, pH 4.00, 0.100 μ., ◑, B, pH 4.62, 0.100 μ., ●, C, pH 5.21, 0.200. [Figure 8 of Garrett, E. R., *J. Am. Chem. Soc.*, **80**, 4049 (1958) (52).]

that ionic strength effects have been controlled by varying buffer concentrations at constant pH and constant ionic strength. The use of a neutral salt such as sodium or potassium chloride is recommended.

A graphic example of a complex general acid-base catalyzed hydrolysis is given in Fig. 5 for the hydrolysis of diethylaminoethyl acetylsalicylate hydrochloride, I (52).

The apparent first-order rate constant, k, is plotted against the acetate ion concentration, $[Ac^-]$, at constant pH and constant ionic strength, μ. The curves A_1, B_1, and C_1, each at a different pH value, have the same intercept, k_2, and thus determine the solvent effect on the hydrolysis of I to diethylaminoethyl salicylic acid hydrochloride, II. The varying slopes, k_{Ac}', of lines A_1, B_1, and C_1 represent the rate constants for acetate ion and acetic acid catalyzed solvolysis of I to II. This k_{Ac}' can be dissected into the component contributions of base (k_{Ac}) and acid (k_{HAc}) catalytic rate constants since

$$k_{Ac}'[Ac^-] = \{k_{Ac} + k_{HAc}/K_a'[H^+]\}[Ac^-] \quad \text{(Eq. 19a)}$$

$$= k_{Ac}[Ac^-] + k_{HAc}[H^+][Ac^-]/Ka' \quad \text{(Eq. 19b)}$$

$$= k_{Ac}[Ac^-] + k_{HAc}[HAc] \quad \text{(Eq. 19c)}$$

where Ka′ is the dissociation constant of acetic acid.

Thus, from the slopes, k_{Ac}', of lines A_1 and A_2 in Fig. 5, the known $[H^+]$ of each curve and the relation

$$k_{Ac}' = k_{Ac} + (k_{HAc}/Ka')[H^+] \quad \text{(Eq. 20)}$$

the acid-base catalytic constants k_{Ac} and k_{HAc} were calculated (52).

The curves A_2, B_2, and C_2 for the hydrolysis of I to aspirin, III, have the same slope within experimental error, and thus only general base

catalysis is concluded. The intercepts of these lines vary and are consistent with hydroxyl ion catalysis.

Since most pH studies of pharmaceutical degradation rates are conducted in acetic acid-acetate, phosphate, borate, or similar buffers, the potential catalytic action of these species must be evaluated. Such effects have also been observed in the hydrolysis of phenylacetates (13, 23, 162) and in the solvolysis of aspirin anhydride (55). In the latter case, undissociated acetic acid had an inhibitory effect. General base catalysis has been shown for thiamine at pH values less than 7 (193), for the antibiotic streptozotocin by the monohydrogen phosphate anion (57), for methyl pyrrolidylacetylsalicylate hydrochloride by acetate ions (51), for barbital and phenobarbital by ammonia (80, 88, 181), for the antibiotic actinospectacin (69) by phosphate, carbonate, and borate buffers. General acid-base catalysis of chloramphenicol (97, 98) has been determined for monohydrogen phosphate ion, undissociated acetic acid, and both monohydrogen and the dihydrogen citrate ions. For the general case where general acid-base catalysis has been found and may be expected, the reader is referred to texts (9, 43, 123). General acid-base effects were tested for but not observed with acetate buffers for psicofuranine (56), for aspirin (34), the antibiotics streptovaricin (53) and streptozotocin (57), diethylaminoethyl salicylate hydrochloride (52), procaine (95, 130), and chlorobutanol (140). They were not observed with phosphate buffers for chlorobutanol (140), for phthalate buffers for alkyl *dl*-α-(2-piperidyl)-phenylacetates (155, 170), and in the high pH region for thiamine (193).

In actuality many of the mechanisms which follow the basic equations for general base catalysis actually go through a nucleophilic participation in the rate-determining step. Examples are given in Bender's fine review (12). Nucleophilic catalysis is involved in the solvolysis of anhydrides (32, 74–77, 79, 108–110) and also aspirin anhydride (55), in the imidazole (13), N-methylimidazole (24), and 4-methylpyridine (108) catalysis of *p*-nitrophenylacetate hydrolysis (24), and in the acetate ion catalyzed solvolysis of methyl pyrrolidylacetylsalicylate hydrochloride (51).

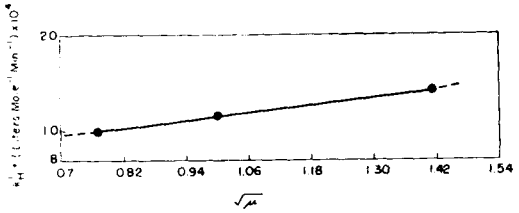

Fig. 6.—Influence of ionic strength on the velocity of a hydronium ion catalyzed solvolysis of a protonated substrate. [Figure 8 of Siegel, S., Lachman, L., and Malspeis, L., THIS JOURNAL, 48, 431(1959)(170).]

Ionic Strength and Dielectric Constant Effects.—The general expression that relates an observed bimolecular rate constant, k_i, with ionic strength, dielectric constant, and other thermodynamic properties of the solution of reactants for ion-ion reactions (1, 2) is

$$\log k_i = \log k_i' + z_A z_B A \sqrt{\mu}/(1 + \beta\sqrt{\mu}) \quad \text{(Eq. 21)}$$

so that

$$k_i = k_i' \, 10^{z_A z_B A \sqrt{\mu}/(1 + \beta\sqrt{\mu})} \quad \text{(Eq. 22)}$$

which to a first approximation may be given as

$$k_i = k_i' \, 10^{(z_A z_B A \sqrt{\mu} + C\mu)} \quad \text{(Eq. 23)}$$

or as

$$\log k_i = \log k_i' + z_A z_B A \sqrt{\mu} \quad \text{(Eq. 24)}$$

so that

$$k_i = k_i' \, 10^{z_A z_B A \sqrt{\mu}} \quad \text{(Eq. 25)}$$

where $\mu = {}^1/_2 \Sigma C_i z_i^2$, the ionic strength, z_A and z_B are the charges on the reacting species, and A and β are functions of the properties of the solution, *e.g.*, dielectric constants, temperature, etc., and thermodynamic constants and can be obtained from the literature (2, 89, 149).

Thus the dependence of log k_i *vs.* $\sqrt{\mu}$ should be a straight line of positive slope for the reactions of ions of like charge sign and negative slope for ions of unlike charge sign. An example of the application of Eq. 24 is given in Fig. 6 for the reaction of the positively charged hydronium ion with the positively charged ester, methyl *dl*-α-phenyl-2-piperidylacetate (170), where the plot of the logarithm of the specific hydrogen ion catalytic rate constant against the square root of the ionic strength is positive. When the positively charged ester is reacted with the negative hydroxyl ion, the salt effect is negative, as evidenced from Fig. 7 where such a plot has a negative slope (170). Such effects have been discussed in detail with many examples by Bell (9) and Amis (2). They have been observed in the acid and base catalyzed hydrolysis of carboxymethyltriethylammonium halide (10, 11, 145).

The salt effect is negative, *i.e.*, $z_A z_B A$, for the hydroxyl ion and general base, A^-, catalyzed solvolysis of the positively charged methyl pyrrolidylacetylsalicylate hydrochloride (51) and of the positively charged thiamine (193); for the

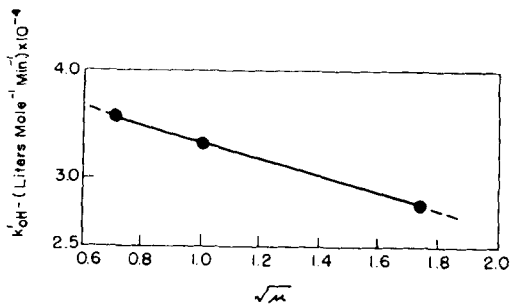

Fig. 7.—Influence of ionic strength on the velocity of a hydroxyl ion catalyzed solvolysis of a protonated substrate. [Figure 9 of Siegel, S., Lachman, L., and Malspeis, L., THIS JOURNAL, **48**, 431 (1959) (170).]

general base, A^-, catalyzed solvolysis of the protonated diethylaminoethylacetylsalicylate hydrochloride (52). The salt effect is positive, *i.e.*, $z_A z_B A$ for the hydroxyl ion catalyzed solvolysis of the negatively charged *m*- and *p*-hydroxybenzoates (154). In one study, salt effects were observed for the solvolysis of barbital (80) but were not quantified.

Salt effects were checked for but not observed in the pH regions studied for the acid and base catalyzed solvolysis of protonated procaine (95, 130), the solvolysis of N-acetyl-*p*-aminophenol (114), the acid solvolysis of chlorobutanol (140), the acid catalyzed solvolysis of doubly positively charged thiamine (193), the solvent catalyzed solvolysis of streptozotocin (57) and streptovaricin (53), the solvolysis of chloramphenicol in phosphate buffer (98), the hydroxyl ion catalyzed solvolysis of diethylaminoethyl salicylate hydrochloride (52), and the solvolysis of acetylsalicylic acid anhydride (55).

Also a plot of log k_i *vs.* the reciprocal of the dielectric constant at $\mu = 0$ should yield a straight line of negative slope for ions of like charge sign and of positive slope for ions of unlike charge sign (1, 2).

It follows that the use of miscible water-organic solvents where the dielectric constant decreases with more of the organic solvent should not increase the stability of a drug if the rate-determining step involves reactants of unlike charge. It can be predicted that the use of alcohol-water, propylene glycol-water, dimethylacetamide-water, sugar-water, or glycerol-water solutions will tend to increase the instability of protonated drugs subject to general or specific base catalysis in the presence of buffer anions if this is the major catalytic species. Examples of such predictions would be the hydrolysis of the scopolamine methylbromides (49, 67), atropine ethyl and benzyl bromides (152), the pH 3–7 solvolysis of methyl *dl*-α-phenyl-2-piperidylacetate (170), and alkyl *dl*-α-(2-piperidyl)-phenylacetates (155), where the major hydrolysis has been assigned to hydroxyl ion attack on a positively charged molecule. Certainly, in the case of the reaction of similarly charged species, such as in the hydroxyl ion catalyzed solvolysis of an anion (59, 61, 68) or the hydrogen ion catalyzed solvolysis of a cation (35, 95, 113, 130, 152, 155, 170, 198), the stability should be increased by decreasing the dielectric constant. The example of the decreased rate of fading of bromphenol blue (negatively charged quinoid dye ion) with hydroxyl ion when the alcohol content of water-ethanol and water-methanol solvents is increased (2, 3) is discussed in detail by Amis (1).

In the limiting case of the attack of an ion on a dipolar molecule (1, 2)

$$\log k' = \log k'_D + K \frac{z\mu}{D} \qquad \text{(Eq. 26)}$$

Thus, with an increase in dielectric constant, D, the rate of the reaction decreases for a positive ionic reactant and increases for a negative ion reactant. If the dielectric constant is decreased the rate should increase for positive ions and decrease for negative ions.

This equation and its indicated interdependencies has been applied with reasonable success to both the hydroxyl and hydrogen ion catalyzed hydrolysis of esters in water and organic solvent-water mixtures.

Examples are the water-ethyl alcohol and water-acetone alkaline solvolysis of ethylacetate (4, 156) and methyl propionate (157); the water-alcohol acid hydrolysis of aspirin (50), the water-acetone acid hydrolysis of methyl propionate (105), ethylacetate (141), ethyl formate (168), and ethyl dichloroacetate (142). In the case of the latter reactions of specific hydronium ion catalyzed ester hydrolysis where a preliminary equilibrium with water prior to the rate determining step may occur, the k' of Eq. 26 may be made specific with respect to water by dividing by the concentration of water. The relation of Eq. 26 is then demonstrated more validly (1, 105, 132, 141). A plot of data consistent to the requirements of this equation for the reaction between a cation and a dipolar molecule is given in Fig. 8 for chloramphenicol hydrolysis (132).

These relationships of rate with dielectric constant can also be used as methods to determine the nature of the reaction. In the hydrolysis of acylsalicylates (50, 58), the increase of rates of solvolysis of the aspirin anion with increasing ethanolic content along with the relative

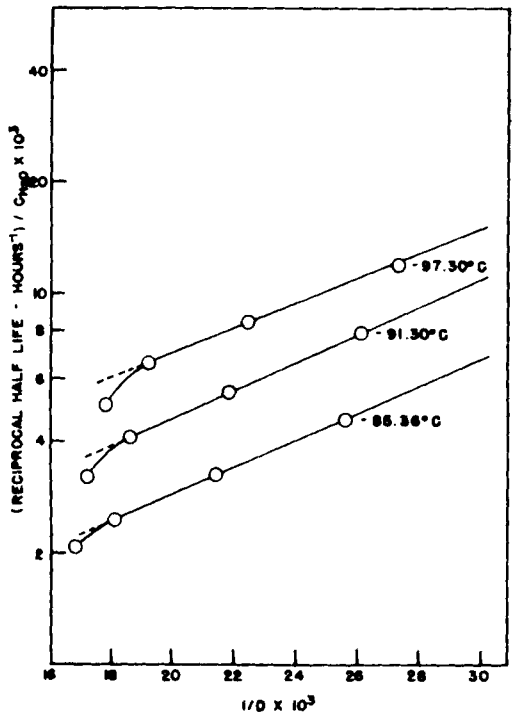

Fig. 8.—Influence of dielectric constant on reaction rates for the apparent reaction between the protonated chloramphenicol and the dipolar molecule water. [Figure 7 of Marcus, A. D., and Taraszka, A. J., THIS JOURNAL, **48**, 77(1959) (132).]

constancy of rate with increasing dioxane content, both concomitant with decreasing dielectric constant, did not implicate direct water attack on the aspirin anion. It led to kinetic evidence for intramolecular catalysis (50) and subsequently to the deduction of a possible rate-determining step in the attack of water or ethanol on an uncharged cyclic intermediate (58). Marcus (132) states that the rates for acid catalyzed solvolysis of protonated chloramphenicol in propylene glycol-water mixture does not fit the requirements for like charged ions and can be explained by the fact that the rate-determining step is an ion-dipolar molecule reaction between hydrogen ions and the hydrated amide. The log $k_1/[H_2O]$ values, when plotted against the reciprocal of the dielectric constant (84) as per Eq. 26, is linear and of positive slope. A point of Marcus (132) is well taken in that it is unwise to make any blanket assumption that lowering the dielectric constant (in general, by increasing the nonaqueous content of a solvent) will increase the stability of a drug. Predictions of stability as functions of the dielectric constant are valid on the basis of the operative mechanisms.

The limiting case for a dipolar molecule-dipolar molecule reaction is usually independent of ionic strength but dependent on dielectric constant (1, 2)

$$\log k_i = \log k_{(D=\infty)} - K(1/D) \quad \text{(Eq. 27)}$$

where a decrease in the dielectric tends to decrease the rate, and conversely.

There are many ways to relate the observed rate constant, k_i, to some function of the dielectric constant, D, for the interaction of dipolar molecules. A general expression to relate linearly the logarithm of the specific rate constant and some function of the dielectric ϕ_i (D), where m and b are constants, is

$$\log k_i = m_i\phi_i(D) + b_i \quad \text{(Eq. 28)}$$

Within small ranges of high dielectric constant, this relation is usually linear for practically any ϕ_i (D), *i.e.*, ϕ_1 (D) = nonaqueous solvent, ϕ_2 $(D) = D$, ϕ_3 $(D) = 1/D$, or ϕ_4 $(D) = (D - 1)/(2D + 1)$ (2, 72) as was shown in the case of the hydrolysis of aspirin anhydride (55). The latter expressions for ϕ_3 (*i.e.*, Eq. 27) and ϕ_4 can be extended to greater ranges of dielectric constant. Examples and further discussion can be found in the literature for the effect of solvent and dielectric constant on rates (38, 125, 153).

A plot of log k *vs.* $(D - 1)/(2D + 1)$ has been made for *t*-butyl chloride (124) in aqueous ethanol and in aqueous dioxane, acetone, ethanol, and methanol (38), for acetic anhydride (74, 78), benzoyl chloride (5, 78), benzyl (111), and substituted benzylsulfonates (112) in aqueous acetone, for ethylene bromo and iodohydrin (28) in aqueous ethanol, for *p*-nitrobenzylbromide (85) in aqueous dioxane. In most cases since m $(1/D) + b$ is the first part of the numerical expansion of $(D - 1)/(2D + 1)$, the fit of log k *vs.* $1/D$ is just as valid. Log k *vs.* log D appears to give the best possible linearity (38).

Solvolysis Rates, pH, and the Ionic Nature of the Substrate.—In many cases the hydrogen and hydroxyl ion catalyzed degradation rates of drugs in solution vary with the kind and amount of charge on the substrate molecule. The complex kinetic expressions that quantify these phenomena have been developed excellently by Higuchi (95) and Edwards (34). The approach of Edwards can be applied to the general case of the charged or uncharged acid substrate. The apparent dissociation constant, K_a, can be defined as

$$K_a = [S^-][H^+]/[HS] = [S][H^+]/[SH^+] \quad \text{(Eq. 28)}$$

In the solvolytic reactions of an uncharged acid the ionic form of the reacting substrate, the catalytic species and the specific rate constant can be given, respectively, as: HS, H^+, k_1;

HS, (H_2O), k_2; HS, OH^-, k_3; S^-, H^+, k_4; S^-, (H_2O), k_5; S^-, OH^-, k_6. With respect to k_2 and k_5 these values may or may not be dependent on the bimolecular attack of water or solvent on substrate and for this purpose are defined as first-order rate constants with respect to substrate rather than the alternatives, $k_2' = k_2/[H_2O]$, or $k_5' = k_5/[H_2O]$. Equivalent definitions and symbolisms and arguments can be constructed for the charged acid, SH^+.

It is reasonable to expect *a priori* that the specific bimolecular rate constant k_1 for the attack of a hydrogen ion on the undissociated uncharged acid, HS, would be less than the k_4 specific rate constant for such an attack on the oppositely charged anion, S^-. This does not necessarily imply that $k_1[H^+][HS] < k_4[H^+][S^-]$ so that the decomposition in acid solution is less than the decomposition in neutral solution since, to achieve a significant concentration of $[S^-]$, the concentration of $[H^+]$ must decrease below the dissociation constant, Ka. Similarly, although it is reasonable to expect *a priori* that the specific bimolecular rate constant k_3 for the attack of a hydroxyl ion on the undissociated uncharged acid, HS, would exceed the specific bimolecular rate constant for the attack of a hydroxyl ion on the anion S^-, it does not necessarily imply that decomposition in solutions of pH less than pKa exceeds that of solutions of pH greater than pKa. In the case of acetylsalicylates, the conditions defined by the dissociation constant of the acids where HS exists at very low concentrations of hydroxyl ion $[OH^-]$, indicate that $k_3[OH^-][HS]$ does not contribute significantly to the overall hydrolysis rate to products (34, 50).

The rate of decrease of the total concentration of substrate, $[HS]_T$, by solvolytic processes is equivalent to the sum of the rates of decrease of the undissociated acid [HS] and the anion $[S^-]$, which in turn can be defined by the specific rate constants

$$-d[HS]_T/dt = k[HS]_T \text{ (at constant pH)} = k([HS] + [S^-]) \quad \text{(Eq. 29)}$$

and

$$-d([HS] + [S^-])/dt = k_1[H^+][HS] + k_2[HS] + k_3[OH^-][HS] + k_4[H^+][S^-] + k_5[S^-] + k_6[OH^-][S^-] \quad \text{(Eq. 30)}$$

It has been shown (34, 95) that

$$k = (k_1[H^+] + k_2 + k_3[OH^-])/(1 + Ka/[H^+]) + (k_4[H^+] + k_5 + k_6[OH^-])/(1 + [H^+]/Ka) \quad \text{(Eq. 31)}$$

where

$$f_{HS} = 1/(1 + Ka/[H^+]) = [HS]/[HS]_T \quad \text{(Eq. 32)}$$

is the fraction of $[HS]_T$ as the undissociated acid [HS] and where

$$f_{S^-} = 1/(1 + H^+/[Ka]) = [S^-]/[HS]_T \quad \text{(Eq. 33)}$$

is the fraction of $[HS]_T$ as the dissociated acid $[S^-]$.

Analogous expressions could be derived for a singly charged (SH^+) or doubly charged substrate (SH^{++}).

If the substrate has two or more functionalities that vary the kind and amount of charge on the reacting molecule with pH, *i.e.*, pKa_1, pKa_2, etc., then a suitable variation of Eq. 31 could be developed on the same principles.

Frequently, kinetic ambiguity may exist. For example, a rate contribution may be assigned to $k_4[H^+][S^-]$ or to $k_2[HS] = k_4K_a[HS]$, as in the case of the hydrolysis of acetylsalicylate (50), and still be consistent with the kinetic data. Similarly, a rate contribution may be assigned to either $k_5[S^-]$ or $k_3[OH^-][HS] = k_5K_a[OH^-][HS]/Kw$, as in the case of the hydrolysis of hydrocortisone hemisuccinate (59).

Another alternative kinetic equivalence is $k_6'[OH^-]^2 f_{HS^{++}} = k_5 f_S$ at high pH values for the solvolysis of thiamine (193) where the mechanism of "spontaneous" decomposition was chosen on the basis of the fact that primary salt and general base catalytic effects could not be observed. Also, for thiamine solvolysis, where $k_3[OH^-]f_{HS^{++}} = k_5 f_{S^+}$, the interaction of hydroxyl ion and double protonated thiamine was chosen over the "spontaneous" decomposition of singly protonated thiamine since a negative dependence on ionic strength pointed to the reaction of a negative and positively charged ion (193). The hydroxyl ion catalyzed solvolysis of the uncharged alkylsalicylate, $k_3[OH^-]f_{HS}$, was chosen over its kinetic equivalent, the "spontaneous" hydrolysis of the ester ion, $k_5 f_{S^-}$, on the basis of the variation of rate with dielectric constant (154). Alternate choices for the solvolysis of pyridine 2-aldoxime methiodide on kinetic grounds are the specific base hydrolysis of the protonated substrate, $k_3[OH^-]f_{SH^+}$, or the spontaneous decomposition of the neutral substrate, $k_5 f_S$ (35).

Predictive equations for the kinetics of solvolysis of drugs are given in Table I in accordance with Eq. 31 for the dependency of the apparent first-order rate constant, k. Where the specific rate constants can be further defined in terms of salt effects (ionic strength) and dielectric constant, this has been done. The log k *vs.* pH profiles given in Figs. 3, 4, and 9–14 show interesting variations when the various specific bimolecular

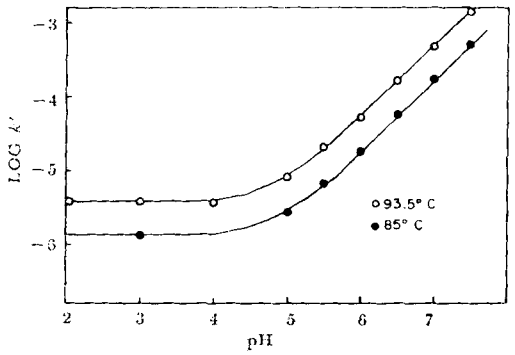

Fig. 9.—The log k-pH profile for the solvolysis of chlorbutanol. [Figure 9 of Nair, A. D., and Lach, J. L., THIS JOURNAL, **48**, 390(1959) (140).]

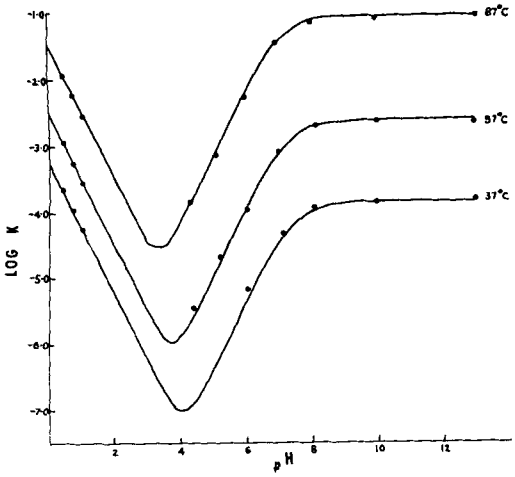

Fig. 10.—The log k-pH profile for the solvolysis of pyridine-2-aldoxime methiodide. [Figure 5 of Ellin, R. I., Carlese, J. S., and Kondritzer, A. A., THIS JOURNAL, **51**, 141(1962) (35).]

rate constants, k_i, $i = 1, 2 \ldots 6$ are observed as having significant contributions to the overall rate. Figure 3 for the protonated methyl *dl*-α-phenyl-2-piperidylacetate (170) exhibits the classic catenary when only specific acid-base catalysis is observed, as does the alkyl *dl*-α-(2-piperidyl)-phenylacetates (155) which exhibits a maximum stability at pH *ca.* 3. A similar profile for N-acetyl-*p*-aminophenol (114) has minimum at pH *ca.* 5–6. The profile of streptovaricin (53) Fig. 4, has a probable minimum plateau at pH values 3–4 due to a probable pH-independent solvolysis when the hydrogen ion concentration is lessened. Chlorobutanol (140), Fig. 9, exhibits no acid catalyzed solvolysis so that its maximum stability is a plateau at pH values less than 5. Pyridine 2-aldoxime methiodide (35), Fig. 10, exhibits minimal instability at pH *ca.* 3–4 and an interesting pH-independent plateau in the alkaline region due to a high sta-

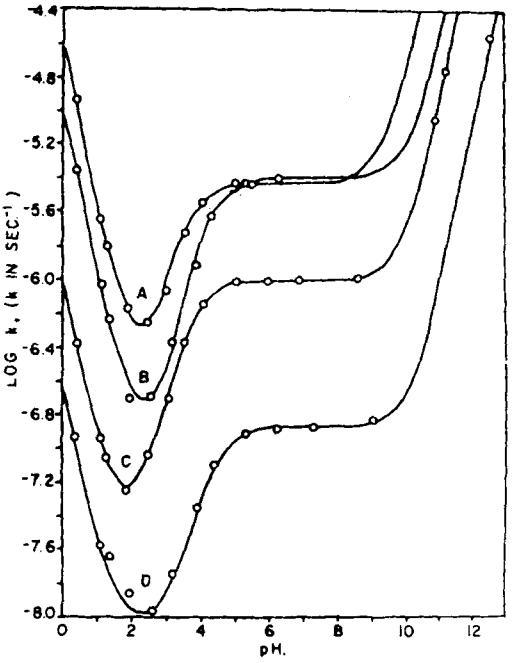

Fig. 12.—The log k-pH profile for the solvolyses of acylsalicylic acids, A, acetyl-; B,β-cyclopentyl-propionyl-; C, trimethylacetyl-; D, diethylacetyl-, at 25°. [Figure 1 of Garrett, E. R., *J. Am. Chem. Soc.*, **79**, 3401(1957) (50).]

bility of the oximate to hydroxyl ion attack. Streptozotocin (57) exhibits two deviations from the expected catenary in its log k-pH profile, Fig. 11. In the alkaline branch, rates in phosphate buffer exceed the specific base catalysis expected due to a general base catalysis by phosphate anions. On the other side of the arte minimum at pH *ca.* 4 in the acid branch, the log k *vs.* pH plots deviates from a slope of unity. Such kinetic data permit the calculation of a dis-

sociation constant difficultly obtainable by potentiometry, and the method described in the original paper (57) may be of interest. The hydrolyses of acetylsalicylic acids (34, 50) have an interesting log k-pH profile, Fig. 12, due to a pH-independent rate of anion solvolysis before hydroxyl ion catalyzed hydrolysis of the anion becomes significant. The pH of maximal stability of these compounds is *ca.* 3. Thiamine (193) also has an interesting profile, Fig. 13, and exhibits the extraordinary phenomenon of a large rate elevation within a short pH range that maintains constancy with large increases in pH. This phenomenon can be assigned to the change in the ionic nature of the substrate with pH where the new solution species of thiamine has a high but constant rate of solvolysis. Psicofuranine's (56) log k-pH profile, Fig. 14, exhibits the classical case of a substrate that can exist in three ionic forms in which the cationic form shows hydrogen ion catalyzed solvolysis, the anionic form hydroxyl ion catalyzed solvolysis, the neutral form is subject to both catalyses, and the pH of minimum hydrolysis is *ca.* 8–8.5.

The importance of a rate-pH profile cannot be underestimated for the prediction of the pH of minimum hydrolysis, the optimum for pharmaceutical stabilities. It can readily be seen that relationships among the magnitudes of the determined k_i values determine the pH of this minimum. Other pH minimum values so obtained are *ca.* pH 1–3 for thiamine (193), *ca.* pH 3 for hydrocortisone hemisuccinate (59) [which rate-pH profile resembles acetylsalicylic acid (34, 50) except for the lack of a significant k_4], and pH < 3 for aspirin anhydride (55) which has no specific acid catalyzed solvolysis similar to chlorobutanol (140). Actinospectacin (69) also showed no pharmaceutically significant acid instability and the barbitals (80, 88, 181) were not attacked by acid.

The isocatalytic point has been discussed for other solvolyses (107), ethylaminoacetate (19), and acetylcholine (25).

Approximative Methods for Log k-pH Relations.—As has been discussed, there are many instances where the ionic strength, general acid-base catalysis, or changes in the ionic nature of the substrate due to pKa properties, known or unknown, will give apparent nonlinear relations between log k and pH. In many cases the relation can be mathematically characterized, however, by an equation of the form

$$\log k = -n\text{pH} + \log k_i \qquad \text{(Eq. 34)}$$

or

$$k = k_i\, 10^{-n\text{pH}} \qquad \text{(Eq. 35)}$$

Similarly

$$k = k_i\, 10^{n\text{pOH}}$$

where the pH or pOH range of effectiveness must be defined. Such relations have been used to characterize the solvolysis of hydrocortisone phosphate in the neutral pH range (132), the racemization of epinephrine (165), the basic solvolytic degradation of actinospectacin (69), and the solvolysis of streptozotocin in phosphate buffers (57) where general base catalysis perturbed the alkaline branch of the specific acid-base catalytic catenary.

Frequently, such perturbations can also be accounted for by defining a rate constant for a particular hydrogen ion or hydroxyl ion range as

$$k = k'[OH^-] + k''; \; a < [OH^-] < b \quad \text{(Eq. 36)}$$

or

$$k = k'[H^+] + k''; \; a' < [H^+] < b' \quad \text{(Eq. 37)}$$

Examples and comparisons of the above two sets (Eqs. 34–37) of approximations with the values given by a true mechanistic dependency are given for actinospectacin (69) and psicofuranine (56, 66).

Prediction of Solvolytic Rates at Various Temperatures.—The quantitative relation of specific reaction rates and temperature is the Arrhenius expression (2, 9, 14, 29, 43, 71, 72, 86, 103, 104, 123, 138)

$$k_i = Ae^{-\Delta H_a/RT} \quad \text{(Eq. 38)}$$

where k is the specific rate of degradation or rate constant, T is the absolute temperature (°C. + 273), R is the gas constant (1.987 calories degree^{-1}mole^{-1}), A is a constant associated with the entropy of the reaction and/or collision factors, and ΔH_a is defined as the heat of activation.

The logarithmic form of Eq. 38

$$\log k_i = -(\Delta H_a/2.303R\,(1/T) + \log A \quad \text{(Eq. 39a)}$$

$$= -S/T + P \quad \text{(Eq. 39b)}$$

shows that the slope, $-S$, and intercept, P, of the plot log k *vs.* $1/T$ and, thus, ΔH_a and A, can be evaluated (Fig. 15) from several studies at various temperatures. Thus, the specific rate constants for any temperature can be calculated from a knowledge of these constants and applied to the prediction of the overall apparent first-order rate constant as previously discussed. It is also apparent that a rate constant at any temperature can be calculated from the knowledge of the heat of activation, ΔH_a and one rate constant at a known temperature (193). The footnotes of Table I specify if A and ΔH_a are available for the various solvolytic degradations of those pharmaceutically important compounds and a list of some of them is tabulated elsewhere (170). Additional sources of such values are in the texts previously cited and may be found for many others, as well as the kinetic dependencies of rates, in two fine compilations published by the National Bureau of Standards (173).

The effect of ΔH_a of the per cent of the organic component in mixed aqueous-organic solvents in the hydrolysis of esters is given by Tommila, *et al.* (154, 182–184). Graphs of this dependency generally pass through a minimum for alkaline solvolysis.

Higuchi and Busse (92) have pointed out that knowledge of the heats of activation for the

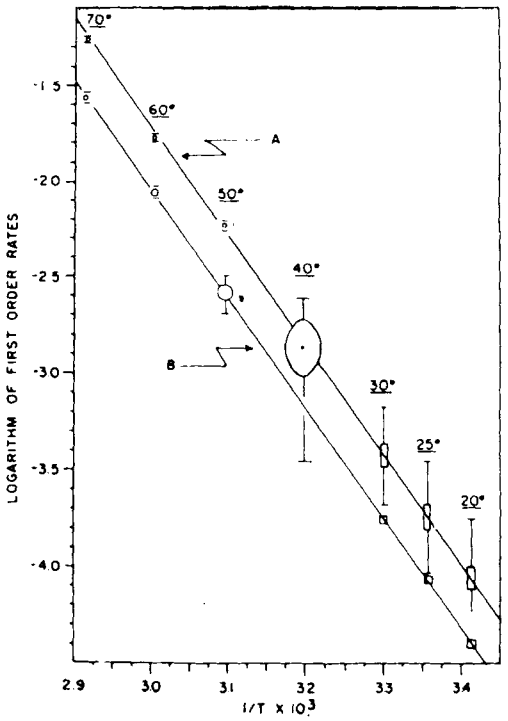

Fig. 15.—Arrhenius plots for thiamine hydrochloride in liquid multivitamin preparations. The circles represent the standard deviation of an experimental log rate in days and the rectangles the standard deviation of a predicted log rate. The horizontal lines represent the 95% confidence limits of experimental and predicted log rates. [Figure 3 of Garrett, E. R., THIS JOURNAL, **45**, 470(1956) (47).]

stability of drugs and the sterilization of microorganisms and their relative magnitudes can permit the proper choice of sterilizing times and temperatures for minimum loss of the drug. For procaine solutions, autoclaving at 120° is preferable to prolonged sterilization at 100°.

Comprehension of the significance of the knowledge of heats of activation can permit the prediction of the feasibility and optimum temperatures and time for the selective degradation of components in a mixture of drugs for the salvaging of lots contaminated by an unwanted material difficult to remove by other methods. This technique has been applied to a mixture of penicillins (65).

A special point must be made of the care that must be taken in estimating the heats of activation which are frequently deduced as "apparent" heats of activation (95, 140, 198).

If rate is dependent on hydroxyl ion concentration, $k_6[OH^-]$, and is determined at constant pH for several temperatures then

$$k_6[OH^-] = k_6Kw/[H^+] = k_6'Kw = Ae^{-\Delta Ha/RT} = A_{k_6'}e^{-\Delta H_{k_6'}/RT}\,A_{Kw}e^{-\Delta H_{Kw}/RT} = Ae^{-(\Delta H_{k_6'}+\Delta H_{Kw})/RT} \quad \text{(Eq. 40)}$$

and the heat of ionization of water, ΔH_{Kw}, must be subtracted to obtain the heat of activation of the specific hydroxyl ion catalyzed reaction $\Delta H_{k_0'}$.

Prediction of Drug Solvolysis in Heterogeneous Systems.—Since rate is a function of the concentration of the substrate, an apparent first-order reaction will become zero order with respect to substrate in saturated solutions as

$$\text{amount/volume/time} = kc_s = k_0c^0 = k_0 \quad \text{(Eq. 41)}$$

since c_s is the concentration of the substrate in the saturated solution.

It is thus possible to decrease the overall rate of hydrolysis of a substrate by solvolytic mechanisms by decreasing its solubility in the pharmaceutical vehicle. Examples are penicillin G procaine suspensions (172) and saturated solutions of acetylsalicylic acids (15, 48). Although the stability of acetylsalicylic acids in homogeneous solution (50) was in the decreasing order; diethylacetyl-, trimethylacetyl-, β-cyclopentylpropionyl-, acetyl-, in saturated solution, β-cyclopentylpropionyl-salicylic acid had the greatest stability due to its lowest solubility. When the kinetic dependencies of the apparent first-order rate constant, k, are known and the solubility, c_s, is also known as a function of pH and temperature, the stability of saturated solutions can be predicted.

The expression (48, 94, 133)

$$\text{pKa}' = \text{pH} + \log c_i/(c_s - c_i) \quad \text{(Eq. 42)}$$

may be used to predict the solubility, c_s, of a material of pKa′ at any given pH where c_i is the intrinsic solubility, *i.e.*, the solubility of the uncharged species which is presumed to be the determining factor of total solubility. The equation has been used to determine the solubility of sulfadiazine sodium (106) and secobarbital (185) in several solvent systems. For example, the stability of saturated solutions of barbitals could be calculated for any pH from the data on solubility (94) and the data on homogeneous kinetics (80, 88, 181) given in the literature.

In general, solubility also follows the Arrhenius law of Eq. 38 where ΔH_a represents the heat of solution, so that with the parameters of this equation, solubility c_s can be predicted for any temperature (54, 185). The complex system of saturated solutions of aspirin anhydride degrading to aspirin to salicylic acid can be quantitatively predicted for any temperature or pH (54). It was also shown, analogous to Eq. 40, that the apparent heat of activation for the degradation of saturated solutions of aspirin anhydride is actually the sum of the heats of solution and of activation of the homogeneous solution hydrolysis for aspirin anhydride (54).

Riegelman (159) has stated that in the heterogeneous system produced by surfactants with benzocaine that hydrolysis rates are more dependent on surfactant concentrations than the chain length of the polymeric surfactant. Anionic and cationic surfactants appear to stabilize the drug to base catalysis.

Bonus Values from Predictive Techniques.—Not only is information obtained from these studies that would permit the prediction of stability with varied substrate concentrations, pH values, salt concentrations, solvent changes, temperature variations, or saturated solutions, but additional information can be gleaned from judiciously designed experiments. The antibiotic psicofuranine is solvolytically degraded to adenine which is uniquely antagonistic to the antibacterial properties of its precursor (66). This was determined from concomitant biological and chemical assays of degrading solutions and the fact that a plot of biological assay *vs.* chemical assay was linear, but of negative intercept. Further investigation proved that the product adenine lessened the biological response. A decision was made that the excellent anticholinergic properties of acetylscopolamine methyl bromide were unique to this compound and not due to its ready gastrointestinal hydrolysis to the already established anticholinergic scopolamine methyl bromide, and that an expensive clinical trial of the former compound was justified (49). Comparison and understanding of the kinetics of solvolysis and solubilities of aspirin anhydride (54, 55) and aspirin (34, 48, 50), plus a comprehension of the rationales for aspirin absorption, led to the clinically confirmed prediction that aspirin anhydride would give higher blood levels of aspirin and less levels of salicylic acid than aspirin on oral administration to fasting subjects (54). The recommended conditions for autoclaving procaine solutions for minimum instability has already been cited (92). Stability studies were consistent with the fact that oral inefficacy of *p*-chlorobenzaldoxime (60) could be ascribed to gastric solvolysis but excluded this as an explanation for the oral inefficacy of N-butylformamide (70). The knowledge of the log k-pH profile of aspirin solvolysis (34, 50) suggested that a protonated amine in the molecule would permit a soluble, stable salicylic acid derivative to be formulated in an acid aqueous media which might readily hydrolyze to aspirin at the pH of the intestine.

TABLE II.—REPRESENTATIVE LOG k *vs.* pH PROFILES FOR VARIOUS KINETIC DEPENDENCIES OF THE APPARENT FIRST-ORDER RATE CONSTANT, k

Figure	k[a]	Substrate HS or S	Reference
3	$k_1[H^+] + k_3[OH^-]$	Methyl *dl*-α-phenyl-2-piperidylacetate	(170)
4	$k_1[H^+] + k_2$	Streptovaricin	(53)
9	$k_2 + k_3[OH^-]$	Chlorobutanol	(140)
10	$(k_1[H^+] + k_3[OH^-])f_{SH^+}$	Pyridine 2-aldoxime methiodide	(35)
11	$k_1[H^+]f_{SH^+} + (k_4[H^+] + k_6[OH^-])f_S$	Streptozotocin	(57)
12	$k_1[H^+]f_{HS} + (k_4[H^+] + k_5 + k_6[OH^-])f_{S^-}$	Acylsalicylic acids	(50)
13	$(k_1[H^+] + k_2 + k_3[OH^-])f_{SH^{++}} + k_8f_S$	Thiamine	(193)
14	$k_1[H^+]f_{SH^+} + (k_4[H^+] + k_6[OH^-])f_S + k_9[OH^-]f_{S^-}$	Psicofuranine	(56)

[a] f_S, f_{SH^+}, f_{HS}, or f_{S^-} represent the fraction of substrate, S or HS, in charged or uncharged form.

One of two such compounds did so readily hydrolyze to aspirin in slightly alkaline media, but both compounds unfortunately exhibited a high degree of general base catalyzed hydrolysis even by water alone in acidic solutions (51, 52). This did lead to a fundamental contribution since general base catalyzed hydrolysis of esters had been presumed to be nonexistent (9, 123) prior to the time of submission of the first paper for publication (51).

An intriguing stabilization technique has been introduced by Higuchi, Lachman, and co-workers (20, 96, 120–122). This technique was based on their comprehension of the fact that a complexed substrate might have negligible degradation rates in contrast to the uncomplexed substrate. Thus, knowledge of the equilibrium constants for the formation of such complexes and kinetic studies should permit the prediction of stability of complex-stabilized substrates. Examples are the stabilization of benzocaine (96, 116), procaine (122), tetracaine (121), and *p*-hydroxybenzoic acid (20) by caffeine, homologs (20, 120), and other agents (116). In many of these instances, the complexed substrate did not hydrolyze at all and the appearance of degradation products could be ascribed solely to the free substrate in equilibrium with the complex. A more recent paper (160) substantiates this principle by demonstrating that boric acid chelation of the catechol nucleus of epinephrine stabilizes against degradation by the attack of sulfite and bisulfite ions on the optically active side chain (100, 102, 118). It has also been shown that lithium chelates with alkylsalicylates and inhibits hydroxyl ion attack (154). This thesis has led workers to consciously seek to find if complexation exists and inhibits degradation rates. Unfortunately, success has not met all such attempts (155, 193).

A more detailed review of the literature on complexation of pharmaceuticals and its potential applications, including the stabilization of these pharmaceuticals, has been recently published by Walker (186, 187). The role of chelation in drug stabilization and other phenomena is covered in a review by Foye (42).

Frequently it is felt that modification of a pharmaceutical compound by appropriate substituents, if therapeutic efficacy was not decreased, could increase the stability of the pharmaceutical. It is apparent that steric blocking was effective in the case where the size and complexity of the acid groups in acetylsalicylic acids (50) and 21-steroid hemiesters (59, 68) varied. The Newman "rule of six" (127, 144) has great predictive power in the estimation of steric hindrance of ester solvolysis.

Another powerful predictive tool is the Hammett linear free energy relation of sigma-rho (43, 86) where

$$\log k = \log k_0 + \sigma\rho \qquad \text{(Eq. 43)}$$

where the substitutent constant σ is determined by the nature of the substituent and independent of the reaction; where the reaction constant ρ is a constant for all substituents. By definition, $\sigma = 0$ when $k = k_0$, the rate constant of the unsubstituted compounds. Hammett determined σ values for various substituents of benzoic acid as the logarithm of the ratio of the dissociation constants of the *m*- and *p*-substituted benzoic to unsubstituted benzoic acids. Astonishing linearity of log k *vs.* σ plots exists for many reactions. Taft (174–176) has extended this concept to the reactions of aliphatic compounds and *ortho*-substituted benzene derivatives. The contributions of Hammond (87) and Grunwald and Winstein (82) should be noted. Recently, Portoghese and Malspeis (155) have shown that when the log k/k_0 for the log ratio of specific base catalyzed hydrolysis rate constant of some alkyl esters of *dl*-α-(2-piperidyl)-phenylacetic acids to that constant for the methyl ester is plotted against a σ obtained from a log ratio of specific base catalyzed hydrolysis of alkyl acetates, astonishing linearity is obtained (Fig. 16). These

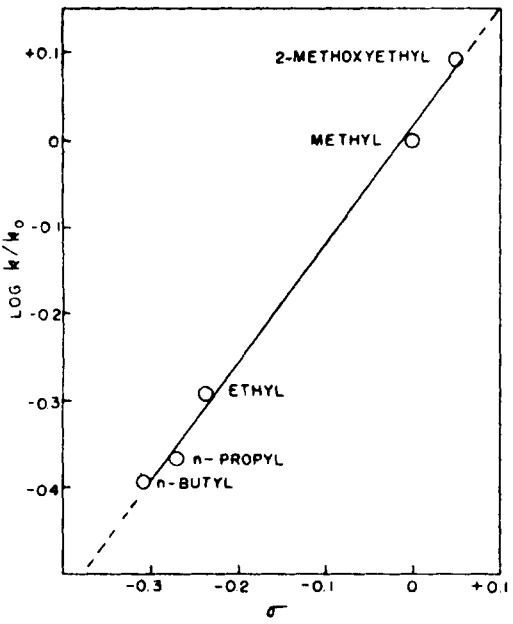

Fig. 16.—Correlation of log k/k_0 values for the specific base-catalyzed hydrolysis of alkyl esters of *dl*-α-(2-piperidyl)-phenylacetic acid at 80°, pH 5.98 with σ values of alkylacetates. [Figure 5 of Portoghese, P., and Malspeis, L., THIS JOURNAL, **50**, 494(1961)(155).]

facts imply that the σ and ρ constants available in the literature may permit the prediction of appropriate substituents to obtain the desired stability of many compounds, or that with a minimum of study on some substituent groups, the effects of many on stability can be quantitatively predicted.

It has also been shown that vitamin A esters of acids in anhydrous solvents have increased stability to proton attack with increasing Ka of such acids and yet in the absence of mineral acids, the instability of the vitamin A ester increases with the Ka of the ester acid portion (41).

Prediction of Stability of Drugs of Unknown Structure.—There is a need in pharmacy to study the changes in structures of molecules of unknown structure to predict stability. The stability of materials must be known for the establishment of treatment of assay standards and for the preparation of samples to be submitted for clinical evaluation.

The application, efficacy, and toxicity of an antibiotic or antibiotic complex is frequently well known before the components can be separated, purified, individually characterized, and structures assigned.

The stability of materials must be known for the establishment of treatment of assay standards and for the preparation of samples to be submitted for clinical evaluation.

Prediction of stability and design of formulations may be based on studies of the rates of change of some physicochemical characteristic. Correlation of changes in the physicochemical properties with the changes in the bioassays may serve as a valid argument for the use of the former. An obvious disadvantage is that variation in the latter may not necessarily reflect in the former although the converse is not probable.

Obvious advantages are that such physicochemical studies will be easy to conduct, less expensive, can lead to prediction of the conditions that affect degradation, and provide information on the properties of the intermediates and products.

Examples of the application of such a philosophy were the stability studies on the antibiotic fumagillin (33, 45, 64), an amebacide, which showed the necessity of protecting the material from light and oxygen and gave the rates of degradation in solution and crystal, as well as Arrhenius' expressions for predicting temperature effects. The ultraviolet absorptivities were correlated with biological activites (64). The prediction of the stabilities of the antitubercular streptovaricins (53) and the antibiotics, streptozotocin (57) and actinospectacin (69), have been previously discussed. The studies on the streptovaricins (53) also provided a correlation of biological activities with spectrophotometric absorptivities, the fact of increased stability in ethanol, physicochemical properties of the degradation product which would abet purification, and a differential kinetic method to assay for individual streptovaricins in the antibotic complex.

The stability studies on streptozotocin (57) correlated the polarographic and color assay due to an N-nitrosomethyl urea function with biological activity, kinetically observed a low pKa, and predicted that the high instability at the pH values of the blood would not permit significant blood levels of the antibotic to be observed. This was found to be true (188).

The stability on actinospectacin (69) correlated a copper chelate assay with biological activity, pointed out that the bioassay reliability was a function of buffer concentration, and kinetically observed a pKa *ca.* 12.

Other Studies.—Other kinetic studies on the stability of drugs that have been reported are the alkaline decomposition of glutethimide (195), the specific acid catalyzed decomposition of chlorothiazine (194) and diphenhydramine hydrochloride (146). The log *k*-pH profile has been given for procaine and tetracaine

(178) hydrolysis, substituted salicylic acid decarboxylation (191) as *p*-aminosalicylic acid (177, 179), and the solvolytic degradation of penicillin (21). The kinetics of formation of anhydrovitamin A for the alcohol and acetate of vitamin A have been investigated (99).

Thermal degradation of glucose solutions exhibited general acid-base catalysis with a rate dependence on substrate concentration (189). The heat of activation was determined from rate constants estimated by the initial slopes of the rate plots. The kinetics of glucose degradation in acid solution were also followed by the initial rate of formation of 5-hydroxymethylfurfural (90). The logarithm of the apparent rate constant varied linearly with the reciprocal of the dielectric constant, as predicted for a reaction between a positive ion and a dipole, as indicated by Eq. 26.

A catenary has been drawn for the pH dependency of the decomposition rate of oxophenarsine hydrochloride and Arrhenius parameters can be calculated from the data given (6).

The kinetics of bisulfite addition to compounds have been studied by Higuchi and Schroeter (100–102, 164, 166). They clearly show that not only can a pharmaceutical degrade in a solution and lose therapeutic potency but that a synthesis to a biologically inactive compound can also occur, as with epinephrine (166) and other benzyl derivatives (100). The probable reaction in these instances is to a benzyl sulfonic acid by reaction with a hydroxyl group (100–102). The bimolecular kinetics of epinephrine with sulfite ion were established, the heat of activation determined, and a quantitative expression derived for the given log *k*-pH profile (102). Bimolecular kinetics of salicyl alcohol reaction with bisulfite and/or sulfite ions were shown to be pH-dependent, with an appropriate predictive expression to explain the log *k*-pH profile (164). The Arrhenius parameters of the reaction were determined and ionic strength effects checked. This work has been recently considered by Schroeter in his discussion on sulfurous acid salts as pharmaceutical antioxidants (163).

The rates of hydrolysis of carbamate and carbonate esters (39, 40, 93) are of great importance in predicting the stability of carbamate esters of pharmaceutical utility (36). Nogami and coworkers have studied the hydrolysis of various quaternary nitrogen compounds (147, 148) and have observed specific acid-base and solvent catalysis, constructed the log *k*-pH profiles, and determined the Arrhenius parameters.

Prediction of Stability in Pharmaceutical Preparations.—A pharmaceutical preparation is frequently complex. Prior discussion in this paper on the prediction of stability has considered those circumstances where most of the variables are known and their specific effects on degradation can be quantified. This is not possible with the many formulations where prediction of market or shelf-life is needed. Typical examples of such a complex formulation are the multivitamin preparations which have been criticized for age on the market (26) and inadequate control, stability, and potency (27).

The legal, moral, economic, competitive, and public health reasons for the need of valid methods for the prediction and verification of drug stability in the marketed formulation have been outlined (26, 27, 44, 62, 63, 117, 136, 137).

Criticism has been leveled at rule-of-thumb methods of predicting shelf-life from accelerated testing (17, 44, 62, 63, 117, 126, 136) since, too frequently, such correlations have been intuitive, based on insufficient numbers of elevated temperatures or on empirical relations found in supposedly similar preparations (16, 63).

The Arrhenius relations of rate with absolute temperature of Eq. 38 and 39 show that any value proportional to the specific rate, k, would permit evaluation of the slope of the plot of log k *vs.* $1/T$ and, thus, prediction of stability at shelf or storage temperatures should be practical.

It is not necessary to determine the mechanisms of degradation. In many cases, the procedure is to follow some property of the degradation as a function of time and to linearize this function. The slopes of such linear plots may be used as estimates of the specific rates (k). The reproducibility of such a degradation rate function at the various elevated temperatures would validate the use of such functions in the prediction of degradation rates at lower temperatures (63).

The order of the degradation rate of a component in a complex preparation is defined as the power, n, of the concentration proportional to the rate of degradation, as is Eq. 1. In most studies on the thermal degradation of complex liquid preparations (46, 47, 63, 135) $n = 0$ or $n = 1$ has served satisfactorily to characterize the loss of initial assay with time within the errors of assay. Analogous procedures can be developed, however, for the other possible values of n. Autocatalytic degradation, however, may need special treatment and the thermal degradation of crystalline fumagillin in air gave apparent second-order kinetics (45).

The decrease in color of a multisulfa preparation was proportional to time (*i.e.*, zero order) at the various elevated temperatures studied (63). The logarithm of the slopes of such plots was linear with the reciprocal of the absolute temperatures of the studies and the values at the extrapolated room temperatures permitted prediction of the color stability at those temperatures. The thermal degradation of many vitamins in liquid multivitamin preparations has also been studied (46, 47, 135). Zero- and first-order plots (a typical example for thiamine hydrochloride is given in Fig. 1) were applicable. The Arrhenius plots, as in Fig. 15 for thiamine hydrochloride, permitted prediction of stability at the lower temperatures.

Although the equations of such plots can be estimated graphically (135), the employment of statistical procedures (22, 30, 31) determines the degree of confidence to be held in the predicted stability. These procedures have been outlined and applied by Garrett (46, 47), and were subsequently given stepwise (135). In general, the rate data are fitted by the method of least squares, as in Fig. 1, to give the best estimated rate constant and estimates of its error as well as estimates of error in the assay methods.

Similarly, the error in a predicted rate constant at a marketing temperature can be estimated (Fig. 15). The final verification of these predictive procedures has been given in detail in the literature (46, 135). An example is the solid line in Fig. 17 which predicted the thermal degradation of thiamine hydrochloride at 30° where the dashed lines encompass the standard error in the predicted thermal degradation and the 95% confidence limits of a single assay. The data were obtained from two separately prepared formulations maintained at 30° and assayed over a year. Another example is given in Fig. 18 and verifies the predicted thermal degradation of folic acid in a liquid multivitamin preparation at 25°. The upper curve was predicted for a modified preparation with an increased concentration of folic acid and was experimentally confirmed. This indicates that it may be used practicably in many cases to predict stability on the basis of one elevated temperature and the known Arrhenius slope.

This type of prediction may serve as an efficient control procedure as, when a batch of one component is introduced from a new source is increased in amount, or a manufacturing process is modified. This procedure is not applicable to two different components; Arrhenius slopes of such will differ even in the same preparation.

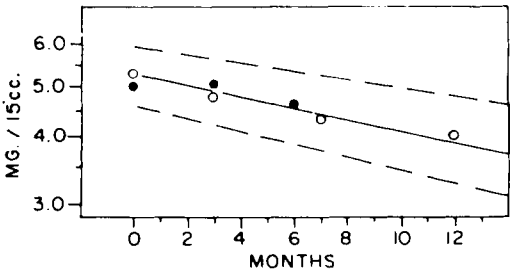

Fig. 17.—Verification of prediction of thiamine hydrochloride stability at room temperature. The solid line is the predicted thermal degradation rate of thiamine hydrochloride in a liquid multivitamin preparation A at 30°. The dashed lines encompass standard error in predicted values and the standard error of a single assay. O, Data from preparation A; ●, data from a similar preparation A′. [Figure 4 of Garrett, E. R., This Journal, **45**, 470(1956) (47).]

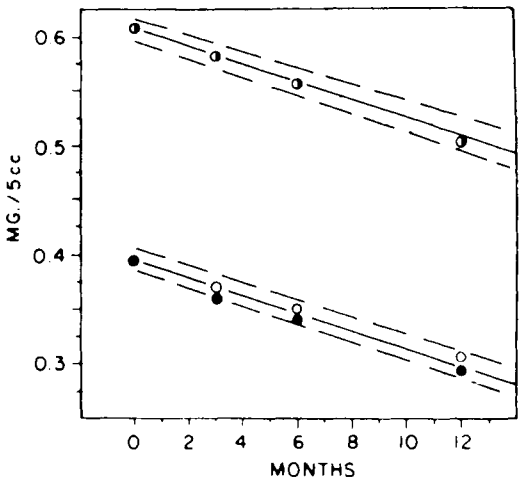

Fig. 18.—Verification of prediction of folic acid stability at room temperature. The solid lines are predicted thermal degradation rates of folic acid in liquid multivitamin preparation A at 25°. The dashed lines encompass standard error in predicted values and 95% confidence of a single assay. O, Data from preparation A; ●, data from a similar preparation B; ◑, data from a modified preparation C with increased initial concentration of folic acid and other vitamin components. [Figure 9 of Garrett, E. R., This Journal, **45**, 171(1956) (46)].

However, when the vehicle or formulation is entirely new, the rate of change of degradation rate of a component with temperature is not the same in both vehicles. Valid prediction is not possible from comparison at only one elevated temperature. The slopes of the Arrhenius equation must be determined anew.

The use of these physicochemical procedures for prediction of stability must be considered in the light of the controlling mechanisms of degradation (47). In the previous discussion components were considered that most probably degrade by solvolytic processes; *i.e.*, reactions

in solution and their heats of activation, as per Arrhenius slope, are generally in the range 10–30 Kcal./mole. Thus, advantage may be taken of significant increases in rate with temperature. However, if diffusion or photolysis are the rate-determining steps, the heat of activation is only of the magnitude 2–3 Kcal./mole and little advantage is gained by accelerated temperature studies in prediction, since the temperature effect on rate is small. In some cases, such rates may be accelerated by increases in pressure or light intensities.

Frequently the thermal degradation of polyhydroxylic materials and the subsequent effect on other components are of interest. However, it must be realized that the heats of activation for such pyrolysis are frequently of the magnitude of 50–70 Kcal./mole. Thus, rates of degradation which may be great at elevated temperatures may not be of any practical significance at the temperature of marketing and storage of the preparation.

Further discussions on design and practice of such predictive methods are given in the literature (44, 117) and the very models of ideal comprehensive stability testing laboratories for application of such techniques are also given (118, 119).

Other examples of the application of these predictive techniques in pharmaceutical formulations are for ascorbic acid in a liquid multivitamin emulsion containing fluoride (180), the kinetics of degradation of amyl nitrite ampuls (196, 197), and the stability of ergonovine maleate (139). Publications of interest in this regard are studies on the influence of the effect of heating and cooling time on prediction of shelf-life by kinetic principles and the Arrhenius equation at exaggerated temperatures (37). It has been shown, however, that for a series of samples subjected to elevated temperatures and when each sample is treated in the same manner (*i.e.*, heated and cooled), the calculated rates of degradation are identical to those measured under isothermal conditions (167).

CONCLUSIONS

The prediction of solvolytic stability of drugs in solution and in liquid pharmaceutical preparations is based on good science. The known quantitative relations between degradative rate and the extant variables (concentration, pH, solvent kind and dielectric constant, ionic strength, substrate pKa's, substrate reactive groups, temperature, solubility, nucleophiles, acids, bases, addend, etc.) have been shown to permit such prediction from a minimum of experiment and data and with a maximum of understanding and confidence. The procedures outlined provide additional pharmaceutical bonuses in the physicochemical characterization of substrates and products of kinetic transformations. They permit the correlation of biological activities and assays, assurance of valid assay methods, and estimations of their error, and the prediction of molecular, solvent, and addend changes to increase stability or increase physiological availability.

The future looms brightly for the prediction of stability of the complicated phenomena involved in photolytic and oxidative transformations. The complex stability problems of suspensions, emulsions, and ointments are leaving the backwoods of empirical correlations and rules-of-thumb and will shortly join the civilized communities of quantified prediction.

Biliary and Urinary Excretion Patterns of Chlorpromazine in the Dog

By T. L. FLANAGAN, L. W. REYNOLDS†, W. J. NOVICK, T. H. LIN, I. M. RONDISH, and E. J. VAN LOON

Chlorpromazine instilled intraduodenally in dogs was excreted in bile and urine as "free" and "bound" chlorpromazine and chlorpromazine sulfoxide. Based upon chromatographic studies and ultraviolet analysis, chlorpromazine and its sulfoxide undergo two types of binding. Strong alkaline treatment hydrolyzed one type while treatment with β-glucuronidase hydrolyzed both types. In urine, the concentration of the "bound" phenothiazines liberated by alkaline hydrolysis was 2–3 times as great as the "free" material. In bile, the concentration of this type of "bound" chlorpromazine and chlorpromazine sulfoxide was 10 to 15 times greater than the "free" forms of these materials.

VARIOUS investigators have reported on the urinary excretion of chlorpromazine and/or its metabolic products in man and experimental animals (1–9). Ross, Young, and Maass (10), Walkenstein and Seifter (11), and Fishman and Goldenberg (12) reported that the side chain which is attached to the phenothiazine nucleus is demethylated. Nadeau and Sobolewski (9) reported that β-glucuronidase treatment increases the amount of phenothiazine-like extractable material from human urine, and Lin, Reynolds, Rondish, and Van Loon (13) reported on the isolation and characterization of glucuronic acid conjugates of chlorpromazine in human urine. Fyodorov (14) administered chlorpromazine-S^{35} to dogs and found that the bile was distinguished by a high degree of radioactivity, especially 3–6 hours after administration.

The purposes of the present studies were (*a*) to obtain an insight into the distribution and

Biliary and Urinary Excretion Patterns of Chlorpromazine in the Dog

By T. L. FLANAGAN, L. W. REYNOLDS†, W. J. NOVICK, T. H. LIN, I. M. RONDISH, and E. J. VAN LOON

Chlorpromazine instilled intraduodenally in dogs was excreted in bile and urine as "free" and "bound" chlorpromazine and chlorpromazine sulfoxide. Based upon chromatographic studies and ultraviolet analysis, chlorpromazine and its sulfoxide undergo two types of binding. Strong alkaline treatment hydrolyzed one type while treatment with β-glucuronidase hydrolyzed both types. In urine, the concentration of the "bound" phenothiazines liberated by alkaline hydrolysis was 2–3 times as great as the "free" material. In bile, the concentration of this type of "bound" chlorpromazine and chlorpromazine sulfoxide was 10 to 15 times greater than the "free" forms of these materials.

VARIOUS investigators have reported on the urinary excretion of chlorpromazine and/or its metabolic products in man and experimental animals (1–9). Ross, Young, and Maass (10), Walkenstein and Seifter (11), and Fishman and Goldenberg (12) reported that the side chain which is attached to the phenothiazine nucleus is demethylated. Nadeau and Sobolewski (9) reported that β-glucuronidase treatment increases the amount of phenothiazine-like extractable material from human urine, and Lin, Reynolds, Rondish, and Van Loon (13) reported on the isolation and characterization of glucuronic acid conjugates of chlorpromazine in human urine. Fyodorov (14) administered chlorpromazine-S^{35} to dogs and found that the bile was distinguished by a high degree of radioactivity, especially 3–6 hours after administration.

The purposes of the present studies were (*a*) to obtain an insight into the distribution and

Received October 19, 1961, from the Research and Development Division, Smith Kline and French Laboratories, Philadelphia 1, Pa.

† Present address: General Electric, Space Science Division, Philadelphia, Pa.

metabolism of chlorpromazine by following its biliary and urinary excretion in the anesthetized dog and (*b*) by the use of chlorpromazine-S^{35}, to study further the metabolites present in urine and to elucidate the type of binding in urine.

EXPERIMENTAL

In the first experiments, mongrel female dogs weighing approximately 10 Kg. were anesthetized by intraperitoneal pentobarbital and operated so as to expose the duodenum and the common bile duct. A polyethylene cannula was inserted into the common bile duct about 1 in. above the major duodenal papilla and held in place by means of sutures. The open end of the cannula was brought to the outside of the animal and terminated in the collection tube. The cystic duct was clamped off to insure collection of only hepatic bile throughout the experiment. At the same time a catheter was inserted into the urinary bladder and all residual urine was drained and discarded.

One-half hour later, 200 mg. of chlorpromazine hydrochloride, dissolved in 10 ml. of saline, was administered to the animal intraduodenally. Bile samples were obtained at hourly intervals and urine samples at 2-hr. intervals for a period of 8 or 10 hours following drug administration. Each sample was analyzed individually for "free" and "bound" chlorpromazine and chlorpromazine sulfoxide by the method of Flanagan, *et al.* (15). The samples were not analyzed for glucuronic acid conjugates.

"Bound" chlorpromazine and "bound" chlorpromazine sulfoxide are the terms given to the chlorpromazine and chlorpromazine sulfoxide which can be extracted from the aqueous residue, following the extraction of the free components, after the aqueous residue is subjected to an alkaline hydrolytic treatment. The analytical procedure determined the ether-extractable chlorpromazine metabolites as either chlorpromazine or its sulfoxide. If demethylation of the side chain occurred, the demethylated components would be determined as chlorpromazine and/or chlorpromazine sulfoxide, since their absorption spectra are similar to the parent compounds.

In the next series of experiments the dogs received a daily oral dose of chlorpromazine hydrochloride for varying periods of time (Table I) prior to the operation. The operative dose was 200 mg. of chlorpromazine hydrochloride in 10 ml. of isotonic saline administered intraduodenally. Before the administration of the operative dose, control samples of bile and urine were obtained to determine any excretion due to the previous chlorpromazine priming.

In the experiments with chlorpromazine-S^{35}, each dog was anesthetized with pentobarbital and the bladder was emptied by inserting a catheter which was allowed to remain *in situ* for the subsequent collection of urine samples. Chlorpromazine hydrochloride, 25 mg./Kg., containing about 60 μc. of S^{35}, were injected into a surgically-exposed loop of the duodenum. Urine samples were collected every 2 hours.

Each sample was reduced *in vacuo* to about one-third of the original volume and 50–100 μl. spotted on $^3/_4$ inch strips of Whatman 3MM paper. The

strips were developed in a descending direction with a solvent system consisting of 100 parts of isoamyl alcohol, 100 parts of water, 15 parts of ethanol, and 10 parts of formic acid.

A portion of the remaining urine was adjusted to pH 13 and extracted with ether to remove the "free" chlorpromazine and "free" chlorpromazine sulfoxide. The aqueous residue was divided into two fractions. One fraction was hydrolyzed with strong alkali, ether extracted, and the ether extract and the aqueous residue were chromatographed. The pH of the second fraction was readjusted to 5.0 and hydrolyzed with mammalian β-glucuronidase. After an ether extraction, the extract and the hydrolyzed urine were chromatographed in the same manner as the original urine.

The metabolites were detected by two independent procedures: (*a*) the chromatograms were sprayed with nitrite reagent as described by Flanagan, *et al.* (15), and (*b*) the developed strips were fed into a scanner (Nuclear-Chicago, model No. 1620-A) and the radioactive areas were detected in this manner.

In all the experiments the animals were maintained by a slow 5% dextrose-saline intravenous infusion and additional pentobarbital as required.

RESULTS AND DISCUSSION

In Table II are listed the per cent recoveries of chlorpromazine and chlorpromazine sulfoxide in bile and urine of four unprimed dogs which received an operative dose of 200 mg. of chlorpromazine hydrochloride intraduodenally. In bile, the concentrations of "bound" chlorpromazine and "bound" chlorpromazine sulfoxide were much greater than the concentrations of "free" chlorpromazine and "free" chlorpromazine sulfoxide. "Free" chlorpromazine sulfoxide was not obtained from the bile specimens of these dogs until 5–6 hours after administration of chlorpromazine; "bound" chlorpromazine sulfoxide was obtained in the first hour following administration of the drug. The ratio of "bound" chlorpromazine to "bound" chlorpromazine sulfoxide was approximately 1:1 in the test period for three of the dogs. The bile recovery of the bound components was 10–20 times greater than the recovery of the free components.

In urine the amount of "free" chlorpromazine and "free" chlorpromazine sulfoxide was much greater than that obtained in the bile. The recovery of "bound" chlorpromazine was from 2–5 times greater than the recovery of "free" chlorpromazine, while the "bound" chlorpromazine sulfoxide was 1.3 to 3 times greater than the "free" sulfoxide.

In the next experiment, four dogs received priming doses of chlorpromazine hydrochloride to see what effect priming would have upon the excretion pattern of the drug. In these animals the control bile samples contained measurable concentrations of "free" and "bound" chlorpromazine and chlorpromazine sulfoxide, although the last oral dose had been administered 18 hours prior to the operation. In the dog that was primed with 200 mg. of chlorpromazine hydrochloride for 14 days, there was an increased recovery of "free" and "bound" chlorpromazine and chlorpromazine sulfoxide. In these primed dogs the ratio of "bound" chlorpromazine to "bound" chlorpromazine sulfoxide in bile varied from 1:1.5 to 1:3, while in three of the unprimed dogs this ratio was 1:1.

The urinary values obtained for "bound" chlorpromazine on the primed animals were lower than the values obtained on the single-dose animals.

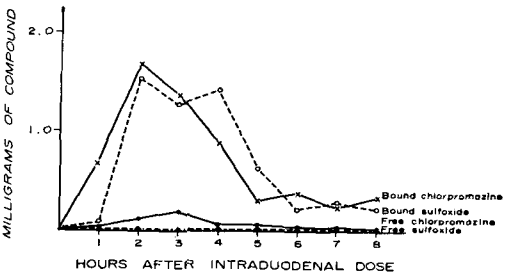

Fig. 1.—Dog No. 1, nonprimed biliary excretion.

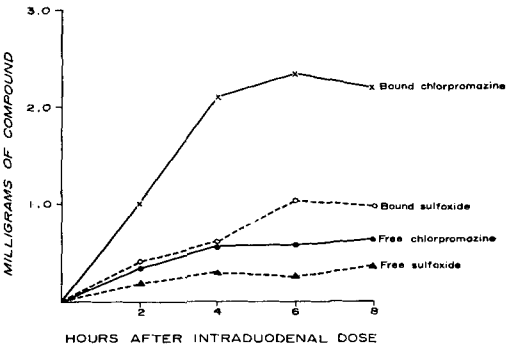

Fig. 2.—Dog No. 1, nonprimed urinary excretion.

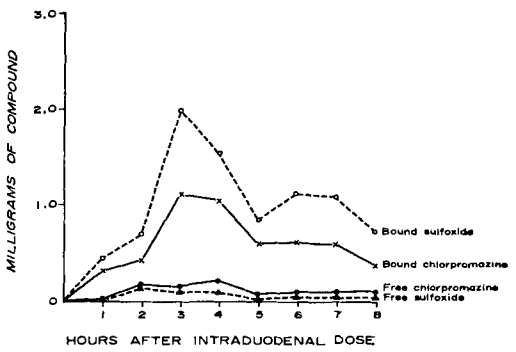

Fig. 3.—Dog No. 6, primed biliary excretion.

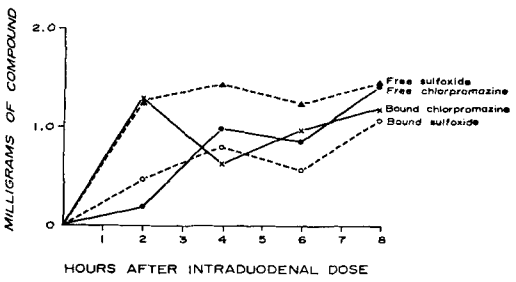

Fig. 4.—Dog No. 6, primed urinary excretion.

However, the ratio of "free" *vs.* "bound" components was increased in the primed animals due to the increased excretion of "free" components by these animals.

Figures 1 and 2 show the biliary and urinary time excretion curves of the four components in a nonprimed dog, while Figs. 3 and 4 illustrate the same curves for a primed dog. The patterns obtained on these two dogs are typical of those obtained on the other test animals.

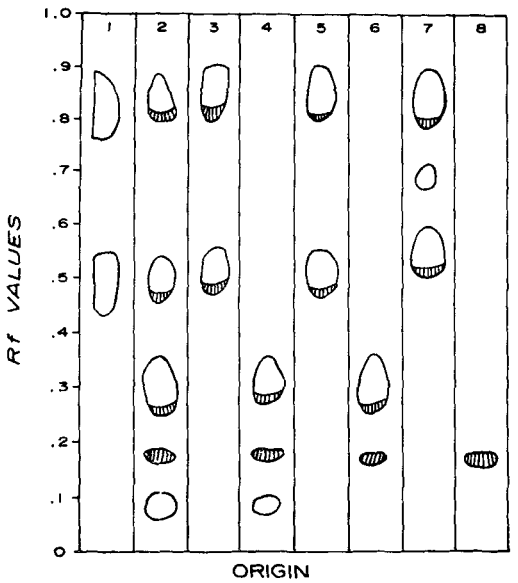

Fig. 5.—Col. 1, Chlorpromazine and chlorpromazine sulfoxide standards; Col. 2, whole urine; Col. 3, ether extract of whole urine (alkaline side); Col. 4, aqueous residue; Col. 5, fraction 1, ether extract after alkaline hydrolysis; Col. 6, aqueous residue; Col. 7, fraction 2, ether extract after β-glucuronidase hydrolysis; Col. 8, aqueous residue.

In the chromatographic studies with chlorpromazine-S^{35} on noncannulated, primed and unprimed dogs, four radioactive peaks were observed. The two peaks following the solvent front corresponded to chlorpromazine and chlorpromazine sulfoxide. The two remaining peaks were attributed to bound metabolites of these compounds. No attempt was made to separate chlorpromazine and chlorpromazine sulfoxide from their demethylated components as did Fishman and Goldenberg (12). Typical chromatographic patterns obtained on urine from dogs administered chlorpromazine-S^{35} by spraying the strips with nitrite reagent are shown in Fig. 5.

In all the experiments, the R_f values obtained for the metabolites by the use of the color developing spray corresponded to the R_f values obtained radiochemically.

The chromatographic patterns of chlorpromazine and chlorpromazine sulfoxide are presented in Col. 1 (Fig. 5). Column 2 shows the chromatographic pattern obtained for whole urine; the spots between the two "bound" metabolic spots represent an endogenous urinary constituent which was obtained with this spray for blank urine specimens. The dark areas behind the chlorpromazine and chlorpromazine sulfoxide were always present and they were purple in color as compared to a light pink shade of the pure compounds. The darker areas did not show increased radioactivity over that obtained for the pink shaded areas. Column 3 shows the pattern for the ether extract of whole urine made alkaline. The "bound" material remained in the aqueous phase (Col. 4).

In regard to Col. 4, it was believed initially that the two "bound" metabolites corresponded to "bound" chlorpromazine and "bound" chlorpromazine sulfoxide. However, following alkaline hydrolysis and subsequent ether extraction, the spot having an R_f of approximately 0.1 disappeared from the aqueous residue, while the R_f 0.3 spot remained (Col. 6). The chromatographic pattern obtained for the ether extract (Col. 5), as well as ultraviolet analysis of this extract, showed both chlorpromazine and chlorpromazine sulfoxide to be present. The R_f 0.1 spot was a mixture of "bound" chlorpromazine and "bound" chlorpromazine sulfoxide, and the type of binding is such that it can be broken by strong alkaline hydrolytic treatment. The "bound" components in this area did not resolve themselves into separate and distinct entities. The separation was not as sharp as that obtained by Lin, *et al.* (13), with human urine.

The chromatogram obtained for the aqueous residue after hydrolysis with β-glucuronidase and subsequent extraction with ether is presented in Col. 8. Only the endogenous spot remained; β-glucuronidase hydrolyzed both "bound" areas. In the ether extract (Col. 7) three spots appeared; two of the spots corresponded to chlorpromazine and chlorpromazine sulfoxide, the small spot in between may be one of the metabolites resulting from partial or total demethylation of the side chain.

Use of Isolated Strips of Cat Spleen for the Assay of α-Adrenergic Blocking Compounds

By ROBERT K. BICKERTON, WILLIAM T. ROCKHOLD, and EDWIN R. MICALIZZI

The response of isolated strips of cat spleen to epinephrine, norepinephrine, and acetylcholine was studied. It was found that spleen strips suspended in glucose-deficient Tyrode's solution exhibited marked sensitivity to the catecholamines and were relatively insensitive to acetylcholine. This differential sensitivity was utilized to advantage in the development of an *in vitro* assay procedure for α-adrenergic blocking agents. In addition, the method offers a qualitative index to the degree of tissue receptor binding of the antagonists.

MANY *in vitro* preparations have been used for the assay of sympathetically active compounds. Brugger (1), Rothlin and Brugger (2), and Rothlin (3) used the isolated seminal vesicle of the guinea pig to assay for the adrenolytic effects of the ergot alkaloids. Stone and Loew (4) used this same preparation as an assay for antiadrenaline drugs and Leitch, Liebig, and Haley (5) used the rat's seminal vesicle for the assay of certain sympatholytic drugs. Burn, Finney, and Goodwin (6) described several *in vitro* techniques for the assay of adrenaline and noradrenaline. Many past reports, and more recently those of Scott (7), Burn and Rand (8, 9), Daly and Scott (10), and Brandon and Rand (11) have described studies concerning the response of the mammalian spleen, both *in situ* and *in vitro*, to a number of drugs. None of these reports has described the use of this organ for the assay of adrenergic blocking compounds. This report deals with the response of isolated strips of cat spleen to epinephrine, norepinephrine, and acetylcholine, and the use of this organ for the assay of adrenergic blocking agents.

EXPERIMENTAL

Methods.—In all experiments, cats weighing 2 to 3 Kg. and unselected as to age or sex were used. The animals were anesthetized by an intraperitoneal injection of 0.7 ml./Kg. of diallylbarbituric acid-urethane.[1] The spleen was exteriorized through a lateral abdominal incision and then removed by section of all vasculature at the junction of splenic pedicle and dorsal hilus. The spleen was then rinsed and placed in warmed Tyrode's solution containing one-half the usual amounts of sodium bicarbonate and anhydrous dextrose. The sides and ends of the spleen were trimmed to leave a central rectangular strip measuring approximately 9 × 1.5 cm. This strip was divided into two equal portions, each measuring 4.5 × 1.5 cm., and each half was placed into a separate 70-ml. muscle bath containing oxygenated (95% oxygen, 5% carbon dioxide) Tyrode's solution of the previously mentioned composition. The bath was maintained at 39°. Each spleen strip was connected to an isotonic ink-writing lever so that contractions could be recorded on a kymograph. A magnification ratio of 13:1 was used and the strips were placed under constant tension of 5.0 Gm. Acetylcholine chloride, *l*-epinephrine bitartrate, and *l*-norepinephrine bitartrate were dissolved in 0.9% sodium chloride just before use. Ergotamine tartrate and tolazoline hydrochloride were prepared by dilution of the commercially available ampuls with 0.9% sodium chloride prior to use. Dibenamine hydrochloride was prepared as a 5% stock solution in propylene glycol and diluted with 0.9% sodium chloride just prior to use. Guanethidine sulfate was dissolved in dilute hydrochloric acid solution and buffered to pH 6 with sodium bicarbonate. Final dilutions of guanethidine were made with 0.9% sodium chloride solution. Doses of all drugs were added to the baths in 0.35- to 2.1-ml. volumes except in the assay procedure where all doses of drugs were added in 1.0-ml. volumes.

In performance of the assay, *l*-epinephrine was added to each bath to give a concentration of 0.5 mcg./ml. and kept in contact with the spleen strip for 5 minutes. During this time maximal contraction to this dose occurred. The epinephrine was then drained and the strip washed and allowed to equilibrate for 10 minutes, and then the wash was repeated. If complete relaxation of the strips did not occur within this interval, the writing lever was manually returned to base line. Five minutes after the last wash, *l*-epinephrine was again added and the above procedure repeated. Epinephrine was added at 20-minute intervals until four consecutive responses were obtained which did not vary more than 5% from their mean. Immediately after the second wash from the last control response, the antagonists were added to the baths in varying concentrations and allowed to remain in contact with the strip for 5 minutes. Without further washing, *l*-epinephrine was again added to the bath and the contraction recorded. The strip was washed as described and a minimum of two more responses to epinephrine were obtained at the usual 20-minute intervals in order to determine how readily the antagonists were removed from their receptor sites. Only one dose of an antagonist was administered to any one spleen strip, with the exception of tolazoline which was administered in repeated doses to

Received December 18, 1961, from the Section of Pharmacology, Eaton Laboratories, Norwich, N. Y.

[1] Dial-Urethane (Ciba)

three strips. Per cent inhibition of epinephrine response from a given dose of antagonist was calculated from the difference in contraction heights of the mean of the four consecutive responses prior to the antagonist, and the response to epinephrine immediately following the antagonist. ED_{50} values for the antagonists were determined with the aid of an IBM 1620 digital computer programmed to determine the log-dose, probit-inhibition least squares regression line, its slope, and 95% confidence limits for the slope for each antagonist. All values were obtained at printout.[2]

The effect of time of contact of the antagonist with the spleen strip was studied in two strips from the same animal. Tolazoline and dibenamine were selected as the antagonists. The standard assay procedure was carried out excepting that the antagonists were allowed to remain in contact with the spleen for only 5 minutes in one strip and for 10 minutes in the remaining strip.

RESULTS

Effect of Epinephrine, Norepinephrine, and Acetylcholine.—Addition of *l*-epinephrine or *l*-norepinephrine to the spleen strips in varying concentrations produced contractions which were initially rapid, and then followed by a slow component which reached a maximum within 5 minutes. The response of the spleen strips to a given dose of these catecholamines increased in magnitude over the first four or five responses and then remained relatively uniform over the next several hours. Dose-response curves obtained from uniformly reacting strips were found to be logarithmically linear throughout a concentration range of 0.05 to 1.0 mcg. free base/ml. Some variation in reactivity to these catecholamines was found with different strips, although all spleen strips tested were more sensitive to epinephrine than to norepinephrine (see Fig. 1).

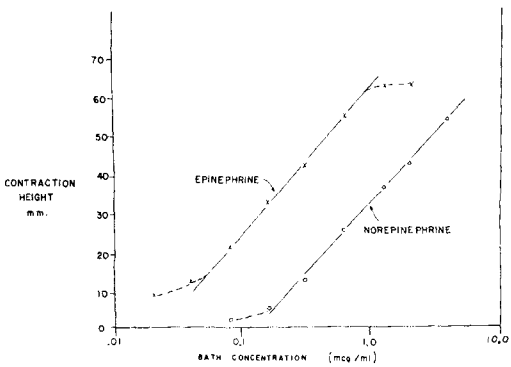

Fig. 1.—Log dose response curves for epinephrine and norepinephrine obtained from uniformly reacting cat spleen strip.

The contractile response of isolated cat spleen strips to acetylcholine, when present, was found to be moderate throughout a concentration range of 10 to 430 mcg./ml. When administered at 5-minute intervals, tachyphylaxis to acetylcholine rapidly developed, often after a single dose, and almost always within four repeated doses, although longer intervals between doses delayed the onset of tachyphylaxis (see Fig. 2).

Assay of Adrenergic Blocking Agents.—Table I lists the ED_{50} values for the α-adrenergic blocking agents dibenamine, ergotamine, and tolazoline. Since the slopes of the log-dose inhibition curves were not parallel,[3] potency comparisons were based

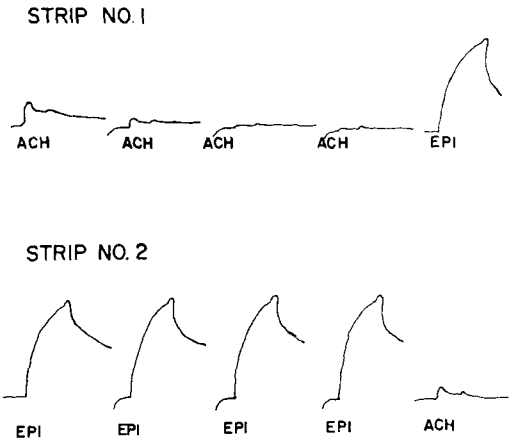

Fig. 2.—Development of tachyphylaxis to acetylcholine while the responses of spleen strip to epinephrine are unimpaired. EPI, 35 mcg. *l*-epinephrine; ACH, 700 mcg. acetylcholine chloride.

upon the ED_{50} values. With respect to the ED_{50} values, the following relationship, in order of decreasing potency, was found: ergotamine > dibenamine > tolazoline. Guanethidine, a sympatholytic agent, in bath concentrations ranging from 10 to 200 mcg./ml., did not inhibit, but in some trials enhanced epinephrine-induced contractions of isolated strips of cat spleen. Guanethidine alone exerted intrinsic contractile activity on the spleen strips in concentrations of 50 to 200 mcg./ml.

Degree of Tissue Receptor Binding of the Antagonists.—Since this assay procedure used repetitive washing and stimulation of the spleen strip by epinephrine, the method offers an index to the degree of binding of the antagonists at tissue receptors. Figure 3 shows the effects of the antagonists when added to the bath at their approximate ED_{50} concentration and the effects of repeated washing and stimulation by epinephrine. It can be seen that dibenamine produced progressive inhibiton of epinephrine-induced contraction seven though the solution containing the antagonist had been drained from the bath. Maximum inhibition of epinephrine by a given dose of ergotamine occurred within 5 minutes and was relatively prolonged. Tolazoline produced an immediate (within 5 minutes) inhibition of epinephrine but was more readily removed from binding sites by fewer washing cycles. The degree of receptor binding of the antagonists occurred in the following order of decreasing affinity for tissue receptors: dibenamine > ergotamine > tolazoline.

In determining the effects of antagonist contact time on the inhibition of epinephrine, it was found

[2] The authors wish to express their sincere appreciation to Dr. R. L. Beinert and G. V. O'Bleness for the statistical analysis used in this study.

[3] Slope parallelism was tested by the method of Davies (12).

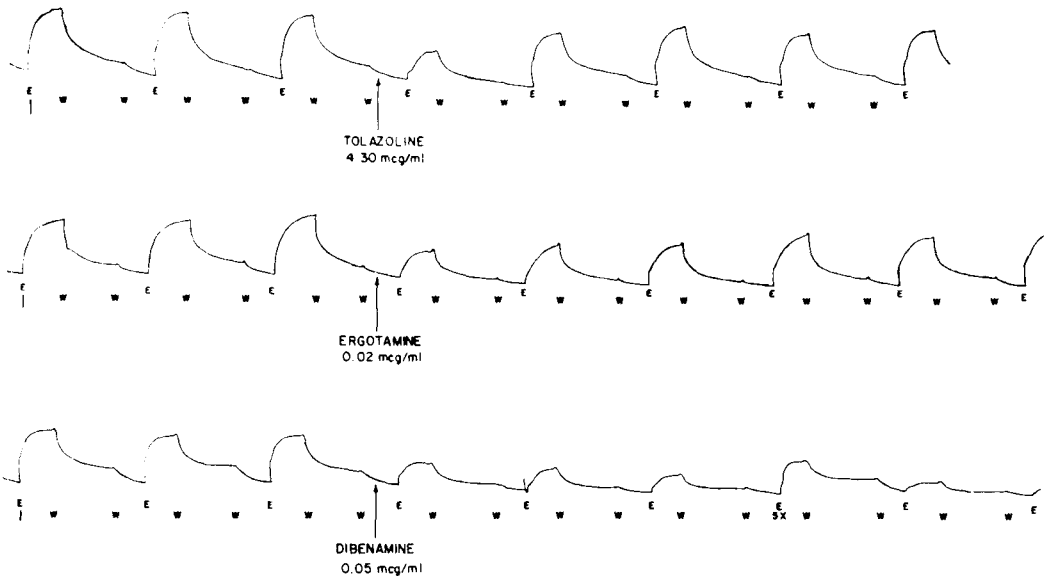

Fig. 3.—The effects of the antagonists when administered at their approximate ED_{50} concentrations on contractile responses of is olatedcat spleen to epinephrine (see text). E, Addition of 35 mcg. of epinephrine; W, wash.

that an increase in the time during which tolazoline was in contact with the spleen did not increase the inhibition of epinephrine by this antagonist but rather a decrease was observed. However, dibenamine produced greater inhibition after 10 minutes contact time than after 5 minutes contact (see Table II).

General Observations.—Throughout this study it has been our experience that the use of isolated strips of cat spleen for the assay of adrenergic blocking agents offers a major advantage over previous *in vitro* techniques in the relative durability of this organ. No special care in handling or removal from the animal is required. The organ is easily accessible through a small lateral incision which may be sutured after removal of the spleen. We have refrigerated excised spleen in Tyrode's solution containing a small amount of blood and have found that refrigeration for as long as 48 hours only slightly diminished the sensitivity to epinephrine. Longer periods of time resulted in greater decrease in sensitivity.

DISCUSSION

The contractile response of isolated cat spleen strips to *l*-epinephrine and *l*-norepinephrine was found to be logarithmically linear over a concentration range of 0.05 to 1.0 and 0.2 to 5.0 mcg. free base/ml., respectively. Responses to these catecholamines were reproducible over a period of many hours while those to administered acetylcholine under the conditions imposed by the assay were not. The order of potency of the three test antagonists was not in complete agreement with the data presented by Nickerson (13) who states that in potency, the ergot alkaloids occupy, in most instances, an intermediate position between the β-haloalkylamines and the imidazoline derivatives. The higher relative potency of ergotamine in our preparation could be explained on the basis of temporal relationships since it is known that the onset of dibenamine blockade is not immediate and that the degree of adrenergic blockade progresses with time up to the point of maximum effect. In our preparation, the dibenamine was in contact with the spleen strips for only 5 minutes. It is conceivable, therefore, that maximum blockade did not occur during this time. Further support of this suggestion was obtained from the fact that progressive inhibition did occur with dibenamine-treated strips, even though the bath containing the dibenamine had been drained and replaced with fresh Tyrode's solution. On the other hand, blockade produced by ergotamine was immediate and the degree of blockade was, therefore, accurately determined after 5 minutes contact time. The high potency of dibenamine and ergotamine in comparison to tolazoline is in agreement with Nickerson (13).

The finding that guanethidine did not inhibit epinephrine is in agreement with the data of Maxwell, *et al.* (14), who demonstrated the purely sympatholytic (as opposed to adrenolytic) action of this agent.

In considering the degree of tissue receptor binding of the antagonists, our results are in agreement with the data described by others (13). The progressive inhibition produced by dibenamine is similar to that which occurs in the intact animal and has been explained on the basis of the transformation from the equilibrium to the nonequilibrium type of blockade, presumably through the formation of ethylene immonium and/or vinyl intermediates, which then react chemically with cell constituents to produce a prolonged blockade. In this same regard, Axelrod *et al.* (15), reported that dibenamine did not disappear rapidly from the body of dogs but was extensively localized in body fat. These authors also found a close correlation between the degree of adrenergic blockade and the concentration of dibenamine in fatty tissue.

The rapidity with which tolazoline can be removed

from tissue receptors suggests that the binding forces involved are small and that removal from binding sites is dependent upon the distribution coefficient of the substance between tissue receptor and bathing medium. Brodie, *et al.* (16), have shown that tolazoline is only 23% plasma protein bound in the intact dog. These authors also found a relatively low degree of tissue localization of this agent and a relatively short biological half-life.

We have found this preparation to be an excellent tool for the investigation of drug action at adrenergic receptors. The relative ease in handling this tissue offers a distinct advantage over other methods. Investigations of the mechanism of action of a number of drugs on this organ are in progress.

Synthesis of Some N- and S-Substituted Derivatives of 2-Aminobenzenethiol

By CHARLES S. DAVIS, GLENN L. JENKINS, ADELBERT M. KNEVEL, and CHARLES PAGET

N- and S-substituted derivatives of 2-aminobenzenethiol were prepared as intermediates in the synthesis of analogs of the phenothiazine tranquilizers. A new synthesis for the preparation of the benzothiazine ring is reported. The ring cleavage of 2,2-pentamethylenebenzothiazoline with alkylating agents is discussed.

IN RECENT years derivatives of 2-aminobenzenethiol have attracted attention in the development of medicinal agents. Gialdi and Baruffini (1) synthesized a series of 2-aminophenyl alkyl sulfides as potential fungicides. Burger, *et al.* (2), prepared N-substituted 2-aminophenyl aryl sulfides and found some of them to be radiation protective agents. We have undertaken the synthesis of analogs of the phenothiazine tranquilizers and found it necessary to prepare N- and S-substituted 2-aminobenzenethiols as intermediates. Bialdi and Baruffini (3) had prepared similar thiols by reducing 2,2′-dinitrodiphenyldisulfide with glucose to 2-nitrobenzenethiol. 2-Nitrobenzenethiol was then substituted with an alkyl bromide to give 2-nitrophenyl alkyl sulfide. This paper reports a one-step procedure of reacting commercial 2-aminobenzenethiol with alkyl halide in the presence of potassium hydroxide solution. Not only are the compounds prepared in fewer steps than those of Gialdi and Baruffini, but the yields of the corresponding products are

significantly higher. The compounds thus obtained are listed in Table I.

2-(2′-Diethylaminoethylamino)phenyl methyl sulfide (IV) was prepared by two methods. 2-Aminophenyl methyl sulfide (I) was alkylated directly with 2-diethylaminoethyl chloride hydrochloride in the presence of a copper catalyst. The compound IV was also synthesized by a method suggested by Burger (2). 2-Aminophenyl methyl sulfide (I) was reacted with chloroacetyl chloride to give 2-(2′-chloroacetamido)phenyl methyl sulfide (II) which was combined with diethylamine to give 2-(2′-diethylaminoacetamido)-phenyl methyl sulfide (III). This was reduced to 2-(2′-diethylaminoethylamino)phenyl methyl sulfide (IV) with lithium aluminum hydride.

2 - (2′ - Diethylaminoethylamino)benzenethiol (V) was synthesized by two procedures. The first was the alkaline hydrolysis of 2-oxo-3-(2′-diethylaminoethyl)benzothiazoline which gave a 50% yield of V. Alternately, the reduction of 2-(2′-diethylaminoethylamino)phenyl methyl sulfide (IV) with lithium in methylamine (4) gave 28% yield of V. In an attempt to purify 2-(2′-chloroacetamido)phenyl methyl sulfides (II) by distillation, methyl chloride was split out to produce 3-oxo-1,4-benzothiazine in 65–75% yields.

The spiro structure, 2,2-pentamethylenebenzothiazoline (VI) was prepared by a modification of the procedure outlined by Elderfield and McClenachen (5). The alkylation of VI was attempted with 3-diethylaminoethyl chloride and a copper catalyst. The major product was the corresponding sulfide and none of the N-alkylated material. Since this ring cleavage was not expected, VI was subjected to the copper catalyst alone. Starting material was recovered and none of the cleavage product could be found. Elderfield (5) reported the cleavage of the pentamethylene ring at high temperatures but not the heterocyclic ring.

EXPERIMENTAL[1]

2-Aminophenyl Methyl Sulfide (I).—To a solution of 34 Gm. (0.6 mole) of potassium hydroxide in sufficient water to just bring about solution, was added 37.5 Gm. (0.3 mole) of 2-aminobenzenethiol.[2] After cooling the mixture to room temperature, 43 Gm. (0.3 mole) of methyl iodide[3] was added slowly with rapid stirring. The rate of addition was such that the boiling temperature of methyl iodide was not exceeded. Water, 1000 ml., was added and an oil separated which was washed with 50 ml. of water and dried. The oil was distilled at 121–123° (18 mm.) to yield 95% of product.

The physical constants of the various 2-aminophenyl alkyl sulfides prepared by the above method are described in Table I.

2 - (2′ - Diethylaminoethylamino)phenyl Methyl Sulfide (IV).—*Method A.*—A suspension of 9.5 Gm. (0.25 mole) of lithium aluminum hydride in 30 ml. of dry ether was stirred and refluxed for 1 hour. To the above suspension was added, dropwise, a solution of 21.0 Gm. (0.1 mole) of 2-(2′diethylaminoacetamido)phenyl methyl sulfide (III) in dry ether over 25 minutes. The mixture was refluxed and stirred for 15 hours. The unreacted lithium aluminum hydride was then decomposed,

[1] All melting points are uncorrected. Analyses were performed by the Alfred Bernhardt, Mikroanalytisches Laboratorium in Max-Planck-Institut fur Kohlenforschung, Mulheim (Ruhr), Germany.

[2] 2-Aminobenzenethiol was supplied by American Cyanamid Co.

[3] It was found that the chloro or bromo compounds reacted as readily as the iodo compound.

with cooling, by dropwise addition of 2 ml. of ethyl acetate followed by 3 ml. of water. After vigorous stirring for 2 hours, the mixture was filtered by vacuum. The filtrate was treated with ethereal hydrogen chloride until the solution was neutral to litmus. The ethereal solution was made basic with 5% potassium hydroxide solution. The aqueous layer was extracted with ether and dried. The resulting oil was distilled at 106–107° (0.35 mm.) to yield 7.9 Gm. (40%).

Anal.—Calcd. for $C_{18}H_{22}N_2S$: S, 13.45. Found: S, 13.56.

Method B from 2-Aminophenyl Methyl Sulfide (I).—Twenty-one grams (0.15 mole) of I and 32 Gm. of anhydrous potassium carbonate were mixed with 20 ml. of dry benzene. To the slurry were added 18.6 Gm. (0.1 mole) of 2-diethylaminoethyl chloride hydrochloride and 0.5 Gm. of copper bronze[4] in 70 ml. of dry benzene. This mixture was stirred and refluxed for 10 hours. The brown mixture was filtered and the residue was washed with benzene. The product was distilled at 123–124° (1.5 mm.) to yield 4.2 Gm. (15%) of material identical to that prepared by method A.

2 - (2′ - Chloroacetamido)phenyl Methyl Sulfide (II). A solution consisting of 13.9 Gm. (0.1 mole) of 2-aminophenyl methyl sulfide (I) and 9.9 Gm. (0.125 mole) of dry pyridine in 200 ml. of dry ether was cooled to 0°. To this mixture was added an ethereal solution of 11.9 Gm. (0.105 mole) of chloroacetyl choride. After standing for 2 hours, the ethereal solution was washed twice with 100 ml. of 5% hydrochloric acid and then dried. The ether was removed and the orange oil crystallized upon standing. After recrystallization from aqueous ethanol, the waxy crystals melted at 43–44° to give 12.5 Gm. of product.

Anal.—Calcd. for $C_9H_{10}ClNOS$: S, 14.87. Found: S, 14.62.

When distillation of 5 Gm. (0.23 mole) of 2-(2′-chloroacetamido)phenyl methyl sulfide (II) was attempted, 3.5 Gm. (75%) of 3-oxo-1,4-benzothiazine resulted. The conversion was brought about by heating II in oil bath at 195° under 20 mm. pressure for 30 minutes. Upon cooling, the mixture solidified and 50 ml. of methanol was added. The alcoholic solution was boiled with Norite and filtered. Upon cooling the filtrate, pale yellow crystals were formed that melted at 177–178° [lit. (6) m.p. 179°.] The infrared spectrum was identical to an authentic sample.

2 - (2′ - Diethylaminoacetamido)phenyl Methyl Sulfide (III).—To a solution of 46 Gm. of 2-(2′-chloroacetamido)phenyl methyl sulfide (II) dissolved in 200 ml. of ether was added 31.2 Gm. of diethylamine in 40 ml. of ether. The ethereal solution was refluxed for 12 hours and then washed with 500 ml. of water. The ethereal solution was dried and distilled. The fraction distilling at 151–153° (3 mm.) was taken as product. The yield was 54 Gm. (85%); m.p. hydrochloride salt, 149–152°.

[4] No. 44 Bronze powder manufactured by Sunbrite Mfg. Co., St. Louis, Mo.

Anal.—Calcd. for $C_{13}H_{20}N_2OS$: S, 12.71. Found: S, 12.85.

2 - (2′ - Diethylaminoethylamino)benzenethiol (V).—A methylamine solution of 0.58 Gm. of lithium wire was added slowly to 10 Gm. of 2-(2′-diethylaminoethylamino)phenyl methyl sulfide (IV) in 150 Gm. of methylamine. To accomplish this, the methylamine was refluxed through a thimble containing the lithium wire cut into small pieces. The thimble was suspended above the reaction flask and under a dry ice condenser so that the methylamine vapors could travel from the reaction flask into the dry ice condenser. The thimble consisted of a 6-in. test tube tapered at the bottom and fitted with a length of glass tubing sufficiently long to extend well down into the neck of the reaction flask. [See (4) for a detailed description of apparatus used.] A small loose plug of glass wool placed in the bottom of the thimble kept small pieces of undissolved metal from dropping into the flask. After all of the lithium had dissolved, the methylamine was allowed to evaporate overnight and the residue was dissolved in water. The aqueous solution was neutralized with 10% acetic acid and extracted with ether. The ethereal solution was dried and concentrated to give an orange solid which melted at 103–105° [lit. (7) m.p. 100–102°]. Yield, 2.7 Gm. (28%).

Attempted Alkylation of 2,2-Pentamethylenebenzothiazoline.—In 200 ml. of dry toluene, 20.5 Gm. (0.1 mole) of 2,2-pentamethylenebenzothiazoline, 18.6 Gm. (0.1 mole) of diethylaminopropyl chloride hydrochloride, 40 Gm. of anhydrous potassium carbonate, and 0.1 Gm. of copper powder were refluxed with stirring for 24 hours. The reaction was allowed to cool and the solid residue filtered. The toluene was removed from the filtrate and the residue was distilled at 124–135° (0.1 mm.).

The distilled liquid mixed with petroleum ether (30:60) was allowed to pass through a column of alumina. The eluate was concentrated and the residue distilled at 162° (2 mm.). This material was found to be (3-diethylaminopropyl)-2-aminophenyl sulfide.

The product has an infrared spectrum identical to that of the material prepared from 2-aminobenzenenethiol, diethylaminopropyl chloride, and potassium hydroxide. The hydrochloride salt melted at 198–200° and gave no depression when mixed with authentic material.

Physical Properties of Lipids Used in Pharmacy II

Use of Heating-Cooling Curves to Study Lipid Materials

By STUART P. ERIKSEN†, DAVIS R. REESE, and JOSEPH V. SWINTOSKY

This report describes the use of heating-cooling curves for the study of polymorphism as it occurs in chemically pure or commercial samples of glyceryl mono-, di-, and tristearate, theobroma oil, spermaceti, white petrolatum, and cetyl alcohol. The interpretation of the data obtained by the heating-cooling method has been simplified by using a log temperature difference plot. With this plot, the usual temperature-time curve can be rationalized into a series of interconnecting straight lines. The effects of heating or cooling rates on crystal form and crystal transition temperatures were studied with the aid of the improved heating-cooling curve plots. Distinct polymorphic transitions were observed in the pure glyceryl stearates. On the other hand, in commercial materials there was little evidence that the observed crystal changes were associated with specific polymorphic transformations. The relationship between the transitions observed and the probable storage stability (i.e., the maintenance of film integrity, moisture permeability, etc.) is discussed.

PHARMACISTS, in general, have not taken full advantage of the analytical techniques utilized in other fields for studying the crystal properties of lipids.[1] One purpose of our work was to determine how some of these techniques could be applied to the study of pharmaceutical products containing lipids. Part I of this series (1) presented a photomicrographic method for observing crystal changes and a recent note (2) has shown that polarized light transmission can also be a valuable technique for studying transitions in crystals. This report describes the use of heating-cooling curves for studying polymorphism as it occurs in pure and commercial samples of several lipid materials of pharmaceutical interest. In the heating-cooling curve technique, sample temperature is measured against time as the sample temperature changes in response to a change in environmental temperature.

The pharmaceutical uses of lipids as matrices, additives, coatings, etc., often demand a high degree of physical and chemical stability. To maintain both the acceptability and efficacy of lipid-containing products, such lipid properties as crystal size, refractive index, density, hardness, and film integrity must not change sufficiently during storage to impair the utility of the product. All of these properties are influenced by the crystalline state of the lipid at the time of testing or use.

The heating-cooling curve method is not the newest of the many analytical tools found useful in studies of the crystalline state but, because of its simplicity, it is still worthy of consideration, both as a research and a control procedure. Heating-cooling curves have proven their utility in the studies of chemically pure lipids (3, 4) and, because samples require minimum pretreatment, have also been found useful with commercial lipids for studying the effects of storage history. The studies on commercial lipids are more difficult to interpret, however, because the crystal changes are observed as small discontinuities on a logarithmic curve. The modification proposed in this report (i.e., replotting temperature vs. time data as logarithm temperature gradient vs. time) has been observed to simplify the graphic interpretation of heating and cooling processes (5a, b). With this modification, even minor changes in heat conduction or content appear as deviations from a straight line.

No attempt has been made in this report to document fully the literature of polymorphism, calorimetry, or even heating-cooling theory. A considerable body of recent information is already available in the literature in review form (3, 4).

EXPERIMENTAL

Raw Materials.—The cetyl alcohol was N.F. grade and purchased from M. Michel and Co. The white petrolatum, spermaceti, and theobroma oil were U.S.P. grade and purchased, respectively, from L. Sonneborn and Sons, McKesson and Robbins and Co., and A. N. Stollwerck, Inc. The commercial glyceryl monostearate was obtained from Hercules Chemical Co.; free glycerin 0.8%, monoglyceride content 36%. The commercial glyceryl distearate was obtained from Kessler Chemical Co.; free glycerin 0.6%, monoglyceride content 12%, saponification number 185, acid value 2.

Received April 28, 1961, from the Research and Development Division, Smith Kline & French Laboratories, Philadelphia 1, Pa.
Accepted for publication November 5, 1961.
Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.
† Present address: School of Pharmacy, University of Wisconsin, Madison.
[1] In this report, the term lipid is used in its broadest sense to include fats, waxes, and other related materials.

The synthetic glyceryl monostearate was prepared by the method of Fischer (6) from 1,2-glyceryl propylidene and octadecanoyl chloride. The saponification number of the purified product was 357.9 (theory 358.5).[2]

The synthetic 1,3-glyceryl distearate was prepared by the method of Jackson (7) from glyceryl monostearate, triphenylchloromethane, and octadecanoyl chloride.[3] The saponification number of the purified product was 311.9 (theory 312.5). The 1,3-structure was confirmed by infrared absorption.

The synthetic glyceryl tristearate was prepared by heating 1,3-distearin in benzene with octadecanoyl chloride and pyridine. The saponification number of the product was 296.1 (theory 297.2). Infrared analysis showed no unesterified hydroxyl groups.

Temperature Recording.—Using crushed ice as a reference bath, sample temperatures were measured with standard, cotton wrapped, 30-gauge iron-constantan thermocouples. The span of a Brown Electronik recorder was set to record temperature directly in °C. For heating curves, a thermoregulator-controlled 5-gal. water bath was used. For cooling curves, either room air or another 5-gal. water bath was used for cooling at or near room temperature, while a 4-L. Dewar flask filled with crushed ice was used for cooling to 0°.

Sample Cell.—Samples were contained in 10 × 75 mm. Pyrex test tubes, which were held in the special Pyrex cell shown in Fig. 1.

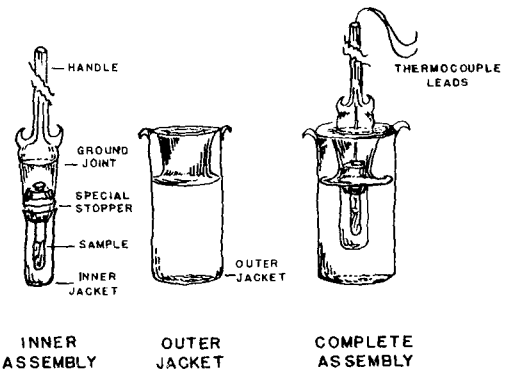

Fig. 1.—Pyrex cell for holding lipid samples during heating-cooling determinations.

Sample Preparation.—Solid samples are normally melted and cast directly into the sample tube. If prior history is being studied, however, the sample is cut into plugs which are then placed in the sample tube. Before measurement, a 2 × 100 mm. melting point capillary is set in the sample to serve as a thermocouple well and a small cork stopper is used to hold this capillary in the center of the test tube. Good contact between the sample and thermocouple capillary is important. Powdered material may be used if it is packed firmly around the capillary, but very coarse material was found to give poor results. Samples should be about 2 Gm. in size, but exact weight is not critical.

[2] The authors gratefully acknowledge the assistance of Dr. Robert J. Meyer of Morton Chemical Co., Woodstock, Ill., for the synthesis of the synthetic mono-, di-, and tristearins.

[3] The octadecanoyl chloride used was prepared from 97% stearic acid by fractional distillation of its methyl ester. By freezing point, its purity was estimated to be 99.9%.

Measurement Procedure.—The prepared test tube containing the sample is fitted into the inner assembly by using a double tapered rubber stopper (Fig. 1). The thermocouple is then inserted and the completed inner assembly is cooled to the starting temperature. (No heat transfer medium was used; the improvement so afforded did not warrant its use.) When the inner assembly has properly cooled, the outer jacket is attached, the complete cell immersed into a hot bath held about 5° above the melting point of the sample, and the temperature rise recorded. When the sample has melted, the cell is placed in the ice-filled Dewar flask until the cooling curve record indicates that the sample temperature is less than 20°, whereupon the sample is again placed in the hot bath and remelted. If desired, the effects of a smaller cooling gradient (i.e., slower cooling) may be studied by recooling the sample in a bath which is at either room temperature or 5° below the sample's freezing point.

Plotting Procedure.—The recorded curve (representing temperature in °C. vs. time) must be replotted as log temperature difference (bath temperature minus sample temperature) vs. time, or simply as log ΔT vs. time. By using 2-cycle semi-log paper and the procedure of Ball (5a), this replotting can be simplified. For heating curves, label the bottom ordinate as "bath temperature − 1°" then continue to label each ordinate upward in order,

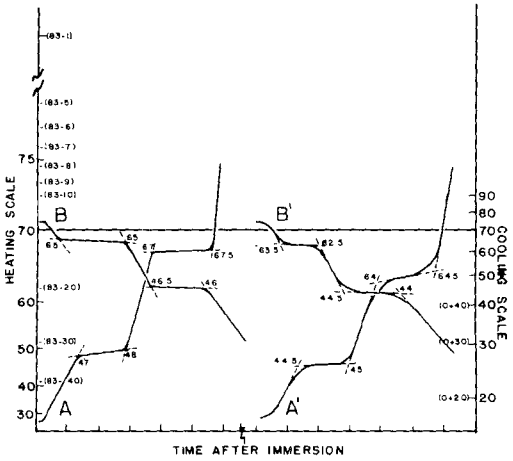

Fig. 2.—Log ΔT plots for a hypothetical substance. Curves A and B depict plausible heating and cooling curves, respectively, for a chemically pure substance. The addition of an impurity to this pure substance might alter the heating and cooling curves to those labeled A′ and B′, respectively. The labeling of the ordinates as described in the text is shown. In this labeling, the single number in the margin is the sample temperature. The first number within the parentheses is the bath temperature, while the second number is the difference between the bath temperature and the sample temperature. It is this latter (difference) number which controls the ordinate positions of the curves. The sample and bath temperatures are added only for convenience in plotting and reading the curves. Each curve is labeled as to (*a*) heating or cooling, (*b*) order of running (e.g., heating-1-, run before cooling-2-), and (*c*) the equilibrium bath temperature. Figures 3 to 13 were plotted in a manner similar to Fig. 2, but only the sample temperatures are designated on the ordinates.

bath temperature − 2°, *bt* − 3°, . . ., *bt* − 10°, *bt* − 20°, etc., until *bt* − *x*° reaches zero. Temperature vs. time is then plotted directly from the recorder curve using this temperature scale as the ordinate. For cooling curves, the bottom ordinate should be labeled "bath temperature + 1°" and the next *bt* + 2°, . . ., *bt* + 10°, *bt* + 20°, etc., and data plotted as before. The procedure described is shown in more detail in Fig. 2.

In the figures shown, all heating plots have been inverted to permit them to be studied in the same perspective as the cooling plots.

RESULTS AND DISCUSSION

Log Temperature Difference Plot.—The heating-cooling curves for chemically pure compounds are characterized by sharp inflections at the transition points. On the other hand, the curves of impure compounds, such as the usual commercial materials, have only minor inflections which are difficult to observe. To make the data on commercial materials easier to interpret, all heating and cooling curves were plotted as log (bath temperature minus sample temperature) vs. time. Called the log temperature difference plot (log ΔT plot), this temperature-time relationship has been found to be useful where samples are heated in constant temperature baths or ovens (5). In theory, as long as any crystalline form does not undergo change during heating or cooling, a log ΔT plot over this region will be a straight line whose slope is a function of the quantity of heat transferred and the specific heat of the crystalline form or forms present. Since phase transitions are accompanied by heat effects, however, the beginning or end of these will be indicated by inflections in the curves (3). Again, in theory, at the melting or transition point a straight line of different slope will be obtained as long as the coefficient of heat input remains fairly constant. These ideas suggest that a melting or solidification curve for a polymorphic material can be represented by a series of intersecting straight lines having different slopes as a result of the phase changes.

The degree of linearity of log ΔT plots is shown in Fig. 3 which depicts the heating and cooling of a substance (water) whose specific heat and phase

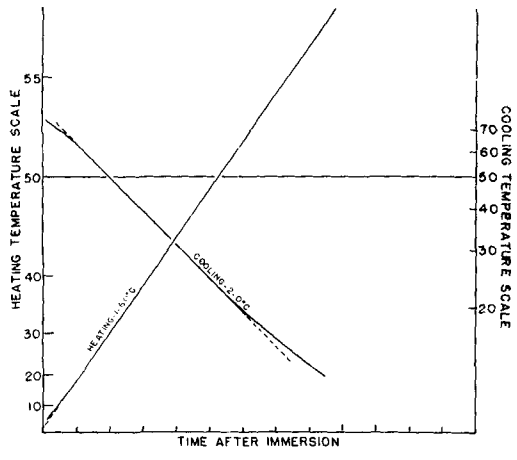

Fig. 3.—Log ΔT plots for the heating and cooling of distilled water.

structure remain the same throughout the temperature range studied. After an initial (10 minutes) equilibration period, in which a steady state heat input is being attained, the heating curve shows good linearity. The cooling curve shows a similar initial equilibration period with subsequent linearity until the sample temperature reaches 10–15°, where it deviates, probably because the ice bath was not stirred. Ball (5a) has observed that log ΔT plots are linear only until log ΔT = *ca.* 5° (i.e., until the sample temperature approaches to within 5° of the bath temperature). For this reason, the recording of heating-cooling curves is generally stopped when the sample temperature is within 2 or 3° of the bath temperature. This procedure limits the recording time in our studies to approximately 30 minutes for samples melting under 60°.

Heating and Cooling Studies of Nine Lipid Materials.—The log ΔT plots of heating-cooling curves for the nine lipid materials studied are shown in Figs. 4–13. The heating ordinates on these graphs are on the left, while the cooling ordinates are on the right. Because the scales cannot be made the same (the heating scale is an inverted log function, while the cooling scale is a normal log ordinate), some compromise had to be made in order to plot heating and cooling on the same graph. One temperature near the center of both curves was used as a point of correlation and the rest of the values were graphed from it (see 50° line, Fig. 3). Only at this temperature are both scales exactly the

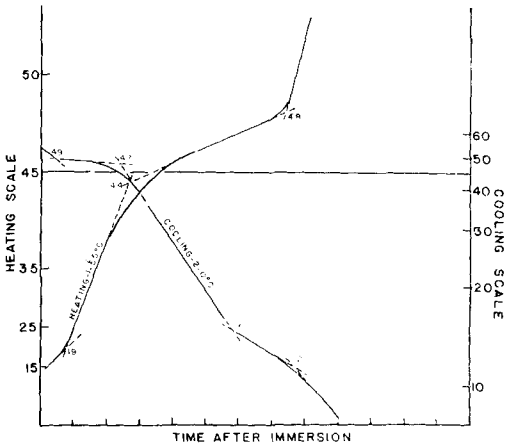

Fig. 4.—Log ΔT plots for the heating and cooling of cetyl alcohol.

same. For clarity, the temperatures of all inflection points have been noted directly on the graphs (e.g., 47 and 48° on curve A of Fig. 2). Each curve is labeled as to (*a*) heating or cooling, (*b*) order of running (e.g., heating-1-, run before cooling-2-, run before heating-3-, etc.), and (*c*) the equilibrium bath temperature.

To clarify interpretation of the data, heating-cooling curves of a hypothetical sample are presented in Fig. 2, preceding a discussion of the data of the lipid samples. In Fig. 2, curves A and B might be the heating and cooling curves, respectively, of a pure substance, while A′ and B′ might be the corresponding curves for the same substance in a less pure state. For simplicity, the same transition is

shown in all four curves, i.e., a reversible (enantiotropic) transition at approximately 47° in the pure substance (curve A). Transition temperatures are often lower on cooling curves because of a tendency to supercool. All four curves exhibit straight line segments, but the slope changes are more abrupt with the pure substance. At the beginning of each curve, there is a time lag before steady state heat transfer occurs across the cell. Most transitions in the lipid substances occur over a temperature range, e.g., in curve A, the transition starts at 47° and ends at 48°. To get exact transition temperatures, it is usually necessary to extrapolate straight line segments until they intersect, e.g., 44.5° on curve A

The terminology used in the following discussion is that found in the literature (3, 4). In general, the forms are named gamma (γ), alpha (α), beta prime (β'), and beta (β), in order of increasing melting points. The β form is the stable form in the materials reported, but in rare cases it is not known to exist and the β' is the stable form.

Figures 4, 5, and 6 show the heating and cooling curves of commercial samples of cetyl alcohol, white petrolatum, and spermaceti. These same N.F. and U.S.P. materials have been studied dilatometrically by Ravin and Higuchi (8). Cetyl alcohol shows a smooth heating curve with a break at 19° and a melting range (44–48°) which ends sharply at 48°.[4] The inflection at 19° probably represents the melting of a component of the commercial material which is normally liquid at room temperature. On the cooling curve, this

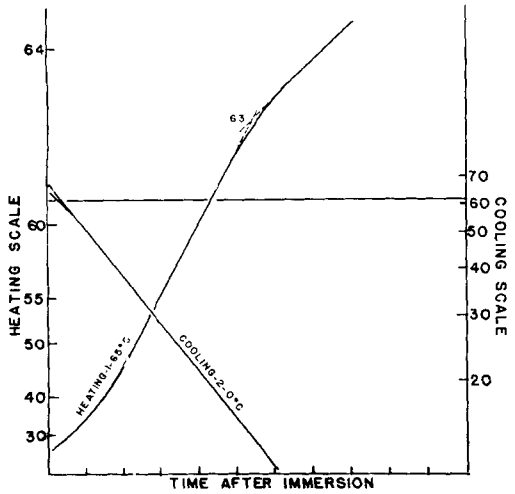

Fig. 5.—Log ΔT plots for the heating and cooling of white petrolatum.

transition occurs between 15 and 12° rather than at 19°. An inflection at 40–45°, observed by Ravin and Higuchi, could not be observed in our studies. In contrast, since they did not study cetyl alcohol below room temperature, they did not report the transition at 19°. Both white petrolatum (Fig. 5) and spermaceti (Fig. 6) show smooth, uninterrupted approaches to the melting point, i.e., there are no detectable transition points. The results are

[4] It is generally a misnomer to speak of melting points in lipids. Any sensitive method will detect a melting range.

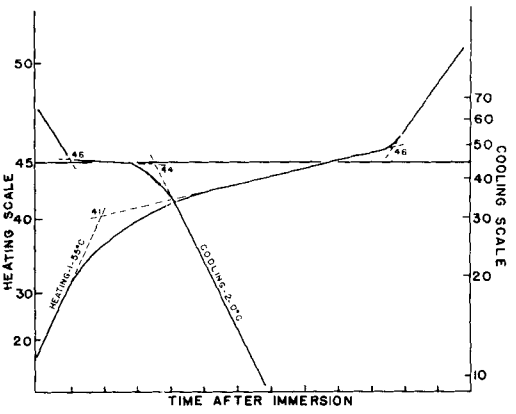

Fig. 6.—Log ΔT plots for the heating and cooling of spermaceti.

essentially the same as those obtained dilatometrically.

Heating and cooling curves run on synthetic glyceryl monostearate (monostearin) are shown in Fig. 7. This material is reported to exist in four forms; namely sub-alpha, alpha, beta prime, and beta (4). The curve labeled heating-1- is the heating curve of material stabilized by prolonged storage at room temperature. Two distinct inflections (65–68° and 74–76°) can be observed and, although they are 5° less than those reported by Malkin (9a), they probably represent the α (along with the subsequent $\alpha \rightarrow \beta$ transition), and the β melting points. The β' form is difficult to observe by these methods (9b). A heating curve, heating-3-, run after rapid cooling (i.e., there was a large cooling gradient), shows only melting of α form crystals, no β form being present or formed during the heating. There is an indication on curve heating-3- of an arrest at 39°, but it is too indefinite to be conclusive. Slow cooling (i.e., using a small cooling gradient) yields essentially the same results except for a definite arrest at 47°, which probably represents alpha → sub-alpha transition (see curve cooling-4-). Commercial

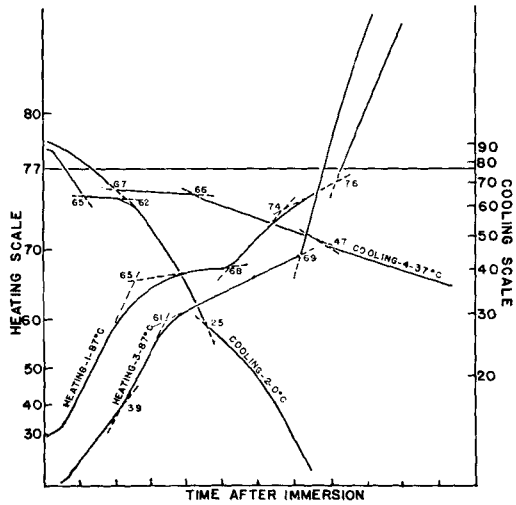

Fig. 7.—Log ΔT plots for a heating-cooling study of synthetic glyceryl monostearate.

monostearin shows little, if any, evidence of polymorphic change when it is remelted after being rapidly cooled (see curves cooling-2- and heating-3- on Fig. 8). While polymorphic transitions probably do occur in commercial monostearin, the presence of large amounts of other glycerides (palmitates, oleates, etc.) and/or other substitutions (di- and triester) apparently obscures the heat effects of these changes.

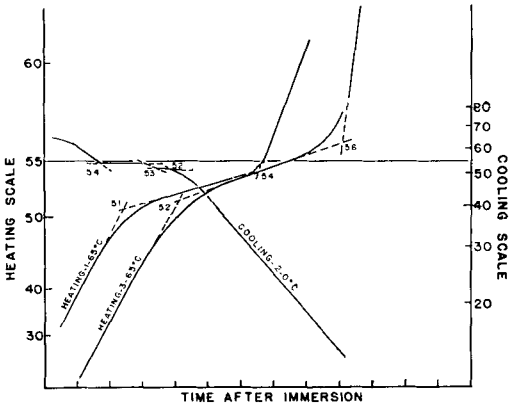

Fig. 8.—Log ΔT plots for a heating-cooling study of commercial glyceryl monostearate.

The heating and cooling behavior of the synthetic glyceryl distearate (distearin) is shown in Figure 9. Forms reported in the literature are α, β', and β (4). Clearcut evidence of two crystal forms appears in the heating curve run on a sample cooled rapidly from a melt (see heating-3-) with the transition occurring at 57–60°. These two forms correspond roughly to the α and β' forms reported by Baur, *et al.* (10a), and Malkin and Shurbagy (10b). The β' melting observed on reheating (heating-3-) could have resulted either from rapid transition of α to β' as the heating curve was being run or from β' crystals formed during the cooling. The curve obtained during rapid cooling (cooling-2-) suggests that very little β' form crystallizes out with the α form. At slower cooling rates, however, both forms definitely appear (cooling-4-).

Note that cooling curves normally produce freezing points well below the melting points of the same form. Smit (11) has theoretically explained this as due to the kinetic nature of heating and cooling determinations, and suggests that only heating curves be used for exact work.

For the same reasons as indicated above with commercial monostearin, the heating-cooling curves of commercial distearin do not show the polymorphic forms found in the pure material (Fig. 10). As expected, the melting and freezing points of this commercial distearin are considerably below those of the synthetic material. The melting point of the commercial mixture is lowered by rapidly cooling the melt (compare heating-3- with heating-1-), but none of the three curves indicates a characteristic polymorphic transition. Lutton (12) has suggested that the higher melting points of aged samples (also observed in synthetic distearin) are due to crystal aging or stabilization. This point is discussed further under theobroma oil.

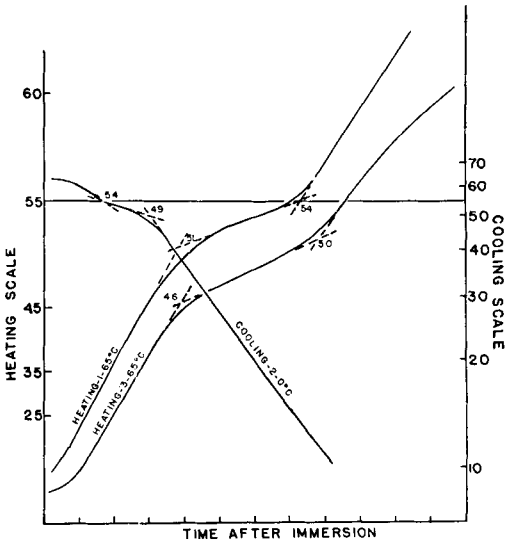

Fig. 10.—Log ΔT plots for a heating-cooling study of commercial glyceryl distearate.

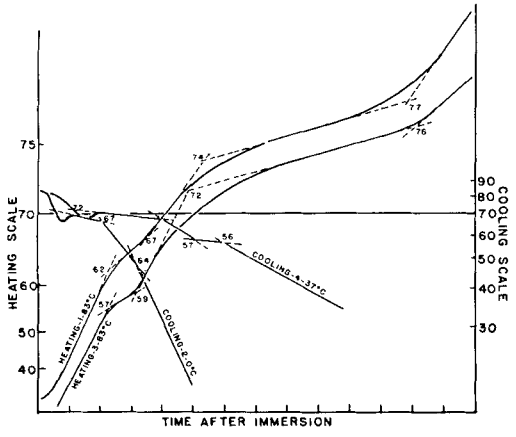

Fig. 9.—Log ΔT plots for a heating-cooling study of synthetic glyceryl distearate.

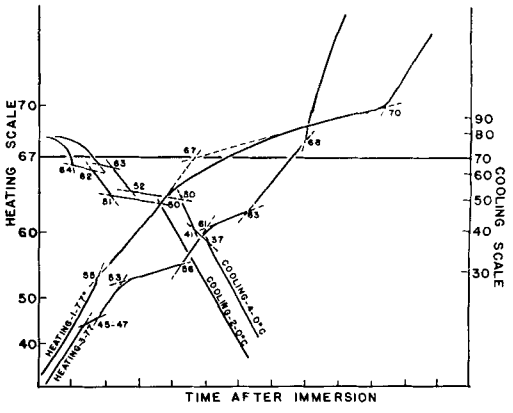

Fig. 11.—Log ΔT plots for a heating-cooling study of synthetic glyceryl tristearate.

Rapidly cooled synthetic glyceryl tristearate shows four distinct melting or transition points, while storage stabilized samples show one or perhaps two (Fig. 11, curves heating-3- and heating-1-, respectively). Three of these points correspond well to the α, β', and β melting points reported by Clarkson and Malkin (13) (melting points found 53–56°, 61–63°, 67–70°; reported in the literature 55°, 65°, 72°). The lowest form observed in this work, melting at 45–47°, is not identifiable from the literature.

Theobroma oil (cocoa butter), although a mixture of several glycerides, has a heating-cooling curve similar to that of a pure compound. This has been explained (14–16) as being due to the high percentage (more than 50%) of one glyceride, 2-oleopalmitostearin. The forms γ, α, β', and β melting at 16–18°, 21–24°, 27–29°, and 34–35° have been reported (17, 18). The heating-cooling characteristics of a commercial sample of theobroma oil are shown in Figure 12. The storage stabilized sample (heating-1-) shows essentially one melting point (33°), that of the stable β form. Although this curve shows no indication of β' crystals (m.p. 28°), some are probably present because both β' and β forms are quite stable at room temperature (17a). Cooling molten theobroma oil to 0°

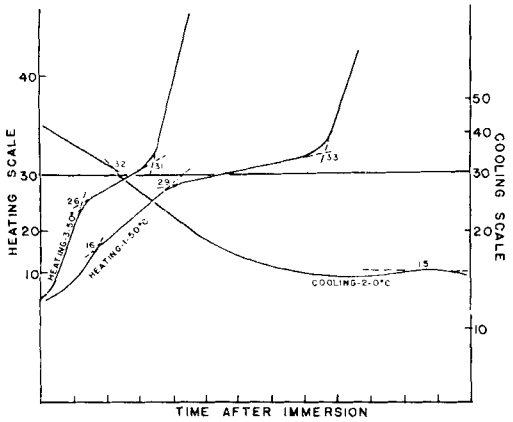

Fig. 12.—Log ΔT plots for a heating-cooling study of a storage stabilized sample of theobroma oil (cocoa butter). Curve cooling-2- was run within 2 hours of curve heating-1-. Curve heating-3- was obtained after the sample used for curve cooling-2- had stood at room temperature for 24 hours.

results in a congealing point of 15–16°. From its translucent appearance, this is probably a glassy form, although Vaeck describes it as the γ form (17c). If this glassy form is immediately reheated, it melts at 16–25° (see, for example, heating-1-, Fig. 13). On the other hand, if the glassy form is allowed to stand for 24 hours at room temperature, complete transformation occurs, primarily to the α form, but at least in part to the β form. If the sample is now reheated (see heating-3-, Figs. 12 and 13) the influence of the β nuclei can be observed; complete melting of the sample occurs above the β' melting point (i.e., >28°).

If theobroma oil (cocoa butter) suppositories are prepared by standard suppository procedures (melt at 40°, pour into 0–2° mold), the suppositories, when immediately reheated, exhibit the behavior shown in heating-1- of Fig. 13. Only $\gamma \rightarrow \alpha$ transition is observed, plus α melting at 25°. When the suppositories are allowed to stand at room temperature for 24 hours after casting, the heating curve (heating-3-) shows that complete transition to the α form and some $\alpha \rightarrow \beta$ transition has occurred. It is unlikely that $\alpha \rightarrow \beta'$ transition occurs in studies conducted under the described conditions because this transition is quite slow when compared to the $\alpha \rightarrow \beta$ transition (17b).

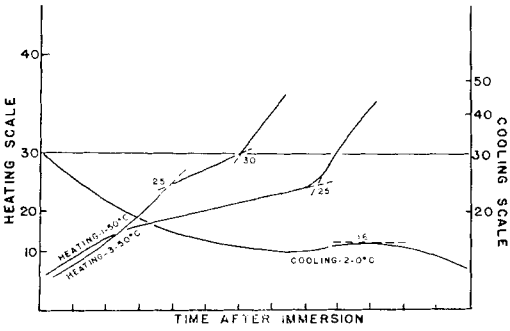

Fig. 13.—Log ΔT plots for a heating-cooling study of theobroma oil (cocoa butter) suppositories (cast at 0 to 2° from a 40° melt). Curves heating-1- and cooling-2- were obtained within 2 hours of casting. Curve heating-3- was obtained after the suppository had stood at room temperature for 24 hours.

In most of the materials where an aged sample was compared with a recently crystallized sample (Figs. 7–13), the melting point of the recently crystallized sample was found to be lower. This has been discussed by Steiner (18) who suggests that these low melting points are due to "mutually soluble binary mixtures." In light of the observation that rapid cooling also produces low melting points, the simpler explanation suggested by Lutton (12), that all samples which are not completely "aged" will give low melting points (lower by as much as 3°), seems a more acceptable one.

Stability Interpretations of Heating-Cooling Data.—Polymorphism is defined as the ability of a substance to exist in more than one crystal form. These crystal forms have different physical properties, e.g., melting points and different energy contents. They are of importance because transitions from one crystal form to another, with simultaneous changes in physical properties, can cause stability problems in pharmaceutical products even under room temperature storage conditions.

Essentially two large classes of polymorphic transitions have been identified in lipids. In the more common type, called monotropism, one crystal form is stable up to the melting temperature. Under these conditions, metastable crystals will tend to transform, with time, to the stable form, irrespective of storage temperature; however, the storage temperature may influence the rate of monotropic transitions. In the less common type of polymorphism, called enantiotropism, each crystal form has a temperature range in which it is stable, and reversible transformation occurs between two forms at the transition temperature.

Because the main concern in lipid stability is the presence and rate of polymorphic transitions rather than their direction, both types of polymorphism may be discussed together.[5] The transition from one polymorphic form to another, with its consequent liberation of heat (heat of transition), probably occurs as both a $solid_1 \rightarrow solid_2$ and a $solid_1 \rightarrow liquid \rightarrow solid_2$ phenomenon (11, 13). The extreme slowness of known $solid_1 \rightarrow solid_2$ transitions (e.g., methyl stearate and palmitate) (19), along with the sharpness and reproducibility of lipid transition temperatures, suggest that $solid_1 \rightarrow liquid \rightarrow solid_2$ transition is the predominant mechanism for transitions occurring at temperatures near the maximum transition temperature. At temperatures below this temperature, some much slower mechanism may be responsible for the crystal transitions (e.g., $solid_1 \rightarrow solid_2$). Since solid phase transitions would logically be functions of viscosity, transformations which have high transition temperatures will probably proceed at negligible rates at room temperature in solids which have a low liquid content. Complete transition, therefore, may require minutes, days, or years, depending on the transition rate at the temperatures of storage.

Estimation of a lipid material's potential for polymorphic change, or in other words its tendency to be unstable, can be made by comparing the heating curve of a sample stored for prolonged periods at room temperature (i. e., stabilized) with one of a sample which has recently been rapidly frozen from a melt. Freezing from a melt usually produces the least stable (γ and/or α) forms of lipids, and reheating the sample will then show the presence of these forms. If a stabilized sample of material is not available, the observation of multiple melting points in a rapidly-frozen sample may be used as criteria of polymorphic potential.

All of the synthetic stearates studied show great polymorphic potential. Synthetic glyceryl monostearate (Fig. 7), glyceryl distearate (Fig. 9), and glyceryl tristearate (Fig. 11), all show multiple melting points even after prolonged storage at room temperature. The degree of transition to the stable polymorphic form was so great in the di- and tristearates, however, that considerable information would have been lost if the rapidly-cooled samples had not been reheated. The commercial stearates (Figs. 8 and 10) show no such polymorphic potential. The difference in melting points observed on the two heating curves of commercial distearin is related to the difference in the "ages" of the two samples, as was discussed in a previous section. It was also mentioned previously that the absence of distinct transition points in commercial materials should not be interpreted to mean that polymorphism is absent. Chemical heterogeneity of a given sample tends to obscure its polymorphic transitions. Careful studies, including the use of purified components of the sample, may be necessary to prove their existence.

The real value of heating-cooling curves, from a stability point of view, is in estimation of the relative rate of a polymorphic transition at room or storage temperature. With lipid-containing pharmaceuticals, we are concerned only with a rather narrow range of transition rates and can adjust the parameters of the heating-cooling measurement procedure so that these rates will be observed. On the one hand, if the transition rates are so high that low melting forms are not observable by heating-cooling methods, the crystal changes in the lipid will probably be completed during the manufacturing process and cause no stability problems in the product. On the other hand, if the crystal changes are extremely slow at the transition temperature or if the transition temperatures are much higher than the storage or use conditions, the rate of transition at room temperature may be negligible and, again, there probably will be no stability problems. Therefore, it seems likely that stability problems occur in pharmaceutical products only when the transitions proceed at rates between these extremes under the temperature conditions to which the product is exposed.

If one considers the synthetic stearin series (Figs. 7, 9, and 11) and in particular the transitions in the range 58–68° (monostearin, $\alpha \rightarrow \beta$; distearin, $\alpha \rightarrow \beta'$; tristearin $\beta' \rightarrow \beta$) the relative rates of these transformations can be estimated. At the transition temperature (61–69°) monostearin showed no transformation to the β form (no 76° m.p.), tristearin (at 61–63°) transformed very slightly (slight melting at 68°), and distearin rather completely. One could expect that the polymorphic stability of these pure lipids would decrease in a similar order (i.e., stability of monostearin > tristearin > distearin). At room temperature, the absolute rate of these transitions would also be influenced by the transition temperature itself. The higher transition temperatures of mono- and tristearin would further suggest that their room temperature transition rates would be less than that for distearin. Another example of this type is shown in theobroma oil, which has the same slow $\alpha \rightarrow \beta$ transition as was shown by rapidly cooled mono- or tristearin (e.g., see Fig. 13, heating-1-). The room temperature transition rate of theobroma oil is fairly rapid (heating-3-) because the transition temperature is near room temperature.

Another possible use for studies like those illustrated here concerns the effects of heat treatment (tempering) on the crystalline state of the lipid. Crystal transformation could be monitored easily by storing the material at the desired temperature and observing the effect of storage on the heating curve of the stored material. Tempering near the transition temperature would then continue until the undesired form had disappeared from the curve.

In general, our experience suggests that the smoother and straighter the entire log ΔT vs. time plot of a heating-cooling curve, the greater the crystal stability of a lipid. Secondarily, the higher the transition temperature, the greater the crystal stability at room temperature.

Effects of Polymorphic Forms on Lipid Properties. —A basic characteristic of polymorphic transitions is the decrease in specific volume which normally occurs as the crystalline form changes from $\gamma \rightarrow \alpha \rightarrow \beta' \rightarrow \beta$. This decrease in specific volume, if it occurs after a container has been filled or a lipid film has been applied, can cause shrinkage away from the container walls or loss in integrity of the film. Changes in the crystal form can also cause more subtle changes, such as in the vapor and

[5] If the storage conditions of stability testing include temperatures above and below the enantiotropic transition temperature, this assumption is not necessarily true.

liquid permeability of a film. It has been observed, for instance, that rapidly cooled wax films transmit water vapor much faster than stabilized films (20, 21), which suggests that crystal size, shape, form, and orientation may have a pronounced effect on vapor and liquid transmission.

Pharmaceutical Utility of Heating-Cooling Curve Techniques.—It has been shown that most fats and waxes are polymorphic and on aging may undergo crystalline changes (3). Since these changes sometimes occur over a significant time span they can cause physical changes in pharmaceutical products during storage, e.g., changes in ointment consistency, changes in the appearance of suppositories, or changes in the integrity of tablets, pellets, or other dosage forms containing lipids. The development pharmacist needs good methods for determining what lipids are likely to undergo such changes, the temperatures at which the changes are accelerated, the rates at which they occur, and methods for eliminating or minimizing these changes during or after the manufacture of dosage forms which contain lipids.

Heating-cooling curves are useful for detecting the propensity of these pharmaceutical agents to undergo polymorphic change, for determining the temperatures of rapid polymorphic transitions, for evaluating the effects of time-temperature history on the polymorphic form which a lipid may assume, and for establishing what manufacturing and handling procedures result in the unstable or the relatively stable crystalline forms.

If, for example, heating-cooling curve data indicate that a substance undergoes polymorphic change in a pharmaceutical product at the usual temperatures of storage and transit, the pharmacist must be alert to the fact that a stability problem may result. Specific manufacturing conditions may be necessary to assure that the integrity of the product remains unchanged from lot to lot. Products containing cocoa butter, for example, fall into this category and may show different degrees of polymorphic change and different physical stabilities, depending upon their methods of preparation, despite the fact that their chemical compositions may be identical.

In other instances, polymorphic changes may be completely inimical to the purpose for which the product is intended. In such instances a stable form must be attained when the product is initially prepared. This can either be accomplished through the use of tempering or special manufacturing techniques. More simply, the lipids may be chosen on the basis of their inabilities to undergo significant polymorphic changes in the product formulas selected and under the anticipated storage conditions. In all product development problems involving lipids, the heating-cooling curve technique can be of considerable value in evaluating the raw lipid materials and as a control method for establishing the materials and manufacturing procedures necessary for attaining the required physical integrity.

The heating-cooling curve measurements described in this study require only relatively simple apparatus, are inexpensive to perform, and can be performed by unskilled personnel with a minimum of training. The quantity of sample required is only about 1 or 2 Gm.; however, in some instances this might be considered inordinately large, as for example when evaluation of a pellet or tablet film is involved. In such an instance, the light transmission technique (2), which utilizes samples weighing only a few mg., might be a preferred evaluation technique.

Because the heating-cooling curve technique of this study is a nonequilibrium method, it is much more rapid than the dilatometric technique (8). A number of samples may be run in a relatively short period of time. On the other hand, it gives no direct indication of the volume changes involved when polymorphic transitions occur. When volume change data are important, the dilatometric technique is valuable, and the heating-cooling approach of this study is of little use unless a direct correlation can be found between the two methods with the particular system under study.

Within the limitations discussed, the heating-cooling curve technique has value in studies of polymorphism. It represents an approach which could see greater use in the solution of pharmaceutical problems relating particularly to the use of lipids in dosage forms.

Defibrillatory Substance from *Pteryxia terebinthina*

By GORDON H. BRYAN

A method for the isolation of a crystalline material from the roots of *Pteryxia terebinthina* has been described. The crystalline material was found to be essentially free from contractile depressant effects, and to be approximately seven times more potent than quinidine sulfate as a defibrillatory agent on isolated rat hearts.

A DESCRIPTION and the history of *Pteryxia terebinthina* (Hook.) Coult. & Rose, var. *terebinthina*, has been written by Pettinato (1) and Call (2). Call (2) obtained a crystalline material that he named pteryxin from the powdered root of this plant. A preliminary chemical and physical characterization was made by Pettinato (1) and later extended by Willette and Soine (3). Pteryxin was reported as having uterine relaxant and coronary vasodilator properties comparable to those of khellin (2, 3).

In unpublished experiments by the author crude, dealcoholized extracts of the root also demonstrated defibrillatory properties and, for this reason, it was of interest to isolate the active principle and compare its cardiac effects with those of quinidine.

EXPERIMENTAL

Extraction and Isolation

A June collection of the root was obtained from the vicinity of Moses Lake, Washington. The roots were dried and powdered in the same manner as described by Pettinato (1). A 5-Kg. quantity of the powder was macerated for 12 hours with 80% ethyl alcohol and extracted by percolation with approximately 60 L. of the menstruum. The percolate was evaporated by forced air draft until an aqueous and oily layer had separated. The aqueous layer was decanted, treated with a saturated lead subacetate solution, and filtered until no further precipitation occurred. Hydrogen sulfide was then passed through the filtrate. Excess lead, as the sulfide, was removed by filtration. The filtrate was evaporated by air to a thick syrupy consistency and partially redissolved in 95% alcohol. Insoluble material was removed by filtration. The clear liquid was stored at room temperature with access to air. Crystals appeared in the bottom of the container after 3 to 4 days. The supernatant fluid was decanted and the crystalline material redissolved in acetone with the aid of a small amount of distilled water. Partial evaporation at room temperature of this solution resulted in recrystallization of the material. Approximately 2 Gm. of crystals were obtained in this manner.

The crystals melted between 191–192°. They were very soluble in water and the solution had a weak blue fluorescence that was not apparently altered by the addition of dilute sulfuric acid nor by dilute ammonium hydroxide. No further attempt was made to determine physical or chemical characteristics.

Pharmacological Studies

Isolated Rat Heart.—Because of availability and small size, rat hearts were selected for this investigation. The procedure and apparatus for left intraventricular cannulation and coronary perfusion as described by Bryan (4) was followed. The composition of the perfusing fluid was: (Gm./L. distilled water) NaCl 7.0, KCl 0.4, $CaCl_2 \cdot 2H_2O$ 0.4, $MgCl_2 \cdot 6H_2O$ 0.2, Na_2SO_4 0.14, $NaHCO_3$ 1.5, and dextrose 1.0. The fluid was gassed with oxygen to saturation and the pH adjusted to 7.4 by means of a Beckman (model H-2) pH meter and with 5% carbon dioxide in oxygen. Perfusion pressure was approximately 40 mm. Hg and at a temperature of 37°.

Quinidine sulfate,[1] aconitine nitrate,[2] and the crystalline material that was isolated were dissolved separately in perfusion fluid for injection into the perfusion apparatus directly above the aortic cannula. Stock test solutions were prepared the day they were to be used.

Surface left ventricular electrogram was recorded through a wick electrode placed on the body at the left ventricle. Left ventricular pulse pressure (via strain gauge) was recorded with the electrogram by means of a two-channel Sanborn apparatus.

Cardioplegia.—Preliminary quantitative analysis with quinidine sulfate indicated an approximately linear relationship between dose and pulse pressure reduction that terminated in reversible cardioplegia. Prior to the isolation of the crystalline material, crude extracts of *terebinthina* also had this effect. Therefore, cardioplegia was the depressant effect used for a comparison of the two substances.

In order to test contractile depression independently from rate, hearts were driven by a Grass square wave stimulator. Rate was constant for each heart but varied between hearts.

Doses from a starting value of 100 mcg. of quinidine sulfate were increased by alternate arithmetic and geometric progression until cardioplegia was achieved. A comparable dosage schedule for the crystalline material was abandoned because of the rapid depletion of the supply, and an unexpected finding.

Received April 28, 1961, from the School of Pharmacy, Montana State University, Missoula.

Accepted for publication December 26, 1961.

This work was supported in part by a Sterling-Winthrop research grant.

Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.

The author wishes to acknowledge indebtedness to T. G. Call for identification and samples of *Pteryxia terebinthina*, R. L. Van Horne for providing unexpected necessities, J. L. Wailes for interest and aid, and F. A. Pettinato for helpful suggestions.

[1] Merck & Co., Inc., Rahway, N. J.

[2] S. B. Penick & Co., New York, N. Y.

Fifteen hearts required an average ± S.D. of 1.72 ± 1.4 mg. of quinidine sulfate to obtain cardioplegia. In contrast, of 10 hearts, 4 showed a pulse pressure reduction of approximately 50% and 6 did not show an obvious contractile change at a dosage of 50 mg. of the crystalline material. Cardioplegia did not occur in two additional hearts with 100 mg. of the crystalline material. No further attempt was made to produce this effect and it was concluded that the crystalline material was virtually without a contractile depressant action on the rat heart.

Fibrillation.—Spontaneously beating rat hearts were used for this portion of the investigation. In order to cause fibrillation, 40 mcg. of aconitine nitrate was injected into the perfusing system. Ventricular fibrillation occurred within 1 minute, however, spontaneous reversion also occurred within approximately 5 minutes (10 hearts). Inasmuch as this unexplained circumstance was not useful, the relevance of potassium reduction in the perfusing fluid as determined by Kärki (5) was explored.

When the potassium chloride content of the perfusing fluid was reduced one-half by isosmotic sucrose substitution, aconitine-induced fibrillation was considered persistent if it lasted 15 minutes and longer. This was found to occur without exception for 10 hearts and is in agreement with Kärki whose observations were made on rate-induced fibrillation with isolated rabbit hearts. Accordingly, hearts fibrillating for 15 minutes after aconitine injection at a reduced potassium perfusing concentration were used to test defibrillation action of quinidine and the crystalline material.

Starting doses of 100 mcg. with arithmetic progression were used for quinidine sulfate, and a similar procedure starting at 10 mcg. was used for the crystalline material. To defibrillate 20/20 hearts required an average ±S.D. of 350 ± 36 mcg. of quinidine sulfate and 50.0 ± 9 mcg. of the crystalline material. At a $P = 0.05$, these means are significantly different. Therefore, it can be stated that the crystalline material possesses a potency of approximately seven times that of quinidine sulfate in its ability to defibrillate rat hearts.

Pulse pressures (reduced to essentially zero after fibrillation) were not restored to control values after defibrillation by either agent. In view of the return to control values when perfusion is continued after quinidine-induced cardioplegia, this observation was of interest. Whether aconitine or low potassium is a causative factor is not known.

In addition, when hearts in either series were defibrillated, fibrillation could not be reproduced by aconitine. This suggests a comparable, although unknown, mechanism of action for quinidine and the crystalline material.

The rat heart was selected, in part, on the premise that smaller quantities of test chemicals would be required, and it was of interest to note that the average quinidine defibrillation dose was nearly the same as that required for this purpose by isolated rabbit hearts (6). This would indicate that concentration rather than absolute amount is a critical factor in defibrillation under these conditions.

DISCUSSION

If the mechanisms for electrical and mechanical activity are considered as separate, but interrelated, then it is of obvious value to select, for defibrillatory purposes, those chemicals that have a higher degree of specificity for the former but with little or no effect on the latter. On this basis, the crystalline material isolated from *Pteryxia terebinthina* would then be preferred to quinidine. However, there are a number of other drugs and chemicals available for this purpose. Information regarding cardioplegic/defibrillatory ratios for these substances is not readily available. Therefore, no further conclusions can be reached concerning the relative potency of the crystalline material.

A second consideration—extensive information regarding *in vivo* effects of the crystalline material was not obtained. This was because of the limited quantities of the crystalline material available. In order to overcome this handicap, an attempt is being made to determine the chemical identity of the crystalline material with synthesis as an eventual objective.

CONCLUSIONS

1. A procedure for the isolation of a crystalline material from *Pteryxia terebinthina* has been described.
2. Through comparison on the isolated rat heart, the crystalline material has been shown to have a defibrillatory potency approximately seven times that of quinidine sulfate.
3. In contrast to quinidine, the crystalline material does not produce cardioplegia at a dose level of approximately 30 times that of quinidine sulfate.
4. A procedure for obtaining persistent fibrillation with aconitine in the isolated rat heart has been described.

Paper Chromatographic Determination of Muscarine in *Inocybe* Species

By J. K. BROWN, M. H. MALONE†, D. E. STUNTZ, and V. E. TYLER, Jr.

A relatively simple, paper chromatographic method was developed for the quantitation of muscarine in dried mushroom tissue. Application of the procedure to 34 species of *Inocybe* revealed detectable quantities of muscarine ranging from 0.01 to 0.80% in approximately 75% of them. No significant relationship was found between distribution of muscarine and infrageneric taxonomy of the genus *Inocybe*.

THE GENUS *Inocybe* is composed of nondescript, generally brownish agarics, often with characteristic odors. Although recognition of a mushroom as an *Inocybe* is comparatively simple, species identification is extremely difficult, even when microscopic characteristics are considered. In 1924, Kauffman (1) recognized 105 North American species, but today this number is known to be very conservative. Unfortunately, no modern comprehensive treatment of domestic species is available; the best European monograph is that of Heim (2).

Not all species of *Inocybe* are toxic, but muscarine is the toxic principle found in all poisonous species which have been examined. Eugster (3) has reviewed the older literature on the occurrence of this compound in mushrooms and has pointed out that the concentrations reported by Loup (4) for *Inocybe* species are too high, being based on physiological tests compared with an impure muscarine standard. Isolation of muscarine from several European species of *Inocybe* has recently been carried out (5). Percentage concentrations, calculated on fresh-weight basis, have been reported for the following species (*sic*): *I. fastigiata* (Fr. ex Sch.) Quél., 0.01%; *I. patouillardi* (Bres.), 0.37%; and *I. umbrina* (Bres.), 0.003%.

Species of *Inocybe* are abundant in western Washington and pose an appreciable health hazard to the indiscriminate collector. It was of interest, therefore, to develop a procedure which would permit the rapid screening of small quantities of carpophore tissue in order to determine the relative toxicity of the species.

Received January 17, 1962, from the College of Pharmacy and the Department of Botany, University of Washington, Seattle 5, and the Division of Pharmacology, Pharmacy Research Institute, University of Connecticut, Storrs.

Accepted for publication February 21, 1962.

Abstracted from a dissertation submitted to the Graduate School of the University of Washington by J. K. Brown in partial fulfillment of the requirements for the M.S. degree.

This investigation was supported by research grants No. RG-7515 (University of Washington) and RG-8239 (University of Connecticut) from the National Institutes of Health, Bethesda, Md.

The authors are indebted to Dr. R. G. Benedict and Dr. L. R. Brady for assistance in the collection of the *Inocybe* species employed in this investigation, to Mrs. G. O. Kempton for supplying the collection of *I. nigrescens* from Alaska, and to Dr. P. H. List for a generous sample of pure muscarine gold chloride.

† University of Connecticut, Storrs.

EXPERIMENTAL

Inocybe Species Examined.—The naturally occurring carpophores used in this investigation were collected in western Washington during the fall and early winter of 1960 through the spring of 1961. One collection of *I. nigrescens* was obtained from the Portage Glacier area in Alaska. Representative herbarium specimens of each collection were deposited in the mycological herbarium of the University of Washington. Some of the species investigated have not been described in the literature; consequently, these are referred to by a herbarium number pending publication of their characteristics.

All collections from western Washington (Table I) were cleaned, dried in a forced-air drying oven at 48° for at least 72 hours, and stored in tightly closed glass containers until examined. The species of Alaskan origin which had been dried prior to shipment was redried and treated similarly. Each collection of any given species was maintained separately from other collections of the same species obtained at other times or places.

Extraction and Purification Procedures.—A number of different methods were investigated to determine their suitability for the quantitative extraction of quaternary ammonium compounds from the dried carpophores. Homogenization with 70% ethanol in a Waring Blendor, extraction of finely powdered carpophores by shaking for prolonged periods with 70% ethanol, and continuous extraction of finely powdered carpophores in a Soxhlet apparatus with 95% ethanol proved to be relatively inefficient extraction procedures. When carpophores (5.0 Gm.) were milled to a No. 40 powder, defatted, macerated for 1 hour with a mixture of absolute ethanol:10% ammonium hydroxide solution (19:1), and extracted in a Soxhlet apparatus with the same solvent for 33 hours, chromatographic examination of a subsequent extract of the marc failed to detect residual quaternary compounds.

Purification of the extract was effected by concentrating it under reduced pressure at 50° in a flash-evaporator until a thick syrupy residue (approximately 2 ml.) was obtained. This residue was dissolved in successive small volumes of distilled water which were combined (total 25 ml.). Sufficient sodium hydroxide was added to produce a concentration of 3 *N*, and 5.0 ml. of a 13% solution of ammonium reineckate in methanol was added to this alkaline solution. The mixture was then refrigerated at 5° for 10 to 12 hours, centrifuged, the supernatant liquid decanted, and the precipitate washed with cold *n*-propanol (three 2-ml. quantities) until the washings were colorless. The washed precipitate was then dissolved in successive small

volumes of acetone (total 7 ml.) which were combined.

Quaternary reineckates contained in the acetone extract were converted to the respective chlorides (6) by adding 1.4 ml. of water, 5.0 ml. of a saturated solution of silver sulfate, and 0.5 ml. of a 20% aqueous solution of barium chloride. This mixture was cooled (12 hours), centrifuged, the supernatant liquid decanted and retained, and the precipitate washed with 5.0 ml. of cold water which was then added to the supernatant liquid. The combined solution was evaporated under reduced pressure at 50° in a flash evaporator and the residue dissolved in absolute ethanol (total volume 10 ml.). Purified extracts prepared in this manner were subjected to chromatographic examination.

Chromatographic Procedures.—A number of different solvent systems, including those employed by previous investigators (7, 8) for the separation of muscarine and other quaternary compounds, were examined to determine their suitability for use in a quantitative chromatographic procedure.

Satisfactory separation of muscarine and choline and discrete spots with minimum tailing were achieved when sheets of Whatman No. 1 filter paper, which had been previously dipped in MacIlvaine's buffer (9) at pH 4.5 and air dried, were formed with a wash liquid composed of *n*-butanol:methanol:water (10:3:2). Reference choline, acetylcholine, and muscarine exhibited average R_f values in this system of 0.09, 0.23, and 0.28, respectively. Since the alkaline extraction procedure employed resulted in the hydrolysis of any acetylcholine present in the mushroom tissues, this compound was not detected in the extracts and did not interfere with muscarine determination.

Quantitation of muscarine was carried out by spotting, in duplicate, suitable quantities (3–100 μl.) of the purified extract on a buffered chromatographic sheet. After formation, the sheet was air dried and sprayed uniformly with Thies and Reuther's reagent (10).

Preliminary investigations had revealed that the sensitivity of this reagent for muscarine varied somewhat according to the length of time following

its preparation from the stock solution but preceding its use. It was determined that maximum sensitivity was reached between 8 and 10 hours after mixing; consequently, the reagent was always prepared this length of time prior to use. Experiments with reference quantities of muscarine also revealed that following formation in the above system, detection of 5 mcg. of muscarine was equivocal, but 6 mcg. could be detected with certainty. This finding is in agreement with the report of Eugster (3).

After spraying with the reagent, the sheet was dried and subjected to careful visual inspection to determine the minimum amount of extract which formed a detectable orange-red spot. This observation was then verified by respotting, in duplicate, the same quantity on an additional sheet together with quantities of extract slightly smaller than, and slightly larger than, this amount. Actual quantities applied varied according to the concentration of muscarine in the extract. If the results of subsequent chromatograms verified the initial observations, the quantity of extract producing a just-detectable muscarine spot was considered equivalent

[a] If muscarine was not detected, this was the largest volume spotted. [b] Muscarine not detected. The maximum quantity which could be present but remain undetected has been derived by calculation.

to 6 mcg. of muscarine. From these data, the concentrations of muscarine in the dried carpophores were calculated. If the maximum quantity of purified extract spotted did not produce a detectable muscarine spot, the maximum concentration which could be present and remain undetected was calculated. These data are reported in Table II.

In order to determine the relative efficiency and accuracy of the entire procedure (extraction, purification, and chromatographic estimation), 7.4 mg. of muscarine was added to a sample (4.41 Gm.) of *I. nigrescens*, a species in which muscarine could not be detected. This control sample was treated as previously described, and the amount of muscarine present in the purified extract was found to be equivalent to 7.0 mg., approximating a 95% recovery of the added compound.

Pharmacological estimations of the muscarine content of certain of the identical collections employed in this investigation have been carried out by Malone, *et al.* (11). With the exception of the assays of *I. napipes*, which apparently contains other potent muscarine-like agents or potentiators, the results of the biological and chromatographic assays were in general agreement.

DISCUSSION

Comparison of the muscarine contents of the species investigated in this study with proposed infrageneric divisions of *Inocybe* based on classical morphological and histological criteria (2) reveals little in the way of a definite relationship between muscarine content and taxonomic position. Certain generalizations may be made, such as the probable occurrence of appreciable muscarine concentrations in species centered about the stirps geophylla Heim of the section Viscosae Heim (*I. geophylla* var. *geophylla*, *I. lilacina*, *I. pudica*, *I. agglutinata*) or the various stirpes of the section Gibbosporae Heim (*I. umbrina*, *I. napipes*, Nos. 1187, 4291, 1540). There are, however, cases in which no correlation is possible such as the easily detectable occurrence of muscarine in *I. mixtilis* but its apparent absence in the closely related *I. xanthomelas* and *I. nigrescens*.

While muscarine has been shown to be of widespread occurrence in the genus *Inocybe*, its occurrence within the various subdivisions of the genus is apparently not entirely predictable on taxonomic grounds. This does not lessen the significance of the compound as a taxonomic criterion in those species in which it occurs, but it does reduce its relative importance as a genus characteristic. Some evidence obtained in this investigation by analysis of different collections of the same species indicates that the capacity of *Inocybe* species to accumulate muscarine may be influenced by certain hereditary (infraspecific races) or environmental factors.

Effect of Sulfate Content of Several Anionic Polymers on *in Vitro* Activity of Pepsin

By L. J. RAVIN, J. G. BALDINUS, and M. L. MAZUR

Carrageenan was degraded with acid to give materials with sulfate contents varying from 5–30%. Antipeptic activities of these materials correlated closely with the sulfate content. Other sulfated polymers such as polyvinyl sulfonate, sulfated rice starch, amylose sulfate, heparin, etc., gave a similar correlation. All these polymers precipitated protein in the antipeptic test. Compounds such as sodium lauryl sulfate and *m*-xylene sulfonate possessed significant antipeptic activity but did not precipitate protein, and no correlation between sulfate content and antipeptic activity was found. The precipitation of protein by carrageenan depends upon the pH, becoming negligible at a pH above 4.5.

THAT SULFATED polysaccharides possess antienzyme activity has been established by a number of workers. Levey and Sheinfeld (1) found that the proteolytic action of pepsin on casein is inhibited by chondroitin sulfate, heparin, and sodium polyanhydromannuronic acid sulfate. Fellig and Wiley (2) demonstrated that heparin and various synthetic anionic polymers are inhibitors of pancreatic ribonuclease. More recently, Anderson and Watt (3, 4) and Houck, Bhayana, and Lee (5) reported that the incidence of ulcers in stress rats and in cortisone- and histamine-treated dogs and rats can be reduced by the oral administration of carrageenan, a sulfated polymer. Anderson (6) states that the degree of peptic inhibition parallels the sulfate content of the polymer. This paper deals with the effect of the sulfate content of several synthetic and naturally occurring anionic polymers on the *in vitro* activity of pepsin with emphasis placed on carrageenan and its degraded forms.

Carrageenan is a heterogenous, water-soluble polysaccharide obtained from marine algae such as *Chondrus crispus*. The two main components are kappa- and lambda-carrageenan, which can be separated by selective precipitation with potassium ions. These components differ in molecular size, viscosity, optical rotation, sugar units, and sulfate content (7–16).

Carrageenan is sensitive to acid. The glycosidic bonds undergo hydrolysis under relatively mild conditions, whereas the sulfate groups require more drastic conditions for their removal. This principle has been utilized by Evans Medical Limited to make C-16, a form of carrageenan with lower viscosity than the starting material yet with essentially the same sulfate content (17). Because of its low viscosity, C-16 is easier to administer orally (6). In the present study C-16 has been subjected to further acid hydrolysis; we will refer to the resulting materials with varying sulfate content as degraded carrageenan. The remaining sulfated polymers used in this study were obtained through commercial sources or through the generosity of several individuals. Amylose sulfate was prepared by the method of Roubal, Placer, and Vokac (18).

Received December 1, 1961, from the Smith Kline & French Laboratories, Philadelphia, Pa.
Accepted for publication February 16, 1962.
The authors are indebted to the Microanalytical Chemistry Group at Smith Kline & French Laboratories for the sulfate analyses reported in this paper; to Marine Colloids, Inc., Rockland, Me. for the supply of lambda- and kappa-carrageenan; to P. Bernfeld of the Bio-Research Institute, Cambridge, Mass. for the sulfated rice starch; and to J. Fellig of Union Carbide Chemical Co., South Charleston, W. Va., for the supply of polyvinyl sulfonate.

EXPERIMENTAL

Materials.—C-16, carrageenan, Evans Medical Ltd., Speke, Liverpool 24, England; lambda-carrageenan; kappa-carrageenan; Sea Kem, type 8, Marine Colloids, Inc., Rockland, Me.; pectin N.F.; sulfated rice starch; polyvinyl sulfonate; amylose sulfate; heparin sodium, 100 units/mg., Nutritional Biochemicals Corp., Cleveland, Ohio; sulfated polyvinyl alcohol, Chemicals Procurement Co., New York 36, N. Y.; polyvinyl alcohol; sodium alginate; carboxymethylcellulose; sodium lauryl sulfate, U.S.P.; sodium heptadecyl sulfate; sodium *m*-xylene sulfonate; sodium 1,2-ethylene disulfonate dihydrate; alginic acid sulfate, Naurylande SARL, Venetta, France; pepsin, 1–10,000, Nutritional Biochemicals Corp., Cleveland, Ohio; hemoglobin, lyophilized, salt free, Mann Research Laboratories, New York, N. Y.; albumen (bovine) fraction V, Nutritional Biochemicals Corp., Cleveland, Ohio; blood plasma, normal, human, irradiated, dried, Hyland Laboratories, Los Angeles, Calif.

Degradation of Carrageenan.—C-16 (100 Gm.) was suspended in a 10% (v/v) solution of concentrated hydrochloric acid in acetone. The suspension was shaken periodically to facilitate hydrolysis. The resulting material was collected on filter paper, washed with anhydrous acetone, dissolved in a minimum quantity of water, and the solution adjusted to pH 7.0 with 40% (w/v) sodium hydroxide. After treatment with charcoal, the solution was filtered and the clear filtrate was added to anhydrous acetone, with constant stirring, until precipitation was complete. The precipitate was washed with anhydrous acetone, dried overnight at 50° and analyzed for antipeptic activity and sulfate content. By varying the time of hydrolysis, carrageenans with different sulfate contents were obtained.

Determination of Antipeptic Activity.—Hunt's (19) method was modified as follows: each run required a control, a carrageenan standard arbitrarily designated as having a 100% antipeptic activity, the unknown, and the appropriate blanks. The control consisted of 1 ml. pepsin, 1 ml. human plasma, and 1 ml. acidified water; the standard had 1 ml. pepsin, 1 ml. plasma, and 1 ml. carrageenan standard; the unknown, 1 ml. pepsin, 1 ml. plasma, and 1 ml. test substance. Concentrations were: pepsin, 0.25 mg./ml.; human plasma, 5%; test substance and standard, 0.5%; pH of these solutions was 1.6 adjusted with hydrochloric acid only.

The mixtures were incubated at 37°; after exactly 1 hour, 10 ml. trichloracetic acid (10% aq.) was added; 15 minutes later, the mixtures were filtered. To 1 ml. filtrate were added: 10 ml. aq. sodium hydroxide (0.4 *N*) and 3 ml. dilute (1 part reagent and 2 parts water) Folin-Ciocalteu reagent. After 15–20 minutes, the absorbances (*A*) were read on a Klett-Summerson colorimeter (No. 66 filter). Results were calculated using the following equation

$$\frac{A \text{ control} - A \text{ test substance}}{A \text{ control} - A \text{ standard carrageenan}} \times 100 = \% \text{ antipeptic activity}$$

When hemoglobin was used to check the method, the antipeptic values were similar to those obtained with human plasma.

Determination of Interaction with Protein.—One-half per cent solutions of the sulfated polymers were adjusted to pH 1.6, 3.0, 4.0, 4.5, and 5.0, respectively, with hydrochloric acid. Then, 4 ml. of each solution was mixed with 1 ml. of 5% solutions of blood plasma; albumen, bovine, fraction V; and hemoglobin; similarly adjusted to the same pH values with hydrochloric acid. The resulting mixtures were kept at 37° for 1 hour, then they were filtered and the tyrosine in the filtrate was measured colorimetrically, as described above. This method does not differentiate between unreacted protein and a soluble protein-sulfated polymer complex.

Determination of Sulfate.—Samples were burned in a Schöniger flask which contained 0.01*N* sodium hydroxide as an absorbent solution. After combustion was complete, the flask contents were shaken and allowed to stand for 1 hour to insure complete absorption of the oxides of sulfur. After treatment with fuming nitric acid, the contents were evaporated to dryness and the residue dissolved in water and neutralized to a phenolphthalein end point. The resulting sulfate was titrated with barium chloride solution (0.02 *N*) using tetrahydroxyquinone as indicator (20–22).

RESULTS AND DISCUSSION

***Interaction between Protein and Carrageenan* (C-16) at Various pH's.**—It is thought that carrageenan exerts its antipeptic activity *in vitro* by precipitating the protein, and *in vivo* by forming a protective coating on the stomach walls (6). Carrageenan does not precipitate pepsin, and recently Piper and Fenton (23), on the basis of paper electrophoresis studies, concluded that there is no interaction at all between pepsin and carrageenan. Carrageenan precipitates protein by virtue of its many negative charges which can interact with positively charged proteins to form insoluble complex salts. The ability of carrageenan to precipitate several proteins has been determined at various pH's; these data are summarized in Table I. It is apparent that protein precipitation depends upon the pH and that the amount of precipitation decreases as the pH rises. At pH 4.5 and higher, little or no protein is precipitated. The reaction between carrageenan and protein is completely reversible; a protein precipitated with carrageenan can be brought back into solution simply by raising the pH. These facts suggest that antacids may be contraindicated when carrageenan is administered.

TABLE I.—EFFECT OF PH ON THE INTERACTION BETWEEN C-16 AND SEVERAL PROTEIN SUBSTRATES

	Interaction, %		
pH	Blood Plasma	Albumen (Bovine) Fraction V	Hemoglobin
1.6	100	100	100
3.0	99	83	79
3.5	...	75	82
4.0	88	8	39
4.5	47	...	...
5.0	0	0	0

Sulfate Content *vs.* Antipeptic Activity.—C-16 was hydrolyzed with acid to decrease the sulfate content and was then assayed for antipeptic activity. Table II lists the sulfate content and antipeptic activity of several degraded samples. These data are also plotted in Fig. 1. It is clear that the antipeptic activity correlates closely with sulfate content. At the lower sulfate contents, however, the antipeptic activity tends to level off.

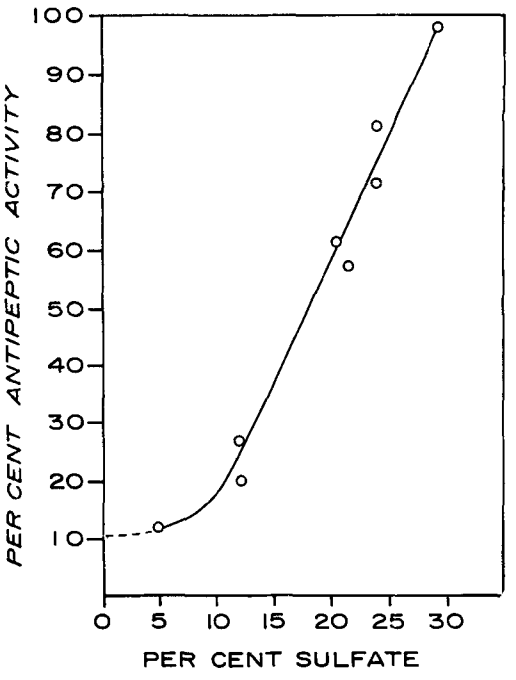

Fig. 1.—Relationship between *in vitro* antipeptic activity and sulfate content for degraded carrageenan.

TABLE II.—RELATIONSHIP BETWEEN SULFATE CONCENTRATION AND ANTIPEPTIC ACTIVITY FOR DEGRADED CARRAGEENAN

Hydrolysis Time, hr.	Sulfate, %	Antipeptic Activity, %
0.0	29.0	98.5
0.5	23.7	81.0
1.0	23.7	71.0
3.0	21.4	57.0
6.0	20.3	61.0
24.0	12.0	27.0
48.0	12.2	20.0
96.0	4.9	12.0

Sulfate Content of Various Natural and Synthetic Polymers *vs.* Antipeptic Activity.—The fact that carrageenan's antipeptic activity parallels its sulfate content prompted us to test other sulfate and sulfonated polymers with varying degrees of sulfation. Table III lists the polymers tested, their antipeptic activity, and their sulfate content. In all cases, the antipeptic activity is that compared with a standard sample of C-16. Figure 2 is a plot of these data. Again, the antipeptic activity correlates with the sulfate content; *i.e.*, the greater the sulfate content, the greater the antipeptic activity.

Since all the polymers precipitated protein in the antipeptic test we can assume that the mechanism of pepsin inhibition is similar to that of carrageenan. In summary, then, for those polymers that precipitate protein, the antipeptic activity is completely dependent upon the sulfate content. Other chemical or physical properties of these polymers may come into play, but these effects are not apparent by the methods used in this study.

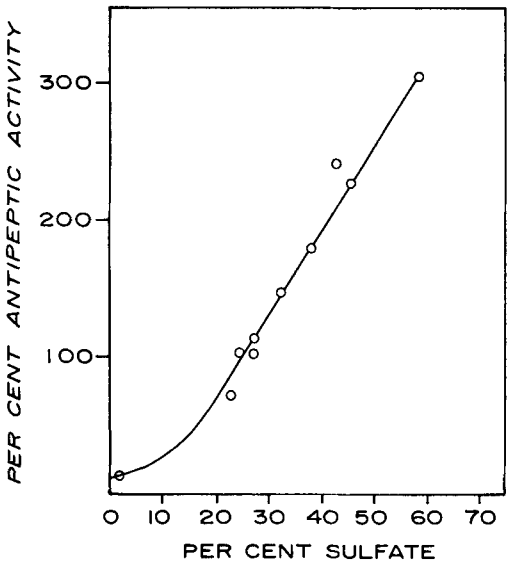

Fig. 2.—Relationship between *in vitro* antipeptic activity and sulfate content for several anionic polymers.

Comparison of Antipeptic Activity of Lambda- and Kappa-Carrageenan Mixtures.—The effect of varying ratios of lambda- to kappa-carrageenan on the *in vitro* activity of pepsin is shown in Fig. 3 which shows that the higher the concentration of lambda fraction the greater the antipeptic activity. Kappa- and lambda-carrageenan differ greatly in viscosity, yet their antipeptic activity correlates with their sulfate content (Table III). *In vivo*, it is possible that the viscosity of carrageenan may have a bearing on its antipeptic activity; *in vitro*, however, it is not the viscosity but the sulfate content that determines its antipeptic effectiveness.

TABLE III.—RELATIONSHIP BETWEEN SULFATE CONTENT AND ANTIPEPTIC ACTIVITY FOR SEVERAL NATURALLY OCCURRING AND SYNTHETIC POLYMERS

Polymer	Antipeptic activity, %	Sulfate, %
Polyvinyl sulfonate	310	59.0
Sulfated polyvinyl alcohol	247	42.5
Sulfated rice starch	230	45.3
Amylose sulfate	182	38.0
Lambda-carrageenan	150	32.2
Kappa-carrageenan	110	24.0
Heparin	103	27.0
Carrageenan, C-16	114	27.1
Sodium alginate	13	0
Carboxymethylcellulose	0	0
Polyvinyl alcohol	15	0
Pectin N.F.	12.5	2.07
Sea Kem, type 8	73	23.0
Alginic acid sulfate	40	15.8
Carrageenan, standard	100	29.0

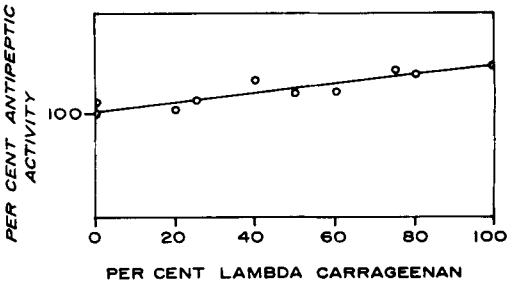

Fig. 3.—Effect of various ratios of lambda- to kappa-carrageenan on the *in vitro* activity of pepsin. Concentration is expressed as per cent lambda-carrageenan.

Compounds That Did Not Precipitate Protein.—During our screening program we found several nonpolymeric compounds with very high antipeptic activities that did not correlate with the sulfate content (Table IV). Since these compounds did not precipitate protein in the antipeptic test it can be assumed that they interact with protein or pepsin to form soluble complexes. In these interactions, factors such as the conformation of the compounds, the size of the micelles in solution, etc., probably predominate so that the role played by the sulfate content becomes insignificant.

TABLE IV.—ANTIPEPTIC ACTIVITY AND SULFATE CONTENT OF COMPOUNDS THAT DID NOT PRECIPITATE PROTEIN

	Sulfate, %	Antipeptic Activity, %
Sodium lauryl sulfate	31.0	408
Sodium heptadecyl sulfate	41.36	240
Sodium *m*-xylene sulfonate	12.84	93
Sodium 1,2-ethylene disulfonate dihydrate	71.50	29

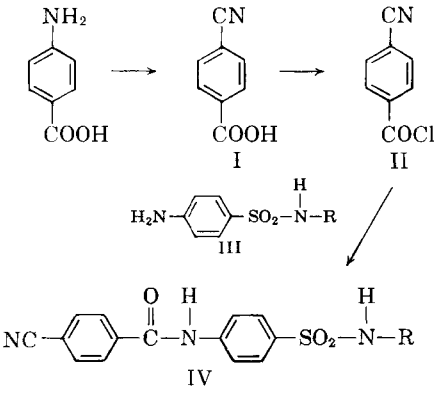
Synthesis of Some New Derivatives of N^4-*p*-Cyanobenzoyl Sulfanilamide

By LAWRENCE J. FISCHER and BERNARD ECANOW



Six new derivatives of N^4-*p*-cyanobenzoyl sulfanilamide were prepared: N^4-*p*-cyanobenzoyl sulfanilamide, N^4-*p*-cyanobenzoyl-N^1-2-pyrimidinylsulfanilamide, N^4-*p*-cyanobenzoyl-N^1-(4-methyl-2-pyrimidinyl)sulfanilamide, N^4-*p*-cyanobenzoyl-N^1-2-thiazolylsulfanilamide, N^4-*p*-cyanobenzoyl-N^1-2-pyridylsulfanilamide, N^4-*p*-cyanobenzoyl-N^1-2-pyrazylsulfanilamide. Infrared spectra of the new compounds were determined. Common absorption bands of the compounds occurred at 2240–2210 cm.$^{-1}$, 1160–1130 cm.$^{-1}$, 1325–1310 cm.$^{-1}$, and 1580–1560 cm.$^{-1}$.

N^4-SUBSTITUTED sulfanilamides have shown important pharmacological actions. N-Sulfanilylbenzamide, which is similar to the derivatives prepared here, has been shown to be effective against the bacillary dysentery organism (1) and against pneumococcus in mice (2).

Some N - alkyl - *p* - cyanobenzamides have been prepared and shown to possess local anesthetic and antimicrobial properties (3). The amidines and imidazolines prepared from these compounds have also shown significant activity (4).

The synthesis of some new sulfonamides containing the *p*-cyanobenzoyl and sulfanilyl moieties was successfully completed.

The synthesis of the N^4-*p*-cyanobenzoyl sulfanilamide derivatives was initiated with the preparation of *p*-cyanobenzoic acid I, which was prepared according to the procedure of Miller and Gisvold (5). *p*-Cyanobenzoyl chloride II was prepared by refluxing the acid with thionyl chloride and recrystallizing from petroleum ether.

Equimolar quantities of *p*-cyanobenzoyl chloride and the finely powdered sulfanilamide derivative III were refluxed in *p*-dioxane for 2 hours. Mechanical stirring was required if the reactants were not completely soluble in dioxane. The solvent was removed and the N^4-*p*-cyanobenzoyl sulfanilamide derivative IV was treated with dilute-hydrochloric acid to remove any unreacted material. Recrystallization was from a mixture of solvents.

The solubility characteristics of the new derivatives (see Table I) were generally predictable.

Received November 4, 1961, from the College of Pharmacy, University of Illinois, Chicago Professional Colleges, Chicago.
Accepted for publication November 29, 1961.
Abstracted from a thesis submitted by Lawrence J. Fischer to the Graduate College of the University of Illinois in partial fulfillment of the requirements for the degree of Master of Science, 1961.

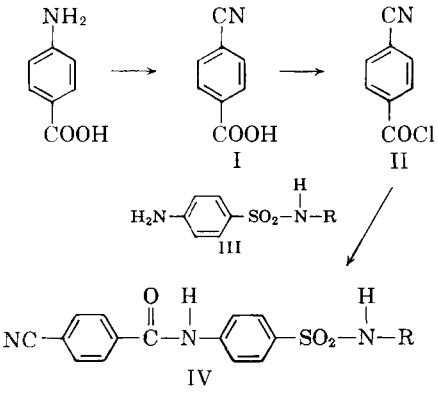
Synthesis of Some New Derivatives of N^4-*p*-Cyanobenzoyl Sulfanilamide

By LAWRENCE J. FISCHER and BERNARD ECANOW



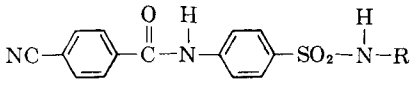
Six new derivatives of N^4-*p*-cyanobenzoyl sulfanilamide were prepared: N^4-*p*-cyanobenzoyl sulfanilamide, N^4-*p*-cyanobenzoyl-N^1-2-pyrimidinylsulfanilamide, N^4-*p*-cyanobenzoyl-N^1-(4-methyl-2-pyrimidinyl)sulfanilamide, N^4-*p*-cyanobenzoyl-N^1-2-thiazolylsulfanilamide, N^4-*p*-cyanobenzoyl-N^1-2-pyridylsulfanilamide, N^4-*p*-cyanobenzoyl-N^1-2-pyrazylsulfanilamide. Infrared spectra of the new compounds were determined. Common absorption bands of the compounds occurred at 2240–2210 cm.$^{-1}$, 1160–1130 cm.$^{-1}$, 1325–1310 cm.$^{-1}$, and 1580–1560 cm.$^{-1}$.

N^4-SUBSTITUTED sulfanilamides have shown important pharmacological actions. N-Sulfanilylbenzamide, which is similar to the derivatives prepared here, has been shown to be effective against the bacillary dysentery organism (1) and against pneumococcus in mice (2).

Some N - alkyl - *p* - cyanobenzamides have been prepared and shown to possess local anesthetic and antimicrobial properties (3). The amidines and imidazolines prepared from these compounds have also shown significant activity (4).

The synthesis of some new sulfonamides containing the *p*-cyanobenzoyl and sulfanilyl moieties was successfully completed.

The synthesis of the N^4-*p*-cyanobenzoyl sulfanilamide derivatives was initiated with the preparation of *p*-cyanobenzoic acid I, which was prepared according to the procedure of Miller and Gisvold (5). *p*-Cyanobenzoyl chloride II was prepared by refluxing the acid with thionyl chloride and recrystallizing from petroleum ether.



Equimolar quantities of *p*-cyanobenzoyl chloride and the finely powdered sulfanilamide derivative III were refluxed in *p*-dioxane for 2 hours. Mechanical stirring was required if the reactants were not completely soluble in dioxane. The solvent was removed and the N^4-*p*-cyanobenzoyl sulfanilamide derivative IV was treated with dilute-hydrochloric acid to remove any unreacted material. Recrystallization was from a mixture of solvents.

The solubility characteristics of the new derivatives (see Table I) were generally predictable.

TABLE I.—N^4-*p*-CYANOBENZOYLSULFANILAMIDE DERIVATIVES

R	Formula	Yield, %	M.p., ° C.	Carbon, % Calcd.	Carbon, % Found	Hydrogen, % Calcd.	Hydrogen, % Found	Nitrogen, % Calcd.	Nitrogen, % Found
—H	$C_{14}H_{11}N_3O_3S$	62.2	277–280	55.81	55.79	3.68	3.70	...	...
	$C_{18}H_{13}N_5O_3S$	70.1	317–318 (decompn.)	57.00	56.96	3.45	3.61	18.44	18.51
	$C_{19}H_{15}N_5O_3S$	78.4	295–297 (decompn.)	58.01	57.89	3.84	4.09	...	...
	$C_{17}H_{12}N_4O_3S_2$	75.2	286–288 (decompn.)	53.10	53.22	3.15	3.29	...	...
	$C_{19}H_{14}N_4O_3S$	83.5	286–288 (decompn.)	60.35	60.48	3.73	3.75	14.81	14.93
	$C_{18}H_{13}N_5O_3S$	82.6	290–291	56.99	57.07	3.45	3.42	18.46	18.36

They were found to be insoluble in the common laboratory solvents such as water, alcohol, ether, and chloroform. The products were soluble to sparingly soluble in *p*-dioxane, and very soluble in dimethylacetamide. Salt formation occurred readily in sodium hydroxide solution, the sodium salts being soluble in water.

EXPERIMENTAL

Infrared spectra were obtained using a Beckman IR-4 infrared recording spectrophotometer. All of the compounds prepared exhibited the characteristic cyano band in the range 2240–2210 cm.$^{-1}$. The spectra of the *p*-cyanobenzoyl sulfanilamide derivatives contained absorption bands common to each member of the series. Such bands occurred at 1160–1130 cm.$^{-1}$, 1325–1310 cm.$^{-1}$, and 1580–1560 cm.$^{-1}$

Preparation of *p*-Cyanobenzoic Acid and *p*-Cyanobenzoyl Chloride.—This was done according to the procedure of Miller and Gisvold (*5*).

Preparation of N^4-*p*-Cyanobenzoyl sulfanilamide.—Four grams of powdered sulfanilamide U.S.P. (0.0242 mole) and 4.1 Gm. (0.0242 mole) of *p*-cyanobenzoyl chloride were placed in a 500-ml., round-bottomed flask fitted with a reflux condenser and mechanical stirrer. The solvent, 270 ml. of *p*-dioxane, was added and the suspension refluxed, while stirring slowly, for 1.5 hours.

The reaction mixture was allowed to cool to room temperature. The solid product formed during the reaction was filtered with suction. The crude product was treated with two 75-ml. portions of 10% hydrochloric acid by mixing in a mortar, filtered with suction, and washed with distilled water after each treatment. The product was dried under vacuum and weighed 4.5 Gm.

Recrystallization was from a dimethylacetamide-distilled water mixture (1:1). The recrystallized product was placed in an oven at 200° for 1.5 hours to remove any adhering solvent.

N^4-*p*-Cyanobenzoyl-N^1-2-pyrimidinyl sulfanilamide.—Sulfadiazine U.S.P., 10.0 Gm. (0.08 mole), and 13.2 Gm. (0.08 mole) of *p*-cyanobenzoyl chloride were placed in a 500-ml., round-bottomed flask, fitted with a reflux condenser and a mechanical stirrer. A 200-ml. quantity of *p*-dioxane was added and the mixture refluxed, while stirring slowly, for 1.5 hours. The reaction mixture was allowed to stand overnight and the product filtered with suction. The product, a white powder, was allowed to dry at room temperature. It was then treated with 150 ml. of 10% hydrochloric acid by mixing in a mortar, filtered with suction, and washed with generous amounts of distilled water. The product was recrystallized from dimethylacetamide.

N^4-*p*-Cyanobenzoyl-N^1-(4-methyl-2-pyrimidinyl)-sulfanilamide.—To a 500-ml., round-bottomed flask equipped with a reflux condenser, 3.44 Gm. (0.013 mole) of sulfamerazine U.S.P. powder and 2.16 Gm. (0.013 mole) of *p*-cyanobenzoyl chloride were added. A 125-ml. quantity of *p*-dioxane was added and a clear, brown, solution resulted. The solution was refluxed for 2 hours and cooled to room temperature. The solvent was removed on a flash evaporator and the residue recrystallized from a dioxane-water mixture.

N^4-*p*-Cyanobenzoyl-N^1-2-thiazolylsulfanilamide.—Sulfathiazole U.S.P. powder, 1.4 Gm. (0.0055 mole), and 0.9 Gm. (0.0055 mole) of *p*-cyanobenzoyl chloride were added to a 250-ml., round-bottomed flask equipped with a reflux condenser. The solvent, 70 ml. of *p*-dioxane, was added and a clear solution was obtained. The solution was refluxed for 1.75 hours and allowed to cool to room temperature.

The solvent was removed on a flash evaporator and the residue treated with 75 ml. of 4% hydrochloric acid by mixing in a mortar. The product was recrystallized by dissolving it in approximately 3 ml. of dimethylacetamide, adding 25 ml. of 95% ethanol, and adding distilled water to the hot solution until the cloudiness just disappeared upon heating. The

light tan crystals were placed in an oven at 165° for 1 hour to remove any adhering solvent.

N^4-*p*-Cyanobenzoyl-N^1-2-pyridylsulfanilamide.—To a 250-ml., round-bottomed flask, equipped with a reflux condenser and a mechanical stirrer, was added 1.52 Gm. (0.00606 mole) of sulfapyridine U.S.P. powder and 1.0 Gm. (0.00606 mole) of *p*-cyanobenzoyl chloride. Seventy milliliters of *p*-dioxane was added and the mixture refluxed, while slowly stirring, for 2 hours.

The reaction mixture was allowed to cool to room temperature and the solvent removed on a flash evaporator. The residue was treated successively with two 100-ml. portions of 4% hydrochloric acid by mixing in a mortar, filtering, and washing with distilled water.

The product was recrystallized by dissolving in 5 ml. of hot dimethylacetamide, then adding 20 ml. of dioxane, and finally adding distilled water until the cloudiness produced just disappeared upon heating. The pale yellow crystals were dried in an oven at 130° to remove any adhering solvent.

N^4-*p*-Cyanobenzoyl-N^1-2-pyrazylsulfanilamide.—Three grams (0.0121 mole) of sulfapyrazine powder and 2.0 Gm. (0.0121 mole) of *p*-cyanobenzoyl chloride were added to a 500-ml., round-bottomed flask, equipped with a mechanical stirrer and a reflux condenser. The solvent, 140 ml. of *p*-dioxane, was added and the mixture refluxed, while stirring, for 2 hours.

The dioxane was removed on a flash evaporator and the residue mixed with 100 ml. of 10% hydrochloric acid in a mortar. The product was filtered with suction, washed with distilled water, and the acid treatment repeated.

The product was recrystallized from a solution consisting of one part dimethylacetamide, four parts dioxane, and four parts of distilled water. The pale yellow crystals were placed in an oven at 140–150° for one-half hour to remove any adhering solvent.

SUMMARY

1. Six new derivatives of N^4-*p*-cyanobenzoyl sulfanilamide were prepared: N^4-*p*-cyanobenzoylsulfanilamide, N^4-*p*-cyanobenzoyl-N^1-2-pyrimidinylsulfanilamide, N^4-*p*-cyanobenzoyl-N^1-(4-methyl-2-pyrimidinyl)sulfanilamide, N^4-*p*-cyanobenzoyl-N^1-2-pyridylsulfanilamide, N^4-*p*-cyanobenzoyl-N^1-2-pyrazylsulfanilamide, N^4-*p*-cyanobenzoyl-N^1-2-thiazolyl-sulfanilamide.

2. The infrared spectra of the new compounds were determined. Common absorption bands of the compounds occurred at 2240–2210 cm.$^{-1}$, 1160–1130 cm.$^{-1}$, 1325–1310 cm.$^{-1}$, and 1580–1560 cm.$^{-1}$.

3. The results of the pharmacologic investigation of the new compounds will be reported in a forthcoming paper.

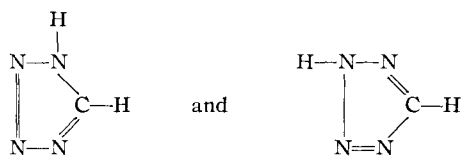
Cyclized Substituted Thioureas II



Preparation of Some 1-Substituted 1,2,3,4-Tetrazole-5-thiones

By RONALD E. ORTH† and JAMES W. JONES

Some 1-alkyl- and 1-aryl-1,2,3,4-tetrazole-5-thiones are synthesized by preparing methyl-(N-alkyl- and N-aryl)-dithiocarbamates by dropwise addition of carbon disulfide to a cold solution of the amine in aqueous sodium hydroxide, followed by slowly esterifying, separating, and purifying the ester. Sodium azide is refluxed with the various esters forming, in several cases, the substituted tetrazole-5-thione on purification.

PREVIOUSLY it has been demonstrated that thiourea has great antithyroidal activity. It appears that the introduction of this moiety into a ring system causes a general decrease in toxicity. However, conjugation of a second ring decreases the physiological activity with respect to the single ring systems. In addition, it has been found that at least one of the thiourea nitrogen must contain hydrogen. This leads investigators to hypothesize that tautomerism within the H—N—C=S portion of the molecule is paramount to good suppression of iodine-uptake.

The synthesis of tetrazole (1) led to much investigation regarding the various substitution products which could be obtained. The parent compound melts at 155° and exists in two isomeric forms

light tan crystals were placed in an oven at 165° for 1 hour to remove any adhering solvent.

N^4-*p*-Cyanobenzoyl-N^1-2-pyridylsulfanilamide.—To a 250-ml., round-bottomed flask, equipped with a reflux condenser and a mechanical stirrer, was added 1.52 Gm. (0.00606 mole) of sulfapyridine U.S.P. powder and 1.0 Gm. (0.00606 mole) of *p*-cyanobenzoyl chloride. Seventy milliliters of *p*-dioxane was added and the mixture refluxed, while slowly stirring, for 2 hours.

The reaction mixture was allowed to cool to room temperature and the solvent removed on a flash evaporator. The residue was treated successively with two 100-ml. portions of 4% hydrochloric acid by mixing in a mortar, filtering, and washing with distilled water.

The product was recrystallized by dissolving in 5 ml. of hot dimethylacetamide, then adding 20 ml. of dioxane, and finally adding distilled water until the cloudiness produced just disappeared upon heating. The pale yellow crystals were dried in an oven at 130° to remove any adhering solvent.

N^4-*p*-Cyanobenzoyl-N^1-2-pyrazylsulfanilamide.—Three grams (0.0121 mole) of sulfapyrazine powder and 2.0 Gm. (0.0121 mole) of *p*-cyanobenzoyl chloride were added to a 500-ml., round-bottomed flask, equipped with a mechanical stirrer and a reflux condenser. The solvent, 140 ml. of *p*-dioxane, was added and the mixture refluxed, while stirring, for 2 hours.

The dioxane was removed on a flash evaporator and the residue mixed with 100 ml. of 10% hydrochloric acid in a mortar. The product was filtered with suction, washed with distilled water, and the acid treatment repeated.

The product was recrystallized from a solution consisting of one part dimethylacetamide, four parts dioxane, and four parts of distilled water. The pale yellow crystals were placed in an oven at 140–150° for one-half hour to remove any adhering solvent.

SUMMARY

1. Six new derivatives of N^4-*p*-cyanobenzoyl sulfanilamide were prepared: N^4-*p*-cyanobenzoylsulfanilamide, N^4-*p*-cyanobenzoyl-N^1-2-pyrimidinylsulfanilamide, N^4-*p*-cyanobenzoyl-N^1-(4-methyl-2-pyrimidinyl)sulfanilamide, N^4-*p*-cyanobenzoyl-N^1-2-pyridylsulfanilamide, N^4-*p*-cyanobenzoyl-N^1-2-pyrazylsulfanilamide, N^4-*p*-cyanobenzoyl-N^1-2-thiazolyl-sulfanilamide.

2. The infrared spectra of the new compounds were determined. Common absorption bands of the compounds occurred at 2240–2210 cm.$^{-1}$, 1160–1130 cm.$^{-1}$, 1325–1310 cm.$^{-1}$, and 1580–1560 cm.$^{-1}$.

3. The results of the pharmacologic investigation of the new compounds will be reported in a forthcoming paper.

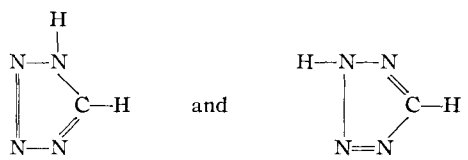
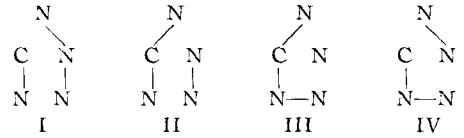
Cyclized Substituted Thioureas II



Preparation of Some 1-Substituted 1,2,3,4-Tetrazole-5-thiones

By RONALD E. ORTH† and JAMES W. JONES

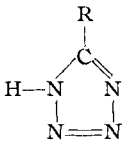
Some 1-alkyl- and 1-aryl-1,2,3,4-tetrazole-5-thiones are synthesized by preparing methyl-(N-alkyl- and N-aryl)-dithiocarbamates by dropwise addition of carbon disulfide to a cold solution of the amine in aqueous sodium hydroxide, followed by slowly esterifying, separating, and purifying the ester. Sodium azide is refluxed with the various esters forming, in several cases, the substituted tetrazole-5-thione on purification.



PREVIOUSLY it has been demonstrated that thiourea has great antithyroidal activity. It appears that the introduction of this moiety into a ring system causes a general decrease in toxicity. However, conjugation of a second ring decreases the physiological activity with respect to the single ring systems. In addition, it has been found that at least one of the thiourea nitrogen must contain hydrogen. This leads investigators to hypothesize that tautomerism within the H—N—C=S portion of the molecule is paramount to good suppression of iodine-uptake.

The synthesis of tetrazole (1) led to much investigation regarding the various substitution products which could be obtained. The parent compound melts at 155° and exists in two isomeric forms

Received November 13, 1961, from the College of Pharmacy, State University of Iowa, Iowa City.
Accepted for publication November 26, 1961.
† Present address: University of Kentucky College of Pharmacy, Lexington.

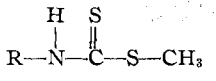


Theoretically, there are four general methods for the preparation of a tetrazole. The following examples show the nuclei needed for all possible combinations

I II III IV

Specifically, tetrazole and its derivatives have been prepared by method I by condensation of an azoimide with prussic acid and its derivatives and by the reaction of the imidochlorides and similar compounds with sodium azide. The reaction of nitrous acid with hydrazadines or amidines, followed by reduction, follows the method III scheme. The condensation of phenylazoimide with aldehyde phenylhydrazones, using sodium alcoholate in ethanol, and the reaction of diazohydrazides and mono- and diacylhydrazines with diazonium salts in the presence of alkali are method IV syntheses. Method II, as yet, has not been used for the preparation of the tetrazole nucleus. The oxidation of suitable tetrazolium compounds is another approach.

Some of the tetrazole derivatives which have been synthesized are illustrated by the general formula



5-R-1,2,3,4, 1-H-tetrazoles where R may be phenyl, tolyl, furyl, anisyl, bromo, amino, or mercapto

With the knowledge that pentylenetetrazole U.S.P. is used in medicine for its central nervous system stimulation in certain mental disorders, particularly in schizophrenia and depressive psychoses (2), it is felt that the tetrazole nucleus is one which should be investigated more extensively in conjunction with pharmaceuticals. Pentylenetetrazole has also been used as an antidote in poisoning by depressant drugs, however it appears to be inferior to picrotoxin (3).

A number of methyl-(N-alkyl- and N-aryldithiocarbamates) have previously been prepared (4). This paper deals in part with the preparation of several new esters, the attempt to purify and characterize these, and a few prepared in earlier investigations.

The esters of N-alkyl- and N-aryldithiocarbamate prepared were used to synthesize some 1-aryl-and 1-alkyl-1,2,3,4-tetrazole-5-thiones not previously reported.

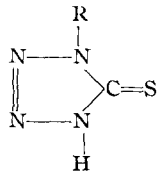
EXPERIMENTAL

Methyl Esters of N-Aryl- and N-Alkyldithiocarbamic Acid.—In a 1-L. round-bottom, three-necked flask, surrounded by an ice bath and fitted with a mechanical stirrer, a reflux condenser, thermometer, and a 250-ml. dropping funnel, were placed a cold solution of 72 Gm. (1.8 mole) of sodium hydroxide in 160 ml. of water and 1.8 moles of primary amine. To this mixture, cooled to 0–10°, 137 Gm. (1.8 mole) of carbon disulfide was added dropwise with continuous stirring. The reaction was exothermic and the mixture turned red in color. When the reaction subsided, 1.8 moles of methyl iodide was added dropwise over a period of 1 hour and, as the reaction proceeded, the color disappeared. The procedure used to separate the esters from the reaction mixtures varied slightly with each ester as follows:

Methyl-N-ethyldithiocarbamate was obtained by repeatedly extracting the reaction mixture with small portions of carbon disulfide or carbon tetrachloride, evaporating the solvent, and washing with water. The thick, yellow oil was fractionally distilled under reduced pressure.



Methyl-N-n-propyldithiocarbamate was obtained by extracting the reaction mixture with many small portions of diethylether, drying over calcium chloride, filtering, and evaporating the solvent. A good yield of thick, yellow oil was fractionally distilled under reduced pressure.

Methyl-N-isopropyldithiocarbamate was prepared by refluxing the mixture for 24 hours after the addition of the methyl iodide. Separation and purification was carried out in the same manner as described for methyl N-*n*-propyldithiocarbamate.

Methyl-N-n-butyldithiocarbamate also required refluxing for 24 hours after the addition of methyl iodide. The ester was isolated from the reaction mixture and distilled, as described under methyl-N-*n*-propyldithiocarbamate. The analyses and boiling points of the methyl esters of N-alkyl- and N-aryldithiocarbamic acid are given in Table I.

1-Ethyl-1,2,3,4-tetrazole-5-thione was prepared by dissolving 24.3 Gm. (0.18 mole) of methyl-N-ethyldithiocarbamate and 8.1 Gm. (0.18 mole) of sodium azide in 100 ml. of 95% ethanol, then diluting to 130 ml. with water to solubilize the inorganic azide. Warming aided in effecting solution at this point. The solution was refluxed over a water bath at 60°

TABLE II.—1-ALKYL- AND 1-ARYL-1,2,3,4-TETRAZOLE-5-THIONES PREPARED

R	C, % Calcd.	C, % Found	H, % Calcd.	H, % Found	N, % Calcd.	N, % Found	Yield, %	M.P., °C.

for several hours, then cooled in an ice bath and acidified. The cold mixture was filtered and the clear filtrate was reduced in volume by evaporation on a steam bath. At the first sign of crystallization, the concentrated filtrate was slowly cooled allowing fine, white, needle-like crystals to precipitate. The crystals were washed with a small portion of water and, upon drying, were taken up in absolute alcohol and precipitated by the addition of absolute ether. The pure crystals melted at 240–245°.

1-n-Propyl-1,2,3,4-tetrazole-5-thione was prepared by dissolving 7.5 Gm. (0.05 mole) of methyl-N-*n*-propyldithiocarbamate and 3.3 Gm. (0.05 mole) of sodium azide in 30 ml. of 95% ethanol. Enough water was added to bring the azide into solution. The reaction mixture was refluxed for 2 hours then cooled in ice, acidified, and filtered. The filtrate was concentrated to small volume. Upon cooling the tetrazole was separated as long, white needles. After purifying in the same manner as used for the ethyl analog, crystals melted at 76°.

The analyses and melting points of 1-alkyl- and 1-aryl-1,2,3,4-tetrazole-5-thiones are given in Table II.

DISCUSSION

A search of the literature revealed that many of the methyl esters of N-alkyl- and N-aryldithiocarbamic acid had previously been prepared as intermediates, but few physical constants were tabulated. It was also found in the preparation of the esters that as the alkyl chain of the primary amine was lengthened, the reactivity with carbon disulfide in aqueous sodium hydroxide decreased slightly and the reactivity with the methylating agent decreased markedly. The methylating agents used, in the order of their reactivity, were methyl iodide, methyl sulfate, and methyl *p*-toluenesulfonate. It was found that primary aliphatic amines with alkyl chains longer than four carbons did not yield appreciable amounts of methyl esters.

In an attempt to find a more general method for the preparation of 1-alkyl- and 1-aryl-1,2,3,4-tetrazole-5-thiones, phenylisothiocyanate was reacted with sodium azide giving near quantitative yields of the phenyl derivative of the tetrazole-5-thiones (5). 1-Allyl-1,2,3,4-tetrazole-5-thione was prepared from allyl isothiocyanate and sodium azide in low yields (6).

It was found that the methyl esters of N-isopropyl-, N-*n*-butyl-, and N-isobutyldithiocarbamic acid did not react under the given conditions to form the corresponding tetrazoles. It became apparent that an increase in chain length and branching decreased the reactivity of the isothiocyanate with sodium azide.

SUMMARY

1. Eight N-substituted methyl esters of dithiocarbamic acid were prepared. Of these, the ethyl, *n*-propyl, isopropyl, *n*-butyl-, and cyclohexyl- had not been reported.

2. Six 1-alkyl- and 1-aryl-1,2,3,4-tetrazole-5-thiones were prepared from the corresponding dithiocarbamate esters. Of these, the ethyl and *n*-propyl had not been reported.

Specificity of the Relationship between Rate of Dissolution and Disintegration Time of Compressed Tablets

By L. C. SCHROETER, J. E. TINGSTAD, E. L. KNOECHEL, and J. G. WAGNER

Dissolution rates and disintegration times of 76 lots of tablets were determined employing the U.S.P. disintegration apparatus without plastic disks. The time for 50% of the drug to dissolve ($t_{50\%}$) or the amount of drug in solution at a specific time was used as criteria of the rate of dissolution. Disintegration times were also obtained with plastic disks. The drugs included a steroid, a sulfonamide, an antidiabetic agent, and an aspirin-phenacetin-caffeine combination. In some cases there was a quantitative relationship between $t_{50\%}$ and one or both of the disintegration times. In other cases there was none. Where a quantitative relationship existed, the slopes of the lines relating the variables varied widely and depended upon the drug(s) involved, and in one case upon the presence of a pharmaceutical adjuvant. With two of the series of tablets, one could not differentiate between lots on the basis of their disintegration times determined with plastic disks. However, in one of these series disintegration times were determined without plastic disks, and in both the $t_{50\%}$ values clearly identified lot-to-lot variation. Questions are raised regarding the use of plastic disks in the official disintegration test and the validity of applying uniform disintegration standards to large groups of drugs in tablets. An explanation for the correlation between *in vivo* availability of certain drugs administered as tablets to human subjects and their disintegration times is presented.

SIXTY YEARS ago Hance (1) defined solubility as applied to compressed tablets to indicate the "power to disintegrate rather than the power to form solutions." This is regrettable terminology. Sperandio, *et al.* (2), pointed out that disintegration of a tablet does not necessarily mean that the drug has dissolved; the tablet is merely broken up into smaller particles when it disintegrates. Nair and Bhatia (3) showed that changing the screen in the U.S.P. disintegration apparatus from a No. 10 mesh to a No. 20 mesh screen could markedly alter observed disintegration times. Parrott, *et al.* (4), stated that "while the disintegration time of a tablet does influence the rate of drug release to the body, a most important aspect is the rate of release from the primary drug particle since solution of the drug is essential in order for absorption to take place."

Nelson (5) and Levy (6) pointed out that rapid disintegration of tablets has been equated by some workers with rapid availability of the drug for absorption. In his excellent review of the history of committee and official action on tablet disintegration tests, Vliet (7) quoted from the April 1949 Contact Committee meeting minutes as follows: "in setting up a list of recommended disintegration times, it was felt that the primary purpose of such a limit is to insure to the user of the tablet that ultimate availability of the medication and in such reasonable time as the nature of the medication might warrant." With a series of sugar-coated tablets containing riboflavin and another series containing sodium *p*-aminosalicylate, Chapman, *et al.* (8, 9), showed that the availability of these drugs for absorption was predictable from the disintegration time of the tablets determined by a modified U.S.P. XIV disintegration test. The modifications involved employing a 3-L. instead of a 1-L. beaker, using rubber disks which exerted a rubbing action on the tablets, and using a simulated gastric juice, pH 1.6, for the first half-hour followed by simulated intestinal juice, pH 8.0. Subsequently, Endicott and Kirchmeyer (10) presented a literature study and new experimental data as evidence that tablets requiring considerably more than 1 hour to disintegrate *in vitro* by the U.S.P. XV method may still be satisfactory drug sources in the human body. With a series of five commercial aspirin tablets, Levy (6) showed that their disintegration times had no relation whatsoever to rate of absorption or to biological availability of the aspirin in human subjects. However, the amount of aspirin in solution after 10 minutes, which was measured in a standardized *in vitro* test and used as a criterion of the rate of dissolution, did correlate linearly with the amount of salicylate excreted during the first hour following administration of the tablets.

Perhaps the reason for this discrepancy in

Received January 10, 1962, from the Department of Product Research and Development, The Upjohn Co., Kalamazoo, Mich.

Accepted for publication January 29, 1962.

The authors acknowledge the excellent technical assistance of Jane Patterson and G. R. Munting.

The authors express their appreciation to the Control Division of The Upjohn Co. for performing the disintegration tests with plastic disks on the tablets containing the antidiabetic agent.

results lies in the specificity of any correlation between either rate or extent of availability *in vivo* and either rate of dissolution or disintegration time determined by a particular *in vitro* method. Assuming that the rate and/or the extent of availability of a certain drug administered in tablets to human subjects will correlate with the *in vitro* rates of dissolution, then the *in vivo* data will also correlate with results of some disintegration test providing the specific dissolution test correlates with the specific disintegration test.

This hypothesis requires experimental proof. In this communication evidence is presented that the nature of the drug, the tablet formulation, and the method of manufacture will determine whether a correlation exists between any two of the variables: rate of dissolution, disintegration time determined without disks, and disintegration time determined with disks. If such a correlation exists, these same factors will also influence the quantitative relationship between the variables. In future communications data will be presented which also support the concept of specificity in correlations between *in vivo* availability and either rate of dissolution or disintegration time determined by particular methods.

Suggestions have been made (6, 11, 12) that the U.S.P. tablet disintegration test be replaced by a dissolution test, and opinions were recently requested (13) on this subject. Before such a change is made, or even seriously considered, it appears to be desirable to test the above hypothesis. If each drug incorporated into a given series of compressed tablets is an individual problem then the attempt to establish uniform standards for large numbers of drugs in many types of compressed tablets is spurious.

EXPERIMENTAL

Tablets.—All tablets were from experimental lots prepared in the process of developing satisfactory formulas for possible commercial use. Series of 12 lots of compressed tablets containing an anti-inflammatory steroid, seven lots of compressed tablets containing a sulfonamide, seven lots of compressed tablets containing an antidiabetic agent, and 16 lots of compressed tablets and one lot of granulation containing a combination of aspirin, phenacetin, and caffeine were studied. Details pertaining to the exact formulation and their methods of manufacture would add nothing to the test results and the conclusions drawn and, hence, are omitted. In one series, the tablets containing the sulfonamide, the presence of one ingredient, sodium chloride, influenced the nature of the statistical correlations presented. This was taken into consideration in interpreting the results.

Dissolution and Disintegration Tests Determined without Plastic Disks.—The disintegration time, without plastic disks, was always determined during the same test in which the fluid was being sampled to obtain rate of dissolution.[1] Hence, all original dissolution data refer to test conditions employing the U.S.P. XV tablet disintegration apparatus. The buffers used in these tests are shown in Table I. When performing such tests, care must be taken that the dissolution medium does not become saturated with the drug before all the dose is released from the tablet or tablets being tested. It is most desirable to arrange the dissolution test so that when all the drug has been released from the sample, the fluid is only 25%, or less, saturated with respect to the drug. If this is the case, then the plots of amount or per cent of drug in solution against time will not be influenced appreciably by this factor, but rather reflect the nature of the tablet itself. The approximate per cent saturations of the buffers with the drugs at the end of the tests are shown in Table I.

In the case of the series of tablets of the anti-inflammatory steroid, one test was performed per lot of tablets, but each test involved five tablets. For two of the lots a repeat test was run. For all other tablet lots only one tablet was tested at a time, but two separate tests were performed on each lot. Tablets were chosen randomly from the lots for the dissolution-disintegration tests with the exception of the tablets containing aspirin-phenacetin-caffeine. In the latter case, tablets of the lot were chosen which had individual weights and thicknesses as closely as possible to the average weight and thickness of the particular lot.

Without stopping the agitation of the U.S.P. tablet disintegration apparatus, aliquots of the dissolution medium were withdrawn at different times through pipets which were wound with glass wool at their tips. When the filtered aliquots had cooled to room temperature they were either transferred directly to 1-cm. silica cells or repipetted and appropriately diluted with the same buffer used as dissolution medium. The filtered aliquots or their dilutions were scanned in a Cary recording spectrophotometer, model 11, over the wavelength region 210 to 400 mμ. The absorbances at the wavelength of maximum absorption of the unknown and standard were used to calculate the concentration of drug. In calculating the amount of drug released at a given time, corrections were applied for the amounts of drug in previously withdrawn aliquots. In the case of the aspirin-phenacetin-caffeine combination, the percentage of drug released at a given time, t, was calculated from the expression

$$\% \text{ drug released} = A_t/A_{t_\infty} \times 100 \quad \text{(Eq. 1)}$$

[1] Apparently, Klein (14), in 1932, was the first investigator to determine the rate of dissolution of a compressed tablet. A year later, Elliott (15), using the same apparatus, which he called a Solvometer, published plots of amount of drug dissolved against time following tests on compressed tablets of five different drugs; he attempted "to show the influence exerted upon the rate of solution by two important variables —temperature and surface in contact with the liquid." Elliott's tablets apparently had essentially constant surface areas since he found the rates of solution were constant until about nine-tenths of the tablets were dissolved. Prior to Klein and Elliott, Noyes and Whitney (16), in 1897, derived their law governing rate of dissolution by studying dissolution from constant surface cylinders of pure benzoic acid in water. Subsequent to Klein and Elliott's investigations, Parrott, Wurster, and Higuchi (17) studied dissolution from spherical tablets of pure benzoic acid. Nelson (18) studied dissolution from cylindrical tablets of pure compounds. To our knowledge, Chapman, Crisafio, and Campbell (9) were the first investigators to determine rates of dissolution at the same time that the distintegration time was being determined; they obtained curved plots similar to some of those illustrated in this paper.

TABLE I.—BUFFERS, NUMBER OF TABLETS PER TEST, NUMBER OF TESTS PER LOT OF TABLETS, AND APPROXIMATE PER CENT SATURATION OF BUFFER WITH DRUG IN THE DISSOLUTION AND DISINTEGRATION TESTS

	Rate of Dissolution and Disintegration Tests without Plastic Disks				Disintegration Tests with Plastic Disks

[a] Buffers and dissolution media were maintained at 37.5 ± 2° during the tests. [b] Simulated gastric fluid T.S. U.S.P. XVI.

where A_t and A_{t_∞} were the absorbances at 230 mμ at time t and at a time when all the aspirin, phenacetin, and caffeine in the tablet had dissolved, respectively. It was shown that when aspirin, phenacetin, and caffeine were mixed in the same ratio as they existed in the tablet, a single absorption maximum at 230 mμ was obtained, whereas the individual components gave absorption maxima at 227, 243, and 272 mμ, respectively.

The other ingredients in the tablets introduced less than 1% error; this is well within the error of the ultraviolet spectrophotometric method. Greater errors were introduced by evaporation and mechanical loss of the dissolution media during prolonged tests. This error amounted to as much as about 10% in the apparent total amount of the antidiabetic agent released from a tablet. However, these tests were carried out for a period of 4 hours or more. Loss of fluid during the first hour was measured. The volumes of fluid lost during the first half-hour and one hour under the conditions employed were about 30 and 40 ml., respectively, or 4 and 5%, respectively, of the initial 750 ml. volume. Hence, the maximum error introduced in any value obtained at a half-hour was 4% and at one hour was 5% of the amount or per cent of drug released at these times. Tests performed on all tablets, other than the antidiabetic agent, were essentially complete after 1 hour. The $t_{50\%}$ values used in the correlations were in the ranges 1 to 14 minutes for the anti-inflammatory steroid and the sulfonamide tablets, and 1 to 38 minutes for the aspirin-phenacetin-caffeine tablets.

Disintegration Times Determined with Plastic Disks.—Disintegration times were determined for the anti-inflammatory steroid, antidiabetic agent, and phenacetin-aspirin-caffeine series of tablets using the U.S.P. XVI tablet disintegration apparatus and the official plastic disks. The fluids used in the individual tests are shown in Table I.

Lack of correlation between rate of dissolution (determined without plastic disks) and disintegration time (determined with plastic disks) in the case of the anti-inflammatory steroid cannot be attributed to the small differences between the buffers used in the two tests. The solubility and rate of dissolution of this particular anti-inflammatory steroid are independent of the pH and such small changes in ionic strength.

Data from the Literature.—Some correlation coefficients were calculated from the data of Chapman, Crisafio, and Campbell (8, 9).

RESULTS AND DISCUSSION

Tablets of Anti-inflammatory Steroid.—Plots of per cent drug in solution against time in minutes are shown in Fig. 1. From these plots the time required for 50 and 100% of the anti-inflammatory steroid contained in the tablets to dissolve was estimated. These times are shown in Table II. The range of disintegration times and the average disintegration time obtained during the dissolution tests are also shown in Table II. The time required for 50% of the drug to dissolve ($t_{50\%}$) is plotted

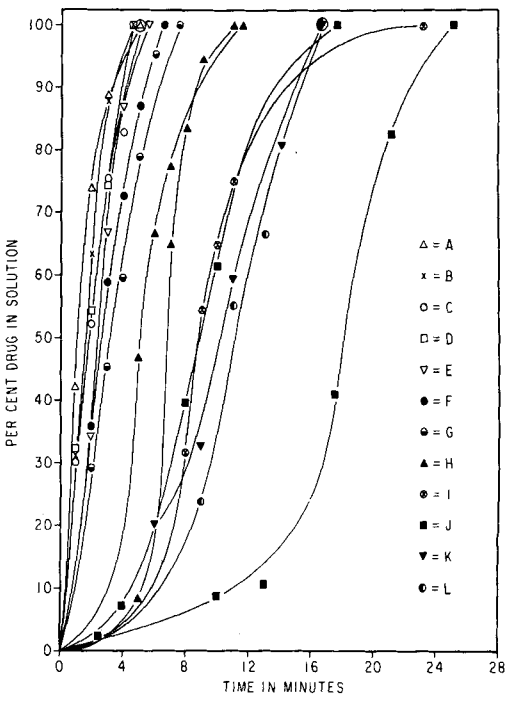

Fig. 1.—Plots of per cent drug in solution against time in minutes for tablets containing the anti-inflammatory steroid.

TABLE II.—ESTIMATED TIMES REQUIRED FOR 50 AND 100% OF THE DRUG TO DISSOLVE, AVERAGE DISINTEGRATION TIMES OBSERVED DURING DISSOLUTION TESTS, AND DISINTEGRATION TIMES BY U.S.P. PROCEDURE FOR TABLETS CONTAINING THE ANTI-INFLAMMATORY STEROID

[a] Based on five randomly selected tablets. [b] Repetitive tests with same lot were performed on separate days.

against the average disintegration time determined during the dissolution tests without plastic disks in Fig. 2. There is a highly significant linear correlation ($P < 0.001$) between the two quantities. The slope of the least squares lines is approximately unity, but there is a significant negative intercept. Since $t_{50\%}$ is a reasonably good criterion of the rate of dissolution, it may be concluded that for this series of 12 lots of tablets of the anti-inflammatory steroid that the rate of dissolution of these tablets is linearly correlated with the average disintegration time obtained under the test conditions. However, use of plastic disks, as in the official U.S.P. disintegration test, masks significant differences between the lots of these tablets. There is no correlation between disintegration times obtained for this series of tablets with the U.S.P. procedure and any criterion of the rate of dissolution such as $t_{50\%}$. These results are different than those reported at the November 1954 Contact Committee meeting (7). At that time it was reported that there was very little difference in time with and without disks, using tablets that disintegrated readily.

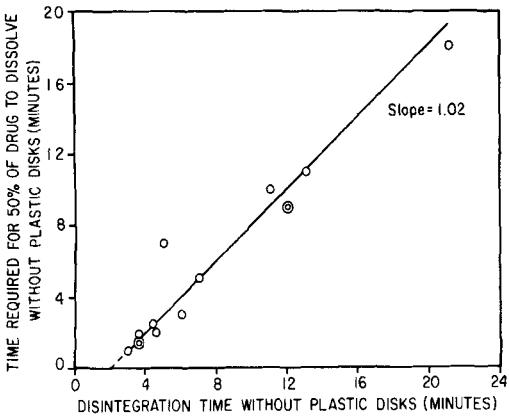

Fig. 2.—Correlation of time required for 50% of drug to dissolve with disintegration time for tablets containing an anti-inflammatory steroid. Each point represents the time required for 50% of the drug contained in five tablets to dissolve and the average disintegration time of the same five tablets observed during the dissolution test.

Tablets Containing the Sulfonamide.—Typical plots of per cent drug in solution against time in minutes are shown in Figs. 3 and 4. Figure 4 is a plot of part of the same data as shown in Fig. 3, but the time scale has been expanded to show more clearly differences between lots in the first 15 minutes of the dissolution tests. From these and similar plots the average time required for 25, 50, 75, and 90% of the sulfonamide contained in the tablets to dissolve was estimated. These times are shown in Table III together with the average of the disintegration times of the two tablets of each lot observed during the dissolution tests. The $t_{50\%}$ value for each individual tablet is plotted against the corresponding disintegration time observed

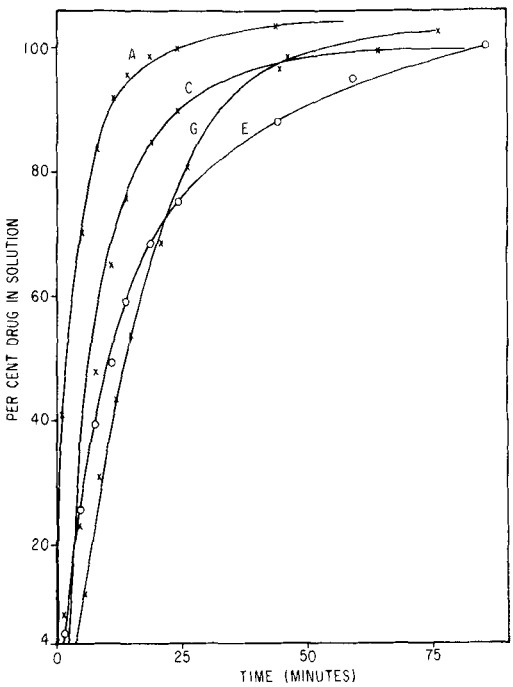

Fig. 3.—Plots of per cent drug in solution against time in minutes for some of the tablets containing the sulfonamide.

during the dissolution test in Fig. 5. The points in Fig. 5 fall into two different populations. In each population there is a highly significant linear correlation between $t_{50\%}$ and disintegration time. The line with slope of 1.82 includes the two tablets of lots A, B, D, and E; all tablets in this series contained sodium chloride as an ingredient. The line with slope of 1.10 includes the two tablets of each of lots C, F, and G; all tablets in this series contained no sodium chloride. These results indicate that correlations between rate of dissolution (using $t_{50\%}$ as a criterion of rate) and disintegration time are highly specific and may be dependent not only upon the type of drug but also upon the nature of pharmaceutical adjuvants in the tablets.

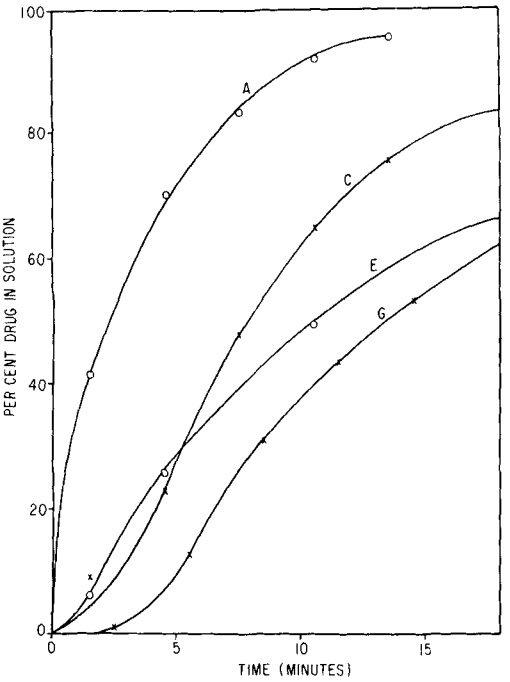

Fig. 4.—Plots of per cent drug in solution against time in minutes for some of the sufonamide tablets; data for first 15 min. only are plotted.

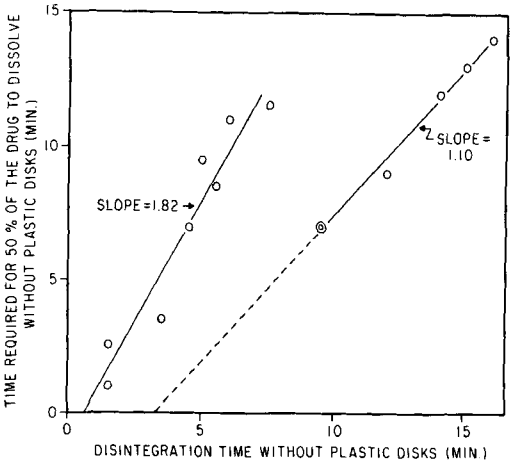

Fig. 5.—Correlation of time required for 50% of drug to dissolve with disintegration time for tablets containing a sulfonamide. Each point represents a single tablet. The line with slope of 1.82 resulted from testing two tablets of each of lots A, B, D, and E; all tablets in this series contained sodium chloride as an ingredient. The line with slope of 1.10 resulted from testing two tablets of each of lots C, F, and G; all tablets in this series contained no sodium chloride.

Tablets Containing the Antidiabetic Agent.—Plots of apparent milligrams of drug in solution against time in hours for all the tablets tested are shown in Figs. 6 and 7. Two tablets of each of the seven lots were tested. The data for the more rapidly dissolving tablets of each lot are plotted in Fig. 6; the data for the more slowly dissolving tablet of each lot are plotted in Fig. 7. The data were not converted to percentages in this case since insufficient assays were performed in some cases to obtain the 100% values. Errors were introduced due to loss in volume of dissolution medium by evaporation during the prolonged dissolution tests. For this reason the word "apparent" has been used.

TABLE III.—AVERAGE TIME REQUIRED FOR THE DIFFERENT PERCENTAGES OF DRUG TO DISSOLVE AND AVERAGE DISINTEGRATION TIME WITHOUT DISKS FOR DIFFERENT LOTS OF SULFONAMIDE TABLETS[a]

Lot	Av. Time Required for the Indicated Percentage of Drug to Dissolve, min. 25%	50%	75%	90%	Av. Disintegration Time without Disks, min.
A	1.0	2.0	5.0	9.5	1.5
B	1.5	5.0	13.5	30.5	4.0
C	5.0	8.0	13.0	24.0	9.5

			2	360	3	7	22	35	72	93

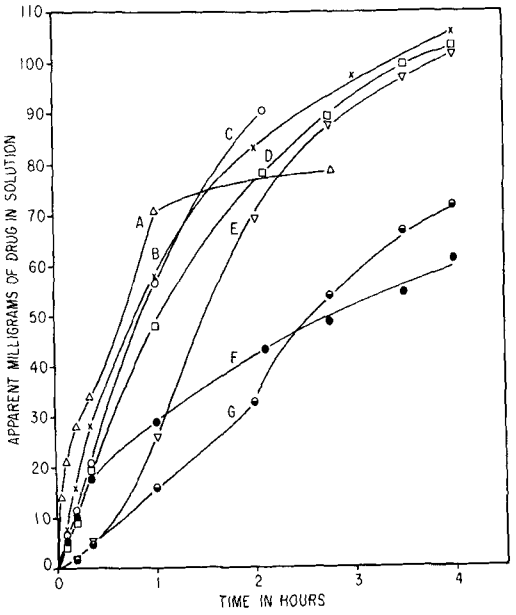

Fig. 7.—Plots of apparent milligrams of drug in solution against time in hours for the more slowly dissolving tablet of each pair of tablets of each lot of tablets of antidiabetic agent tested.

However, such loss in volume of fluid and subsequent error in the amount of drug in solution was not appreciable during the first hour of the tests. From the plots shown in Figs. 5 and 6, the apparent milligrams of drug in solution at 0.25, 0.50, 1, 2, 3, and 4 hours were estimated; these values are shown in Table IV. The disintegration times of the individual tablets observed during the dissolution tests and the average disintegration time obtained using the U.S.P. procedure are also shown in Table III.

Similar to the $t_{50\%}$ value, the apparent milligrams of drug in solution at a given time should be a useful criterion of the rate of dissolution. However, no suitable correlation of the amount of drug in solution at a given time and the disintegration time of the tablet observed during the dissolution test was obtained with this series of tablets. Although there was some tendency for the more rapidly dissolving tablets to disintegrate and to pass through the screen of the apparatus sooner than the more slowly dissolving tablets, there were exceptions and no suitable quantitative correlation could be found. The U.S.P. XVI disintegration test gave results which masked the differences between lots of tablets. This can be seen by comparing the U.S.P. disintegration times shown in Table IV with the dissolution data shown in the same table or with the plots shown in Figs. 6 and 7.

Tablets Containing Aspirin-Phenacetin-Caffeine.—Typical plots of per cent drug in solution against

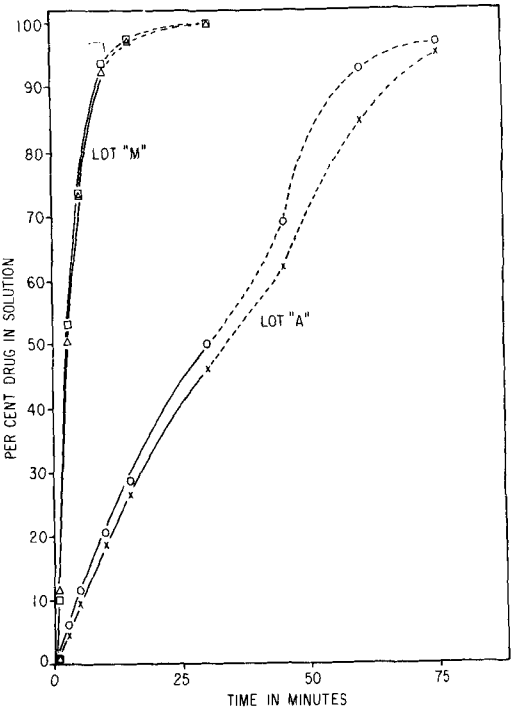

Fig. 8.—Plots of per cent drug in solution against time in minutes for the most rapidly dissolving lot (M) and the most slowly dissolving lot (A) of the tablets containing aspirin-phenacetin-caffeine.

time in minutes are shown in Fig. 8. Of the 16 lots of tablets and 1 lot of granulation tested, tablet lot M was the most rapidly dissolving and tablet lot; A was the most slowly dissolving lot (see Table V). The initial portion of the dissolution curves for this series was found to give excellent pseudo first-order plots. For example, the points joined by solid lines in Fig. 8 are replotted in Fig. 9. The slopes of the linear segments were obtained by the method of "least squares." From these slopes, or pseudo first-order rate constants, the half-lives were calculated. Since there was usually a brief lag time before the tablet started to release drug to solution at a pseudo first-order rate, the half-life does not correspond exactly with the time required for 50% of the drug to dissolve. The latter values were also estimated from the type of plots shown in Fig. 8. The relationship between the time required for 50% of the drug to dissolve and the half-life calculated from the pseudo first-order rate constant is shown in Fig. 10. The slope of the "least squares" line through the origin in Fig. 9 is 1.07; this indicates that, in general, the $t_{50\%}$ value is slightly greater than the half-life.

The $t_{50\%}$ values for this series are plotted against the disintegration times of the tablets observed during the dissolution tests in Fig. 11. The slope of the "least squares" line is 0.56 which is distinctly different from the slope of 1.02 found for the tablets of the anti-inflammatory steroids and the slopes of 1.10 and 1.82 found for the two series of tablets containing the sulfonamide.

The average disintegration time determined on six tablets using plastic disks is plotted against the average disintegration time of two tablets determined without plastic disks in Fig. 12. The slope of the "least squares" line through the origin is 0.67; this indicates that, in general, the effect of the plastic disks, with this series of tablets, was to decrease the disintegration time to about two-thirds of the time obtained without disks. Because of the significant linear correlations shown in Figs. 10, 11, and 12, it is obvious there are also significant linear correlations for this series between either $t_{50\%}$ or half-life and average disintegration time determined with plastic disks.

Tablets Containing Riboflavin.—The data of Chapman, Crisafio, and Campbell (8) were used. A plot of the average disintegration time determined with rubber disks against the average disintegration time determined without rubber disks is shown in Fig. 13. The values for lot 17 were omitted in estimating the regression. Although the slope (0.62) of the "least squares" line in Fig. 13 is similar to that (0.66) found for the aspirin-phenacetin-caffeine combination in our studies, the intercepts of two plots are significantly different. The slopes of the lines forced through the origin are 0.72 for the

riboflavin tablet data and 0.67 for the aspirin-phenacetin-caffeine data. This is remarkable correspondence in the effect of the disks in these two series when one takes into consideration the marked differences in the other experimental conditions of the disintegration tests in the two series. It should be mentioned, however, that in the riboflavin tablets series, rubber disks were used whereas in the aspirin-phenacetin-caffeine series, plastic disks were used. In a series of seven sugar-coated tablets of sodium

p-aminosalicylate, Chapman, *et al.*, showed that results of disintegration tests obtained with rubber disks were significantly different ($P = 0.05$) than results obtained with plastic disks.

Tablets Containing Sodium *p*-Aminosalicylate.—The data of Chapman, Crisafio, and Campbell (9) were used. For five of the tablets studied in this series, the order of excretion rates of NaPAS in human subjects was A > D > E > F > G, whereas the order of *in vitro* dissolution rates reported was A > D > F > E > G. The order of per cent availability of NaPAS based on 8-, 24-, and 32-hr. excretion data was A ≃ D > E > F > G. As an index of the rates of dissolution *in vitro*, we have estimated the time required for 50% of the drug to dissolve ($t_{50\%}$) from their Fig. 2. Plots of the variables, per cent availability *vs.* $t_{50\%}$ and per cent availability *vs.* disintegration time with rubber disks, are shown in Fig. 14A. Plots of $t_{50\%}$ (obtained with method of Chapman, *et al.*) against disintegration time determined with method of Chapman, *et al.*, and with U.S.P. XV fluids plus plastic disks

TABLE VI.—SUMMARY OF SLOPES (s), INTERCEPTS (y_0), LINEAR CORRELATION COEFFICIENTS (r), NUMBER OF OBSERVATIONS (n), AND PROBABILITIES OF SIGNIFICANCE (P) FOR CORRELATIONS BETWEEN DISINTEGRATION TIMES WITH AND WITHOUT DISKS AND RATE OF DISSOLUTION

Ordinate (y) → / Abscissa (x) → / Tablet Series	Linear Regression: Average Disintegration Time with Disks *vs.* Average Disintegration Time without Disks	Linear Regression: Time Required for 50% of the Drug to Dissolve *vs.* Disintegration Time without Disks	Linear Regression: Time Required for 50% of the Drug to Dissolve *vs.* Disintegration Time with Disks
Anti-inflammatory steroid, lots A–L	Relationship curvilinear and not satisfactory for predictive purposes since too scattered	$s = 1.02$ $y_0 = -2.1$ $r = 0.969$ ($n = 14$) $p < 0.001$	No significant relationship
Sulfonamide lots A, B, D, E	Not studied	$s = 1.82$ $y_0 = -1.1$ $r = 0.942$ ($n = 8$) $P < 0.001$	Not studied
Sulfonamide lots, C, F, G	Not studied	$s = 1.10$ $y_0 = -3.6$ $r = 0.995$ ($n = 6$) $P < 0.001$	Not studied
Antidiabetic agent lots A–G	Not significant[a] $P > 0.10$	No significant relationship	No significant relationship[a]
Aspirin-phenacetin-caffeine combination	$s = 0.66$ (0.67) $y_0 = 0.54$ (0)	$s = 0.56$ $y_0 = +1.65$	$s = 0.82$ $y_0 = +1.65$
Lots A–P and granulation	$r = 0.987$ ($n = 17$) $P < 0.001$	$r = 0.984$ ($n = 35$) $P < 0.001$	$r = 0.959$ ($n = 35$) $P < 0.001$
Calculated from literature data			
Sugar-coated tablets containing riboflavin. data of Chapman, *et al.* (8)[b]	$s = 0.62$ (0.72) $y_0 = 11.5$ (0) $r = 0.917$ ($n = 26$) $p < 0.001$	...	...
Sugar-coated tablets containing sodium *p*-aminosalicylate, data of Chapman, *et al.* (9)	...	...	With Rubber Disks $s = 0.83$ $y_0 = -1.75$ $r = 0.995$ ($n = 5$) $p = 0.001$ With Plastic Disks $s = 0.48$ $y_0 = +16.0$ $r = 0.966$ ($n = 5$) $P < 0.001$

[a] It should be noted that with these tablets the disintegration times with and without disks were determined in different fluids. [b] Includes lots J through N and 1 through 22, with the exception of lot 17.

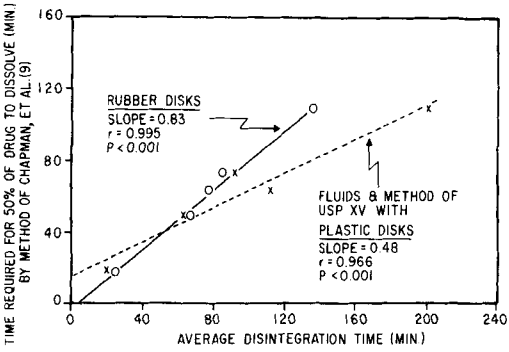

Fig. 14B.—A plot of time required for 50% of the drug to dissolve (determined by method of Chapman, *et al.*), against average disintegration time in min.; data from Ref. 9.

are shown in Fig. 14B. It is of interest that the correlation between $t_{50\%}$ and the disintegration method of Chapman (rubber disks with pH 1.6 and pH 8.0 fluids) gives a highly significant regression coefficient ($r = 0.995$). In this case the dissolution rate was determined during the same test as the disintegration time. One may conclude that the disintegration time determined by the method of Chapman, *et al.* (8, 9), was truly an indication of the rate of dissolution of the sodium *p*-aminosalicylate from the tablets. It is most probably for this reason that there was also a relationship between the per cent availability of the sodium *p*-aminosalicylate in human subjects and the disintegration time.

SUMMARY AND CONCLUSIONS

1. A total of 27 simultaneous dissolution-disintegration tests employing the U.S.P. tablet disintegration apparatus but without plastic disks were performed. These tests involved 12 lots of compressed tablets containing an anti-inflammatory steroid, seven lots of compressed tablets containing a sulfonamide, seven lots of compressed tablets containing an antidiabetic agent, and 16 lots of compressed tablets and one lot of granulation containing a combination of aspirin, phenacetin, and caffeine. A disintegration test employing the same apparatus but with plastic disks was also performed on all of these lots except those containing the sulfonamide.

2. The time required for 50% of the drug to dissolve ($t_{50\%}$) was estimated from each of the amount (or per cent) of drug in solution *vs.* time plots and used as a criterion of the rate of dissolution of the drugs from the tablets.

3. The existence or absence of a quantitative relationship between (*a*) $t_{50\%}$ and the results of the two types of disintegration tests, and (*b*) between results of the two types of disintegration tests were determined. Results are summarized in Table VI.

4. The results indicate there is an extreme specificity in the presence or absence of a relationship between rate of dissolution and disintegration time. In those cases where a quantitative relationship exists, the slopes of the "least squares" lines relating the variables were found to vary widely and depend upon the particular drug(s) involved, and in one case upon the presence or absence of a pharmaceutical adjuvant in the compressed tablet with the drug.

5. With two of the four series of tablets studied, the use of plastic disks in the tablet disintegration test was observed to mask real differences between the lots. In both of these series of tablets, one could not conclude that the tablets differed from lot-to-lot on the basis of their disintegration times determined with plastic disks. However, disintegration times determined without plastic disks and the $t_{50\%}$ values clearly indicated pronounced differences from lot-to-lot in each series. This indicates adoption of plastic disks in the official tablet disintegration test was perhaps hasty and not based upon enough experimental data.

6. These results raise questions as to the validity of uniform disintegration tests and disintegration time limits applied to large groups of drugs in compressed tablets. There will most probably be similar specificity of any correlation between either rate or extent of availability of drugs from tablets *in vivo* and either rate of dissolution or disintegration time determined by a particular test method. If this hypothesis is borne out by future experimentation, then limits of disintegration time or dissolution rate of individual drugs should be based on *in vivo-in vitro* correlations which, in turn, would be specific for the drug and the particular type or types of tablets to be controlled later by the *in vitro* test.

Effect of Nicotine and Epinephrine on *in Vivo* Coagulation Time in Rabbits

By DUANE G. WENZEL and JASBIR SINGH

The intravenous administration of 0.01 or 0.02 mg./Kg. of nicotine to rabbits induced significant reductions in the time for blood to coagulate as measured by the Lee-White capillary tube method. Epinephrine induced a biphasic response with significant reductions resulting from small doses (0.01 and 0.02 mg./Kg.) and an increase from a larger dose (0.08 mg./Kg.). Intermediate doses (0.04 and 0.06 mg./Kg.) did not produce changes that were significantly different from control values. The combined treatment with nicotine, 0.01 mg./Kg., and epinephrine, 0.04 or 0.06 mg./Kg., increased the time to coagulate over that of the smaller doses of epinephrine or nicotine alone. The administration of piperoxan, 0.25 mg./Kg., 10 minutes before either nicotine or epinephrine, 0.01 mg./Kg., blocked the increased rate of coagulation.

Previous investigations have demonstrated that the chronic administration of nicotine to rabbits, in doses roughly comparable to the amount absorbed during smoking, produces a significant reduction in the blood coagulation time (1, 2). Because of the considerable epidemiological evidence relating smoking to the mortality from coronary heart disease, it is suggested that nicotine may serve as a precipitating factor through its effect upon the coagulation time.

Observations of the acute effects of nicotine upon blood coagulation have been few and generally contradictory. Takatsuki (3) reported that the subcutaneous administration of nicotine to rabbits in doses of from 0.5 to 5.0 mg./Kg. resulted in a decreased coagulation time. When he injected larger doses of from 10 to 30 mg./Kg. the coagulation times were then lengthened. The increase in rate as induced by the smaller quantities was found to be augmented by epinephrine and by cocaine, and either inhibited or reversed by yohimbine or ergotamine. From these findings Takatsuki concluded that the effect of nicotine on blood coagulation was dependent upon epinephrine release. In a later study, Kanowoka (4) administered nicotine intravenously to rabbits in doses of from 0.05 to 2 mg./Kg. and observed that the coagulation time was lengthened in a majority of the animals. The results, however, were inconsistent for a given dose and some animals responded to the treatment with a fall in the time to coagulate. The amount of nicotine employed was so large as to induce convulsions in most of the animals Doses of this magnitude, in addition to being unrelated to the amount of nicotine absorbed during smoking, are decidedly unphysiological and the extreme central stimulation may have induced secondary effects on the coagulation time.

The reported effects of smoking upon blood coagulation in humans have been at least as contradictory as those from animal studies. Grassi and Caltabiano (5) have presented evidence to indicate that smoking one cigarette results in an increased platelet count, shortened plasma coagulation and clot retraction times, and an augmentation of prothrombin activity and utilization. These findings are in accord with those of Eisen (6) who determined that smoking three to four cigarettes after a month's abstinence results in a coagulation time reduction to about one-half of the presmoking level. Blackburn, Orma, Härtel, and Punsar (7), on the other hand, were unable to demonstrate a significant effect of smoking upon blood coagulation as measured by the recalcified plasma Stypven time.

The primary purpose of this study was to reexamine the effect and the mechanism of action of acute nicotine administration upon *in vivo* blood coagulation. In order to establish the relationship of the nicotine effects to epinephrine release, actions of the latter agent were also examined. Despite the fact that epinephrine's role in blood coagulation has been studied by a number of investigators, there is still some confusion regarding its effects. That epinephrine influenced the coagulation time was first recognized by Vosburgh and Richards in 1903 (8). This work could not be confirmed by Wiggers (9), but was later verified by Van den Velden (10). It was in 1914 that Cannon and Gray (11) performed their classical studies indicating that epinephrine in small doses (0.001 mg./Kg.) shortened the coagulation time, but in larger doses (0.03 mg./Kg.) lengthened it. This experiment and many others which followed were performed with the coagulometer of Cannon and

Mendenhall (12). The preceding observations regarding the clot accelerating effect of epinephrine have been found, by Forwell and Ingram (13), to be reproducible in anesthetized dogs or cats when the coagulometer principle was employed. The results could not be verified, however, under the same conditions by the standard Lee-White test tube method. For reasons that are not apparent, the administration of epinephrine to humans by these same investigators resulted in a shortened time when measured by the Lee-White tests. Furthermore, a significant fall in the time to coagulate with humans was observed only when silicon-coated tubes were employed. From this and additional evidence, Forwell and Ingram suggested that the action of epinephrine, at least in part, results from an increase in factor V activity. It was also suggested that the epinephrine effect may be duplicated by the unpleasant stimulus of blood withdrawal. Härtel (14), employing the plasma Stypven time previously found to be unaffected by smoking (7), observed that the subcutaneous injection of 0.7 mg. of adrenaline in humans caused a significant shortening. In this study all apparatus was siliconized.

As previous studies of the chronic effects of nicotine on blood coagulation had been satisfactorily performed using uncoated capillary tubes and with unanesthetized animals (1, 2), it was accordingly decided to determine the effects of nicotine and epinephrine in the same manner for this experiment.

EXPERIMENTAL

Six unanesthetized, adult, female, albino rabbits were employed for each drug treatment. To determine the mean coagulation times, three replications were made with each animal at each test period. Control mean clotting times were measured for each group immediately prior to the administration of the test agent. Blood was obtained from a puncture wound in the tail. After lightly and quickly blotting the first few drops of blood, an uncoated capillary tube with an internal diameter of approximately 1 mm. was used to collect blood to a length of about 3 cm. Capillary tubes were thoroughly washed with distilled water and dried before being employed. The end of the tube containing the blood first withdrawn was repeatedly broken off in small sections at a speed as great as was consistent with the observation of the fibrin thread. It was found that this could be accurately performed once in about every 2.5 seconds. Time was measured by a foot-actuated stopwatch.

Following the control coagulation time determinations and the administration of the appropriate drug dose, the measurements were repeated at 1 minute, 15 minutes, and every 15 minutes thereafter until the time to coagulate had returned to within 1 to 2 seconds difference from that of the control value. For some of the treatments, testing was continued beyond this point in order to demonstrate the absence of any delayed action. As three replications were performed at each period tested, the first determination was started shortly before the indicated time and the last one shortly thereafter. Each mean coagulation time therefore represents three determinations upon each of six animals for a total of 18 individual values. The *t*-tests and standard errors of the mean were calculated on the basis of six mean values for each test.

Drugs were administered in normal saline with a total volume of 0.25 ml. It has been suggested that, by what may be a stress response, repeated venepuncture alone may induce a reduction in the coagulation time. The injection of 0.25 ml. of saline followed by repeated blood collections did not produce a significant change in the time at any of the periods tested.

The following drug doses and combinations of drugs expressed as mg. drug per Kg. body weight were tested for their effect upon the coagulation time: nicotine 0.01 and 0.02; epinephrine 0.01, 0.02, 0.04, 0.06, and 0.08; nicotine 0.01 and epinephrine 0.04; nicotine 0.01 and epinephrine 0.06; piperoxan 0.25; piperoxan 0.25 and nicotine 0.01; and piperoxan 0.25 and epinephrine 0.01. Administration of the piperoxan preceded that of the

TABLE I.—COAGULATION TIMES IN RABBITS TREATED WITH NICOTINE AND EPINEPHRINE[a]

Treatment, mg./Kg.	Coagulation Times, sec. ± S.E. Initial Time	1 Min. After Treatment	% Change	P
Saline	28.8 ± 1.3	28.4 ± 1.6	−1.4	>0.50
Nicotine 0.01	37.4 ± 1.1	30.7 ± 1.0	−17.9	<0.01[b]
Nicotine 0.02	34.7 ± 0.34	23.1 ± 0.67	−33.4	<0.001[b]
Epinephrine 0.01	28.9 ± 1.3	24.2 ± 1.1	−16.3	<0.02[b]
Epinephrine 0.02	30.9 ± 0.86	26.7 ± 1.27	−13.6	<0.02[b]
Epinephrine 0.04	31.0 ± 1.4	28.9 ± 1.9	−7.0	>0.05
Epinephrine 0.06	33.1 ± 2.2	36.4 ± 1.3	+9.1	>0.05
Epinephrine 0.08	30.1 ± 0.75	34.5 ± 1.5	+12.8	<0.02[b]
Nicotine 0.01, epinephrine 0.04	29.4 ± 1.2	31.4 ± 1.2	+6.4	>0.05
Nicotine 0.01, epinephrine 0.06	30.9 ± 1.88	33.4 ± 1.89	+7.5	>0.05
Piperoxan 0.25	31.7 ± 0.89	29.6 ± 0.85	+6.6	>0.05
Piperoxan 0.25, epinephrine 0.01	31.2 ± 1.87	30.0 ± 2.08	−3.8	>0.05
Piperoxan 0.25, nicotine 0.01	29.4 ± 1.58	29.4 ± 1.25	0	>0.05

[a] Coagulation times were measured using the Lee-White capillary tube method. Six animals were employed for each treatment tested with three replications at each period of testing. [b] Significant values.

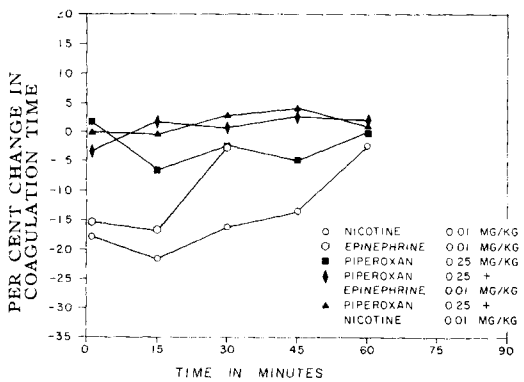

Fig. 3.—The effect of piperoxan upon the mean blood coagulation response of rabbits to nicotine and epinephrine. The first reading was obtained at 1 minute.

nicotine or epinephrine by 10 minutes in order to allow adequate time for the development of adrenergic blockade. The times at which the rate of clotting was measured for the combined treatment with piperoxan were relative to the time of nicotine or epinephrine administration.

RESULTS AND DISCUSSION

The mean initial coagulation times (controls), the times at the 1-minute period, their standard errors, the per cent change in coagulation time during this period, and the level of significance of the difference between the means are given in Table I. As the greatest drug-induced effects, with few exceptions, were apparent at the 1-minute test period, these mean experimental values were compared by the *t*-test to those of the corresponding controls. The results are treated graphically in Figs. 1, 2, and 3 to present the time-related pattern of the response.

Separate Nicotine and Epinephrine Effects.—Doses of nicotine were selected so as to induce changes in the coagulation time without the convulsive seizures reported by previous investigators (3, 4). Initial exploratory experiments indicated that the intravenous administration of 0.03 or 0.04 mg./Kg. of nicotine induced tremors in many of the animals tested. It was further determined that neither nicotine nor epinephrine in intravenous doses up to 0.02 and 0.08 mg./Kg., respectively, would cause excessive stimulation with the exception of occasional animals which responded with respiratory stimulation. These doses were then selected as the arbitrary limits to be employed.

From the values in Table I and the points in Fig. 1, it is apparent that nicotine at both of the doses tested significantly reduced the time required for blood to coagulate ($P < 0.01$ and 0.001). It seems likely that the intravenous doses of 0.01 and 0.02 mg./Kg. as employed in this study are comparable to larger subcutaneous doses reported to induce a similar effect (3). Others (4) have noted that the intravenous injection of larger doses (0.5 to 2mg./Kg.) of nicotine results in a lengthened time to coagulate, although some of the animals tested responded with reduction in the time. Such variance was not encountered with the smaller doses used in this study as all animals, without exception, responded by an increased rate of coagulation.

Epinephrine in doses of 0.01 and 0.02 mg./Kg. also significantly reduced the coagulation times ($P < 0.02$). The response to these doses was strikingly similar except for a longer significant reduction with the larger dose. Doses of 0.04 and 0.06 mg./Kg. induced a fall and an increase, respectively, in the times to coagulate. While these differences were not significant in the statistical sense, from an examination of the time-effect curves in Fig. 1 it appears unlikely that the changes were not attributable to the treatments involved. As the largest dose of the epinephrine 0.08 mg./Kg. resulted in a significant extension of the coagulation time ($P < 0.02$), it is apparent that the results of the epinephrine treatment are in agreement with those of Cannon and Gray (11) who first demonstrated the biphasic response. The data provide no explanation for the inability of Forwell and Ingram to observe an effect upon coagulation time in animals when using the Lee-White test tube method

(13). While the capillary method was employed, the tubes were uncoated and the animals were unanesthetized which, if anything, would be expected to mask the effect of epinephrine rather than to increase the sensitivity.

Combined Nicotine-Epinephrine Effects.—The results obtained by combining 0.01 mg./Kg. of nicotine with either 0.04 or 0.06 mg./Kg. of epinephrine are shown in Fig. 2 and Table I. Changes in both instances were in the direction of an increased time to coagulate, although both drugs individually had depressed the coagulation time. It is perhaps worthy of note that the combined nicotine-epinephrine, while not inducing a significant increase in the coagulation time as measured by the *t*-test, apparently prolonged the duration of the response. Further, the direction of the change is what would be anticipated if nicotine exerts its action through catecholamine release.

Modification of Nicotine and Epinephrine Responses by Piperoxan.—The injection of piperoxan alone in a dose of 0.25 mg./Kg. caused a minimal and nonsignificant increase in the rate of coagulation (Table I and Fig. 3). Administration of this dose 10 minutes prior to either 0.01 mg./Kg. of epinephrine or nicotine resulted in coagulation times which varied no more than did repeated control determinations. This blockade of the nicotine effect is consistent with the results of Takatsuki (3), demonstrating that nicotine exerts its characteristic action on the coagulation time through the release of catecholamines. As the actions of nicotine and epinephrine are both apparently mediated through the latter agent, and as the response to their combined administration indicates an additive effect, it is likely that the combination of smaller doses of each would result in a shorter coagulation time. Although the experimental evidence does not directly support the contention, it is further likely that the amounts of nicotine absorbed during smoking would increase rather than decrease the rate of coagulation, even in the presence of systemic catecholamine release. In man, Johnston has reported that 0.08 to 0.13 mg. of nicotine intravenously produces effects similar to those induced by one deep inhalation of cigarette smoke (15).

Use of 3-Azabicyclo[3.2.2.]nonane in the Mannich Reaction I

Substituted β-Amino Ketones

By C. DeWITT BLANTON, Jr., and W. LEWIS NOBLES

A group of Mannich bases, indicated as types I, II, and III, have been prepared utilizing 3-azabicyclo[3.2.2.]nonane as the amine component. These β-aminoketones are to be screened for possible pharmacodynamic activity.

RECORDED in the literature (1–11) are numerous ketonic Mannich bases, prepared for pharmacological testing as antispasmodics, analgesics, chemotherapeutic agents, and local anesthetics. Such compounds may, in general, be prepared easily by means of the Mannich reaction which utilizes the appropriate ketone, formaldehyde, or paraformaldehyde, and the desired amine. This may be illustrated as follows

$$RCOCH_3 + HCHO + R'_2NH \cdot HCl \rightarrow RCOCH_2CH_2NR'_2 \cdot HCl + H_2O$$

Received October 23, 1961, from the School of Pharmacy, The University of Mississippi, University.
Accepted for publication November 24, 1961.

The rather extensive literature dealing with this reaction has been reviewed by Blicke (12), Karbe (13), Reichert (14), and more recently by Hellmann and Opitz (15).

The great versatility of these ketonic Mannich bases prompted us to prepare a number of Mannich bases of types I, II, and III, in which the amine moiety is 3-azabicyclo[3.2.2.]nonane. In addition, the concept of vinylogous substances, as set forth by Fuson (16), has led us to prepare several vinylogs of types I and II. (See Tables I–III.)

To study more fully the effect of structural variants, Mannich bases have been prepared of

(13). While the capillary method was employed, the tubes were uncoated and the animals were unanesthetized which, if anything, would be expected to mask the effect of epinephrine rather than to increase the sensitivity.

Combined Nicotine-Epinephrine Effects.—The results obtained by combining 0.01 mg./Kg. of nicotine with either 0.04 or 0.06 mg./Kg. of epinephrine are shown in Fig. 2 and Table I. Changes in both instances were in the direction of an increased time to coagulate, although both drugs individually had depressed the coagulation time. It is perhaps worthy of note that the combined nicotine-epinephrine, while not inducing a significant increase in the coagulation time as measured by the *t*-test, apparently prolonged the duration of the response. Further, the direction of the change is what would be anticipated if nicotine exerts its action through catecholamine release.

Modification of Nicotine and Epinephrine Responses by Piperoxan.—The injection of piperoxan alone in a dose of 0.25 mg./Kg. caused a minimal and nonsignificant increase in the rate of coagulation (Table I and Fig. 3). Administration of this dose 10 minutes prior to either 0.01 mg./Kg. of epinephrine or nicotine resulted in coagulation times which varied no more than did repeated control determinations. This blockade of the nicotine effect is consistent with the results of Takatsuki (3), demonstrating that nicotine exerts its characteristic action on the coagulation time through the release of catecholamines. As the actions of nicotine and epinephrine are both apparently mediated through the latter agent, and as the response to their combined administration indicates an additive effect, it is likely that the combination of smaller doses of each would result in a shorter coagulation time. Although the experimental evidence does not directly support the contention, it is further likely that the amounts of nicotine absorbed during smoking would increase rather than decrease the rate of coagulation, even in the presence of systemic catecholamine release. In man, Johnston has reported that 0.08 to 0.13 mg. of nicotine intravenously produces effects similar to those induced by one deep inhalation of cigarette smoke (15).

2-acetonaphthone and phenolic compounds, *viz.*, the disubstituted product of *p*-cresol (see Table IV). The change in activity with variation in chemical structure in other chemical series led us to study additional transformations. Denton and his co-workers (4) indicated that the reduction of the piperidino Mannich bases to the corresponding aminoalcohols led to a marked increase in antispasmodic activity in all cases except those involving a thiophene derivative. Also, many of the tertiary alcohols, prepared by these workers by the addition of a Grignard reagent to the Mannich base, exhibited increased activity over that of the parent ketone. Certain of these suggested modifications have been incorporated into the structures presented here and these studies, along with the results of pharmacological screening, will be reported in subsequent publications. Preliminary evaluation of compound No. 1 from Table II has been obtained.[1] Oral administration of 300 mg./Kg. of this compound to a rat (Pratt) failed to produce any overt activity.

EXPERIMENTAL

Experimental Results.—β-[3-(3-Azabicyclo-[3.2.2.]nonyl)]-4-aminopropiophenone was prepared according to the method of Wright and Freifelder (17). *p*-Chlorobenzalacetone was synthesized according to the method previously outlined (18). 2,6-di-[3-(3-Azabicyclo[3.2.2.]nonyl)-methyl]-*p*-cresol was prepared according to the method of Bruson and MacMullen (19). 2-Propionylthiophene was synthesized by the procedure of Kosak and Hartough (20), employing propionic anhydride rather than acetic anhydride. 2-Propionyl-5-bromothiophene was prepared according to the method of Hartough and Conley (21). This procedure was

[1] The authors wish to thank Dr. Paul Craig of Smith Kline & French Laboratories for arranging for the pharmacological testing.

modified by substituting 2-bromothiophene for 2-chlorothiophene and propionic anhydride for acetic anhydride. 3-Azabicyclo[3.2.2.]nonane was supplied through the courtesy of Eastman Chemical Products, Inc. All other ketones in this study were commercially available.

The Mannich reaction was carried out as previously described (8), utilizing procedure B. A solid usually appeared within 30–90 minutes and acetone was added to complete precipitation. It was observed that some of these compounds were only slightly soluble in ethanol, especially the ones of more complex structure. In such cases a few drops of water were added to help facilitate solution in the recrystallization processes. In general, the reactions proceeded smoothly to yield the expected product. It may be noted, however, that excellent yields are seldom obtained in the Mannich reaction due to the complexity of the products obtained which may be occasioned by by-product formation. The furan derivatives consistently produced low yields.

Sympathetic Nervous System Blocking Agents

Investigation of Ethyl-, Hydroxyethyl-, Vinyloxyethyl-, and Propargyl-benzyldimethylammonium Halides and Related Compounds

By JAMES H. SHORT and URSULA BIERMACHER

A series of quaternary benzylamine derivatives has been prepared. They were examined for their ability to block the sympathetic nervous system without also blocking the parasympathetic system. The most active compounds were derivatives of benzyl(vinyloxyethyl)dimethylammonium halide. The *o*-bromo analog has activity of the same order of magnitude as bretylium. Pharmacological results and structure-activity relationships are discussed.

THROUGH routine screening of compounds for cardiovascular effects, it was observed that benzyl(vinyloxyethyl)dimethylammonium bromide (Table I, No. 1) had a blocking effect on the sympathetic nervous system, but apparently had little or no effect on the parasympathetic system. It appeared, therefore, to have activity of the same type as bretylium, which has recently been investigated in the clinic as an antihypertensive agent (1).

Interest in this type of pharmacological activity led us to synthesize a series of quaternary salts in order to investigate structure-activity relationships. Some of these compounds were prepared by the reaction of a benzyl halide with a tertiary amine. For those desired compounds which were not accessible by this route, the alternative procedure, reaction of an N,N-dimethylbenzylamine with an alkyl halide was employed.

The required intermediate amines and halides were prepared by standard methods and are described in the experimental section.

PHARMACOLOGICAL RESULTS[1]

The effectiveness of these compounds as sympathetic blocking agents was determined in unanesthetized cats. The candidate drugs were administered orally, and the degree and duration of the prolapse of the nictitating membrane were the criteria used to determine whether or not the desired activity was present. Since parasympatho-

[a] R^1R^2N = 2,2,4,6-tetramethylpiperidino. [b] Recrystallized from acetone. [c] Recorded m.p. is 103–104° (9).

lytic agents and ganglionic blocking agents alter the pupillary responses of the eye, normal responses were taken as indications that the parasympathetic nervous system was not also being blocked.

When the candidate drugs failed to cause a prolapse of the nictitating membrane at an initial low dose level, dosage was increased as high as 30 mg./Kg. Those substances which failed to show a response at such a high dose were classified as inactive. The active compounds are compared in Table III.

Several compounds related to bretylium, but bearing different substituents on the benzene ring, were examined. It was found that when the benzene ring carried a substituent in the *para* position (Table I, Nos. 10, 11, 12) the desired activity was not observed. However, when the bromine atom in the *ortho* position of the benzene ring was replaced by hydrogen, methoxy, or chloro (Nos. 7, 8, 9) these compounds were still active, but less so than bretylium (see Table III).

The compounds obtained by replacing the *o*-bromobenzyl moiety of bretylium with the 1-bromo-2-naphthylmethyl or 2-furylmethyl groups were inactive.

The quaternary salts prepared from various ethanol- and propanolamines were uniformly inactive (Table I, Nos. 14–21).

The most active group of compounds were those quaternary salts derived from (vinyloxyethyl)-dimethylamine (Table I, Nos. 1–5). Of this group, the *o*-bromo derivative (No. 4) was outstanding. It appears to be as potent as bretylium (No. 24), but with longer duration of activity. It is interesting to note that when the dimethylamino group of No. 4 is replaced by the piperidine group (No. 6), activity is lost.

The analogs of Nos. 4 and 24 containing no substituent on the benzene ring (Nos. 1 and 7) have comparable activity, as do the *o*-chloro analogs (Nos. 3 and 9).

Acute toxicity studies were carried out only with Nos. 1, 4, and 24. They were administered orally to mice, and all three failed to cause death at doses of 500 mg./Kg.

The activity shown by 1,1,2,2,4,6-hexamethylpiperidinium iodide (Table II, No. 25) appears to be due to ganglionic blockade rather than the desired activity.

EXPERIMENTAL[2]

***o*-Bromobenzyl Bromide.**—The procedure of DeTar and Carpino (2) was modified by running the reaction at 150° in the absence of benzoyl peroxide for 3 hours. The colorless oil boiled at 129–130° (15 mm.), n_D^{21} 1.6195.

1-Bromo-2-bromomethylnaphthalene.—A mixture of 53 Gm. (0.3 mole) of N-bromosuccinimide and 66.3 Gm. (0.3 mole) of 1-bromo-2-methylnaphthalene (Aldrich Chemical Co.) in 700 ml. of carbon tetrachloride was illuminated from below by a 150-watt light bulb. The light and flask were enclosed in a metal shield and the reaction was illuminated and stirred for 2 hours. The heat from the light bulb was sufficient to cause the carbon tetrachloride to reflux. The hot mixture was filtered, after which the product precipitated from the filtrate. The

[2] Microanalyses are due to Mr. Elmer F. Shelberg and staff of the Abbott Microanalytical Laboratory.

TABLE III.—COMPARATIVE PHARMACOLOGICAL ACTIVITIES

No.[a]	Relative Activity[b]	No.	Relative Activity
4	3.0	7	1.0
24[c]	2.5	1	1.0
3	2.25	5	1.0
9	2.0	25	0.5
2	1.5	8	0.1

[a] The numbers refer to the compounds in Tables I and II. [b] Activity is rated on a 0–3 scale, in which 3.0 is assigned as the relative activity of our most active compound. In arriving at these relative values, the dose and duration of effect have been given more weight than the actual degree of prolapse. The figures in this table represent approximate values, and are not to be considered definitive. [c] Bretylium iodide.

material was recrystallized once from Skelly B and weighed 63 Gm. (70%), m.p. 107.5–109°. The recorded m.p. is 107–108° (3).

o-Trifluoromethylbenzyl Alcohol.—Reduction of 36 Gm. (0.19 mole) of *o*-trifluoromethylbenzoic acid (4) with lithium aluminum hydride was accomplished in diethyl ether. The yield was 20.5 Gm. (61.4%) of material boiling at 124–126° (57 mm.), n_D^{25} 1.4661.

Anal.—Calcd. for $C_8H_7F_3O$: C, 54.56; H, 4.00. Found: C, 54.08; H, 3.88.

o-Trifluoromethylbenzyl Bromide.—A solution of 20.5 Gm. (0.12 mole) of *o*-trifluoromethylbenzyl alcohol and 4 ml. of pyridine was added, with stirring, dropwise over a period of 3 hours to 12.6 Gm. of phosphorus tribromide at −5 to −10°. After addition was complete, the reaction mixture was slowly allowed to come to room temperature overnight. It was poured onto ice. The white solid which formed was collected and washed well with ice water. On warming to room temperature the solid liquified; it was then distilled at 116–118° (60 mm.), n_D^{25} 1.4967. The yield was 21.5 Gm. (77.5%).

Anal.—Calcd. for $C_8H_6BrF_3$: C, 40.20; H, 2.53. Found: C, 40.11; H, 2.41.

Preparation of Substituted N,N-Dimethylbenzylamines.—The compounds listed below were prepared from dimethylamine and the appropriate benzyl halide according to the procedure of Eliel, Ferdinand, and Herrmann (5): 4-chloro-N,N-dimethylbenzylamine (5), b.p. 104–106° (19 mm.), n_D^{25} 1.5172; 2,4-dichloro-N,N-dimethylbenzylamine (5), b.p. 127–129° (20 mm.), n_D^{25} 1.5370; 2-chloro-N,N-dimethylbenzylamine (6), b.p. 103° (19 mm.), n_D^{25} 1.5212; 2-bromo-N,N-dimethylbenzylamine (7), b.p. 112–113° (17 mm.), n_D^{25} 1.5445; 4-bromo-N,N-dimethylbenzylamine (8), b.p. 98–102° (8 mm.), n_D^{26} 1.5401.

1-Bromo-2-dimethylaminomethylnaphthalene.—It was prepared from 1-bromo-2-bromomethylnaphthalene in the manner described above, b.p. 195–200° (2.5 mm.), n_D^{26} 1.6202.

Anal.—Calcd. for $C_{13}H_{14}BrN$: C, 59.10; H, 5.34; N, 5.30. Found: C, 59.04; H, 5.42; N, 5.15.

N,N-Dimethylfurfurylamine.—This compound was prepared by the Leuckart reaction as previously described (9), b.p. 142–144°, n_D^{25} 1.4592.

N,N-Dimethyl-*o*-methoxybenzylamine (10)—This compound was prepared from *o*-methoxy-N-methylbenzylamine[3] by methylation with formaldehyde and formic acid (11), b.p. 99–101° (10 mm.), n_D^{25} 1.5147.

1,2,2,4,6-Pentamethylpiperidine.—Methylation of 28 Gm. (0.2 mole) of 2,2,4,6-tetramethylpiperidine (Shell Development Co., Emeryville, Calif.) was accomplished with formaldehyde and formic acid (11). The yield of colorless liquid was 20.3 Gm. (65.5%), b.p. 60–61° (12 mm.), n_D^{25} 1.4508.

Anal.—Calcd. for $C_{10}H_{21}N$: C, 77.35; H, 13.63. Found: C, 77.29; H, 14.06.

A sulfate salt was prepared and recrystallized from a mixture of acetone and 2-propanol. It melted at 147–149°.

Anal.—Calcd. for $C_{10}H_{21}N \cdot H_2SO_4$: C, 47.41; H, 9.15; N, 5.53. Found: C, 47.54; H, 8.59; N, 5.52.

Preparation of the Quaternary Salts.—A solution of 0.1 mole of the amine and 0.1 mole of the halide[4] in 50 to 100 ml. of methyl ethyl ketone was allowed to stand at room temperature. The product precipitated after a few hours to several days. The less reactive combinations could be obtained more quickly by refluxing the reaction mixture. If the product precipitated as an oil, it was scratched and chilled until a solid formed. To purify the compounds, they were recrystallized from a suitable solvent such as acetone, methyl ethyl ketone, methanol, ethanol, or 2-propanol. These substances are described in Tables I and II.

(*o*-Chlorobenzyl)(vinyloxyethyl)dimethylammonium Iodide (Table I, No. 3).—A solution of 5.8 Gm. (0.05 mole) of (vinyloxyethyl)dimethylamine (Peninsular Chemresearch, Inc.) and 16 Gm. (0.1 mole) of *o*-chlorobenzyl chloride in 50 ml. of acetone was allowed to stand at room temperature for 3 days and then refluxed for 6 hours. To the solution was added a solution of 15 Gm. (0.1 mole) of sodium iodide in 100 ml. of acetone. After standing overnight at room temperature, the sodium chloride was collected, and the filtrate was concentrated and chilled to obtain 8.8 Gm. (48%) of white solid, m.p. 127–128.5°. One recrystallization from ethanol-acetone raised the melting point to 128.5–129°.

Paper Chromatography of Alkaloidal Extracts of *Lobelia* Species

By M. G. CHAUBAL†, R. M. BAXTER, and G. C. WALKER

Total alkaloidal extracts from four closely related *Lobelia* species, *L. cardinalis* L., *L. syphilitica* L., *L. puberula* Michaux, and *L. elongata* Small, and ten crosses and hybrids involving *L. cardinalis* and *L. syphilitica,* were examined using two-phase descending paper chromatography with formamide-ammonium formate-formic acid as the stationary phase and chloroform-benzene as the mobile phase. The chromatogram of *L. elongata* showed the presence of lobinaline, suggesting its closer relationship with *L. cardinalis.* The chromatograms of *L. cardinalis, L. syphilitica,* and *L. puberula* were different from each other, suggesting the elaboration of different alkaloids by each of these related species. Lobinaline was present in the first species and absent in the latter two species. The *L. cardinalis* × *L. syphilitica* hybrids gave chromatograms suggesting the elaboration of alkaloids characteristic of both the parent plants.

As a result of extensive chemical investigations on various plant species, especially those of economic importance, as, for example, vegetable drugs, the occurrence of "chemical races," "physiological races," or "chemical varieties" has been suggested (1, 2). These plants have similar phenotype but different genotype, and as such are identical in external characters but differ in their chemical composition. Study of chemical composition in relationship to the taxonomy of plants and the development of "chemical systematics" or "biochemical systematics" has interested many workers in recent years (3–9). Systematic chemical studies of genera and families have led to the discovery of new and sometimes unexpected structural types. The observation that certain compounds sometimes do not occur in groups of plants where their presence for botanical reasons could be expected, or that these compounds are replaced, has stimulated study of the deeper causes of such anomalies and led to the deeper understanding of the mechanisms of evolution and the later stages of biosynthetic processes.

The genus *Lobelia* has been of interest from the above point of view. *L. inflata* L. contains lobeline as the major alkaloid while *L. nicotianaefolia* Heyne contains similar alkaloids, lobelanidine being the major alkaloid (10). Bowden (11) has correlated taxonomic, ecological, and cytogenic data on 21 species of *Lobelia* L. section *Lobelia* and has observed the relationship between these species. The alkaloidal extracts from four species of *Lobelia: L. cardinalis* L., *L. syphilitica* L., *L. elongata* Small, and *L. puberula* Michaux, and ten crosses and hybrids involving *cardinalis* and *syphilitica*, have been examined by the technique of descending paper chromatography in this work.

EXPERIMENTAL

Plant Materials.—Total alkaloidal extracts of the following four species of *Lobelia* and ten hybrids were obtained.[1] The method of preparation of the extracts was as outlined by Manske (14). The quantity of dried plant material extracted and the total amount of extractive are indicated in brackets following each species or cross (Gm.). X-515: diploid, *cv.* "Illumination" × *L. cardinalis* subsp. *graminea* var. *pseudosplendens* (N. Mex.) (933-3.90); X-517: *cv.* "Queen Victoria" × *L. cardinalis* subsp. *cardinalis* (584-2.55); X-518: *cv.* "Queen Victoria" × *L. cardinalis* subsp. *cardinalis* (677-2.50); X-537: tetraploid, from a double hybrid cross (two F_1's) involving two accessions of *L. cardinalis* subsp. *cardinalis* and two accessions of *L. syphilitica* var. *syphilitica* (545-1.52); X-520: *L. cardinalis* subsp. *cardinalis* × *L. cardinalis* subsp. *graminea* var. *pseudosplendens* (N. Mex.); X-552: *L. cardinalis* subsp. *graminea* var. *graminea* (Mexico) × *L. cardinalis* subsp. *graminea* var. *graminea* (Mexico); X-628: *L. cardinalis* subsp. *graminea* var. *graminea* (Honduras) × *L. cardinalis* subsp. *graminea* var. *graminea* (Mexico) (X-520, X-552, and X-628 were mixed) (256 + 281 + 125-3.24); X-917-S: selfed, complex tetraploid hybrid involving *cardinalis* and *syphilitica* tetraploid: X-918: same as X-917-S, but two seedlings of the parent hybrid were intercrossed to give X-918, tetraploid X-917-S and X-918 were mixed (343-1.28); X-897: tetraploid, complex parentage involving *L. cardinalis* and *L. syphilitica*, had some of the same parentage as X-537 (523-1.80); X-749: tetraploid, involving *L. cardinalis* and *L. syphilitica;* X-909: tetraploid, involving *L. cardinalis* and *L. syphilitica* (X-749 and X-909 were mixed) (179 + 390-1.35); L.C.C.

This research was supported in part by a grant from the Canadian Foundation for the Advancement of Pharmacy and the National Research Council of Canada, and this support is gratefully acknowledged.
The authors are indebted to Dr. R. H. F. Manske for supplying the alkaloidal extracts, to Dr. W. M. Bowden for supplying much of the plant material, and to Dr. S. I. Kandel for his interest and cooperation during the progress of the investigation.
† Present address: College of Pharmacy, University of Rhode Island, Kingston.

[1] The materials were supplied by Dr. R. H. F. Manske, Dominion Rubber Co., Guelph, Ontario, and Dr. W. M. Bowden, Botany and Plant Pathology Laboratory, Department of Agriculture, Ottawa, Ontario.

403-407 (681-2.83); *L. cardinalis* var. *cardinalis* 5-6-B-S7: *L. elongata* Small, grown from seeds collected at Edenton, N. C. (591-2.42); 17-21-S1-3: diploid, mostly *cardinalis* genes but may be a hybrid, from Erfurt, Germany (681-1.08); *L. puberula* Michx.: composite sample of seedlings grown from seeds collected in North and South Carolina and Florida (196-0.35); *L. cardinalis* var. *cardinalis*; *L. syphilitica* var. *syphilitica*.

Chromatographic Procedure.—Preliminary separations showed that Whatman No. 3 chromatographic paper gave better separations, more constant R_f values, and little or no streaking.

The following two-phase system developed by Steinegger and Ochsner (12) was selected following preliminary screening. Stationary phase: 9 ml. of formamide (laboratory reagent) was dissolved in 20 ml. of acetone (distilled at 56–57° and dried over anhydrous sodium sulfate). The solution was saturated with ammonium formate (0.9 Gm. laboratory grade) and the supernatant filtered through dry filter paper. One milliliter of concentrated formic acid (98–99%) was added to the filtrate. Mobile phase: 9 parts of chloroform (analytical) was mixed with 1 part of benzene (analytical).

Whatman No. 3 paper strips, 19 cm. wide and 57 cm. long, were impregnated with the stationary phase by passing the strips through the solution in a flat dish from about 2.5 cm. above the starting line and down to the lower edge. Excess solution was blotted between filter paper sheets and the paper hung in air to remove all acetone. Six spots were applied to the paper in methanol (synthetic) solution. Approximately 400 mcg. of the total alkaloidal extract and 100 mcg. of the pure alkaloid were applied. Each strip carried one spot of lobinaline which served as a control spot. The spotted paper was then allowed to equilibrate with the vapor of the mobile phase in Pyrex glass chromatographic jars for 12 to 15 hours. The chromatogram was developed after this equilibration period until the mobile phase had run approximately 45 cm. from the starting line. The paper strips were then taken out of the jars and dried in air for one-half hour. Formamide was removed from the strips by keeping them in a hot-air oven at 90° for 2 hours. The color of the alkaloidal spots was developed by spraying with modified Dragendorff's reagent (13). The orange-red alkaloidal spots were marked off on the paper with a pencil and the R_f values of

each noted. (See Tables I and II; Figs. 1, 2, and 3.) The R_f values given are only a guide and are average values of about 10 determinations. The variables governing R_f values are numerous and, for this reason, the locator spot of a solution of pure crystalline lobinaline was applied on each strip.

RESULTS

The chromatograms and R_f values (Figs. 1, 2, and 3 and Tables I and II) were compared with each other on the basis of the presence or absence of lobinaline (14). Other alkaloids in these species have not been isolated or characterized to any extent. *L. cardinalis* L. gave three spots, and that corresponding to lobinaline at R_f 0.46 to 0.53 was the most prominent (Fig. 1). *L. syphilitica* L. gave eight spots, and the two prominent spots at R_f 0.16 and 0.3 have been attributed to the presence of two liquid alkaloids, lopheline and lophilacrine, respectively (15). This species did not appear to contain lobinaline. *L. puberula* Michaux gave six small spots and the chromatograms would indicate an absence of lobinaline in this species also. The chromatograms appeared to be different from those of the extracts from the other three species (Fig. 1). *L. elongata* gave six spots. The prominent spot at R_f 0.46 was eluted out and rechromatographed after mixing with pure lobinaline. Only one spot was obtained, thus indicating the presence of lobinaline in this species.

Chromatograms of the extracts from crosses involving *L. cardinalis* varieties alone, X-515, X-517, X-518, X-520 + X-552 + X-628, and L.C.C. 405-407 (Fig. 2) showed the presence of lobinaline. In these cases there were a greater number of alkaloids (5 to 6 spots) than the three elaborated by *L. cardinalis* L. The hydrids involving *L. cardinalis* L. and *L. syphilitica*, X-537, X-917-S + X-918, X-897, X-909 + X-749 (Fig. 3), gave chromatograms showing spots due to lobinaline and also due to lopheline and lophilacrine. The extract 12-21-S1-3 gave spots corresponding to lobinaline, lophilacrine, and lopheline (Fig. 3).

DISCUSSION

According to Bowden (11), *L. elongata* Small appears to have originated by the crossing of a *puberula*-like ancestor and some other closely related species. The presence of lobinaline and the chromatograms in general with this species would appear to indicate a closer relationship to *cardinalis* than to *puberula*. Bowden has also observed that although strong morphological differences distinguish *L. cardinalis* from *L. syphilitica*, cytogenetically these two species are certainly related, *L. cardinalis* having been derived by some mutational process from a *syphilitica*-like ancestral species, the

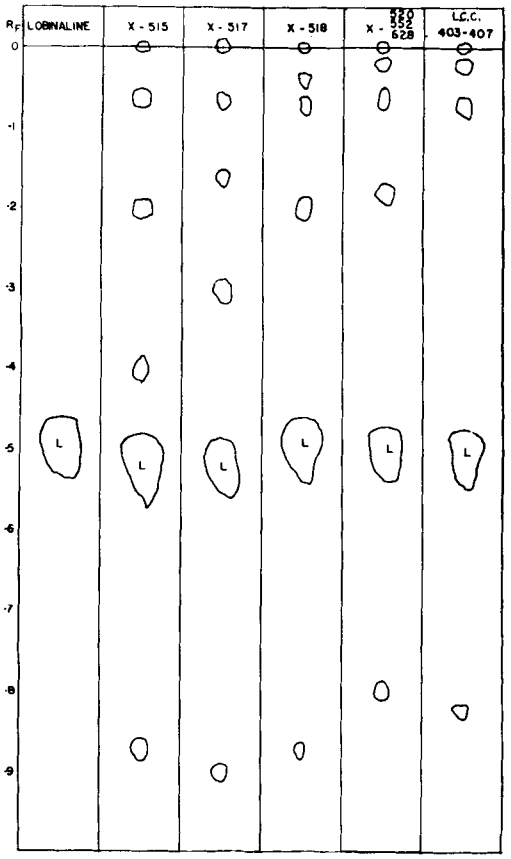

Fig. 2.—Chromatograms of total alkaloidal extracts of crosses involving *L. cardinalis* L. L, lobinaline.

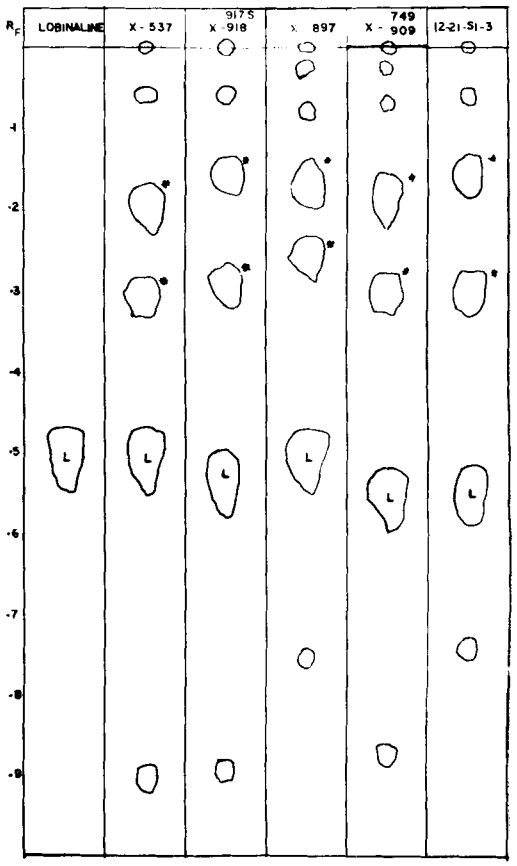

Fig. 3.—Chromatograms of total alkaloidal extracts of *L. cardinalis* and *L. syphilitica* crosses. L, lobinaline; *, lopheline and lophilacrine.

mutational changes involving changes in chromosome structure. The chromatograms of these two species showing the occurrence of lobinaline in the first species and its absence in the latter would suggest that these mutational changes have also resulted in changes in alkaloidal composition and in structural type in these two species. *L. syphilitica* and *L. puberula* have been shown to be cytogenetically related by Bowden. The chromatograms of these two species do not seem to show any close relationship. The *cardinalis* × *syphilitica* hybrids produce alkaloids from both the parent plants. These observations on *L. syphilitica* and the *cardinalis* × *syphilitica* hybrids support and extend the observations of Steinegger, *et al.* The plant 12-21-S1-3 (Fig. 3) was observed to be a diploid plant with mostly *cardinalis* genes but which might have been a hybrid. The chromatograms having spots due to lobinaline and lopheline and lophilacrine indicate that the sample was a hybrid involving *cardinalis* and *syphilitica*.

The chromatograms of *L. cardinalis* L. (Fig. 1 and Table I) show three spots: R_f 0.00, 0.48, and 0.80. Kaczmarek and Steinegger (16) obtained only two spots, R_f 0.45 and 0.86, with fresh extracts of the species. However these same authors observed an increased number of spots (5–8) with a 6-year-old petroleum ether extract.

Bisulfite Reduction of *p*-Nitrobenzyl Alcohol

By LOUIS C. SCHROETER and TAKERU HIGUCHI

Bisulfite reduction of *p*-nitrobenzyl alcohol appears to follow a Piria mechanism leading to formation of α-hydroxy-6-sulfoamino-*m*-toluenesulfonic acid. Stoichiometry of the reaction involves one mole of nitro compound and three moles of bisulfite; pH profile of the initial rate of the stoichiometric reaction has been studied. Preliminary kinetic studies indicate an apparent heat of reaction of about 22 Kcal. mole^{-1}. This complicated sequential reduction reaction appears to involve two mechanistic pathways: a rate-determining initial S_N1 reaction dominates at pH 4, while at pH 7 the initial rate-determining reaction appears to possess typical S_N2 characteristics.

BISULFITE REACTIVITY toward the *p*-nitrobenzyl alcohol moiety of chloramphenicol was demonstrated during an investigation of the stability of the antibiotic in the presence of the thio compound (1). Complexity of the antibiotic molecule made evaluation of the kinetic results rather difficult and, for this reason, *p*-nitrobenzyl alcohol was employed as a model compound for the antibiotic so that certain mechanistic details of the reaction could be evaluated. Spectrophotometric and chromatographic evidence obtained during the kinetic study of both the antibiotic and the model compound indicated involvement of nitro reduction with formation of a very polar product; this served to differentiate the reaction from that which occurs between nitrobenzyl halides and sulfite (2). Nitro reduction plays only a minor role under reaction conditions which lead to near-quantitative yields of the nitrobenzyl sulfonic acid from the corresponding nitrobenzyl halides.

The reaction of either *p*-nitrotoluene or *p*-nitrobenzoic acid with sulfite in dilute aqueous solution under conditions similar to those employed with the *p*-nitrobenzyl alcohol leads to formation of both sulfoamino and sulfoaminosulfonic acid compounds (3, 4). This reduction-sulfonation reaction is known as the Piria reaction (3). The mechanism of the Piria reaction for *p*-nitrotoluene analogs of *p*-nitrobenzyl alcohol and other aromatic nitro compounds has been treated

mutational changes involving changes in chromosome structure. The chromatograms of these two species showing the occurrence of lobinaline in the first species and its absence in the latter would suggest that these mutational changes have also resulted in changes in alkaloidal composition and in structural type in these two species. *L. syphilitica* and *L. puberula* have been shown to be cytogenetically related by Bowden. The chromatograms of these two species do not seem to show any close relationship. The *cardinalis* × *syphilitica* hybrids produce alkaloids from both the parent plants. These observations on *L. syphilitica* and the *cardinalis* × *syphilitica* hybrids support and extend the observations of Steinegger, *et al.* The plant 12-21-S1-3 (Fig. 3) was observed to be a diploid plant with mostly *cardinalis* genes but which might have been a hybrid. The chromatograms having spots due to lobinaline and lopheline and lophilacrine indicate that the sample was a hybrid involving *cardinalis* and *syphilitica*.

The chromatograms of *L. cardinalis* L. (Fig. 1 and Table I) show three spots: R_f 0.00, 0.48, and 0.80. Kaczmarek and Steinegger (16) obtained only two spots, R_f 0.45 and 0.86, with fresh extracts of the species. However these same authors observed an increased number of spots (5–8) with a 6-year-old petroleum ether extract.

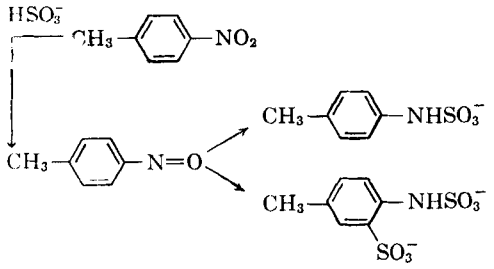
Bisulfite Reduction of *p*-Nitrobenzyl Alcohol

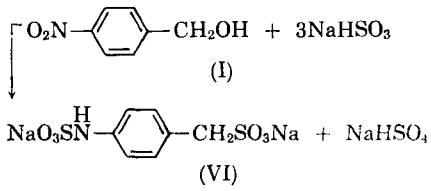
By LOUIS C. SCHROETER and TAKERU HIGUCHI



Bisulfite reduction of *p*-nitrobenzyl alcohol appears to follow a Piria mechanism leading to formation of α-hydroxy-6-sulfoamino-*m*-toluenesulfonic acid. Stoichiometry of the reaction involves one mole of nitro compound and three moles of bisulfite; pH profile of the initial rate of the stoichiometric reaction has been studied. Preliminary kinetic studies indicate an apparent heat of reaction of about 22 Kcal. mole^{-1}. This complicated sequential reduction reaction appears to involve two mechanistic pathways: a rate-determining initial S_N1 reaction dominates at pH 4, while at pH 7 the initial rate-determining reaction appears to possess typical S_N2 characteristics.

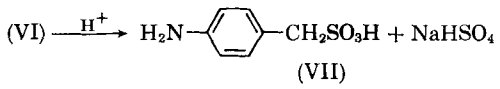
BISULFITE REACTIVITY toward the *p*-nitrobenzyl alcohol moiety of chloramphenicol was demonstrated during an investigation of the stability of the antibiotic in the presence of the thio compound (1). Complexity of the antibiotic molecule made evaluation of the kinetic results rather difficult and, for this reason, *p*-nitrobenzyl alcohol was employed as a model compound for the antibiotic so that certain mechanistic details of the reaction could be evaluated. Spectrophotometric and chromatographic evidence obtained during the kinetic study of both the antibiotic and the model compound indicated involvement of nitro reduction with formation of a very polar product; this served to differentiate the reaction from that which occurs between nitrobenzyl halides and sulfite (2). Nitro reduction plays only a minor role under reaction conditions which lead to near-quantitative yields of the nitrobenzyl sulfonic acid from the corresponding nitrobenzyl halides.

The reaction of either *p*-nitrotoluene or *p*-nitrobenzoic acid with sulfite in dilute aqueous solution under conditions similar to those employed with the *p*-nitrobenzyl alcohol leads to formation of both sulfoamino and sulfoaminosulfonic acid compounds (3, 4). This reduction-sulfonation reaction is known as the Piria reaction (3). The mechanism of the Piria reaction for *p*-nitrotoluene analogs of *p*-nitrobenzyl alcohol and other aromatic nitro compounds has been treated

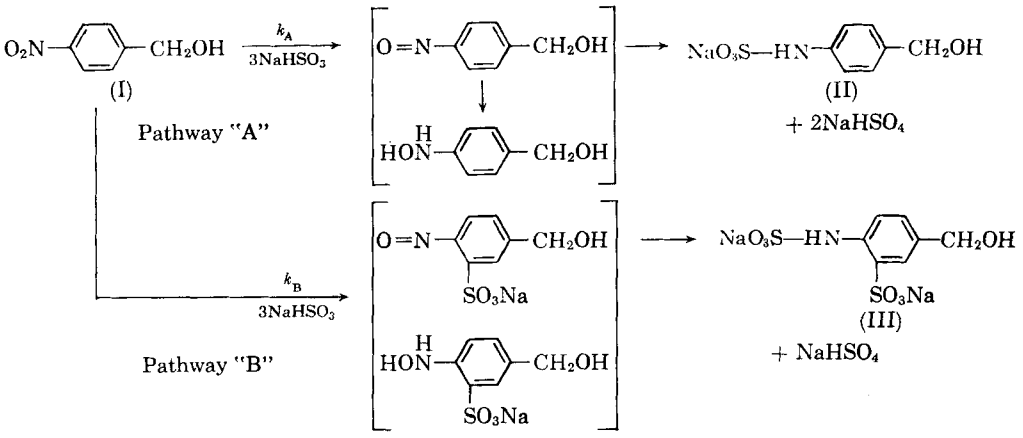


Received October 14, 1961, from The Pharmacy Research Section, Product Research and Development, The Upjohn Co., Kalamazoo, Mich., and The School of Pharmacy, The University of Wisconsin, Madison.
Accepted for publication November 20, 1961.
The authors wish especially to thank Mr. Marvin Grostic, formerly of Physical and Analytical Chemistry Unit, The Upjohn Co., for spectrophotometric interpretations.

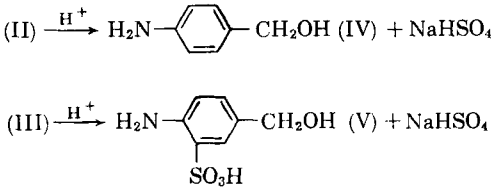
in detail (3–6), and the following pathway has been suggested (6) for the reaction of *p*-nitrotoluene with sulfite in aqueous systems



Hunter and Sprung (3) reported that the main product (72%) of the reaction was *p*-tolylsulfamic acid, while under similar conditions with *p*-nitrobenzoic acid as the reactant, the nuclear sulfonated product, 3-sulfo-4-sulfoaminobenzoic acid, was the main product (61%). The analogous mechanistic pathways for the *p*-nitrobenzyl alcohol-bisulfite reaction would be as follows



Isolation of product is of paramount significance in considering mechanisms because the following postulated reaction also consumes three moles of sulfite and produces a sulfoamino-sulfonic acid product



Acid Hydrolysis of Product:

Validity of this postulated mechanism could be tested simply by subjecting the product to acid hydrolysis; this would yield the slightly soluble zwitterionic *p*-aminobenzylsulfonic acid (VII). The highly polar nature of the products proposed

Acid Hydrolysis of Products:

Applicability of the above mechanism and determination of the main pathway (A or B) requires evaluation of several factors: (*a*) stoichiometry of reaction, i.e., total loss of bisulfite with respect to nitro compound; (*b*) molar yield of inorganic sulfate obtained by acid hydrolysis of reaction mixture; (*c*) product isolation.

in the above schemes makes isolation from contaminating inorganic sulfate very difficult. Repeated ethanolic extractions have been used with some success for the isolation of products from Piria reactions (3, 4). Although this technique is rather cumbersome, it serves to isolate all possible products under mild conditions. The procedure described by Nomine (7) for the isolation of a steroid sulfaminate offers a unique, rapid method in which the product is isolated as a water-insoluble quaternary ammonium salt. This latter procedure is generally applicable to the isolation of all postulated products from the reaction of sulfite with *p*-nitrobenzyl alcohol.

EXPERIMENTAL

Stoichiometry and Kinetic Studies

Solutions of *p*-nitrobenzyl alcohol and sodium bisulfite were prepared separately in various 0.3 *M* buffers. The nitro compound was dissolved in 150 ml. of buffer and the bisulfite in 50 ml. of nitrogen-flushed buffer. Ionic strength of the final combined solution (200 ml.) was maintained constant at 1.0 by addition of appropriate amounts of sodium chloride to the bisulfite solution. Solutions were equilibrated separately at the reaction temperature, then rapidly and simultaneously transferred to a reaction vessel immersed in a thermostat; this marked "zero time" for the reaction. Reaction solution was stirred at a fixed rate under nitrogen atmosphere during course of the reaction. Thermostat temperature was maintained ±0.1°. The pH of the reaction mixture was determined at the temperature of the study with a Beckman Zeromatic pH meter standardized against known buffers maintained at the same temperature. Sampling was performed by periodically withdrawing 5-ml. aliquots from the reaction mixture and quenching in an ice-water bath. Bisulfite content was determined by iodometric titration. Concentration of *p*-nitrobenzyl alcohol and of its reduction product was determined by ultraviolet spectrophotometry. Appropriate dilutions of the aliquots were made with pH 6.50, 0.01 *M* phosphate buffer; absorption was rapidly recorded from 350 to 220 mμ using a Cary model 11 recording spectrophotometer. Resultant spectra were evaluated by two component analysis using 235 and 277 mμ maxima.

Acid Hydrolysis and Sulfate Determination

Reduction Reaction.—Six millimoles (0.919 Gm.) of *p*-nitrobenzyl alcohol (Eastman WL recrystallized twice from water, m.p. 93°) were dissolved in 150 ml. of nitrogen-flushed water maintained at 55°. Sulfite solution was prepared to contain 12 mmoles (1.249 Gm.) of sodium bisulfite A.R. and 12 mmoles (1.543 Gm.) of sodium sulfite A.R. in 50 ml. of water at 55°. The solutions were simultaneously introduced into a reaction vessel fitted with a dropping funnel, nitrogen flushing tube, and a gas exit tube. The reaction was maintained at pH 6.5 ± 0.3 by appropriate additions of acid or base. The solution was thermostatted at 55° for 7 hours while water-saturated nitrogen bubbled through to mix the solution and to prevent autoxidation of sulfite.

Hydrolysis Reaction.—Subsequent to the reduction reaction, 30 ml. of concentrated hydrochloric acid was slowly added to the reaction solution through the dropping funnel. Flow of nitrogen through the solution was increased to expel sulfur dioxide; the exit tube was then connected to a sodium hydroxide absorption train. The acid hydrolysis reaction was maintained at 55° for 48 hours; nitrogen was constantly bubbled through the solution to expel sulfurous acid.

Sulfate Determination.—Barium chloride solution was added dropwise to the acidified hydrolysis reaction solution until no further precipitation of barium sulfate occurred. The collected precipitate was digested, washed, ignited, and weighed in the customary manner. The weight of barium sulfate from similarly treated blank containing no *p*-nitrobenzyl alcohol was subtracted from sample value to give net inorganic sulfate formed on hydrolysis: 12.32 mmoles $BaSO_4$ from sample minus 0.23 mmoles $BaSO_4$ from blank equals 12.09 mmoles $BaSO_4$ from sample hydrolysis. Ratio of sulfate obtained on hydrolysis to react nitro compound (PNBA): 12.09 sulfate/6.0 PNBA = 2.015 moles sulfate per mole PNBA.

Isolation of Acid Hydrolysis Product

Reduction reaction was carried out as described above. The following variations in hydrolysis conditions were employed

Added HCl, ml.	Hydrolysis—Time, hr.	Hydrolysis—Temp., ° C.	Product Analyses—Carbon, %	Product Analyses—Hydrogen, %
30	48	55	47.92	4.67
20	48	55	46.38	4.50
10	48	55	42.67	3.97
10	12	55	37.53	3.77
10	12	35	29.84	3.20
10	6	25	25.98	3.34

After cooling, the solutions were extracted with five 50-ml. portions of diethyl ether. The combined ethereal extracts were evaporated to dryness and weighed. Less than 10 mg. residue was obtained. The pH of the aqueous acid solution was adjusted to 2.5 by the addition of sodium carbonate. The yellow precipitate which formed was filtered from solution after 24 hours and dried under vacuum. Combustion analyses of products are tabulated above. Filtrate pH was adjusted to 9 with carbonate. The solution was extracted with five 50-ml. portions of chloroform. Chloroformic solutions evaporated to dryness yielded less than 10 mg. residue. Infrared spectra of products were compared with the known spectrum of *p*-aminobenzylsulfonic acid prepared as described below.

Product Isolation.—*A. Isolation of Sodium α-Hydroxy-6-sulfoamino-m-toluene Sulfonate (III) from a pH 6.5 Reduction Reaction.*—The reduction reaction between a fourfold molar excess of bisulfite with *p*-nitrobenzyl alcohol as described above was repeated at 55° with the pH maintained at 6.5.

One hundred milliliters of a reaction solution containing 3 mmoles of product, as shown by spectrophotometric analysis, was allowed to evaporate spontaneously to dryness at ambient temperatures. Care was taken in all subsequent operations to avoid temperatures higher than 25° so that product decomposition would be minimized. The dry residue was extracted with three 25-ml. portions of diisopropyl ether. The combined ethereal extracts, evaporated to dryness, yielded less than 5 mg. residue. The dried reaction residue was then extracted with four 50-ml. fractions of 65% ethanol. The combined ethanolic solutions were evaporated to dryness. The resultant residue was extracted with 200 ml. of 75% ethanol; the procedure was repeated using 85 and 95% ethanol. Residue from the 95% ethanol extraction was dissolved in 5 ml. of water and filtered. Residue from the aqueous filtrate was recrystallized four times from water-ethanol. Yield: 476 mg. (48.5%).

Anal.—Calcd. for $C_7H_7NNa_2O_7S_2$ (III): C, 25.69; H, 2.16; N, 4.28; S, 19.59. Found: C, 25.93; H, 4.08; N, 4.06; S, 16.97. Ultraviolet spectrum in water: ε 235.5 mμ = 10,850; ε 280 mμ = 1600. Infrared spectrum shows the following bands: –OH/–NH: 3550, 3425, 3300 cm.$^{-1}$; $-SO_3-$: 1300, 1250, 1230, 1170 cm.$^{-1}$; C–O: 1040.

B. Isolation of Sodium α-Hydroxy-6-sulfoamino-m-toluene Sulfonate (III) from a pH 4 Reduction Reaction.—The isolation was carried out exactly as described for the pH 6.5 product. Yield: 394 mg. (40.2%).

Anal.—Calcd. for $C_7H_7NNa_2O_7S_2$ (III): C, 25.69; H, 2.16; N, 4.28. Found: C, 25.15; H, 3.07; N, 4.26. The infrared spectrum was identical with that obtained from the pH 6.5 product.

C. Isolation of Potassium α-Hydroxy-6-sulfoamino-m-toluene Sulfonate (III) from a pH 6.5 Reduction Reaction.—An aliquot of a pH 6.5 reduction reaction was diluted to 100 ml., cooled to 25°, and extracted with six 50-ml. fractions of diisopropyl ether. The combined ethereal extracts evaporated to dryness yielded less than 10 mg. residue. A 150-ml. quantity of 5% benzethonium chloride solution was added slowly with stirring to the aqueous phase. The solution was allowed to stand 24 hours at 5° before pouring off the supernatant aqueous solution from the oily residue. The oily residue was dissolved in 200 ml. chloroform which was then washed with three 75-ml. portions of water and passed through a 2 × 20 cm. column containing anhydrous sodium sulfate. Eluate volume was adjusted to 200 ml. with chloroform rinsings from the column: eluate was evaporated to dryness under nitrogen at 25°. Residue was dissolved in 150 ml. absolute ethanol, and 50 ml. of 1 *M* ethanolic potassium acetate was added slowly with stirring. After 24 hours standing at 5°, the yellow precipitate was filtered from solution. Product recrystallized twice from ethanol-water.

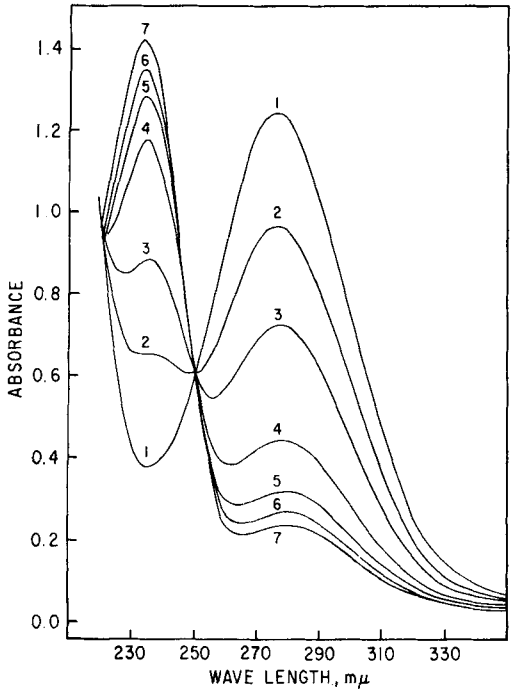


Fig. 1.—Ultraviolet spectra showing reduction of nitro compound (277 mμ) to sulfoamino product (235 mμ) in presence of excess bisulfite at 55°. Initial solution composition: 0.03 *M* *p*-nitrobenzyl alcohol and 0.12 *M* total sulfite in pH 6.50, 0.3 *M* buffer. Final ionic strength adjusted to 1.0. Figure redrawn from original spectrogram.

Anal.—Calcd. for $C_7H_7K_2NO_7S_2$: C, 23.39; H, 1.96; N, 3.90; S, 17.85. Found: C, 22.65; H, 1.91; N, 3.79; S, 16.82.

4-Aminobenzylsulfonic Acid (VII) Synthesis

Five mmoles (1.20 Gm.) of *p*-nitrobenzyl sulfonic acid, sodium salt synthesized by the procedure of Clutterbuck and Cohen (3), was dissolved in 50 ml. of water containing 1.4 Gm. finely powdered iron. The solution was acidified with acetic acid and warmed (70–80°) on a steam bath for 2 hours. After cooling, the solution was filtered. The filtrate was acidified with dilute hydrochloric acid and allowed to stand 24 hours at 5°, yielding light yellow crystals. The product was recrystallized three times from dilute hydrochloric acid. Yield: 465 mg. (49.6%).

Anal.—Calcd. for $C_7H_9NO_3S$ (VII): C, 44.90; H, 4.85; N, 7.48; S, 17.13. Found: C, 45.08; H, 4.91; N, 7.38; S, 16.94. The pKa determined in water was 4.56. Ultraviolet spectrum in water showed the following absorption maxima: ε 239.5 mμ = 4100; ε 283 mμ = 232; ε 325 mμ = 65. Infrared spectrum showed the following bands: –NH: 3180, 3040 cm.$^{-1}$; C=C/–NH deformation: 1628, 1582, 1540 cm.$^{-1}$; $-SO_3^-$/C–N: 1222, 1210, 1168, 1130, 1033, 1030 cm.$^{-1}$.

RESULTS AND DISCUSSION

Stoichiometry of the reaction was followed by iodometric titration of available sulfite and by two-component analysis of ultraviolet spectral curves such as Fig. 1. Rapid ultraviolet spectrophotometry of reduction reactions showed the presence of only two components and a single isosbestic point which suggested that the slow, rate-determining step in the sequential reaction was followed by more

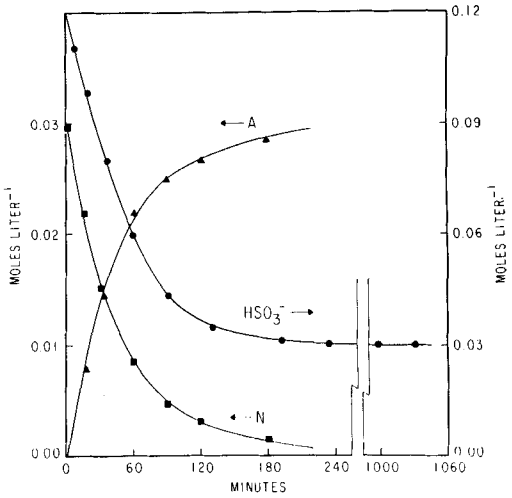

Fig. 2.—Reduction of nitro compound (*N*) with formation of product (*A*) and loss of bisulfite at 55° from solution containing excess bisulfite: 0.03 *M* *p*-nitrobenzyl alcohol and 0.12 *M* total sulfite in pH 6.50, 0.3 *M* buffer. Final ionic strength adjusted to 1.0. Molar concentration of *p*-nitrobenzyl alcohol (■) and its reduction product (▲) indicated by ordinate values to the left of the figure, while total molar concentration of sulfite (●) indicated by right ordinate values.

rapid steps so that the concentration of intermediates was always quite low. Excess bisulfite leads to total conversion of nitro compound with consumption of three moles of bisulfite for each mole of product formed, as shown in Fig. 2. Prolonged reaction times do not lead to further loss of bisulfite, thus establishing the ratio of three moles of bisulfite to one mole nitro compound; this was further verified by repeating studies at higher temperatures for prolonged periods, as shown in Table I. Equimolar concentrations of nitro compound and bisulfite lead to total consumption of bisulfite with formation of one-third molar concentration of product, as shown in Fig. 3.

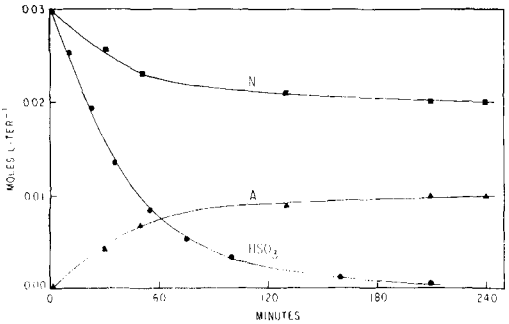

Fig. 3.—Reduction of nitro compound (N) with formation of product (A) and loss of bisulfite at 55° from solution containing excess nitro compound: 0.03 M p-nitrobenzyl alcohol and 0.03 M total sulfite in pH 6.50, 0.3 M buffer. Final ionic strength adjusted to 1.0.

TABLE I.—STOICHIOMETRY OF p-NITROBENZYL ALCOHOL BISULFITE REACTION AT pH 6.50 AND VARIOUS TEMPERATURES[a]

Temperature, °C.	—Bisulfite Concentration (moles L.⁻¹) at— 0 hr.	4 hr.	8 hr.	24 hr.
55	0.120	0.030	0.029	0.030
65	0.120	0.029	0.031	0.030
80	0.120	0.030	0.030	0.029

[a] Solution buffered with 0.30 M phosphate contained 0.03 M p-nitrobenzyl alcohol and 0.12 M sulfite. Ionic strength adjusted to 1.0 by addition of sodium chloride.

Total bisulfite consumption appears to be the same regardless of which mechanism is followed. Acidification of the reduction reaction followed by determination of inorganic sulfates is a powerful tool for establishing which mechanism predominates under given conditions: excess unreacted sulfite is driven off as volatile sulfurous acid, while total sulfate formed during reduction and acid hydrolysis is quantitatively recovered as the insoluble barium salt. Only the sulfoamino group is split under these conditions of acid hydrolysis; nuclear sulfonates are not affected. Isolation of approximately two moles of sulfate upon formation and subsequent hydrolysis of one mole of reaction product strongly supports pathway B of the Piria mechanism; nuclear sulfonation appears to predominate. Isolation of products from acid hydrolyses carried out under varied conditions yields products of variable composition. Under relatively mild conditions (6 hours at 25°), little or no sulfoamino hydrolysis takes place; this is confirmed by both infrared and combustion analysis. More rigorous conditions (30 ml. hydrochloric acid, 55° for 24 hours) lead to product decomposition as evidenced by infrared changes in bonded —NH and —OH. This is not too surprising since aryl sulfamates are known to be alkylating agents at higher temperatures (8). Optimal hydrolysis conditions appear to be at 55° for 48 hours; however, these and other conditions failed to yield infrared evidence for presence of either p-amino-benzylsulfonic acid or p-aminobenzyl alcohol hydrochloride. Reaction solutions made weakly basic, concentrated, and extracted with ether also failed to yield evidence for presence of p-aminobenzyl alcohol.

Product isolation under conditions of acid hydrolysis was complicated by observed tendency of the product to polymerize with heating. Also, strongly acidic conditions introduce the uncertainty factor of secondary reactions leading to artifacts. Isolation of the same product (III) from pH 4 and pH 6.5 reactions by two different procedures in which rigorous conditions were not employed strongly supports mechanism B. It is especially noteworthy that neither isolation procedure is especially selective, i.e., all possible sulfoamino products would be isolated. This is especially significant in considering possible mechanisms since 4-sulfoaminobenzyl alcohol (II) would be isolated under identical conditions if it were present in substantial amounts.

Dependence of the absolute initial rate of loss of bisulfite, $-d(\mathrm{Bi})/dt$, on pH is shown in Fig. 4, in which stoichiometric amounts of reactants (3 bisulfite:1 nitro compound) were reacted at 55°. The initial rate of reaction remains very nearly invariant from pH 3 to 6 exhibiting a rather complex relationship toward hydrogen ion concentration at values above 6. There appears to be a different sensitivity toward singly and doubly charged thio compound: the marked rate increase at pH 7 corresponds to higher initial concentrations of sulfite ion. Actually, considerable concentrations of pyrosulfite, $S_2O_5^{2-}$, ion may be present in concentrated bisulfite solutions (pH 4); however, this species exists in equilibrium with bisulfite ion (9). De-

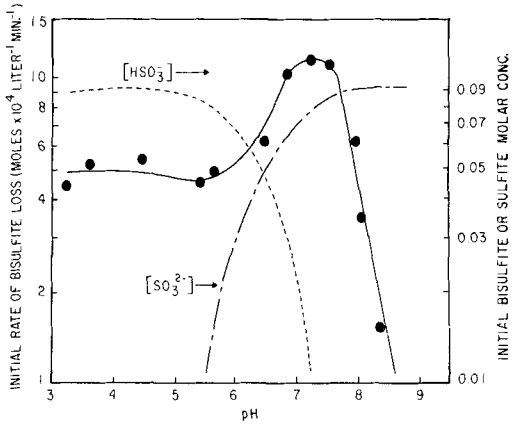

Fig. 4.—Semilog plot of absolute initial rate of bisulfite loss at 55° as a function of pH shown as solid circles joined by solid line. Initial solution composition: 0.03 M p-nitrobenzyl alcohol and 0.09 M total sulfite in 0.3 M buffer; total ionic strength adjusted to 1.0. Initial bisulfite or sulfite ion concentration at 55° in buffers (apparent second ionization constant of sulfurous acid, $pK'_2 = 6.5$) represented by dashed lines.

crease in reaction rate between pH 7.5 and 8 appears dependent on bisulfite ion concentration, but this effect may be more apparent than real inasmuch as this may reflect sensitivity toward increasing hydroxyl ion concentration.

The dependency of the initial rate of nitro loss on initial bisulfite or sulfite concentration is shown in Fig. 5. The initial reaction at pH 4.2 exhibited little dependence on bisulfite ion, and extrapolation of rate values to zero bisulfite concentration suggested that the slow, rate-determining step may involve a S_N1 mechanism. At higher pH values the intercept rate value, [Bi] → 0, decreases, becoming zero at pH values above 7. Plotting intercept rate values, [Bi] → 0, of the initial rates of nitro loss as a function of pH yields Fig. 6 which shows that the initial rate-determining reaction has S_N1 characteristics below about pH 4.6 while S_N2 characteristics predominate above pH 7. The following scheme appears consistent with observed results on the absolute initial rates of nitro loss from *p*-nitrobenzyl alcohol (PNBA) solutions in the presence of bisulfite or sulfite ion

$$\text{PNBA (I)} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \text{(PNBA*)}$$

$$+ SO_3^{2-} \xrightarrow[k_3]{HSO_3^-} \text{Reduction Product (III)}$$

$$\downarrow k_4$$

$$\text{(III)}$$

$$-d(\text{PNBA})/dt = k_4(\text{PNBA})(SO_3^{2-}) + k_3(\text{PNBA*})(HSO_3^-) \quad \text{(Eq. 1)}$$

$$d(\text{PNBA*})/dt = k_1(\text{PNBA}) - k_2(\text{PNBA*}) - k_3(\text{PNBA*})(HSO_3^-) = 0 \quad \text{(Eq. 2)}$$

$$(\text{PNBA*}) = \frac{k_1(\text{PNBA})}{k_2 + k_3(HSO_3^-)} \quad \text{(Eq. 3)}$$

Substituting for (PNBA*) from Eq. 3 into Eq. 1, we have

$$-d(\text{PNBA})/dt = k_4(\text{PNBA})(SO_3^{2-}) + \frac{k_3 k_1(\text{PNBA})(HSO_3^-)}{k_2 + k_3(HSO_3^-)} \quad \text{(Eq. 4)}$$

At pH 4, the initial, rate-determining, reduction reaction may be approximately described by Eq. 5

$$-d(\text{PNBA})/dt = k_1(\text{PNBA})/k_2 \quad \text{(Eq. 5)}$$

which clearly indicates the proposed S_N1 characteristics and is in accord with observed results.

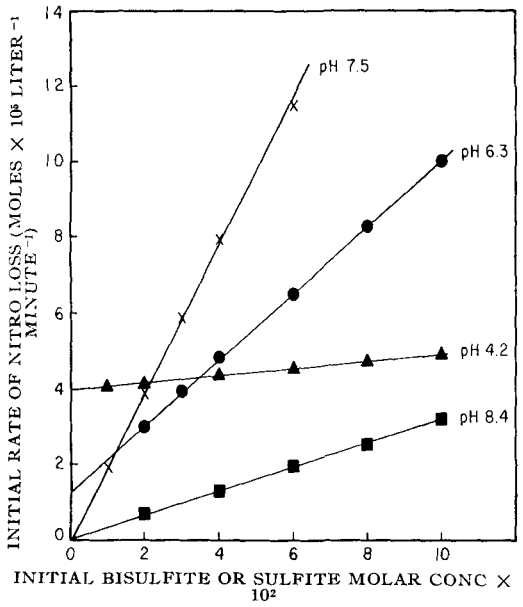

Fig. 5.—Initial rate of nitro loss, $-d(\text{Nitro})/dt$, as a function of initial bisulfite or sulfite ion concentration from buffered (0.3 *M*, μ1.0) solutions at 55°. Solutions initially contained 0.01 *M* *p*-nitrobenzyl alcohol.

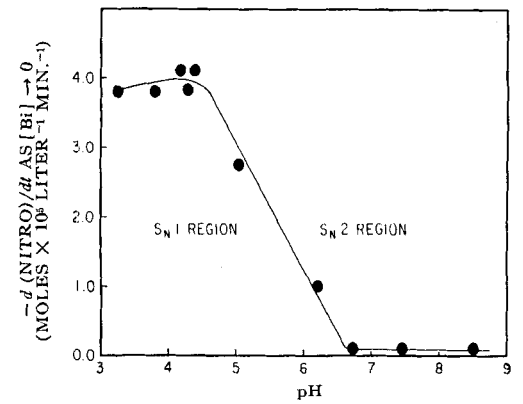

Fig. 6.—Initial rates of nitro loss, $-d(\text{Nitro})/dt$, from bisulfite-*p*-nitrobenzyl alcohol reactions extrapolated to zero bisulfite ion concentration, [Bi] → 0, (*cf.* Fig. 5) plotted as a function of pH. Buffered solutions (0.3 *M*, μ 1.0) initially contained 0.01 *M* *p*-nitrobenzyl alcohol and were thermostatted at 55°.

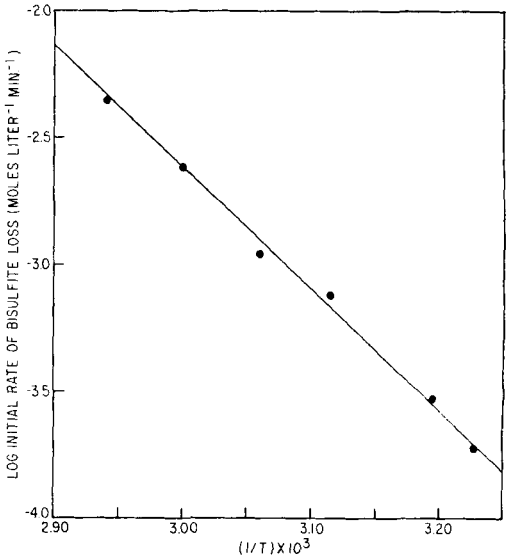

Fig. 7.—Log of initial rate of bisulfite loss from pH 7.0 solutions as a function of reciprocal absolute temperature. Initial solution composition: 0.03 *M* *p*-nitrobenzyl alcohol and 0.09 *M* total sulfite in 0.3 *M* buffer. Final ionic strength adjusted to 1.0.

While at pH 7, the initial, rate-determining, reduction reaction shows dependence on both the nitro and thio species, indicating that Eq. 4 may be simplified to

$$-d(\text{PNBA})/dt = k_4 (\text{PNBA}) (SO_3^{2-}) \quad \text{(Eq. 6)}$$

to describe the S_N2 initial reaction which dominates at higher pH values.

The apparent heat of activation of the initial reaction between stoichiometric amounts of reactants (3 bisulfite:1 nitro compound) determined at pH 7 where S_N2 characteristics dominate gave the value 22 Kcal. mole^{-1} (Fig. 7).

Thioacetamide II

Substitute for Hydrogen Sulfide in the Quantitative Analysis of Medicinal Chemicals

By M. A. GHAFOOR and C. LEE HUYCK†

Assay procedures utilizing thioacetamide and hydrogen sulfide gas have been compared. The advantages of using thioacetamide are discussed.

THE PURPOSE of this study is to investigate the use of thioacetamide as a substitute for hydrogen sulfide in the analysis of medicinal chemicals. A survey of the literature concerning the use of thioacetamide as a substitute for hydrogen sulfide has been made by Jue and Huyck (1).

Swift and Butler (2) reported that since the rate of acid-catalyzed hydrolysis follows the equation

$$\frac{d\text{TA}}{dt} = -K\,\text{H}^+\,\text{TA}$$

(where TA = thioacetamide), the value of K is 0.21 L. mole^{-1} min.$^{-1}$ at 90° and 0.019 L. mole^{-1} min.$^{-1}$ at 60°. The activation energy is 19.1 Kcal. per mole. These figures mean that in a solution which is 1 M in hydronium ion, thioacetamide would be half hydrolyzed at 100° in 100 seconds, at 60° in 36 minutes, and at 25° in 21 hours. In solutions of pH 10 or more, hydrolysis is quite rapid and yields both thioacetate ions and acetamide.

The relation of hydronium ion concentration to the time of precipitation of arsenic in 0.1 M thioacetamide was studied by Butler and Swift (3). Two kinds of reactions with thioacetamide in sulfide precipitations were proposed: (*a*) hydrolysis controlled reaction in which hydrogen sulfide or hydrosulfide ions are formed as intermediates; (*b*) a direct reaction of metal ions with thioacetamide itself. Thioacetamide is a more rapidly acting reducing agent than hydrogen sulfide since arsenic acid is reduced much faster with thioacetamide than with hydrogen sulfide. The rate of precipitation of arsenic with valence of three by thioacetamide was measured in solutions from pH 1.0 to 3.8 and was found to follow quantitatively the calculated rate of hydrolysis of thioacetamide to hydrogen sulfide.

Molybdenum in titanium alloys was determined by precipitation as sulfide with thioacetamide by McNerney and Wagner (4). Stoner and Finston (5) clearly separated uranium from 200 times its weight of bismuth by precipitating bismuth sulfide from solution. Such a separation is impossible with gaseous hydrogen sulfide without a long digestion period.

The precipitation of metal sulfides is governed by the solubility product relation as shown by

Received January 30, 1962, from the St. Louis College of Pharmacy, St. Louis 10, Mo.

Thioacetamide II

Substitute for Hydrogen Sulfide in the Quantitative Analysis of Medicinal Chemicals

By M. A. GHAFOOR and C. LEE HUYCK†

Assay procedures utilizing thioacetamide and hydrogen sulfide gas have been compared. The advantages of using thioacetamide are discussed.

THE PURPOSE of this study is to investigate the use of thioacetamide as a substitute for hydrogen sulfide in the analysis of medicinal chemicals. A survey of the literature concerning the use of thioacetamide as a substitute for hydrogen sulfide has been made by Jue and Huyck (1).

Swift and Butler (2) reported that since the rate of acid-catalyzed hydrolysis follows the equation

$$\frac{d\text{TA}}{dt} = -K\,\text{H}^+\,\text{TA}$$

(where TA = thioacetamide), the value of K is 0.21 L. mole^{-1} min.$^{-1}$ at 90° and 0.019 L. mole^{-1} min.$^{-1}$ at 60°. The activation energy is 19.1 Kcal. per mole. These figures mean that in a solution which is 1 M in hydronium ion, thioacetamide would be half hydrolyzed at 100° in 100 seconds, at 60° in 36 minutes, and at 25° in 21 hours. In solutions of pH 10 or more, hydrolysis is quite rapid and yields both thioacetate ions and acetamide.

The relation of hydronium ion concentration to the time of precipitation of arsenic in 0.1 M thioacetamide was studied by Butler and Swift (3). Two kinds of reactions with thioacetamide in sulfide precipitations were proposed: (*a*) hydrolysis controlled reaction in which hydrogen sulfide or hydrosulfide ions are formed as intermediates; (*b*) a direct reaction of metal ions with thioacetamide itself. Thioacetamide is a more rapidly acting reducing agent than hydrogen sulfide since arsenic acid is reduced much faster with thioacetamide than with hydrogen sulfide. The rate of precipitation of arsenic with valence of three by thioacetamide was measured in solutions from pH 1.0 to 3.8 and was found to follow quantitatively the calculated rate of hydrolysis of thioacetamide to hydrogen sulfide.

Molybdenum in titanium alloys was determined by precipitation as sulfide with thioacetamide by McNerney and Wagner (4). Stoner and Finston (5) clearly separated uranium from 200 times its weight of bismuth by precipitating bismuth sulfide from solution. Such a separation is impossible with gaseous hydrogen sulfide without a long digestion period.

The precipitation of metal sulfides is governed by the solubility product relation as shown by

Received January 30, 1962, from the St. Louis College of Pharmacy, St. Louis 10, Mo.

† Present address: The Norwich Pharmacal Co. and Division of Eaton Laboratories, Norwich, N. Y.

Butler, *et al.* (6). If the solubility product is high, precipitation with thioacetamide may be incomplete due to insufficient hydrogen sulfide in the solution.

In volumetric analysis titrations, thioacetamide was used as a reagent for determination of silver in photographic fixing solutions by Bush, *et al.* (7). The solutions were made 0.1 to 1.0 *N* in sodium hydroxide and titrated with 0.01 *N* thioacetamide to an end point determined potentiometrically, using the silver sulfide electrode. This method made it possible to overcome the interference of thiosulfate and halide ions in the usual Volhard titration of silver

Interference of other divalent ions such as Cu^{++}, Cd^{++}, Zn^{++}, Co^{++}, and Ni^{++} was prevented by adding ethylenediaminetetraacetic acid tetrasodium salt.

Using hydrogen sulfide, zinc can be precipitated completely at pH 3.0, or even less, but thioacetamide precipitated only a very little zinc at this pH (8). One remedy is to use a large excess of thioacetamide and perform the precipitation under pressure in a closed vessel. Hydrogen sulfide gas escapes faster than it is generated in the hydrolysis of thioacetamide solutions when they are heated. The solution of thioacetamide should not be boiled during

precipitation of metallic sulfides but should be as hot as possible without actually boiling.

EXPERIMENTAL

A comparison was made of the methods and results of the quantitative analysis of merbromin N.F. (9) and mercury bichloride U.S.P. (10) for mercury content, using hydrogen sulfide gas and thioacetamide solution.

The hydrogen sulfide gas was generated by the conventional method of adding dilute acid to iron sulfide and then charging the generators after each precipitation. Sufficient commercial, reagent grade thioacetamide was dissolved in distilled water to make a 1 *M* or 7.5% w/v solution, and it was stored in a dark amber-colored bottle. The solution was heated to approximately 80° before use to hasten hydrolysis of thioacetamide. Otherwise, the analysis of mercuric chloride was carried out in accordance with the United States Pharmacopeia (10); the analysis of merbromin was carried out in accordance with the National Formulary (9, 11).

Identical analyses were conducted for each of the two chemicals described above (see Tables I–IV), using thioacetamide wherever hydrogen sulfide was called for. The amount of thioacetamide required for the reaction was calculated on the basis of its hydrolysis product, hydrogen sulfide:

For mercuric chloride

$$HgCl_2 + H_2S \longrightarrow HgS + 2HCl$$
$$271.52 \qquad 34 \longrightarrow 232.68$$
$$CH_3CSNH_2 + H_2O \longrightarrow H_2S + CH_3CONH_2$$
$$75 \qquad 18 \longrightarrow 34$$

75 Gm. thioacetamide is needed to convert 271.52 Gm. of $HgCl_2$ to HgS, giving a gravimetric factor of 75/271.52 = 0.276.

COMPARISON BETWEEN TABLES I AND II[a]

	Table I	Table II
No. of analyses	12	12
Mean	25.73	25.78
S.D.	0.5214	0.2886

$$\text{S.D.D.} \sqrt{\frac{\sigma_1^2 + \sigma_2^2}{n_1 + n_2 - 2}} = \frac{0.5214 + 0.2886}{\sqrt{0.22}} = \frac{0.8100}{4.69} = 0.1727$$

$$\text{Computing } t \text{ from } \frac{\bar{X}_1 - \bar{X}_2}{\text{S.D.D.}} = \frac{0.05}{0.1727} = 0.2895$$

$t_{0.01}$ 22 *d.f.* = 2.819

[a] S.D. = standard deviation, S.D.D. = standard deviation of the difference, σ_1 and σ_2 = standard deviation of the arithmetic mean, $\bar{X}_1$ = mean of first group, $\bar{X}_2$ = mean of second group, and n = No. of analyses.

For merbromin

$$C_{20}H_8Br_2HgNa_2O_6 + H_2S \longrightarrow C_{20}H_8Br_2Na_2O_5 + HgS + H_2O$$
$$750.71 \qquad 34 \longrightarrow 232.68$$

75 Gm. thioacetamide is required for 750.71 Gm. of merbromin, giving a gravimetric factor of 75/750.71 = 0.0999.

A statistical evaluation (12) for the confidence limits for the two methods was made for both chemicals assayed. These tests indicate no significant difference of results between the use of hydrogen sulfide and thioacetamide in the analysis of mercuric chloride and merbromin.

COMPARISON BETWEEN TABLES III AND IV

	Table III	Table IV
No. of analyses	13	14
Mean	99.64	99.58
S.D.	0.2112	0.1725

$$\text{S.D.D.} \sqrt{\frac{\sigma_1^2 + \sigma_2^2}{n_1 + n_2 - 2}} = \frac{0.2112 + 0.1725}{\sqrt{25}} = \frac{0.3837}{5} = 0.0767$$

$$\text{Computing } t \text{ from } \frac{\bar{X}_1 - \bar{X}_2}{\text{S.D.D.}} = \frac{0.06}{0.0767} = 0.3395$$

$t_{0.01}$ 25 *d.f.* = 2.787

DISCUSSION

In the preceding analyses, it was found that thioacetamide could be used in place of hydrogen sulfide gas in the assay of merbromin and mercuric chloride. Results between the two methods agree fairly well. Thioacetamide solution is easier to use than hydrogen sulfide gas. Since, in the use of thioacetamide a moderate excess yielding, in turn, a moderate excess of hydrogen sulfide can be calculated quite accurately, there is very little danger of toxicity and hardly any unpleasant odor.

Hydrolytic Stability of Calcium Acetylsalicylate Carbamide in the Presence of High Concentrations of Additives

By EUGENE L. PARROTT†

The hydrolysis of calcium acetylsalicylate carbamide in aqueous solution at 25, 40, and 50° in the pH range from 1 to 9 has been studied. The effect of high concentrations of several additives, commonly used in pharmaceutical formulation, on the rate of hydrolysis was determined.

NUMEROUS studies (1–5) of the stability of acetylsalicylic acid and its derivatives have been made over a wide range of pH and temperature; however, few reports have been quantitatively concerned with their hydrolytic stability in the presence of high concentrations of additives commonly used in pharmaceutical formulation.

In the development of dosage forms, not only the pH effect but other effects of the ingredients on the stability of a drug must be considered. The kinetics of degradation of many drugs have been studied as a function of pH or in the presence of a low concentration of additives. A limited number of studies have been conducted with additives utilized as stabilizers by virtue of complex formation; yet, even these studies have employed low concentrations of complexing agents (6–8). Practical formulations often contain large amounts of additives beyond the concentration range at which the laws of dilute solutions apply.

The purpose of this investigation was to study the kinetics of hydrolysis of calcium acetylsalicylate carbamide in the presence of a high concentration of several pharmaceutical additives.

Calcium acetylsalicylate carbamide,[1] a complex salt of urea, is an amorphous, white powder with a melting point of 243–245°, at which decomposition occurs. It has a molecular weight of 458. Its solubility made it particularly suitable for this work. At 37° it is soluble to the extent of 231 mg./ml. of solution, yielding a solution with a pH 4.8.

EXPERIMENTAL

Apparatus and Reagents.—Unless specified otherwise all chemicals were reagent grade. Aminoacetic acid N. F.; calcium acetylsalicylate carbamide (Calurin), Dorsey Laboratories; gelatin U. S. P.; glycerin, U. S. P.; polyethylene glycol (Carbowax 6000), Union Carbide and Carbon Co.; polyvinylpyrrolidone (Plasdone K 30), Antara Chemicals; sodium lauryl sulfate U. S. P.; sorbitol; 0.2 *M* ammonium chloride; 0.2 *M* ammonium hydroxide; 0.2 *M* boric acid; 0.1 *M* citric acid; 0.2 *M* disodium phosphate; 0.1 *N* hydrochloric acid; 0.5 *M* sodium borate; constant temperature bath; thermometer calibrated to 0.1°; Beckman pH meter; Beckman model DU spectrophotometer; silica cells.

Procedure.—Calcium acetylsalicylate carbamide, 0.250 Gm., was accurately weighed into a 250-ml. volumetric flask and dissolved in a sufficient amount of buffer to bring to a volume of 250 ml. of solution. The buffer solutions, ranging from pH 1 to 9, were preheated to the temperature at which the particular determinations were to be made. The flask was placed in the constant temperature bath and a 10-ml. sample, representing the zero-time sample, was withdrawn by pipet, transferred to a 100-ml. volumetric flask, and the volume was made to 100 ml. with 0.1 *N* hydrochloric acid. Absorbance of this solution was determined at 302 mμ, using a spectrophotometer with a blank of an identical system not containing calcium acetylsalicylate carbamide but diluted in the same manner. By means of a standard absorption curve, the amount of salicylic acid formed was measured and the concentration of calcium acetylsalicylate carbamide was calculated. Samples were removed at definite intervals of time and analyzed by this procedure. The method used is essentially that of Edwards (1).

McIlvaine's buffer was used from pH 3 to 6; Palitzsch's buffer was used from pH 7 to 9. At less than pH 3, Sorensen's citrate-hydrochloric acid buffer was employed. In the presence of polyhydric alcohols, an ammonium hydroxide-ammonium chloride buffer was used instead of Palitzsch's buffer to avoid the formation of a strongly ionized, complex acid (9). The additives were dissolved in the buffer and equilibrated to 40°. Any adjustments in pH were made using a Beckman pH meter model H. All concentrations are expressed in terms of per cent weight in volume.

RESULTS AND DISCUSSION

The rate of hydrolysis of calcium acetylsalicylate carbamide was followed over a pH range of 1 to 9 at 25, 40, and 50°. A plot of the logarithm of concentration against time produced a straight line

Received November 29, 1961, from the College of Pharmacy, University of Nebraska, Lincoln.

indicative of a pseudo first-order reaction with the net velocity being a function of several possible reactions (1, 3). Figure 1 is typical of the results obtained.

The observed velocity constants were determined and are plotted in Fig. 2. The velocity constants are expressed in reciprocal hours.

It was thought desirable to compare the stability of calcium acetylsalicylate carbamide under these conditions with the stability of acetylsalicylic acid.

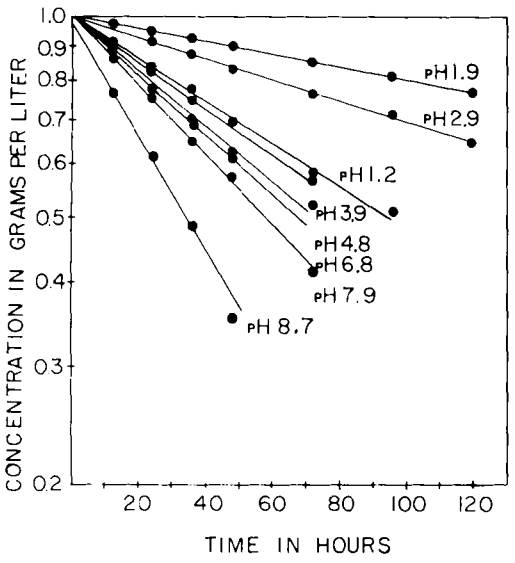

Fig. 1.—Pseudo first-order hydrolysis of calcium acetylsalicylate carbamide at 25°.

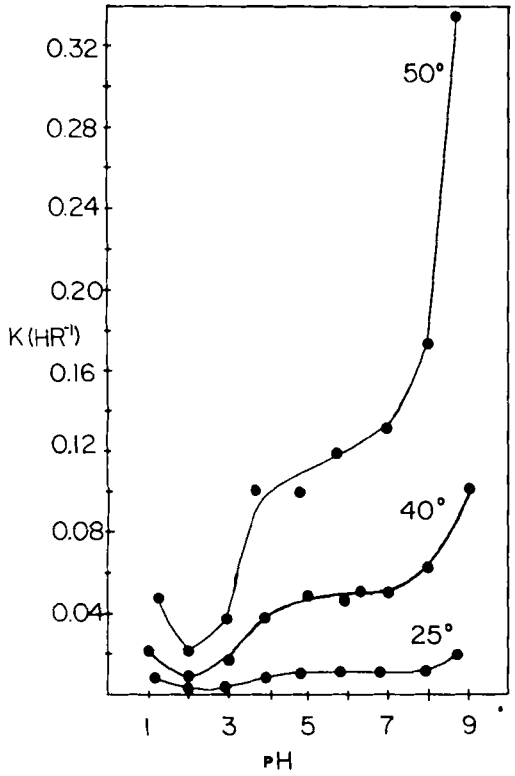

Fig. 2. -Observed velocity constants for calcium acetylsalicylate carbamide hydrolysis as a function of pH.

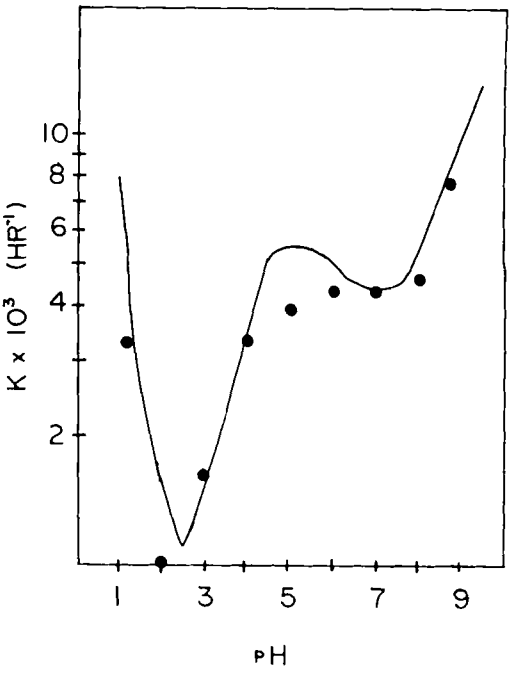

Fig. 3.—Observed velocity constants for aspirin and calcium acetylsalicylate carbamide hydrolysis at 17° as a function of pH. ——, drawn from Edwards, L., *Trans. Faraday Soc.*, **46**, 730(1950); ●, calculate K at 17° for calcium acetylsalicylate carbamide.

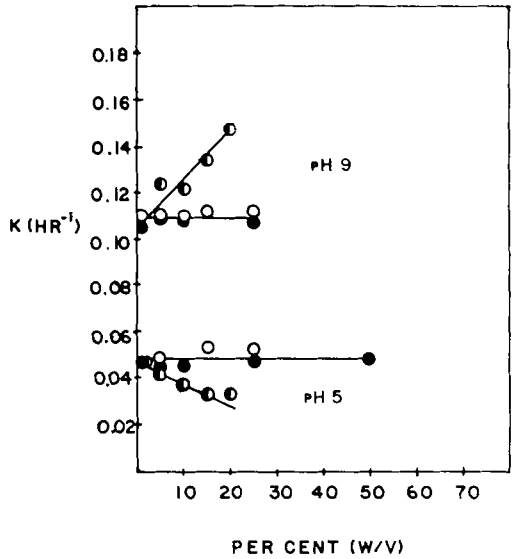

Fig. 4.– Observed velocity constants for calcium acetylsalicylate carbamide hydrolysis at 40° as a function of concentration of polyethylene glycol 6000, polyvinylpyrrolidone, and sodium lauryl sulfate. ●, Polyethylene glycol 6000; ○, polyvinylpyrrolidone; ◐, sodium lauryl sulfate.

By the use of the Arrhenius equation, the energy of activation was determined and the velocity constants for calcium acetylsalicylate carbamide at 17° were calculated for comparison with the work of Edwards. An examination of Fig. 3 shows that within experimental error, the hydrolytic stability of acetylsalicylic acid and calcium acetylsalicylate carbamide are identical. At 25° the velocity constant for the hydrolysis of calcium acetylsalicylate carbamide was the same as that of acetylsalicylic acid as determined by Garrett (3).

Bolton (4) has shown that although the pH of an acetylsalicylic acid solution is the major consideration in determining the rate of hydrolysis, certain additives, such as a solution of sodium citrate and phosphate, increase degradation. A similar effect was found at a pH 9 with a change of buffer in a solution of calcium acetylsalicylate carbamide. As shown in Figs. 4 and 6, at pH 9 the velocity constant is 0.11 hr.$^{-1}$ and 1.44 hr.$^{-1}$ in Palitzsch's buffer and ammonium hydroxide-ammonium chloride buffer, respectively. This variation presents another example of the necessity of considering the additives, *per se*, as well as the pH the additives maintain.

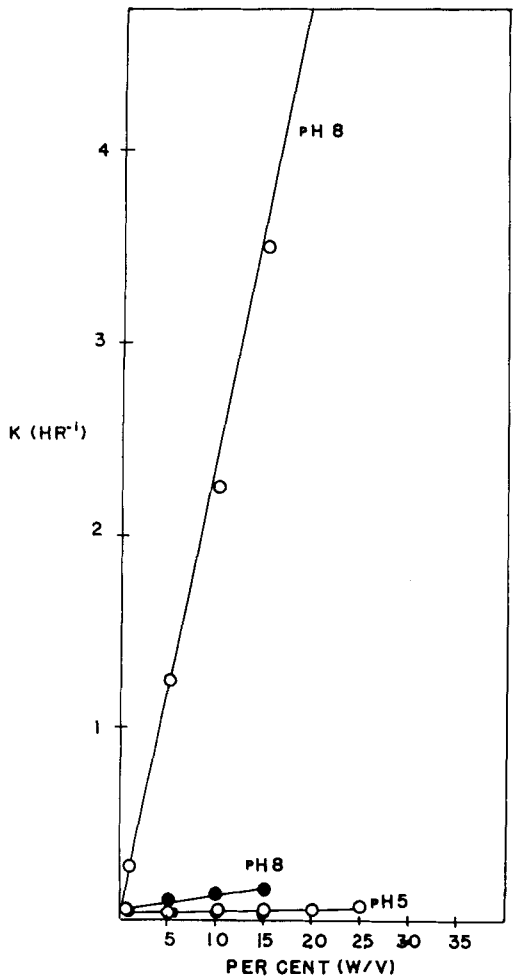

Fig. 5.—Observed velocity constants for calcium acetylsalicylate carbamide hydrolysis at 40° as a function of concentration of glycine and gelatin. O, Aminoacetic acid; ●, gelatin.

Also, it is shown in Fig. 5 that aminoacetic acid increased the rate of hydrolysis of calcium acetylsalicylate carbamide. Thus, if one attempted to buffer a calcium acetylsalicylate carbamide solution at an acidic pH using Sorensen's glycocoll-hydrochloric acid buffer, the resulting formulation would be less stable than a similar product buffered to the same pH, using McIlvaine's buffer.

It is the purpose of this work to observe, at an acidic and an alkaline pH, the rate of hydrolysis as a function of the concentration of common pharmaceutical ingredients; therefore, no attempt has been made to maintain a given ionic strength but the additives were added as they might be in actual developmental procedures.

Nonionic Polymers.—Polyethylene glycol 6000 and polyvinylpyrrolidone were chosen as examples of polymers frequently used in compounding pharmaceuticals. From 0.1 to 50% polyethylene glycol 6000 was added to calcium acetylsalicylate carbamide solutions buffered at pH 5 and 9 at 40°. The observed velocity constants were determined at each concentration and plotted in Fig. 4. Polyethylene glycol 6000 in concentrations up to 50% had no effect on the hydrolytic rate of calcium acetylsalicylate carbamide at pH 5 and 9 at 40°.

Similar experimentation with polyvinylpyrrolidone in concentrations from 1 to 25% showed no effect on the rate of hydrolysis of calcium acetylsalicylate carbamide.

It has been reported that polyethylene glycols retard the hydrolysis of acetylsalicylic acid solutions (10). Although the concentrations of these polymers were high, the mole fractions of the polymers were small. It may be for this reason that no stabilization was observed in this work and it would appear that to have any value as a stabilizer of solutions of acetylsalicylic acid or its derivatives, the polymers should completely replace water in a liquid preparation.

Polyols.—The use of sugar and glycerin has been suggested as a means of retarding the hydrolysis of solutions of aspirin (11, 12). The wide-spread use

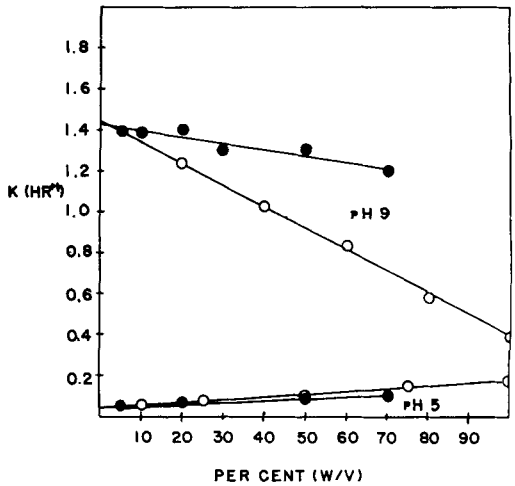

Fig. 6.—Observed velocity constant for calcium acetylsalicylate carbamide hydrolysis at 40° as a function of concentration of polyols. ●, Glycerin; O, sorbitol.

of sorbitol in liquid pharmaceuticals suggested that sorbitol be investigated in regard to its effect on the hydrolysis of calcium acetylsalicylate carbamide. As shown in Fig. 6, at pH 9 an increase in the concentration of glycerin or sorbitol decreased the rate of hydrolysis. With 70% sorbitol, the half-life was increased approximately 15%; with 100% glycerin, the half-life was increased almost threefold. This is in agreement with other workers who suggested that sorbitol and glycerin may bind water tenaciously so the water is less available for chemical interaction, thus enhancing the stability of the preparation (13).

At pH 5 the rate of hydrolysis increased as the concentration of glycerin or sorbitol increased. At pH 5, the half-life of calcium acetylsalicylate carbamide in 70% sorbitol decreased approximately one-half; in 100% glycerin, the half-life decreased to roughly one-third. It is difficult to rationalize this behavior in view of the above statement. According to the available water theory, a given concentration of sorbitol or glycerin should bind the same amount of water in both alkaline and acidic medium. The fact that this is not actually the case suggests that some other mechanism is operative.

Amphoteric Amines.—Aminoacetic acid and gelatin were chosen as typical amphoteric substances that might be used in pharmaceutical formulation. As shown in Fig. 5, an increase in aminoacetic acid concentration in both alkaline and acidic medium increased the rate of hydrolysis. At pH 5, the addition of 25% aminoacetic acid decreased the half-life of calcium acetylsalicylate carbamide approximately 40%; at pH 8, the addition of 25% aminoacetic acid decreased the half-life almost tenfold.

At pH 5, there was little significant change in the stability of calcium acetylsalicylate carbamide upon the addition of up to 15% gelatin. At a pH 8, the increase in gelatin concentration caused an increase in the rate of hydrolysis; 15% gelatin produced approximately a 60% decrease in the half-life.

It appears that protein-type additives decrease the hydrolytic stability of calcium acetylsalicylate carbamide in both alkaline and acidic solutions.

Surfactant.—Anionic surface-active agents are occasionally used as aids to facilitate tablet disintegration, as wetting agents, and as dispersing agents. Although the amounts employed are small, it seemed advisable to determine the effect of a typical anionic surfactant, such as sodium lauryl sulfate, on the hydrolysis of calcium acetylsalicylate carbamide. At pH 5, it was found that an increase in the concentration of sodium lauryl sulfate retarded hydrolysis; 20% sodium lauryl sulfate increased the half-life approximately one-third. At pH 9, 20% sodium lauryl sulfate produced approximately 30% *reduction* in half-life.

One might postulate that in acidic medium the surfactant is in the highly polar form of a sulfuric acid derivative. This strong dipole may decrease the activity of the water, thus slowing the rate of hydrolysis. In alkaline medium, the salt form of the surfactant may have less affinity for water, resulting in a greater activity for water and a more rapid hydrolysis in alkaline solution.

SUMMARY

1. The hydrolytic kinetics of calcium acetylsalicylate carbamide were studied over a pH range from 1 to 9 at 25, 40, and 50°.

2. In evaluating the stability of a solution, the effect of the constituents *per se* should be evaluated as well as the pH effect.

3. In acidic solution, aminoacetic acid, glycerin, and sorbitol increased the rate of hydrolysis of calcium acetylsalicylate carbamide solutions.

4. In alkaline solution, aminoacetic acid, gelatin, and sodium lauryl sulfate increased the rate of hydrolysis of calcium acetylsalicylate carbamide solutions.

5. In alkaline solution, glycerin and sorbitol decreased the rate of hydrolysis of calcium acetylsalicylate carbamide solutions.

6. In acidic solutions, sodium lauryl sulfate decreased the rate of hydrolysis of calcium acetylsalicylate carbamide solutions.

7. In both acidic and alkaline solution, polyethylene glycol and polyvinylpyrrolidone had no effect on the rate of hydrolysis of calcium acetylsalicylate carbamide solutions.

Anticancer Evaluation of *Amphipterygium adstringens*

By EDWARD E. GONZALEZ†, GEORGE F. McKENNA‡, and JAIME N. DELGADO

The antineoplastic activity of numerous *Amphipterygium adstringens* fractions has been studied on dba mice bearing RC mammary adenocarcinoma. Methods of anticancer evaluation are fully described. Several tumor inhibitors, as well as activators, were found in the various drug fractions. The methanol extract of the whole drug exhibited the most pronounced inhibitory activity. The tumor-damaging capacity of the drug has been shown to be mainly associated with the saponin-containing fractions.

THE POSSIBILITIES of discovering natural products with anticancer activity have been the motivation for establishing and maintaining many screening programs in cancer laboratories throughout the country. Although research in this area is mainly concerned with negative data, it is hoped that reports of this nature will spare others the time and effort of investigating sources which have proved to be of no value, and secondly, will focus attention on substances that are worthy of further exploration. Little progress has been reported in the field of cancer chemotherapy and promising leads are still as scarce today as they were several years ago (1, 2).

Several laboratories with cancer screening programs have reported the testing of plant extracts for possible adverse tumor effects. Belkin and associates have published a series of papers on the tumor-damaging action of numerous plant preparations (3–5). Faust and coworkers have reported in some detail the antineoplastic activity of *Citrullus colocynthis* on Sarcoma-37 (6). More recently, McKenna, *et al.* (7), examined numerous essential oils as potential antitumor agents. Testing and screening materials for anticarcinogenic activity have been routine in the Clayton Foundation Biochemical Institute cancer research laboratories for a number of years (8–12).

This study was initiated after preliminary screening tests showed that *Amphipterygium adstringens* Schlecht, fam. *Julianiaceae* possessed a certain degree of anticancer activity in both mice and embryonated eggs (9). Since *Amphipterygium adstringens* was readily available in ufficient quantity, a simultaneous chemical investigation was conducted on the drug in an effort to ascertain the nature of the component responsible for the antineoplastic activity (13).

Received December 6, 1961, from the College of Pharmacy, Division of Pharmaceutical Chemistry, University of Texas, Austin 12.

Accepted for publication January 5, 1962.

This paper is abstracted in part from a thesis submitted to the Graduate School of The University of Texas by Edward E. Gonzalez in partial fulfillment of the requirements for the degree of Master of Science.

EXPERIMENTAL

Fractionation of Drug.—The drug fractions used in this study were essentially those isolated during the course of the phytochemical investigation (13). The various drug fractions that were isolated and prepared for this study are schematically outlined in Fig. 1.

Preparation of Drug Fractions.—The drug fractions were stored in the refrigerator and processed for testing as soon as possible to avoid possible loss of biological activity. Before the drug fractions were tested biologically, they were sterilized by one of two methods. Water-soluble extracts were sterilized by filtering through a Selas No. 2 porcelain filter. Other extracts were sterilized by placing the material in a sterile Erlenmeyer flask containing a small quantity of 70% alcohol. The flask was placed in a desiccator under aseptic conditions and the alcohol evaporated by use of a vacuum pump. Acetone-soluble extracts were tested by the latter method with the exception that acetone was used in place of 70% alcohol. The extracts were then checked for sterility according to procedures described in previous reports (9). Sterile extracts were tested for toxicity by trials in mice. Subdermal injections of various concentrations were made and the effect produced on weight and visceral organs was noted. It was important to select a dosage range that would give distinguishable results between possible toxic reactions and tumor damage.

Type of Neoplasms.—The fractions were tested for antineoplastic activity against RC mammary adenocarcinoma in dba mice. This mammary tumor has been employed for screening purposes in other cancer research laboratories (14). Transplants of RC mammary adenocarcinoma in the dba strain have been maintained in the Clayton Foundation Biochemical Institute cancer laboratories since the time of their spontaneous development in 1941. The preliminary screening tests were conducted on C_3H mouse mammary carcinoma cultivated in eggs (15), since the time and effort involved is much less than that required by the animal transplant method.

Methods of Anticancer Evaluation.—The method described for the anticancer evaluation studies is somewhat similar to that reported earlier by

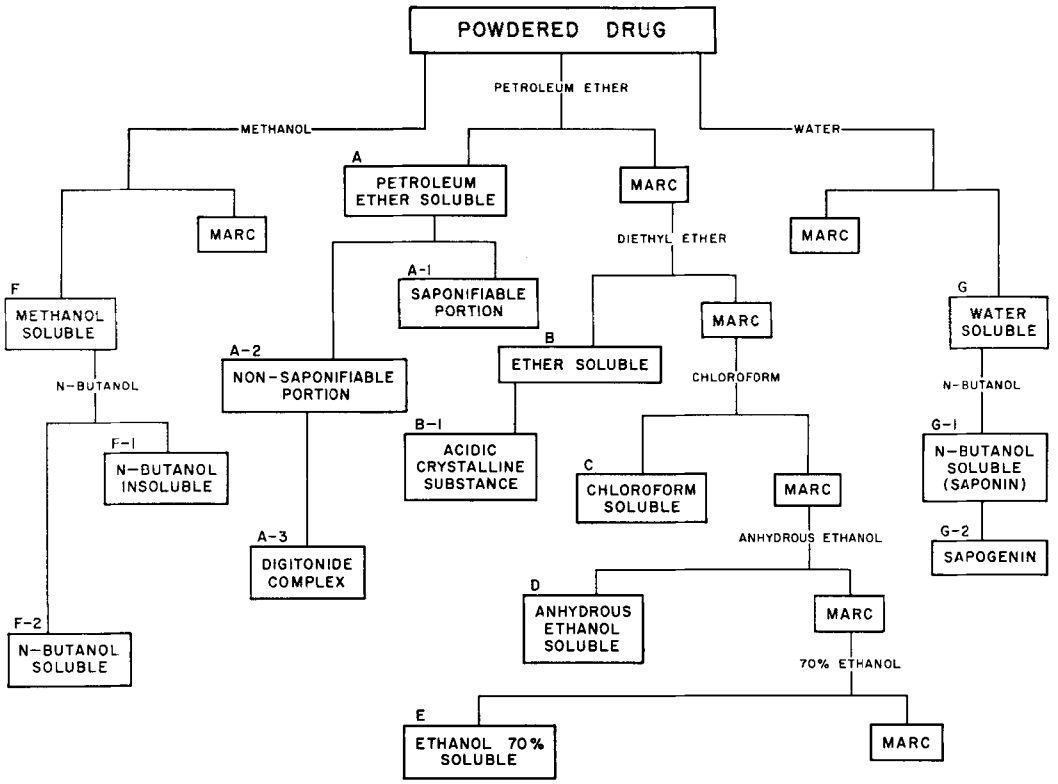

Fig. 1.—Fractionation of *Amphipterygium adstringens*.

McKenna and co-workers (9, 11). The dba mice used in this study were kept in stock at least 10 days before use and were maintained on regular laboratory chow and water, *ad libitum*. Transplants of the RC mammary adenocarcinoma were made by subdermal injections of sterile tumor suspensions. Fresh homogenized tumor tissue (0.02 ml.) dispersed in 0.2 ml. of 0.85% saline solution was injected in the right inguinal area. The mice were then divided randomly into equal groups. One group was kept as control, and received in the left inguinal area an injection of 0.2 ml. of sterile water for injection. The remaining mice, designated as the experimental group, received daily injections of the test fraction for 7 days. The test fractions were likewise administered in the left inguinal region, in the form of either aqueous solutions or suspensions, 72 hours after tumor implantation. All of the test fractions were used in concentrations of 750 mcg./ml. Only during the preliminary experiments were saturated solutions near maximum tolerated doses employed. All the animals were sacrificed on

[a] Control equals 100%.

the eleventh day of tumor growth and the weights of the animals and tumors recorded. The effectiveness of the drug fractions was evaluated on the basis of the difference in the average weight of the tumor in the experimental group as compared with the tumor growth in the control animals.

RESULTS AND DISCUSSION

The experimental results are given in Table I. It will be noted from the data shown that the methanol extract (F) of the whole drug exhibited the greatest amount of inhibition. This particular extract (F) induced a 54% decrease in tumor growth as compared with controls. Comparable inhibitory activity was exhibited by the *n*-butanol fraction (F-2) of the methanol extract (F). The F-2 fraction evinced a 50% decrease in tumor growth as compared with controls. In general, the most significant inhibitory activities were demonstrated by fractions D, E, F, F-2, G, and G-1. In addition to these inhibitory fractions, growth activators were found among the various drug fractions. Tumor growth was stimulated primarily by the petroleum ether (A) and chloroform (C) extracts of the drug. The petroleum ether extract (A) increased tumor growth by 57% as compared with controls. The chloroform extract (C) accelerated and increased tumor growth by as much as 113%. Body weight was not affected by the various fractions, with the possible exception of the acidic crystalline substance (B-1) isolated from the ether extract (13). The B-1 treated animals experienced an average body weight loss of 4.21 Gm. as compared with the average body weight of all other treated animals.

None of the experimental animals showed any toxic drug symptoms. However, upon autopsy, it was noted that some of the experimental animals did have irritation at the site of drug release and that, in a few cases, the drug was not thoroughly dispersed and absorbed. These manifestations were mainly associated with those fractions (A, A-1, A-2, B) which were administered in the form of suspensions.

Since the inhibitory activities of the saponin-containing fractions (D, E, F, F-2, G) were comparable to that of the isolated saponin (G-1), it is suggested that the anticarcinogenic action of *Amphipterygium adstringens* is primarily attributed to the presence of the steroidal saponin. Although this generalization is well supported by the fact that the saponin-exhausted fraction (F-1) exhibited a loss of inhibitory activity, it is rather difficult to justify completely the inhibitory activity on this observation since saponins are well known for their characteristic hemolytic activity, and yet no deleterious effects were observed. It should be noted also that the aglycon fraction (G-2) possessed no biological activity. Compared with the saponin (G-1), the aglycon fraction (G-2) lost inhibitory activity by 49%. These data indicate that the carbohydrate residues may play an important role in the biological action of the steroidal saponin. It may well be that the carbohydrate residues significantly affect absorption and distribution of the agent, as in the case of the cardioactive glycosides.

SUMMARY

Over 150 dba mice bearing RC mammary adenocarcinoma were used to study the antineoplastic effect of *Amphipterygium adstringens*, Schlecht. Numerous drug fractions were prepared and evaluated for anticancer activity. The results of this investigation are summarized.

1. The methanol extract (F) of the whole drug exhibited the most pronounced inhibitory activity. A 54% decrease in tumor growth was induced by the crude extract as compared with controls

2. Tumor growth was stimulated by the petroleum ether (A) and chloroform (C) extracts of the drug.

3. The saponin-containing fractions (D, E, F, F-2, G) exhibited inhibitory activity comparable to the isolated saponin (G-1).

4. The saponin-exhausted fraction (F-1) showed complete loss of inhibitory activity.

5. In contrast to the saponin (G-1), the aglycon (G-2) evinced no biological activity. Compared with the saponin (G-1), the aglycon (G-2) lost inhibitory activity by 49%.

6. Body weight was affected only by the acidic crystalline substance (B-1) isolated from the ether extract. An average body weight loss of 4.21 Gm., as compared with other treated animals, was noted.

7. The experimental results indicate that the anticarcinogenic activity of *Amphipterygium adstringens* may be due to the presence of the steroidal saponin (G-1).

Isotonic Solutions XII

Permeability of Red Corpuscles to Various Water-Soluble Organic Iodine Compounds

By LORNE A. SCHNELL† and WILLIAM J. HUSA

In the present investigation, inquiry was made into the penetration effects of certain water-soluble organic iodine compounds with respect to the human erythrocyte membrane. Employing the hemolytic method, van't Hoff factors were calculated for each compound. The results indicated that all compounds studied yielded hemolytic *i* values which were higher than *i* values obtained by the freezing point method. Experiments were also conducted in the presence of 0.2% sodium chloride; in some cases this had the effect of lowering the hemolytic *i* values. Some tests were made in which the defibrinated blood used in determination of hemolytic *i* values was replaced by whole blood containing heparin sodium. The *i* values obtained with heparinized blood were in agreement with the *i* values resulting from the use of defibrinated blood. None of the compounds studied appeared to cause hemolysis of erythrocytes by penetration of the cell; hemolysis was noted only in hypotonic solutions of these compounds.

PREVIOUS investigations (1–10) have dealt with the permeability of erythrocytes to a variety of chemical compounds. The purpose of the present study was to determine the permeability of erythrocytes to various water-soluble organic iodine compounds used as contrast media in roentgenographic diagnostic procedures. This class of compounds is administered parenterally in relatively high concentrations. No references were found in the literature on the permeability of erythrocytes to any of the compounds used in the present study. Hence, experiments were conducted to determine the hemolytic *i* values of some of the water-soluble organic iodine compounds; *i* values were also determined by the freezing point method.

EXPERIMENTAL

Collection of Blood.—In experiments utilizing defibrinated blood, samples were obtained and treated in precisely the same manner as described by Husa and co-workers (1–10). In experiments requiring heparinized blood, the sample was obtained in an identical fashion and immediately added to a 10-ml. graduated centrifuge tube which contained 0.05 ml. of heparin sodium solution, 10,000 units per ml., such that the 10-ml. heparinized blood sample contained 50 units of heparin sodium per ml. The centrifuge tube was inverted several times to insure thorough mixing, and the heparinized sample was then transferred to a 50-ml. Erlenmeyer flask and treated in the same manner as defibrinated blood.

Samples were obtained principally from the forearm veins of a 27-year old white male. On several occasions samples were generously donated by volunteers.

Preparation of Solutions.—Solutions of compounds which were available as water-soluble salts were prepared in essentially the same manner as described by other workers (1–10). Iodipamide sodium, iodipamide methylglucamine, and diatrizoate methylglucamine solutions were prepared by dissolving a quantity of the free acid in a solution containing an equimolar quantity of the proper base.

Calculation of Hemolytic *i* Values.—Quantitative determinations of per cent hemolysis and calculations of hemolytic *i* values were carried out in the manner described by Grosicki and Husa (2).

Chemicals.—All organic iodine compounds used in the investigation were generously contributed by their manufacturers: sodium diprotrizoate, sodium acetrizoate, and sodium iodohippurate by Mallinckrodt Chemical Works; sodium methiodal, iodopyracet, and sodium diatrizoate by Sterling-Winthrop Research Institute; iodipamide, diatrizoic acid, and methylglucamine by Squibb Institute for Chemical Research.

Freezing Point Determinations.—The apparatus used to determine the freezing points was that of Bartley (11), as modified by Husa and Adams (1). van't Hoff *i* factors were calculated according to the formula

$$\Delta T_f = K_f i m$$

where ΔT_f is the change in the freezing point of water after the addition of solute, K_f is the molal freezing point constant for water (1.86), i is the van't Hoff factor, and m is the molality of the solution.

Results with Heparinized Blood.—Some investigators (12) have used heparinized blood in experiments on isotonicity of solutions. Hence, the question arose as to whether results obtained with heparinized blood would be comparable with those using defibrinated blood. To throw light on this question, hemolytic *i* values were determined for the 10 compounds listed in Table I using the same procedure as before except that defibrinated blood was replaced by whole blood containing 50 units/ml. of heparin sodium. The *i* values obtained with

Diatrizoate methylglucamine	2.37	2.49	2.73	2.53
Diatrizoate methylglucamine[b]	2.48	2.54	2.75	2.59

[a] All *i* values represent an average of two blood samples.
[b] Values determined in the presence of 0.2% sodium chloride.

TABLE II.—VALUES OF *i* OF VARIOUS ORGANIC IODINE COMPOUNDS CALCULATED FROM FREEZING POINT DATA OBTAINED WITH A MODIFIED BARTLEY APPARATUS

Compound	Molality of Solution	Average Freezing Point Depression	*i* Value
Sodium diprotrizoate	0.025	0.087	1.87
Sodium methiodal	0.025	0.085	1.83
Sodium acetrizoate	0.025	0.089	1.91
Sodium iodohippurate	0.025	0.091	1.95
Sodium iodomethamate	0.025	0.138	2.97
Iodipamide sodium	0.025	0.138	2.97
Iodipamide methylglucamine	0.025	0.137	2.94
Iodopyracet	0.025	0.077	1.66
Sodium diatrizoate	0.025	0.091	1.95
Diatrizoate methylglucamine	0.025	0.093	2.00

heparinized blood agreed closely with the *i* values which resulted from the use of defibrinated blood, the differences being within experimental error.

DISCUSSION

The values of *i* obtained by the hemolytic method for the organic iodine compounds were consistently higher than the corresponding *i* values obtained by the freezing point method (see Table II). In solutions of some substances, erythrocytes lose electrolytes from within the cell, thus causing a decrease in internal osmotic pressure and a corresponding ncrease in resistance to hemolysis (2). Possibly such exosmosis from erythrocytes may occur in solutions of the organic iodine compounds, causing the higher *i* values obtained experimentally.

The difference between the hemolytic *i* value and the *i* value obtained by the freezing point method was smallest with sodium methiodal; in this case the hemolytic *i* value was 1.95 and the *i* value by the freezing point method was 1.83. In this connection it is of interest to note that sodium methiodal was the only nonaromatic compound used in this investigation.

The exosmosis from erythrocytes in solutions of some substances can be corrected in some cases by addition of a small proportion of sodium chloride (2). The presence of 0.2% sodium chloride reduced the hemolytic *i* values of some of the compounds tested, *e.g.*, sodium iodomethamate, iodipamide sodium, and iodipamide methylglucamine. In case of iodopyracet the hemolytic *i* value was reduced from 2.18 to 1.63 by the presence of 0.2% sodium chloride; the latter value agreed closely with the *i* value of 1.66 obtained by the freezing point method. For some of the other compounds, the abnormally high values of *i* by the hemolytic method were not reduced by the presence of 0.2% sodium chloride.

SUMMARY

1. Hemolytic *i* values obtained for various organic iodine compounds were consistently higher than the corresponding *i* values obtained by the freezing point method. In some, but not all, cases the hemolytic *i* values were lowered by the presence of 0.2% sodium chloride.

2. The organic iodine compounds tested apparently do not penetrate the human erythrocyte.

3. Hemolytic *i* values obtained for the organic iodine compounds using defibrinated blood were in agreement with similar values obtained with heparinized blood.

Ergotamine Tartrate U.S.P.

By G. L. SZENDEY

On the basis of melting point and solubility, ergotamine tartrate U.S.P. is a mixture of ergotamine tartrate and ergotamine bitartrate. Several samples with different properties were studied by means of titrimetric methods in nonaqueous media using 0.05 *N* perchloric acid and 0.1 *N* potassium methoxide. The melting point well indicates the approximate ratio of ergotamine tartrate-bitartrate mixture. Ergotamine tartrate with a melting point of about 180° (decompn.) contains about 83% ergotamine base, equivalent to 94% ergotamine tartrate.

SEVERAL authors reported (1–4) a discrepancy concerning ergotamine tartrate U.S.P. It was stated that requirements for solubility and melting point represent, contrary to the British Pharmacopoeia, a mixture of ergotamine tartrate and ergotamine hydrogen tartrate (ergotamine bitartrate).

Table I lists the differing requirements of the British Pharmacopoeia and the United States Pharmacopeia of ergotamine tartrate.

The present paper reports on quantitative studies of ergotamine tartrate samples with different melting points and discusses questions deriving from the above-mentioned problem.

METHOD

Apparatus.—Microburets, 3 or 5 ml. Melting range apparatus with light paraffin bath and calibrated thermometer (type II, U.S.P. XVI).

Assay of Ergotamine Base in Ergotamine Tartrate

Reagents.—All reagents are analytical grade. *Glacial acetic acid*, Merck. *Anhydrous acetic acid* (1000 ml. of glacial acetic acid mixed with 60 ml. of acetic anhydride). *Crystal violet indicator*, 0.25% in anhydrous acetic acid. *Perchloric acid*, 0.05 *N*, prepared by mixing 5.5 ml. (8.4 Gm.) of perchloric acid (60%, d. 1.54) with 200 ml. of anhydrous acetic acid and 20 ml. of acetic anhydride; cooling the solution, then adding anhydrous acetic acid to make 1000 ml. The normality factor was obtained by titration against sym.-diphenylguanidine (mol. wt. 211.26, m.p. 147–149): approximately 20 mg., accurately weighed, was dissolved in 15 ml. of anhydrous acetic acid, 1–2 drops of crystal violet indicator was added and titrated with the perchloric acid solution until the violet color changed to blue-bluish green. Each 10.56 mg. of sym.-diphenylguanidine is equivalent to 1 ml. of 0.05 *N* perchloric acid.

Procedure.—About 70 mg. of ergotamine tartrate, accurately weighed, was dissolved in 15 ml. of anhydrous acetic acid, 1–2 drops of crystal violet indicator was added and titrated with 0.05 *N* perchloric acid until the violet color changed to blue-bluish green. Each 32.84 mg. of ergotamine tartrate [mol. wt. 1313.46, $(C_{33}H_{35}N_5O_5)_2.C_4H_6O_6$] or each 29.08 mg. of ergotamine base (mol. wt. 581.65, $C_{33}H_{35}N_5O_5$) is equivalent to 1 ml. of 0.05 *N* perchloric acid. Accuracy, ±0.5%.

Assay of Tartaric Acid in Ergotamine Tartrate

Reagents.—All reagents are analytical grade. *Anhydrous methanol. Potassium metal. Benzene*, dried over potassium metal. *Pyridine. Naphtholbenzein* (Merck) indicator, 1% in pyridine. *Potassium methoxide*, 0.1 *N*, prepared as follows: about 4.3 Gm. of freshly cut potassium metal was added, in small portions, to 150 ml. of ice-cooled anhydrous methanol contained in a 1000-ml. volumetric flask. When dissolved, sufficient benzene was added to make 1000 ml. The solution was preserved in a container, well protected from light and moisture. Standardization was made by titration against benzoic acid, Merck (mol. wt. 122.12): approximately 25 mg., accurately weighed, was dissolved in 15 ml. of neutralized pyridine, 1 drop of naphtholbenzein indicator was added and titrated with the potassium methoxide solution until the yellow color changed to green. Each 12.21 mg. of benzoic acid is equivalent to 1 ml. of 0.1 *N* potassium methoxide.

Procedure.—Ergotamine tartrate, 100–150 mg., accurately weighed, was dissolved in 15 ml. of neutralized pyridine, 3 drops of naphtholbenzein indicator was added and titrated with 0.1 *N* potassium methoxide until the yellow color changed to green. Protect the solution from the carbon dioxide of the atmosphere. Each 7.504 mg. of tartaric acid is equivalent to 1 ml. of 0.1 *N* potassium methoxide. Accuracy of the method, ±1.0%.

RESULTS

Analytical data of assays are reported in Table II. Estimation of ergotamine base was carried out in anhydrous acetic acid by using 0.05 *N* perchloric acid. Each value presented is the average of four parallel analyses. Evidently there is a large scale of possibilities between ergotamine tartrate and bitartrate to produce mixtures of both salts, where melting point indicates the approximate ratio.

Received January 27, 1962, from Research Laboratories, Sanol-Arzneimittel Dr. Schwarz GmbH., Monheim bei Düsseldorf, Bundesrepublik Deutschland.
Accepted for publication February 26, 1962.

183–184 (decompn.)	84.51	88.57	15.17	11.43	99.68
187–188 (decompn.)	86.63	88.57	12.59	11.43	99.22
189–191 (decompn.)	89.03	88.57	10.49	11.43	99.52

[a] All values are calculated on dried substance (100° *in vacuo*). The present data are average values of three parallel analyses.

assay of tartaric acid in ergotamine tartrate was carried out by a modified titrimetric method of Gyenes and Szász (5), using 0.1 *N* potassium methoxide and naphtholbenzein indicator which gave an exact end point.

All samples were checked for purity by paper chromatograms using a modified Macek method (R_f of ergotamine, about 0.1) (4, 6, 7). No ergotaminine or other alkaloid contaminant was found.

DISCUSSION

As is shown in Table II, ergotamine tartrate U.S.P. contains about 60% ergotamine bitartrate and 40% ergotamine tartrate. On the basis of the found base content, calculated on ergotamine tartrate, there is a deviation of about 6% (in case of ergotamine bitartrate, 10.25%) from 100.00% ergotamine tartrate.

The van Urk colorimetric method (*p*-dimethylaminobenzaldehyde T.S. as reagent) yields an accuracy of about ±4–6% when the U.S.P. XVI directions are followed. Positive errors of estimation reduce the deviation partly or completely, recording a more-or-less pure ergotamine tartrate. Against that, negative errors in the van Urk method and the alleged error in composition (due to presence of bitartrate) together caused a deviation of up to 10 to 12%. Such a variation can be avoided by application of the much more exact perchloric acid method. Furthermore, the use of an exact method is not sufficient to reach the minimal U.S.P. requirement of 97.0%, simultaneously maintaining the requirement for melting point of 180° (decompn.) (see Tables II and III); these two requirements are incompatible.

A good soluble ergotamine salt, *e.g.*, ergotamine bitartrate, is often requested for solutions or injections. In our opinion, the slighter solubility of ergotamine tartrate is not disadvantageous for the use in pharmaceutical preparations, because in the case of tablets, ergotamine (base or tartrate) is absorbed by the stomach in the form of the hydrochloric salt, and in the case of injections or solutions (prescribed pH 3–4, adjusted by tartaric acid), ergotamine tartrate is converted into the bitartrate salt.

SUMMARY

1. Quantitative studies using titrimetric methods in nonaqueous media indicated that ergotamine tartrate U.S.P. with a melting point of 180° (decompn.) contains about 60% ergotamine bitartrate.

2. Melting points between 170–192° (decompn.) indicate the approximate ratio of ergotamine bitartrate-tartrate mixture.

3. Application of the perchloric acid titrimetric method (accuracy, ±0.5%) for the assay of ergotamine tartrate substance yields more exact quantitative data than the official van Urk colorimetric method (accuracy, ±4–6%).

Quaternary Ammonium Germicides as Surface Disinfectants

By CHARLES J. BANKS†, GEORGE F. REDDISH, and C. LEE HUYCK‡

The quaternary ammonium compounds tested proved to be excellent germicides in the dilutions recommended by the manufacturer for waxed and unwaxed floor coverings. In the case of waxed stainless steel, it was assumed that the wax interfered with the disinfectant action because the unwaxed stainless steel was found to be sterile. Quaternary ammonium germicides were found to be unsatisfactory disinfectants for vinyl tile.

THE PURPOSE of this study is to determine whether the quaternary ammonium germicides are useful as sanitizing agents in preventing the spread of infections caused by the staphylococci organisms.

The quaternary ammonium germicides are odorless, colorless, highly stable, and are relatively nontoxic when used in their recommended germicidal concentrations. In general, the quaternary ammonium germicides have been found to inhibit the oxidation of certain carbohydrates (1) and thereby interfere with respiration and glycolysis of bacteria. They are usually tested by the phenol coefficient method. Since in the United States 5% phenol is accepted as the standard of excellence for general disinfection, Reddish (2) has pointed out that dilutions 20 times the phenol coefficient afford a wide margin of safety. The dilution calculated on this basis is usually of sufficient strength to kill all pathogenic microorganisms which cause epidemics.

Although the phenol coefficient is an excellent *in vitro* test, in light of the increase of staphylococcus infections in hospitals, a practical test is recommended. The phenol coefficient test employs *Salmonella typhosa* which is similar in resistance to most disease-producing microorganisms. There are some organisms that are more resistant to disinfectants than *Salmonella typhosa*, one of which is the nonspore forming *Staphylococcus aureus*.

Of particular importance to this study are the incompatabilities of the quaternary ammonium germicides which occur under normal sanitizing conditions. Domagk (3) in 1935 was the first to call attention to the interfering action of ordinary soap on the quaternary ammonium germicides. Since then, incompatibilities such as the nitrate and benzalkonium chloride incompatibility (4) have been pointed out. It is generally recognized that when surfaces have been washed with ordinary soap and water, the objects must be thoroughly rinsed with water before applying a quaternary ammonium disinfectant for sterilizing purposes. This applies to the disinfection of wounds following the cleansing procedure with soap and water.

EXPERIMENTAL[1]

Roccal 10%[2]—The active ingredient is a mixture of technical grade alkyldimethylbenzyl ammonium chlorides in which the alkyl is a mixture of C_8H_{17} to $C_{18}H_{37}$ groups. The phenol coefficient of Roccal 10% is 25 when tested against *Salmonella typhosa* at 20°. It is used for sanitizing eating and drinking utensils.

Quaternary Ammonium Germicides as Surface Disinfectants

By CHARLES J. BANKS†, GEORGE F. REDDISH, and C. LEE HUYCK‡

The quaternary ammonium compounds tested proved to be excellent germicides in the dilutions recommended by the manufacturer for waxed and unwaxed floor coverings. In the case of waxed stainless steel, it was assumed that the wax interfered with the disinfectant action because the unwaxed stainless steel was found to be sterile. Quaternary ammonium germicides were found to be unsatisfactory disinfectants for vinyl tile.

THE PURPOSE of this study is to determine whether the quaternary ammonium germicides are useful as sanitizing agents in preventing the spread of infections caused by the staphylococci organisms.

The quaternary ammonium germicides are odorless, colorless, highly stable, and are relatively nontoxic when used in their recommended germicidal concentrations. In general, the quaternary ammonium germicides have been found to inhibit the oxidation of certain carbohydrates (1) and thereby interfere with respiration and glycolysis of bacteria. They are usually tested by the phenol coefficient method. Since in the United States 5% phenol is accepted as the standard of excellence for general disinfection, Reddish (2) has pointed out that dilutions 20 times the phenol coefficient afford a wide margin of safety. The dilution calculated on this basis is usually of sufficient strength to kill all pathogenic microorganisms which cause epidemics.

Although the phenol coefficient is an excellent *in vitro* test, in light of the increase of staphylococcus infections in hospitals, a practical test is recommended. The phenol coefficient test employs *Salmonella typhosa* which is similar in resistance to most disease-producing microorganisms. There are some organisms that are more resistant to disinfectants than *Salmonella typhosa*, one of which is the nonspore forming *Staphylococcus aureus*.

Of particular importance to this study are the incompatabilities of the quaternary ammonium germicides which occur under normal sanitizing conditions. Domagk (3) in 1935 was the first to call attention to the interfering action of ordinary soap on the quaternary ammonium germicides. Since then, incompatibilities such as the nitrate and benzalkonium chloride incompatibility (4) have been pointed out. It is generally recognized that when surfaces have been washed with ordinary soap and water, the objects must be thoroughly rinsed with water before applying a quaternary ammonium disinfectant for sterilizing purposes. This applies to the disinfection of wounds following the cleansing procedure with soap and water.

[2] Winthrop Laboratories, New York, N. Y.

ingredient is *p*-diisobutylphenoxyethoxyethyldimethylbenzyl ammonium chloride. The phenol coefficient is 20. It is used in sanitizing sickrooms.

Anti-Staph. Concentrated Antiseptic Cleaner.—The active ingredients are 10.75% methyliodododecylbenzyltrimethyl ammonium chloride, isopropyl alcohol, methylododecyl xylylene bis-(trimethyl ammonium chloride), triethanolamine, potassium hydroxide, and tetrasodium salt of ethylenediamine tetraacetic acid. Inert ingredients include water, nonyl phenoxypolyoxyethylene ethanol, perfume oils, artificial color, and citric acid. The phenol coefficient by a modified Rideal-Walker method against *Salmonella typhosa* is 10 and against *Staphylococcus aureus*, 20. It is used for ordinary cleansing, sanitizing, and deodorizing.

Braxene.[3] The active ingredients are 20% high molecular weight alkyl (C_{12}, C_{14}, C_{16}, and related C_8 to C_{18}) dimethylbenzyl ammonium chlorides. Water (less than 25 p.p.m. hardness) is the diluent. Braxene is used in the asepsis of linen. The phenol coefficient for *Salmonella typhosa* is 85 at 37° and 50 at 20°; the phenol coefficient for *M. pyogenes* var. *aureus* is 81 at 37° and 55 at 20°. In addition to its effectiveness in the treatment of linen, Braxene is also recommended as a disinfectant for sorting tables, storage shelves, laundry carts, and other equipment used in the handling and storage of clothing.

Blue Chip Concentrate.[4]—The active ingredients are *n*-alkyl (50% C_{12}, 30% C_{14}, 17% C_{16}, 3% C_{18}) dimethylbenzyl ammonium chlorides 1.25%. Inert ingredients are water, detergents, a synergizing compound, water softener, dye, and perfume. In addition to cleaning and disinfecting surfaces it deodorizes, and sanitizes.

METHOD

In any practical test, a large number of organisms must be used. Floor materials used in this test were: painted wood, vinyl tile, terrazzo, and linoleum. Stainless steel was also used because of its widespread use in hospitals.

Unwaxed and waxed floor coverings were used in the tests. After washing with soap and water and rinsing with plain tap water, the slabs of floor coverings (9 in. × 9 in.) were air dried for 20 minutes. The slab was divided into 5 equal parts designated: control I, control II, blank, 5 minutes, 15 minutes, and 30 minutes. One milliliter of 1:1000 dilution of a 24-hour broth culture of *Staphylococcus aureus* at 37° was uniformly spread over the surface of the slab by means of a sterile pipet and allowed to air dry for 20 min. A control count was made on control I by streaking it 3 times with a sterile cotton swab moistened with sterile water followed by inoculation into 20 ml. of nutrient agar, swirled vigorously for 15 sec., poured into a sterile Petri dish, incubated for 48 hours at 37°. Immediately after the control swabs were made, portions designated as 5, 15, and 30 min. were covered with 2 ml. of the dilution of solution being tested which was either 20 times the phenol coefficient, or the dilution (5) recommended by the manufacturer. At the end of 5, 15, and 30 min., the portion of the slab so designated was streaked 3 times with a sterile cotton swab moistened with sterile water, followed by inoculation into 20 ml. of nutrient agar, and incubated at 37° for 48 hours. At the end of the 30-min. period, another control swabbing was made from the second control area designated control II, inoculated as previously into nutrient agar, and incubated. The total counts of the staphylococci present were made and the reductions from the control counts determined.

[3] Wyandotte Chemicals Corp., Wyandotte, Mich.
[4] S. C. Johnson & Son, Inc., Racine, Wis.

DISCUSSION

The floor coverings used were either porous or nonporous. The porous floors were either painted wood or terrazzo, while nonporous were vinyl tile or linoleum. The porous material gave a lower count than the nonporous for the controls, but this material had no effect on the germicidal activity of the quaternary germicides. In the test, a portion was designated as blank between control II and a portion designated as 5 min. These designations were safety measures to prevent the germicides from reaching the control area. Each plate that exhibited no growth was streaked with a 24-hr. culture of the test organism and incubated at 37° for 48 hours. Growth occurred in each instance, showing no bacteriostatic action of the plates. In swabbing the floor coverings, the germicide could be transferred from the floor covering to the agar. If a substantial amount was transferred, the plate would exhibit bacteriostatic action.

Phenol 5% and cresol compound 2% were used as standards for comparison since they are excellent germicides under conditions of use. Therefore, all germicides used in these tests should have the same relative bactericidal efficacy.

SUMMARY

Phenol 5% and cresol compound 2% were used as standards in performance tests on various floor coverings. The quaternary ammonium germicides were compared with these standard disinfectants on waxed and unwaxed floor coverings. The quaternary ammonium compounds tested proved to be excellent germicides in the dilutions recommended by the manufacturer. Wax on the floor coverings did not interfere with germicidal action. In the case of stainless steel, wax did interfere with the disinfectant action, probably because the wax was not absorbed on the metal. Only in one case did an organic material interfere with the germicidal activity of the quaternary ammonium compound; the interfering substance in this case was unwaxed vinyl tile.

Determination of *m*-Aminophenol (MAP) in Calcium Aminosalicylate [$Ca(PAS)_2$]

By R. B. LUERS, Jr., and L. B. STADLER

The MAP test in the N.F. XI monograph for $Ca(PAS)_2$ has been re-evaluated. Experimental data showed the test to be in need of minor changes to correct sources of error. Based on this study, recommendations are made to use sulfuric acid instead of hydrochloric acid, to change the correction factor, to determine maximum absorbance through a range of 425 to 435 mμ, and to change the time allowed for color development to 3 hours.

THE MAP test in the N.F. XI monograph for $Ca(PAS)_2$ (1) is basically a good analytical method. However, our previous work with aminosalicylic acid (PAS) and sodium aminosalicylate (PASNa) (2) showed that certain discrepancies existed in the MAP test. Subsequent studies made on $Ca(PAS)_2$ showed that the variables affecting the MAP test for PAS and PASNa applied also to the MAP test for $Ca(PAS)_2$.

To establish the absolute MAP content of some production samples of $Ca(PAS)_2$, the chromatographic procedure used in our previous studies of PAS and PASNa (2) was applied (see Table I).

EXPERIMENTAL

Proposed Modified Colorimetric Method for MAP in $Ca(PAS)_2$.—The proposed revisions of the N.F. XI test for MAP, as described under *Procedure*, were performed on samples of $Ca(PAS)_2$. The N.F. XI test for MAP was performed also on the same samples of $Ca(PAS)_2$. The basis for the revisions proposed are discussed under *Conditions Affecting the Colorimetric Determination of MAP.*

Conditions Affecting the Colorimetric Determination of MAP

Effect of Acid Used upon Absorbance Maximum of the Color Developed.—Samples of $Ca(PAS)_2$ tested by the N.F. XI method, using hydrochloric acid, gave absorbance values at 440 mμ that were about 3% lower than absorbance values obtained using sulfuric acid with the N.F. XI procedure (see Table II). In the proposed modified method described under *Procedure*, the absorbance values using hydrochloric acid were about 3 to 5% lower than were the absorbance values using sulfuric acid. Also, it was found that the use of hydrochloric acid in the initial solution sometimes produced a precipitate which could complicate the test. Based on these results and to be consistent with the proposed revised colorimetric procedure recommended for MAP in PAS and PASNa in our previous studies (2), sulfuric acid was selected.

Effect of Time upon the Color Intensity Developed.—As had been established by our previous investigations (2), the color intensity stabilized in about 3 hours after the addition of the sodium carbonate solution. Since our studies showed this to occur in the MAP test for $Ca(PAS)_2$ as well, the time lapse between the addition of the sodium carbonate solution and the measurement of color intensity has been changed to 3 hours in the proposed revised colorimetric method for MAP in $Ca(PAS)_2$, as described under *Procedure*. This characteristic in the color development was found evident in all samples of $Ca(PAS)_2$ tested.

Effect of Change in Concentration of MAP upon the Absorbance Maximum of the Color Developed.—As was shown in our previous studies (2), a shift in absorbance maximum occurred as the concentration of MAP in $Ca(PAS)_2$ was varied from 0.02 to 1.0% (see Table III). These results justified the use of a 425 to 435 mμ range for the measurement of absorbance of the color developed by the proposed revised colorimetric method described under *Procedure* for the determination of MAP in $Ca(PAS)_2$. None of the samples of $Ca(PAS)_2$ tested showed absorbance maxima at 440 mμ.

Absorbance Correction Value for Color Produced Other Than by MAP.—Based upon our study of a number of production samples of $Ca(PAS)_2$ and the correlation of data between the paper chromatographic procedure and the proposed modified colorimetric method for MAP, it was clearly established that the correction value for color produced other than by MAP should be 0.320 rather than 0.372 (see Table I).

Procedure

Weigh accurately an amount, calculated on the basis of the *Assay*, of Calcium Aminosalicylate equivalent to 562 mg. of anhydrous calcium aminosalicylate (500 mg. of aminosalicylic acid), and transfer to a 100-ml. volumetric flask. Add 1.8 ml. of sodium hydroxide T.S., and dilute to about 80 ml. with water. Add 10 ml. of dilute sulfuric acid (1 in 10), add water to volume, and mix. Within 150 seconds from the time the acid is added, transfer 5 ml. of this

TABLE I.—PER CENT OF MAP FOUND IN $Ca(PAS)_2$ BY THE DIFFERENT METHODS TESTED

Sample of $Ca(PAS)_2$ Tested	MAP Found, %		
	By Paper Chromatography	By N.F. XI Method	By Proposed Modified Method
I	<0.01	negligible[a]	<0.01
II	<0.01	negligible	<0.01
III	<0.01	negligible	<0.01
IV[b]	...	0.04	0.14
V[b]	...	0.05	0.17

1.00	435	Sharp peak occurs

solution to a second 100-ml. volumetric flask, immersed in an ice bath and containing 50 ml. of water at 0 to 5°, and add 2.5 ml. of sodium nitrite solution (1 in 100). Mix and allow to stand in the ice bath for 3 minutes ± 5 seconds. Add 25 ml. of sodium carbonate T.S., mix, and place the flask in a water bath at 25° for 15 minutes. Add water to volume, mix, allow the solution to stand at 25° for 3 hours, and filter. Determine the absorbance of the clear solution at the absorbance maximum observed in a range of 425 to 435 mμ in a 1-cm. cell with a suitable spectrophotometer, using water as the blank. Calculate the per cent of *m*-aminophenol by the formula $(A - 0.320/1.09)$, in which A is the absorbance of the solution, 0.320 is the absorbance correction factor representing color produced other than by the reaction of *m*-aminophenol initially present, and 1.09 is the factor converting absorbance to per cent of *m*-aminophenol in Calcium Aminosalicylate.

SUMMARY AND CONCLUSIONS

1. The MAP content found by the proposed modified colorimetric method was comparable to that found by paper chromatography for the $Ca(PAS)_2$ tested in this study.

2. In the addition of acid to the initial solution in the MAP test, sulfuric acid should be added instead of hydrochloric acid.

3. The color produced by both the N.F. XI and the proposed modified colorimetric method stabilized after standing for 3 hours at 25°.

4. The absorbance spectra obtained for MAP by both the N.F. XI method and the proposed modified colorimetric method showed the absorbance maxima to be between 425 and 435 mμ.

5. The correction factor for color produced other than by MAP should be 0.320, not 0.372.

6. The N.F. XI method for the determination of MAP in $Ca(PAS)_2$ is a basically reliable procedure.

7. The value, 1.09, for the conversion of absorbance to per cent MAP was correct.

8. It is recommended that the modifications, as herein described, be adopted by N.F. XI to correct minor sources of error in the determination of MAP in $Ca(PAS)_2$.

Ultraviolet Emission Spectrographic Determination of Trace Palladium to Ascertain the Method Used to Produce Tetracycline

By WILLIAM L. DUTTON and R. C. HIRT

Ultraviolet emission spectrography may be readily employed to determine trace amounts of palladium in ashed samples of tetracycline. Palladium is not found in samples prepared by direct fermentation and is always found when chlortetracycline is dechlorinated using palladium catalytically.

TWO KNOWN commercial methods are used to produce the antibiotic tetracycline. The catalytic reduction of chlortetracycline using palladium or another of the noble metals (1) and the direct fermentation of the microorganism *Streptomyces aureofaciens* (2).

METHOD

The general procedure is essentially the carbon arc method of qualitative analysis by Harvey (3) and Nachtrieb (4). The sensitivity of the method was increased by using the slowly rotating slotted disk and stationary emulsion method (5). Using a 35-mg. charge, 0.1 mcg. or 3 p.p.m. can be detected. A charge containing 3.5 mcg. or 100 p.p.m. of palladium produces up to 10 spectral lines of the metal in the region 3500 to 2450 Å.

The 600–800° ash cake is ground fine in the porcelain crucible. The exposure is 3 min. as required by the 11-slot disk (5). The spectral line palladium 3242.703 Å. is used for detecting the least amount of palladium, even though it is theoretically not the strongest. It is conveniently close to copper 3247.540 Å. for positive identification and has very little interference from a carbon line.

The length, width, and density of the line are mentally integrated into an order of magnitude value (3, 4) and applied to the least detectable concentration of 3 p.p.m. The least detectable concentration is different in each ashed sample. It depends greatly upon the amount of reduction in weight by dry ashing at 600 to 800°.

Relative Antiplasmin (Antifibrinolysin) Activity of ω-Aminocarboxylic Acids

By MICHIO MIYAMOTO† and KWAN-HUA LEE

ω-Aminocarboxylic acids with carbon chain lengths of three to eight are shown to possess antifibrinolytic activity *in vitro*. ω-Aminohexanoic acid (ε-aminocaproic acid) is the most active compound studied.

IN RECENT YEARS one of the most exciting achievements in therapeutics probably has been the introduction of several enzymes for clinical uses. One of the latest developments is human plasmin (or fibrinolysin) preparation. Plasmin is the enzyme normally present in the blood plasma in its inactive zymogen form, known as plasminogen. In the laboratory, plasminogen may be converted into plasmin by streptokinase or urokinase. Plasmin is used in the treatment of venous thrombosis, such as thrombophlebitis or phlebothrombosis, pulmonary embolism, and topical debridements. However, overdosage of injected plasmin may cause hypofibrinogenemia and uncontrolled hemorrhage. An antiplasmin agent which serves as an antidote in controlling plasma plasmin activity is highly in need.

In 1957 workers in Japan announced the discovery of an antiplasmin (antifibrinolysin) agent known as ε-aminocaproic acid. This compound was patented in Great Britain (1) and distributed by Daiichi Seiyaku Co. of Japan. Remarkable effects were obtained by the Japanese workers on cases of hemorrhagic metropathia, dysmenorrhea, threatened abortion, toxemia of pregnancy, hyperemesis gravidarum, and eczema urticaria and other dermatitis. All of these diseases are thought to be associated with increased plasmin activity. They gave this acid in doses of 10–20 Gm. per day, orally or intravenously, to more than 100 patients and observed no toxic effect (2).

The effect of ε-aminocaproic acid on a large number of clinical coagulation defects was systemically investigated in Sweden in 1960 (3). Enhanced fibrinolysis has been reported in various diseases. Pathological fibrinolysis most probably arises from increased circulating levels of plasminogen activator. Fibrinogen, often given in large quantities under these circumstances, is usually without significant effect because of its rapid destruction by plasmin. Theoretically, control of fibrinolysis by giving an inhibitor of plasminogen activation, followed by the use of fibrinogen, should be satisfactory. In these respects, ε-aminocaproic acid has proved to be promising. Favorable results have been obtained by Nilsson, Sjoerdsma, and Waldenstrom (3) in a limited number of clinical cases.

It has been suspected for some time that activated blood fibrinolysin may also play a prominent role in the pathogenesis of anaphylactic shock. Recently, Burden and co-workers (4) have demonstrated that the spontaneous lysis of clotted blood samples collected during acutely fatal shock in guinea pigs following intravenous injection of peptone, histamine, trypsin, and anaphylatoxin was found to be a regular feature of these reactions just as observed previously in guinea pigs undergoing specific anaphylactic shock (5). With the aid of a potent fibrinolysin inhibitor, it is possible to find out whether increased fibrinolytic activity is the consequence or the cause of anaphylactic shock.

The potential importance of this antiplasmin agent prompted our interest in studying the mode of action of ε-aminocaproic acid. As the first step of approach, we chose to study the relative antiplasmin activity of the homologous series of ω-aminocarboxylic acids. The results of this study are reported in this paper.

METHODS AND MATERIALS

Measurement of Fibrinolytic Activity.—For the measurement of fibrinolytic activity, the method described by Lewis and Ferguson was used with modifications (6). To a small tube add 0.5 ml. of 1% human plasma fraction I (fibrinogen) and 0.5 ml. of borate buffer (0.1*M*, pH 7.5). To a second tube, add 0.5 ml. of enzyme solution (purified human plasmin solution, 150 units) and 0.5 ml. of human thrombin (2 units). Mix the contents of the tubes by pouring back and forth twice, and then incubate at 37°. The amount of fibrinogen in the tube after being acted upon by the excess amount of thrombin present was just enough to form a turbid gelatinous fibrin solution. The amount of plasmin added was sufficient to clarify the turbid solution about 10 minutes after incubation. Buffer alone or buffer with antiplasmin agents was added in a volume of 0.3 ml. to the fibrinogen solution. The final volume in all cases was 2.3 ml. Time for the clarification of the gelatinous fibrin solution was recorded. The effect of concentration of different ω-amino acids was assayed separately at first, since preliminary experimental results indicated that the concentration range varied widely. The effective concentration range for each acid studied has been located with this method. The purpose of this type of study was to supply information for selecting an appropriate concentration at which the activities of all of the acids studied could be compared. Under the conditions described in this paper, the concentration selected was 50 mmoles per L., and the relative antifibrinolysin activity of ω-aminocarboxylic acids at this concentration was then studied.

Materials Used.—The biological materials used in the present studies were all commercial products.

Received December 9, 1961, from the University of California, School of Pharmacy, San Francisco 22.

Accepted for publication January 12, 1962.

The authors wish to thank Dr. Joseph Krezanoski of Barnes-Hind Laboratories, Sunnyvale, Calif., who first called our attention to the biological activity of ε-aminocaproic acid, for his untiring interest in this work.

† Recipient of the Lunsford Richardson Pharmacy Award, 1961.

Human fibrinogen used was Parenogen of Cutter Laboratories and the fibrinolysin used was Actase of Ortho Pharmaceutical Corp. Thrombin was obtained from Upjohn Co. All of the ω-aminocarboxylic acids used were commercial preparations and were recrystallized from either water or ethanol four times and dried in a vacuum desiccator over phosphorus pentoxide.

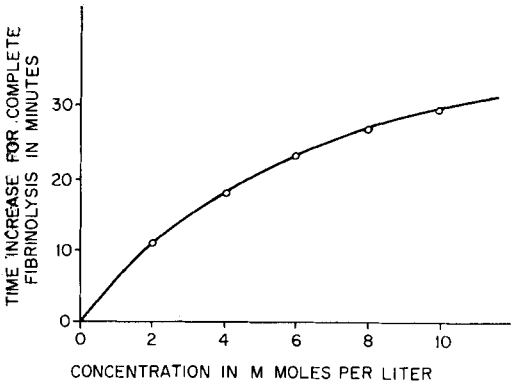

Fig. 1.—Antiplasmin activity of ε-aminocaproic acid.

RESULTS AND DISCUSSION

The inhibitory effect on fibrinolysis of each of the ω-aminocarboxylic acids at graded concentrations was studied. Only the results of the study on ε-aminocaproic acid are presented in Fig. 1 as representative of these studies. The relative antifibrinolysin activity of the ω-amino acids at 50 mmoles per L. concentration was studied in four experiments and the results obtained, in general, were essentially the same. Representative results of these studies are shown in Fig. 2. The results indicated that ε-aminocaproic acid was the most active compound. The shape of the curve in Fig. 2 suggests a sharp, geometrical fitness of the ε-aminocaproic acid molecule at the site of inhibition. The natural amino acid lysine is α,ε-diaminocaproic acid. It is a known fact that plasmin, like trypsin, can specifically hydrolyze the lysinyl bond of lysinyl peptides or lysinyl esters. These facts raised the question as to whether or not ε-aminocaproic acid exerts its inhibitory action by competing with the lysine moiety in the fibrin molecule. It was unexpected that L-lysine did not inhibit plasmin activity even at higher concentrations. At very high concentration of lysine solution,

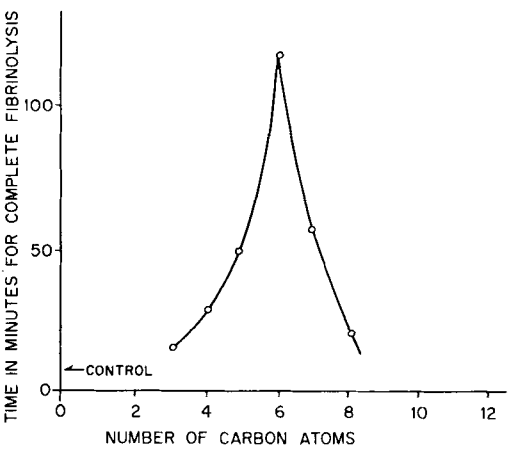

Fig. 2.—Relative antiplasmin activity of ω-aminocarboxylic acids at 50 mmoles per L.

fibrin was soluble. D-Lysine or L-arginine showed no inhibitory effect. We also found that lysine exerted no effect on the antiplasmin effect of ε-aminocaproic acid. It is interesting to point out that γ-aminobutyric acid also has considerable antiplasmin activity. This finding may be of significance since no other clue has been found on the physiological or biochemical function or functions of the large amount of γ-aminobutyric acid generally present in the normal central nervous system.

The low toxicity (3, 7) and high activity of ε-aminocaproic acid are the desirable properties of a useful therapeutic agent; however, its rapid rate of excretion (3) reduces its practical use. Further studies on these problems are under way.

SUMMARY

An enzyme system for assaying antifibrinolytic activity is described. The relative antifibrinolysin activity of the homologous series of ω-aminocarboxylic acids has been studied. It has been found that ε-aminocaproic acid has the highest antifibrinolytic activity.

Book Notices

Organic Reactions. Vol 12. Edited by ARTHUR C. COPE. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1962. vii + 538 pp. 15 × 23 cm. Price $13.

The important synthetic organic chemical reactions considered in this volume are: Cyclobutane derivatives from thermal cycloaddition reactions; Preparation of olefins by the pyrolysis of xanthates; The Chugaev reaction; Synthesis of aliphatic and alicyclic nitro compounds; Synthesis of peptides with mixed anhydrides; and Desulfurization with Raney nickel. A subject index is appended together with cumulative author and chapter indexes for volumes 1–12.

Progress in Polarography. Vols. 1 and 2. Edited by P. ZUMAN. John Wiley & Sons, Inc., Interscience Div., 440 Park Ave. South, New York 16, N. Y., 1962. Vol. 1, xiv + 255 pp. 15 × 23 cm. Price $12. Vol. 2, x + 451 pp. 15 × 23 cm. Price $15.

Authoritative discussions of many applications of polarography are given in 38 chapters in the two volumes. Although much of the literature in this field is of foreign origin, only two of the published chapters in these volumes are in a foreign language (German). The chapter numbers and the pagination are continuous and the general author and subject indexes are given at the end of volume 2. An excellent working and reference publication.

Basic Facts of Medical Microbiology. 2nd ed. By STEWART M. BROOKS. W. B. Saunders Co., West Washington Square, Philadelphia 5, Pa., 1962. vii + 329 pp. 20.5 × 14.5 cm. Price $5.

A simple and direct textbook on microbiology for nursing students and other beginning science students.

A Textbook of Pharmacognosy. 8th ed. By GEORGE EDWARD TREASE. Exclusive U. S. agents, The Williams & Wilkins Co., 428 East Preston St., Baltimore 2, Md., 1961. viii + 808 pp. 13.5 × 22 cm. Price $11.

Although the author notes that most of the new work in pharmacognosy is concerned with the constituents of drugs and the newer methods of physical and chemical evaluation, much of the text relates to living plants and their macro and microscopical characters.

A Manual of Cosmetic Analysis. By SYLVAN H. NEWBURGER. Association of Official Agricultural Chemists, Inc., P. O. Box 540, Benjamin Franklin Station, Washington 4, D. C., 1962. vi + 84 pp. 17.5 × 25.5 cm. Paperbound. Price $4 domestic, $4.25 foreign.

The technically sound and laboratory tested methods of analysis included in this manual were developed in the FDA Division of Cosmetics (now the Division of Color and Cosmetics). The applications of infrared and ultraviolet spectrophotometry and also chromatography to cosmetic analysis are concisely and clearly described and illustrated. Many of the analytical methods presented have not appeared in the literature and others will be further subjected to collaborative studies. Some of the methods, probably those involving more stabilized formulations, eventually may be incorporated into A.O.A.C. Methods of Analysis.

Readings in Pharmacy. Edited by PAUL A. DOYLE. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1962. xiv + 429 pp. 15 × 23 cm. Price $6.50.

A series of selected essays from professional journals are collected in this book for use, primarily, as a textbook for pharmacy students. Topics covered include pharmacy and society, famous pharmacists, pharmacy in literature and music, history of pharmacy, and pharmacy around the world. Each section contains a bibliography of additional readings on the general subject area to supplement the complete essays included in the volume.

Antimicrobial Agents and Chemotherapy—1961 Edited by MAXWELL FINLAND and GEORGE M. SAVAGE. American Society for Microbiology, 115 Huron View Blvd., Ann Arbor, Mich., 1962. xiv + 984 pp. 15 × 23 cm. Price $10.

This volume of an annual series covers papers presented at the Interscience Conference on Antimicrobial Agents and Chemotherapy on research activity in the field of microbiology, chemistry, pharmacology, biochemistry, clinical medicine, and pathology. Section headings include infectious diseases, cancer chemotherapy, mode of action: biogenesis, clinical evaluation of new antibiotics, new penicillins, chemistry and biological properties, and synthetic antimicrobials, among others. The volume is a collection of numerous research reports in the various areas noted.

The Chemistry and Manufacture of Cosmetics. 2nd ed. Vol. 1. By MAISON G. DENAVARRE. D. Van Nostrand Company, Inc., 120 Alexander St., Princeton, N. J., 1962. xii + 389 pp. 15 × 22.5 cm. Price $10.75.

This first volume of a four volume set, subtitled "Background," covers a wide array of subjects including aerosols, antibiotics, cosmetic colors, emulsions, federal regulations, perfume creation, pharmacology and toxicology, preservation, rancidity and rheology, and tested product formulas. Also included is a 30-page section devoted to incompatibilities of numerous cosmetic ingredients.

Progress in Polarography. Vols. 1 and 2. Edited by P. ZUMAN. John Wiley & Sons, Inc., Interscience Div., 440 Park Ave. South, New York 16, N. Y., 1962. Vol. 1, xiv + 255 pp. 15 × 23 cm. Price $12. Vol. 2, x + 451 pp. 15 × 23 cm. Price $15.

Authoritative discussions of many applications of polarography are given in 38 chapters in the two volumes. Although much of the literature in this field is of foreign origin, only two of the published chapters in these volumes are in a foreign language (German). The chapter numbers and the pagination are continuous and the general author and subject indexes are given at the end of volume 2. An excellent working and reference publication.

Basic Facts of Medical Microbiology. 2nd ed. By STEWART M. BROOKS. W. B. Saunders Co., West Washington Square, Philadelphia 5, Pa., 1962. vii + 329 pp. 20.5 × 14.5 cm. Price $5.

A simple and direct textbook on microbiology for nursing students and other beginning science students.

A Textbook of Pharmacognosy. 8th ed. By GEORGE EDWARD TREASE. Exclusive U. S. agents, The Williams & Wilkins Co., 428 East Preston St., Baltimore 2, Md., 1961. viii + 808 pp. 13.5 × 22 cm. Price $11.

Although the author notes that most of the new work in pharmacognosy is concerned with the constituents of drugs and the newer methods of physical and chemical evaluation, much of the text relates to living plants and their macro and microscopical characters.

A Manual of Cosmetic Analysis. By SYLVAN H. NEWBURGER. Association of Official Agricultural Chemists, Inc., P. O. Box 540, Benjamin Franklin Station, Washington 4, D. C., 1962. vi + 84 pp. 17.5 × 25.5 cm. Paperbound. Price $4 domestic, $4.25 foreign.

The technically sound and laboratory tested methods of analysis included in this manual were developed in the FDA Division of Cosmetics (now the Division of Color and Cosmetics). The applications of infrared and ultraviolet spectrophotometry and also chromatography to cosmetic analysis are concisely and clearly described and illustrated. Many of the analytical methods presented have not appeared in the literature and others will be further subjected to collaborative studies. Some of the methods, probably those involving more stabilized formulations, eventually may be incorporated into A.O.A.C. Methods of Analysis.

Readings in Pharmacy. Edited by PAUL A. DOYLE. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1962. xiv + 429 pp. 15 × 23 cm. Price $6.50.

A series of selected essays from professional journals are collected in this book for use, primarily, as a textbook for pharmacy students. Topics covered include pharmacy and society, famous pharmacists, pharmacy in literature and music, history of pharmacy, and pharmacy around the world. Each section contains a bibliography of additional readings on the general subject area to supplement the complete essays included in the volume.

Antimicrobial Agents and Chemotherapy—1961 Edited by MAXWELL FINLAND and GEORGE M. SAVAGE. American Society for Microbiology, 115 Huron View Blvd., Ann Arbor, Mich., 1962. xiv + 984 pp. 15 × 23 cm. Price $10.

This volume of an annual series covers papers presented at the Interscience Conference on Antimicrobial Agents and Chemotherapy on research activity in the field of microbiology, chemistry, pharmacology, biochemistry, clinical medicine, and pathology. Section headings include infectious diseases, cancer chemotherapy, mode of action: biogenesis, clinical evaluation of new antibiotics, new penicillins, chemistry and biological properties, and synthetic antimicrobials, among others. The volume is a collection of numerous research reports in the various areas noted.

The Chemistry and Manufacture of Cosmetics. 2nd ed. Vol. 1. By MAISON G. DENAVARRE. D. Van Nostrand Company, Inc., 120 Alexander St., Princeton, N. J., 1962. xii + 389 pp. 15 × 22.5 cm. Price $10.75.

This first volume of a four volume set, subtitled "Background," covers a wide array of subjects including aerosols, antibiotics, cosmetic colors, emulsions, federal regulations, perfume creation, pharmacology and toxicology, preservation, rancidity and rheology, and tested product formulas. Also included is a 30-page section devoted to incompatibilities of numerous cosmetic ingredients.

Book Notices

Organic Reactions. Vol 12. Edited by ARTHUR C. COPE. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1962. vii + 538 pp. 15 × 23 cm. Price $13.

The important synthetic organic chemical reactions considered in this volume are: Cyclobutane derivatives from thermal cycloaddition reactions; Preparation of olefins by the pyrolysis of xanthates; The Chugaev reaction; Synthesis of aliphatic and alicyclic nitro compounds; Synthesis of peptides with mixed anhydrides; and Desulfurization with Raney nickel. A subject index is appended together with cumulative author and chapter indexes for volumes 1–12.

Progress in Polarography. Vols. 1 and 2. Edited by P. ZUMAN. John Wiley & Sons, Inc., Interscience Div., 440 Park Ave. South, New York 16, N. Y., 1962. Vol. 1, xiv + 255 pp. 15 × 23 cm. Price $12. Vol. 2, x + 451 pp. 15 × 23 cm. Price $15.

Review Article

Absorption of Implanted Solid Drug

By BERTON E. BALLARD and EINO NELSON†

DRUG ABSORPTION is a subject which is attracting increasing interest in the areas of pharmacy and pharmacology. The technique of solid drug pellet implantation has particular importance in the livestock and poultry fields, in the area of cancer research where carcinogens or potential ones are studied, in theoretical studies involved with solid drug absorption, in endocrinological work, in studies concerned with metabolism and fate of drugs, and in many more areas where a prolonged "continuous infusion" of drug is required.

Recent reviews have summarized much of what is known concerning processes and factors influencing rate of absorption when drugs are administered by several routes. Thus, with respect to gastrointestinal absorption, Schanker (1) has discussed mainly the influence of a drug's dissociation constant and fat solubility on the process, and Wagner (2) has reviewed the influence of solution kinetics. Cooper and Lazarus (3, 4) and Nelson (5) have considered mainly the properties of sustained-release dosage forms intended for oral administration. Absorption following subcutaneous injection has been exhaustively discussed by Schou (6). The paper of Riegelman and Crowell (7) reviews information available on absorption after administration of drug by the rectal route. Past work on percutaneous absorption has been summarized by Gemmel and Morrison (8) and Barr (9). Work on sublingual absorption has been listed by Katz and Barr (10).

Apparently there has been no general review on absorption after implantation of either pure solid drug or solid drug in mixture with either inert or active materials, although brief reviews on specific topics have appeared. These are listed in an Appendix.[1] This review has been prepared in two parts. In the first part are considered the various physiological and physical factors that have been found to influence absorption rate. The second part of the review is presented in the form of an Appendix and lists and gives references to work in which a variety of drugs have been implanted. For simplicity in organization, each part of the review has its own set of references, numbered consecutively. One reason for the organization adopted is that there is much work reported in the literature which merely describes pharmacological effects elicited from the implanted drugs and bears only indirectly on absorption *per se*. This type of work is listed in the Appendix. Also listed in the Appendix are more complete references to some of the subjects discussed in the main body of the review itself.

In some ways, understanding absorption of implanted solid drug is simplified by the physical nature of materials logically administered by this route. Implantation is nearly synonymous with

[1] EDITOR'S NOTE: The Appendix which is referred to is not published with this review article in THIS JOURNAL. However, copies of it, in mimeographed form, are available on request from the authors, and interested readers should send their written request direct to the authors.

long duration of action and, as a consequence of this, recent work has shown that understanding the absorption process in many cases is reduced to the problem of understanding solution kinetics *in vivo* (11), because release of drug from pellet implant in the usual case is a much slower process than passage of drug across the membrane at the absorption site. Absorption, then, is solution rate limited.

Solution Kinetics.—A number of factors influence the rate of the solution *in vitro* and *in vivo*. Most of these factors have been discussed in detail in recent reviews (2, 11, 12). One of the most important aspects of absorption from implant is the influence of the implant's geometry and how its weight and surface area change with time.

Influence of the Geometry and/or Surface Area of Implant on Absorption.—Apparently Shelesnyak and Engle (13) were the first to recognize that absorption rate was proportional to the surface area of the implant at a given time. This finding has been confirmed since then, without exception, in many investigations. Surface area will decrease with time, and the function describing the rate of decrease is given by the derivative of the expression describing surface area as a function of time with respect to time.

For regular geometric objects, surface area is usually easy to express as a function of the dimensions of the objects. Thus, the surface area, S, of a sphere is given by

$$S = \pi D^2 \qquad \text{(Eq. 1)}$$

If diameter, D, decreases uniformly with time, *cf.* (14–20), then

$$dD/dt = -k \qquad \text{(Eq. 2)}$$

where k is the rate of decrease of diameter with time. On integrating Eq. 2 and evaluating the constant of integration at zero time, the following equation results

$$D = D^0 - kt \qquad \text{(Eq. 3)}$$

where D^0 is the initial diameter. Substituting Eq. 3 into 1 gives

$$S = \pi (D^0 - kt)^2 \qquad \text{(Eq. 4)}$$

as the relationship between surface area and time. The weight, W, of spheres is given by

$$W = \frac{\pi\rho}{6} D^3 \qquad \text{(Eq. 5)}$$

where ρ is the density of the drug. Decrease of weight with time will be given, using Eq. 3

$$W = \frac{\pi\rho}{6} (D^0 - kt)^3 \qquad \text{(Eq. 6)}$$

or by substituting for D^0 in Eq. 6 by its value from Eq. 5

$$W = \frac{\pi\rho}{6} \left[\left(\frac{6\,W^0}{\pi\rho} \right)^{1/3} - kt \right]^3 \qquad \text{(Eq. 7)}$$

Equation 7 solved for k becomes

$$k = \frac{1}{t} \left[\left(\frac{6\,W^0}{\pi\rho} \right)^{1/3} - \left(\frac{6W}{\pi\rho} \right)^{1/3} \right] \qquad \text{(Eq. 8)}$$

Alternatively, the value of k could be found by dividing the difference between initial and final diameter by the length of time in implant. However, in general, weight is measured more accurately than dimensions because of slight surface irregularities and shape distortions. Once k is determined from experimental measurements, it may be substituted back into Eq. 6 or 7, and weight may then be calculated at any time. Further, when the derivative of Eq. 6 is taken, instantaneous absorption rate, dA/dt, with negative sign is given. Thus

$$\frac{dW}{dt} = -\frac{dA}{dt} = -\frac{k\pi\rho}{2} (D^0 - kt)^2 \qquad \text{(Eq. 9)}$$

Data on the absorption of tolbutamide from implanted spheres of this material, as given by Ballard and Nelson (21), serves as an example to illustrate information that can be obtained from some of the preceding equations. Using their data for sphere B (*loc. cit.*), Eq. 6 becomes

$$W = 606\,(1.048 - 0.00245t)^3 \qquad \text{(Eq. 10)}$$

where W is in mg. and t in hours.

Figure 1 is a plot of Eq. 10 and also of Eq. 9. The latter equation with constants evaluated is

$$dW/dt = -4.45\,(1.048 - 0.00245t)^2 \qquad \text{(Eq. 11)}$$

If the implant were cylindrical, then its weight would be given by

$$W = \rho \frac{\pi D^2 h}{4} \qquad \text{(Eq. 12)}$$

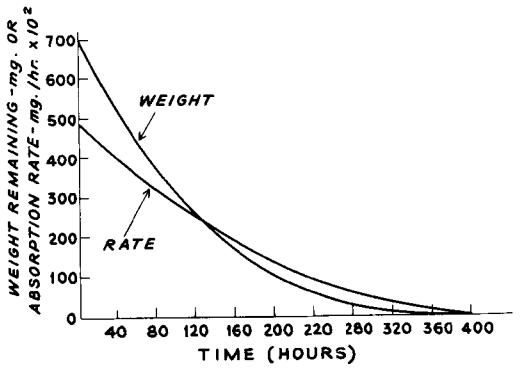

Fig. 1.—Decreases in weight and rate of change of weight as functions of time of an implanted sphere of drug.

where h is its thickness. If the rate of change of thickness and diameter with time were constant then, by same procedure that led to Eq. 3

$$D = D^0 - kt \qquad \text{(Eq. 13)}$$

and

$$h = h^0 - kt \qquad \text{(Eq. 14)}$$

where h^0 is the initial height.

Using Eqs. 13 and 14, Eq. 12 becomes

$$W = \frac{\pi\rho}{4}(D^0 - kt)^2(h^0 - kt) \qquad \text{(Eq. 15)}$$

Determination of the value of k using Eq. 15 is complicated by necessity of obtaining a solution to a cubic equation. However, the solution may be obtained without too much difficulty if a table for the solution of cubic equations, such as that prepared by Salzer, Richards, and Arsham (22), is available.

The rate of change of weight with time is found by taking the derivative of Eq. 15, hence

$$-dW/dt = \rho\frac{\pi k}{4}[(D^0 - kt)^2 + 2(D^0 - kt)(h^0 - kt)] \qquad \text{(Eq. 16)}$$

Equation 15 may be written in terms of the ratio of initial height to initial diameter, *i.e.*, $r = h^0/D^0$, to give

$$W = \frac{\pi\rho}{4}(D^0 - kt)^2(D^0 - kt) \qquad \text{(Eq. 17)}$$

It is of interest to examine the value of Eq. 17 with respect to the value of r. This has been done using data on the absorption of tolbutamide used in the example on absorption from spherical implants. Equation 17 in terms of these data becomes

$$W = 909(D^0 - 0.00245t)^2(D^0 r - 0.00245t) \qquad \text{(Eq. 18)}$$

where W is in mg.

Equation 18 is plotted on Fig. 2 for values of r from 0.1 to 10. This was done by writing Eq. 12 as

$$W^0 = \frac{\rho\pi D^{03} r}{4} \qquad \text{(Eq. 19)}$$

and solving for D^0 at arbitrarily taken values of r. The value of W^0 was that taken from the report previously cited (*loc. cit.*, sphere B). On Fig. 2, all curves shown lie to the left of the curve for a sphere (dotted line) since, for a given material, a sphere has a minimum surface area per unit weight among the various geometric configurations that may be taken. In Fig. 2, the slope of a line at any time is the instantaneous absorption rate. It will be seen in this figure, that for small values of the ratio of thickness to diameter, that absorption rate is nearly constant for most of the time that drug is in implant.

Equations similar to the preceding may be developed easily for other geometric configurations such as oblate and prolate spheroids, etc. Many implants are rod-like with rounded ends, and equations for change in their weight and surface with time would be satisfactorily approximated by the equations for cylinders.

Equation 15 of the preceding has been experimentally verified by Shimkin and co-workers (16) for the case of $h^0 = D^0$. This was done by rearranging this equation to give

$$W^{1/3} = bD^0 - bkt \qquad \text{(Eq. 20)}$$

where $b = (4/\rho\pi)^{1/3}$. Plots of the cube root of weight of implant remaining at various times plotted *vs.* time were linear. They also examined data from work of others wherein $h^0 \neq D^0$ and found that plots of the cube root of weight implant remaining *vs.* time were reasonably linear. Of the various regular geometric objects that would likely be implanted, the implanted cylinder provides the most rigorous test of the assumption made in deriving Eq. 15 and others, *i.e.*, that all dimensions decrease uniformly with time. The work of Shimkin and his co-workers indicates that this assumption is correct (16). The reason that a cylinder provides the most rigorous test is that solution, which is always normal to a surface, is taking place from surfaces normal to each other. The same situation would hold in the case of cubes, for example, but it seems highly unlikely that this object would ever be implanted.

If the intensity of agitation on all faces of a crystalline solid were equal, dimensions would not decrease uniformly if the crystal was anisotropic. This might be a factor to be considered

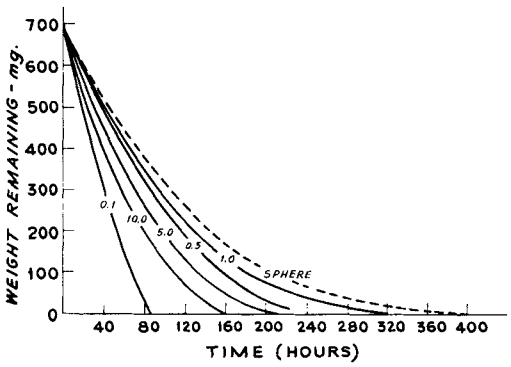

Fig. 2.—Decrease of weight as a function of time for implanted cylinders and a sphere. The numbers by the curves refer to the initial ratio of height to diameter.

with fused implants, but not one with compressed implants. The particles comprising a compressed implant could be expected to be distributed randomly throughout the implant and on its surfaces. The rate of absorption found would be an average representing the arithmetic mean of the rate that would be found for the individual surfaces of the crystal.

It has been reported that absorption of diethylstilbestrol after implantation could be described as a first-order process (23). It seems highly unlikely that this could be the case because absorption of this material is certainly solution rate limited. The result was no doubt an artifact. Many mathematical functions can be roughly fitted to the integrated expression describing a first-order process. For example, if Eq. 15, with constants evaluated for a cylinder with an initial height equal to initial diameter, is used to calculate weight remaining at several times, and values of weight so calculated for the first 100 hours are plotted on semilogarithmic paper as a function of time, the points can be roughly fitted with a straight line. Also, the dimensions given for the apparent first-order rate constant were incorrect.

Body Level of Drug Following Implantation—Mathematical Treatment.—As in the case of any other route of administration, drug absorbed from implant distributes itself in blood and other body fluids and, at the same time, the elimination processes of metabolism and excretion begin. Very little work has been done to express either body level of drug or drug elimination as a function of time in mathematical terms. In many cases, drug elimination may be approximated by considering the process as one whose rate is directly proportional to body level at any time (first order). Assuming this, then the following differential expression should express the rate of change of body level with time when an absorption process is involved

$$\frac{dAb}{dt} = \frac{dA}{dt} - KAb \qquad \text{(Eq. 21)}$$

In Eq. 21, Ab is body level, dA/dt is absorption rate, K is the first-order rate constant for removal of drug from the body, and t is time. If the implant is a sphere, then absorption rate is given by Eq. 9, and if this equation is substituted in Eq. 21, Eq. 22 results

$$\frac{dAb}{dt} = \frac{k\pi\rho}{2}(D^0 - kt)^2 - KAb \qquad \text{(Eq. 22)}$$

Equation 22 may be integrated to give, with constant of integration evaluated at zero time (no drug in the body)

$$Ab = a\left[\frac{(D^0 - kt)^2}{K} + \frac{2k}{K^2}(D^0 - kt) + \frac{2K^2}{K^3} - \left(\frac{D^{0^2}}{K} + \frac{2kD^0}{K^2} + \frac{2k^2}{K^3}\right)\exp\left[-Kt\right]\right] \qquad \text{(Eq. 23)}$$

In Eq. 23 $a = k\pi\rho/2$ and the other terms have been previously defined. The value of the constants in Eq. 23 are all determinable experimentally. Analogous equations based on other implant geometries may also be derived by the procedure shown.

A mathematical treatment similar to the preceding has not been applied to experimentally obtained data. However, drug blood level after implantation of drug has been followed (24–26, 53). In one of these studies (25), pellets of progesterone were implanted both subcutaneously and intrasplenically in mice. Both the free and total progesterone blood levels plateaued after some time following intrasplenic implantation. However, the total progesterone blood level continued to rise after subcutaneous implantation.

In another study, procaine benzylpenicillin tablets were implanted in the vicinity of wounds in human patients undergoing surgery (24). These implantations were either subcutaneous or intramuscular. Penicillin blood level was followed and it was found that, after a few days delay to allow for the attainment of equilibrium, levels fluctuated around a reasonably constant level in a given patient. It was remarked that this method of administering procaine benzylpenicillin was extremely innocuous since no local or general reactions were observed.

In still another study (26), blood level of gold following subcutaneous or intramuscular implantation of pellets of a gold salt in arthritic patients was followed. Measureable quantities of gold were present in blood for many months following implantation.

Absorption and excretion of drug following implantation of spheres has been studied with a different procedure than the one used above to follow absorption (21). It was recognized in this case that absorption from the sphere, which was slow, would eventually become rate limiting in excretion of the drug's metabolite. Thus, for a good part of the time the amount of drug in circulation in the body was small as compared to the amount of drug remaining in solid form in implant and excreted in urine as metabolite. Then the weight of drug in implant at any time should have been given by the Hixon-Crowell cube root law (27) which is

$$W^{0^{1/3}} - W^{1/3} = k't \qquad \text{(Eq. 24)}$$

In Eq. 24, k' was the absorption rate constant whose value depended on solubility of drug at the absorption site, agitation, and other factors. The weight at any time was deducible from the following equation

$$W = W^0 - \frac{Wu}{f} \qquad \text{(Eq. 25)}$$

where Wu was cumulative amount of drug metabolite excreted and f the fraction of a dose of the drug excreted as the metabolite. The quantity Wu was expressible directly in terms of precursor. Substituting Eq. 25 in Eq. 24 gave

$$W^{0^{1/3}} - (W^0 - Wu/f)^{1/3} = k't \qquad \text{(Eq. 26)}$$

When the left hand side of Eq. 26 was plotted as a function of time, a linear relationship was found after a sufficient time had elapsed to allow attainment of equilibrium. The linear relationship indicated the correctness of the assumptions made concerning the absorption, metabolism, and elimination of the drug.

In other work, the kinetics of the excretion of sulfadiazine, following implantation of thin, cylindrical discs of this material in rats, was followed (28). Mean excretion rate over the implantation period was nearly directly proportional to surface area, as estimated by a graphical method (29), at the same time. These results indicated the rate limiting nature of absorption from implants of this drug.

Urinary excretion after implantation of drug has been followed in other work (30). In this instance, 50 mg. of riboflavin with 50 mg. of cholesterol was implanted intramuscularly in two humans. In one patient not deficient in riboflavin, a substantial increase in riboflavin excretion was observed for about 1.5 months. In the other case, the patient was riboflavin deficient and could not be maintained by oral dosage because of severe gastric and intestinal disorders that prevented absorption of this vitamin. The patient could be maintained after parenteral administration of vitamin in solution three times a day, but showed symptoms of deficiency 2 days after cessation of administration. However, after implantation he showed no signs of deficiency for 2 months. Further, his riboflavin excretion was about 10 times greater per day throughout this period than his preimplantation excretion.

Other studies in which drug blood level, excretion of drug or its metabolites, or change in physiological function have been followed after implantation are listed in the Appendix.

Absorption Rate and Surface Area.—It is of interest to consider the relationship between absorption rate and surface area, particularly in regard to the ratio of rate to surface as given in Eq. 27

$$\frac{dA}{dt}\frac{1}{S} = R \qquad \text{(Eq. 27)}$$

In Eq. 27, R is the value of the ratio. For spheres, it is easily shown by Eqs. 4 and 9 that the value of R is given by

$$R = \frac{k\rho}{2} \qquad \text{(Eq. 28)}$$

and R is independent of time.

If the implant is cylindrical in shape, it can be shown by using Eq. 16 and the equation for determining the surface area of this geometric form that the ratio is not a constant, except in one special case, and is, instead, a function of time. This function is given by

$$R' = k\rho\left(\frac{1 + \dfrac{2(h^0 - kt)}{(D^0 - kt)}}{2 + \dfrac{4(h^0 - kt)}{(D^0 - kt)}}\right) \qquad \text{(Eq. 29)}$$

where R' is the function of time. In the special case where initial diameter equals initial height, Eq. 29 reduces to

$$R' = \frac{k\rho}{2} \qquad \text{(Eq. 29a)}$$

and a direct proportionality independent of time exists between absorption rate and surface area of the implant.

A set of widely applied solution rate laws which were written in several forms, depending on initial conditions, are the Hixon-Crowell laws (27). In the several forms of the law, derivations are based on assuming that a direct proportionality exists between surface area and the two-third power of weight of the dissolving substance, which is true among a few common geometric shapes such as spheres, cubes, and cylinders whose initial height equals initial diameter. For the most simple case of dissolution where the object is dissolving in a large enough volume of medium so that the concentration changes may be neglected, the starting equation to derive the law may be written as [a reduced form of the Noyes-Whitney law (31)]

$$dW/dt = -K'S \qquad \text{(Eq. 30)}$$

where K' is constant whose value is a function of several other constants. The physical meanings of these other constants do not bear on the present discussion. When Eq. 30 is rearranged to find the ratio of rate of change of weight (or absorption rate if the process is thought of in terms of rate of change with time of amount of

drug dissolved) to surface area, it will be seen that the resulting equation is of the same form as Eq. 27. If the dissolving solid is a cylinder, then an equation of the same form as Eq. 29 will also express the relationship between rate of weight loss and surface area. Clearly, K' may be a function of time. The Hixon-Crowell laws are in error when any object is considered whose ratio of dimensions change with uniform loss of material from all faces, and this conclusion is explicit from considering Eq. 29.

The reduced form of the Noyes-Whitney law (31) which has been considered in the preceding discussion written for the case of a cylindrical solid undergoing dissolution with uniform loss of all dimensions is, using Eq. 30 and the formula for calculating surface area for a cylinder written in the form that expresses this uniform loss as a function of time

$$-\frac{dW}{dt} = \pi K' \left[\frac{(D^0 - kt)^2}{2} + (D^0 - kt)(h^0 - kt)\right] \quad \text{(Eq. 31)}$$

Equation 31, when integrated, becomes

$$W = \pi K' \left[\frac{(D^0 - kt)^3}{6k} + \frac{(D^0 - kt)(h^0 - kt)^2}{2k} - \frac{(h^0 - kt)^3}{6k}\right] + A \quad \text{(Eq. 32)}$$

where A is the constant of integration. At zero time, $W = W^0$, and when the value of A is evaluated at this time and substituted in Eq. 32 this equation becomes

$$W = W^0 - \pi K' \left[\frac{D^{0^3} - (D^0 - kt)^3}{6k} + \frac{D^0 h^{0^2} - (D^0 - kt)(h^0 - kt)^2}{2k} - \frac{h^{0^3} - (h^0 - kt)^3}{6k}\right] \quad \text{(Eq. 33)}$$

Acidic or Basic Properties and Molecular Weight of the Implanted Drug.—One reason that pellet absorption rate has not been found to correlate well with water solubility, as will be discussed later, is due to the fact the hydrogen ion concentration as well as buffer capacity of the tissue fluids at the site influence the solubility of acidic or basic drugs. These factors have been studied in detail (11).

Absorption rate was assumed to be solution rate limited and expressions derived from Fick's law were obtained to give absorption rate as a function of an acidic or basic drug's dissociation constant, water solubility, and molecular weight. For acidic drugs, experimentally found absorption rates were found to follow, within experimental error, the following equation

$$\frac{dA}{dt} = \frac{cSs}{M^{1/2}}\left(1 + \frac{Ka}{[H^+]_d}\right) \quad \text{(Eq. 34)}$$

In Eq. 34, c is a proportionality constant, M is the molecular weight of a given drug, s is the water solubility of the undissociated acid, Ka the drug's dissociation constant, and $[H^+]_d$ the hydrogen ion concentration of the diffusion layer covering the surface of the implant. This latter quantity was determined by a modification of a method previously used *in vitro* (31). Diffusion layer hydrogen ion concentrations were sometimes substantially different from the hydrogen ion concentrations of the fluids at the implant site, the difference increasing with increasing acidity or basicity of the substances implanted. This is one of the reasons why absorption rate often does not correlate with water solubility.

For basic drugs, the equation appropriate to describe absorption rate was

$$\frac{dA}{dt} = \frac{cSs}{M^{1/2}}\left(1 + \frac{Kb}{[OH^-]_d}\right) \quad \text{(Eq. 35)}$$

In Eq. 35, s is the water solubility of the undissociated base. Equations were also developed for polyfunctional substances (11).

Pellet Density.—Several investigators (14, 32–41) have suggested that pellet density is an important factor influencing absorption rates of implants. It is known that variations in compression pressure used in pellet manufacture affects their densities (or, as some authors put it, their hardness).

Variations in density or compression pressure do affect the weight/area ratio. However, since the absorption rate is directly proportional to the pellet's area exposed to the body fluids at a given time, density alone should not have a direct effect on absorption rate, but only an indirect one in so far as it affects the implant's initial area. In support of this view, Cowie and Folley (17) and Hays, *et al.* (42), have demonstrated *in vivo* that variation of pellet density is a factor of no great importance in implant absorption rate. Parrott, Wurster, and Higuchi (43), correcting for area, have shown *in vitro* that the dissolution rate of spheres was independent of density. They stated that "... although with less dense tablets a greater increment of volume was dissolved per unit time than with the more dense tablets, an equal weight of material was dissolved per unit time from a given surface area for both cases."

In fact, most investigators (17, 44, 45) agree that absorption rates of cast (or fused) and compressed pellets of a given drug are practically the same per unit area. Bishop and Folley (44)

seem to have reversed an earlier claim to the contrary (15).

In more recent work (46) comparing absorption from cast and compressed pellets, it was found that there was no difference when the drug was estradiol. However, compressed desoxycorticosterone acetate pellets were more slowly absorbed than fused pellets. This last result is easily explained if the fusing process produced a more rapidly dissolving polymorphic form of this steroid than the original form that was compressed. Alternatively, the compression process may have produced a more slowly dissolving polymorphic form. Differences in absorption rate between two polymorphic forms of α-methylprednisolone have been observed (11).

In conclusion, the absorption rate and dissolution rate of solid implants are independent of density when corrections are made for area.

Size of Crystals Used in Preparation of Implants.—Soule and Burstein (36) and Greenblatt and Hair (38) asserted that the size of the crystals used in making pellets affects their absorption rate. But Forbes (47) and Hays, *et al.* (42), with experimental evidence, have shown *in vivo* that the size of crystals used in the manufacture of pellets has no effect on absorption rate. The lack of influence of crystal size is most likely due to a factor discussed in a report on some *in vitro* dissolution rate studies (31). Using the equation discussed by Jost (48)

$$Td \cong \sqrt{\eta L/v\rho} \qquad \text{(Eq. 36)}$$

where Td was the thickness of the diffusion layer, η is the viscosity of the medium, L is the linear dimension of surface of solid across which the medium flowed, v was the velocity of flow of the medium as a result of stirring, and ρ was the density of the medium, it was concluded that under the conditions of the experiments, the thickness of the diffusion layer was much greater than the highest point on the pellet's surface (31). Thus, the medium surrounding the pellet was in contact with a diffusion layer of homogeneous composition.

With implanted pellets where the velocity of flow of the medium over the pellet surface is unquestionably much less than the velocity used in the *in vitro* experiments (31), the thickness of the diffusion layer would be large; this can be predicted from Eq. 36. Whether the pellet surface was formed by compression of large or small crystals, or during the fusion process, the diffusion layer is thick enough to mask any of the pellet's minor surface imperfections. Therefore, the absorption rate of compressed pellets should be independent of their method of manufacture, assuming a constant stirring velocity.

Solubility of the Drug.—Deanesly and Parkes (49) were apparently the first to state that the absorption rate of implanted pellets was correlated with the solubility of the substance in body fluids. Others have agreed (32, 33, 50, 51). Biskind, *et al.* (37), stated that the solubility of the compound in various chemical solvents does not influence absorption rate. What they meant by this statement is not clear.

While Lewin and Huidobro (52) could not correlate absorption rate with the water solubility of the drugs they used, they did correlate absorption rate with their experimentally measured serum solubilities.

Influence of Diluents.—It would be expected that the admixture of an inert substance with drug prior to formation of an implant would slow absorption rate of the implant because of the decrease in surface area of drug. On the other hand, it might be expected that, after correction for surface area, diluents could either increase or decrease absorption rate per unit surface area of the implant. If the diluent were a more rapidly dissolving substance than the drug, then drug particles could be expected to be released from the implant with dissolution of the diluent. This process would increase effective surface area of drug. If the drug were a more rapidly dissolving substance than the diluent, then it could be expected that absorption rate per unit area, or even pellet area in some cases, of drug might either remain unchanged or decrease, depending on the relative amounts of drug and diluent. With small amounts of diluent, the diffusion layer would cover the face of the pellet and the absorption site would "see" this area. With large amounts of diluent, as absorption proceeded, drug would have to diffuse to the surface before absorption, and this step could be expected to slow absorption.

The absorption of hexestrol mixed with 25, 49, or 50% lactose has been studied by Cowie and Folley (17). Lactose would be expected to be much faster dissolving than the hexestrol. However, no increase was noted in absorption rate of hexestrol plus lactose as compared to implants of hexestrol alone. With testosterone this was not the case, and the difference in rate became more marked as absorption progressed. This apparent discrepancy can be explained if it is assumed that hexestrol particles were more tightly bound to each other in the implants than were the testosterone particles.

In other work with lactose as a diluent, in amount of 39 to 49%, for hexestrol and diethyl-

stilbestrol, it was stated that absorption was "probably less rapid" with diluent present (54).

Absorption studies of various steroids from implants containing cholesterol have given some unexpected and surprising results. Some of this work has been briefly reviewed by Fuenzalida (55). When a number of steroids were mixed with cholesterol, the absorption of the steroids per unit surface area of drug was very markedly decreased. Further, cholesterol by itself, which is absorbed so slowly that its rate is difficult to measure even in implant studies, was absorbed at measurable rates when a number of steroids were admixed with it. During the course of absorption, the cholesterol-drug ratio did not change (55). These results strongly suggest compound formation between the steroids and cholesterol. It is known that cholesterol forms 1:1 compounds with β-sitosterol, vitamin D_2, and other structurally similar substances, as well as a variety of other substances (56).

Paraffin wax has been used as a diluent to slow absorption of implanted drug (57, 58). Most of the other studies with implants containing inert diluents are listed in the Appendix under cholesterol or the sugars, lactose and glucose. From results obtained in work with implant mixtures, as discussed above and listed in the Appendix, it is rather clear that little quantitative information on the role of the diluent exists.

Phagocytosis.—Forbes (14) and Foss (32) supposed that pellet absorption might be connected with the process of phagocytosis. But after Lewin and Huidobro (52) reviewed the literature on this point, they demonstrated experimentally that implants could be absorbed without the occurrence of phagocytosis. This factor, therefore, does not appear to be important.

Physiological Need of the Animal.—Neither physiological need for the implanted substance nor the animal's sex seems to affect the absorption rates of implants (14, 33, 34, 38, 40, 42, 47, 59–66). These experiments and observations lend support to the view that absorption rate is solution rate limited in the usual case. In the nonsolution rate limited case, absorption rate varies with the difference between the concentration of drug in the implant's diffusion layer and the concentration in the fluids at the membrane in contact with it. The physiological need of an animal might control the concentration of drug in the fluids at the membrane in some cases, but it is explicit in solution rate limited absorption that this concentration is negligible in comparison to the concentration of drug at the pellet's surface. Cholesterol implants serve as a good example of a nonsolution rate limited case of absorption (11).

Site of Implantation and Body Movement.—Statements in the literature regarding absorption rates of implants at various sites in the body are not in agreement. Some authors (14, 36, 38, 50, 51, 54, 67) say that absorption site is important, while others (40, 68, 69) say that absorption rate is essentially independent of the site of implantation. Unfortunately, the statistically significant key experiment which would resolve these opposing views has not been conducted. Reported absorption rates, in the main, are based on results from too few pellets and animals, and the many possible implantation sites have not been systematically studied. It would seem that site of implantation should influence absorption rate because degree of agitation may be different at different sites.

Variations in absorption rate are observed even when a single, carefully defined anatomical region is implanted. Absorption rate varies inversely with the thickness of the diffusion layer surrounding the implant's surface. The thickness of this fluid layer in a particular animal can change with a variation in stirring rate, either due to animal movement or change in flow of interstitial fluid in the region of the pellet.

The clinical variations in absorption rates of desoxycorticosterone acetate pellets observed by McCullagh, *et al.* (70), might well be explained by stirring, and its effect on the thickness of this liquid layer. In this connection, Kearns (71) suggests that the patient massage the area over the implant to increase the rate of absorption.

Encapsulation.—After some drug pellets are implanted for a time, they become surrounded by a fibrous capsule whose morphology and histology have been described (14, 41, 72–75, 84). While many claim that such capsules retard the implant absorption rate (32, 36, 39, 51, 61, 72, 76–83), others think it has no effect (15, 16, 42, 50, 85).

Although no completely convincing experiment has settled this question, the latter view is probably correct because of the solution rate limited nature of absorption from implant. There is evidence (32) that the more rapidly absorbed substances have thicker capsules than the more slowly absorbed ones. Very rapidly absorbed substances do not form capsules, because there is not time enough for the body to form them. The view, which follows, by Shimkin *et al.* (16), seems correct: ". . . it is just as likely that the thickness of the capsule is determined by the slow absorbability of the material rather

than the slowness of absorption being due to the deposition of the surrounding fibrous tissue."

Until more quantitative work is available relating absorption rate of pellets to capsule formation, encapsulation can be disregarded as a factor of major importance.

"Ghost" Formation.—The term "ghost" was coined by Folley (82) who observed that proteinaceous material had infiltrated into the pores of compressed implants. "Ghost" formation was subsequently studied in more detail (15, 17, 42, 45, 52, 54, 65, 83, 86, 87). Some believe that the presence of a "ghost" affects absorption rate (15, 17, 42, 54, 65, 87), while others claim it does not (45, 52). Folley (65), who used hexestrol pellets of differing weights, noted that for small pellets (50 mg.) the correction for the "ghost's" weight made no detectable difference in the absorption rate.

For precise measurements of absorption rate there is no doubt that the weight of the "ghost" should be considered. But whether the "ghost" actually inhibits absorption rate due to plugging of the pellet pores, as some claim, is open to question. On this point two lines of evidence suggest that the "ghost" does not affect absorption rate. (*a*) The absorption rates of cast and of compressed pellets *in vivo* are generally agreed to be the same, as previously discussed, in spite of the fact that the compressed pellet histologically has the more extensive "ghost." (*b*) The *in vitro* studies of Wurster and Seitz (88) have shown that the pores in pellets compressed in air are largely occluded by air and are almost entirely unavailable to the aqueous solvent. One might suppose, then, that the absorption rate of a pellet whose pores are occluded by air or by proteinaceous material would be almost identical.

"Ghost" formation as a factor influencing absorption rate can be considered unimportant. The weight of the "ghost," however, should be accounted for when the weights of pellets are measured after implantation.

Animal's Age.—Forbes (62) observed that the absorption rate of testosterone propionate pellets implanted into young rats decreased during the first 2 months of life. This effect of age on absorption rate may be due in part to the fact that the newborn rat is more responsive to changes in external temperature than older rats (89), and the solubility and rates of diffusion of substances are directly related to temperature. In fact, Deanesly (63) hinted at this when she attributed the different absorption rates of estrone pellets in rats and mice to differences in body temperature or metabolism. Animal physical activity is also a function of the animal's age.

Species Difference.—Very little work has been done to determine species difference in absorption rate. The observation has been made that rats absorb certain drugs after implantation more rapidly than man (46). A comparative study has been done using albino rats, desert rats, and golden hamsters (90). Rate of absorption decreased in the order listed. Species differences are no doubt due to differences in physical activity, body temperature, and composition of the body fluids at the implantation sites.

SUMMARY

Factors that clearly affect absorption rates of implants are their surface area and solubility in body fluids. Factors proposed that do not affect absorption rate greatly (if at all), with the present information, are pellet density (when area corrections are made), crystal size used in implant preparation, phagocytosis, physiological need or sex of the animal, encapsulation, "ghost" formation, and the age of the animal (if it is not young). Factors such as site of implantation and body movement and diluents do have an effect, but little quantitative information is available concerning the magnitude of the effect.

Study of the Lipid Fraction of Freeze-Dried Dandelion Root

By SALAH ELDIN F. ALI† and EARL P. GUTH

Gas chromatographic studies of the lipid fraction from oven-dried and freeze-dried dandelion root reveal significant difference. Synthesis of fatty acids apparently continues during the oven drying process.

IT IS WELL known that on harvesting an entire plant or removing parts from the plant, many of the vital processes do not stop immediately (1). It is also known that the length of time and the degree of temperature required for drying plant materials affect the rate and intensity of these processes and, consequently, could affect the nature of some constituents normally present. The chemical reactions which occur in plant cells are apparently accelerated by enzymes. Therefore, as long as conditions are favorable to enzymatic action, these reactions will proceed. The rate at which an enzymatic reaction proceeds is influenced not only by the temperature, but also by the length of time that the reaction mixture has been maintained at that temperature. Within limits, an increase in the

temperature increases the rate of enzymatic reactions. When the optimum temperature is exceeded, there is a decrease in the rate of these reactions because of a denaturation effect upon the enzyme (2–4).

Since high temperatures do affect some plant materials during the process of their drying, it would be reasonable to dry these materials at low temperatures. The freeze-drying process has proved to be feasible for drying and preserving plant and animal products and the application of this method as a means of drying crude drugs and drug extracts has been employed by many investigators (5–10).

The purpose of this study is to investigate the possibility that certain plant principles which are now known may not necessarily be the actual constituents of that source. In order to achieve this objective, an attempt was made to examine specifically some of the chemical changes which may occur after the plant has been harvested and dried.

This paper is concerned with the differences found in the lipid fraction of dandelion root (*Taraxacum officinale*).

EXPERIMENTAL

Collection and Drying.—The roots of dandelions were gathered at three different seasons; Autumn, Spring, and Summer, from a field adjacent to the Ohio State University.

The roots were gathered and divided in two lots each time; one lot was immediately frozen with dry ice.

The unfrozen roots were cleaned and then dried in an oven at 50°; these were designated as O.D. samples. The frozen roots were rapidly cleaned and freeze-dried at a temperature not higher than 25° and a pressure of 100 to 200 μ of mercury; these were designated as F.D. samples.

Determination of Fatty Acids.—The lipid-containing fraction of the roots was extracted with ether in a Soxhlet apparatus. The ether was then removed by vacuum distillation, the extracts dried in a desiccator, and stored under nitrogen at 0° in a tightly closed container.

Preparation of the Methyl Esters of the Fatty Acids.—The dried ether extract was saponified with 10% alcoholic potassium hydroxide. After the nonsaponifiable matter was removed, the soap solution was acidified with 25% sulfuric acid and washed with ether. The ether was removed by vacuum distillation.

The fatty acids so obtained were dissolved in anhydrous ether and methyl esters prepared using diazomethane.

The constituent fatty acids were tested and identified, as their methyl esters, using gas-liquid chromatography.[1] The gas-chromatographic apparatus employed in this study was a Wilkens Areograph model A-110-C.

[1] These findings were confirmed by Mr. Robert B. Iden, Battelle Memorial Institute, Columbus, Ohio.

Preferred Operating Conditions.—To minimize the effects of the many operative variables, the following conditions were established: a column packed with 10% diethylene glycol succinate on 60–80 mesh firebrick; column dimension, 72 in. × 0.25 in. (i.d.); flow rate, 90 ml./min. helium; temperature, 185° for the resolution of low molecular weight fatty acid methyl esters and 195 to 198° for the resolution of higher molecular weight fatty acid methyl esters. The linearity of the plot of the logarithm of apparent retention volume (V_R') *vs.* the chain length for a number of known saturated straight-chain fatty acid methyl esters was used as an indication of constant column temperature for each analysis.

Identification of Fatty Acids.—The retention volume (V_R') of each component fatty acid was precisely measured to the nearest 0.1 cm.

The preliminary characterization of the fatty acid components of the lipid fraction in each of the oven-dried and freeze-dried root, collected at different seasons, was obtained by simple comparison of their apparent retention volume with those of known saturated fatty acid methyl esters from a standard curve prepared under similar conditions.

The identification of the peaks was further confirmed by the addition of a known synthetic mixture of pure fatty acid methyl esters that correspond to the suspected peaks to the solution of the unknowns, and a new chromatogram was obtained. The results and the relative proportions of the fatty acid methyl esters separated from the lipid fraction of the root are listed in Table I.

DISCUSSION

The neutralization number of the crude ether extracts of the root (Table II) indicate that there was a significant increase in the saponification number of the ether extract of freeze-dried Summer root as compared with the corresponding oven-dried sample. This would indicate that the concentration of low molecular weight fatty acids in the extracts obtained from the freeze-dried sample was higher than those present in the extracts obtained

TABLE II.—SAPONIFICATION NUMBER OF THE LIPID FRACTION OF THE FREEZE-DRIED AND OVEN-DRIED DANDELION ROOT (U.S.P. XVI)

Sample	Autumn O.D.	Autumn F.D.	Spring O.D.	Spring F.D.	Summer O.D.	Summer F.D.
1	111.5	90.8	124.5	123.6	152.1	276.3
2	105.2	96.3	123.7	118.5	159.3	280.5

Av.	108.9	95.5	122.5	121.8	159.2	279.4

from the oven-dried sample. Extracts from the oven-dried Autumn and Spring collections showed a slight increase in saponification numbers over those obtained from the freeze-dried samples. Such differences between crude products are not usually considered to be reliable. Therefore, no immediate interpretation was made, the composition and degree of purity of the extracts being unpredictable. A negative iodine number was obtained for the ether extract prepared from the freeze-dried Summer root as compared with the extract prepared from the oven-dried sample. The iodine number of the extracts prepared from the oven-dried Autumn and Spring roots indicated the existence of a relatively higher degree of unsaturation as compared with the corresponding freeze-dried samples.

The distribution of fatty acids (Table III and Fig. 1) found in the freeze-dried and oven-dried root of the Spring collection shows some interesting differences. Myristic and stearic acids appear to be slightly greater in the freeze-dried sample. In addition, unknown fatty acids Nos. 2, 3, and 7 are greater in the freeze-dried sample. Unknown fatty acids Nos. 5 and 8 appear only in the freeze-dried sample. On the other hand, palmitic, linoleic, and linolenic acids appear in greatest quantity in the oven-dried sample.

Myristic, palmitic, and oleic acids appeared to be greatly increased (Fig. 2 and Table IV) in the freeze-

Myristic	C_{14}	5.24	15.06
Palmitic	C_{16}	31.66	37.63
Oleic	$C_{18}{}^{1=}$	3.14	4.68
Linoleic	$C_{18}{}^{2=}$	47.43	33.86
Linolenic	$C_{18}{}^{3=}$	12.77	8.70

dried sample of the Autumn collection. Linoleic and linolenic acids are found to be considerably greater in the oven-dried sample of this collection.

Unknown fatty acid No. 1 (Fig. 3) appeared in greatest quantity in the freeze-dried root of the Summer collection, while it appeared only in a minute quantity in the oven-dried sample. This increase may explain, in part, the reason for a higher saponification number of the freeze-dried Summer sample over that of the corresponding oven-dried samples.

The presence of traces of caprylic and capric acids in the oven-dried sample of the Spring collection is also indicated by a slight increase in the saponification number of the ether extract obtained from the roots that were oven-dried over those of the corresponding freeze-dried sample. The appearance of these two acids in the oven-dried samples, while none appear in the freeze-dried sample, may be due to loss of these fatty acids during the freeze-drying process, since this was performed at a pressure of 200 μ. On the other hand, this difference might represent a breakdown of larger fatty acids due to higher temperature in the oven-drying process.

In view of these findings, it might be reasonable to assume that the decrease in the quantities of myristic acid in the lipid fraction of the oven-dried samples of the Spring and Autumn roots as compared with the freeze-dried samples indicates a continued synthesis of fatty acids in the oven-dried samples. Such process may be blocked by freeze-drying the root. This is also indicated by a considerable decrease in palmitic acid content of the oven-dried Autumn samples as compared with the corresponding freeze-dried samples. The loss in

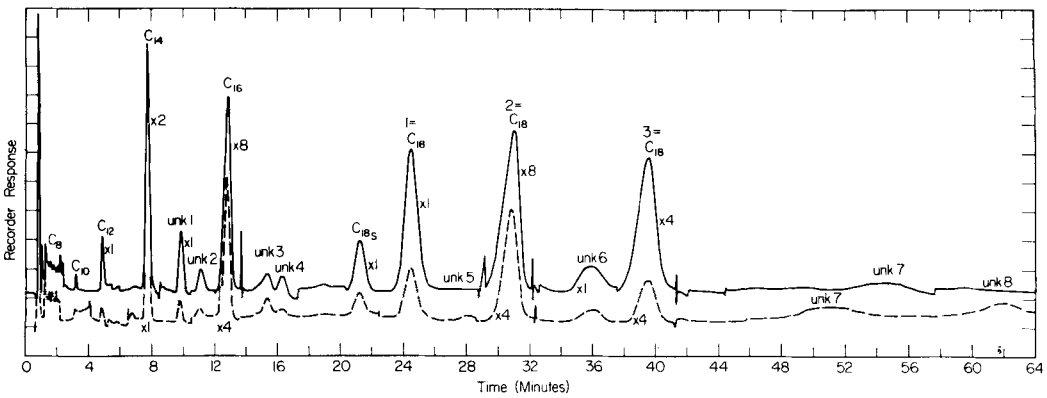

Fig. 1.—Separation of methyl esters of fatty acids in freeze-dried and oven-dried dandelion root at 196°, Spring collection. Samples: —— (B) 4.0 μl. O.D., – – (A) 5.7 μl. F.D.; column packing, 10% E.G.S. on firebrick; column, 144 in. × 0.25 in.; flow rate, 105 ml./min.; temp., 196°; current, 236 mv.

stearic acid of the oven-dried samples of the Spring collection and that of oleic acid in the oven-dried samples of the Spring and Autumn collection tends to support this conclusion.

In the oven-drying process, the Spring collected root shows a higher content of palmitic, linoleic, and linolenic acids over the freeze-dried sample, which seems to indicate that synthesis of the fatty acids continues in the oven-drying process. It is further believed that little degradation occurs in the oven-drying process since, if this did occur, there should be less of these larger fatty acids and a greater percentage of smaller fatty acids. The data (Table I) show, however, that there is a greater percentage of small molecular weight fatty acids and a smaller percentage of the larger fatty acids in the freeze-dried sample. This finding also supports the contention that synthesis does continue for a time during the oven-drying process. This is further supported by the fact that these differences are more marked

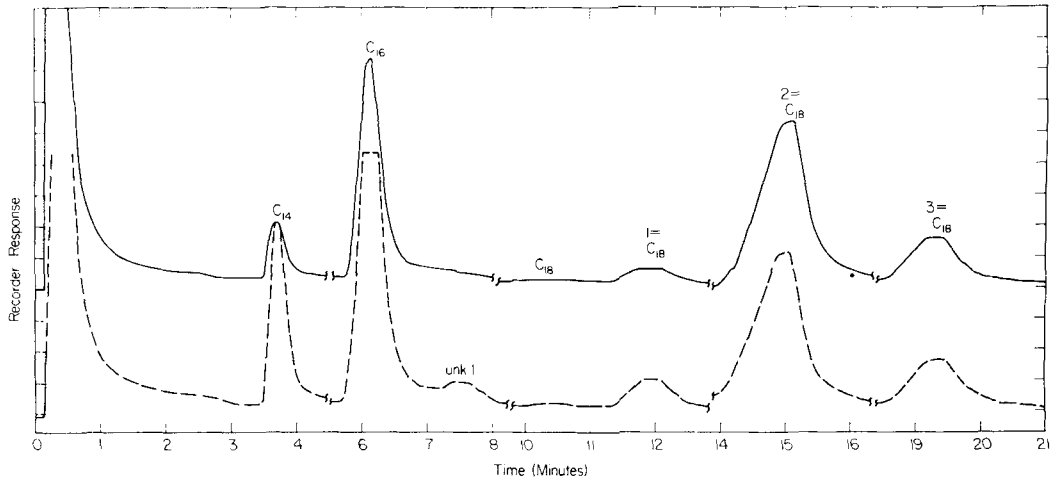

Fig. 2.—Separation of methyl esters of fatty acids in freeze-dried and oven-dried dandelion root at 195°, Autumn collection. Samples: ——(B) 5.0 μl. O.D., – –(A) 5.0 μl. F.D.; column packing, 10% E.G.S. on firebrick; column, 72 in. × 0.25 in.; flow rate, 90 ml./min.; temp., 195°; current, 220 mv.

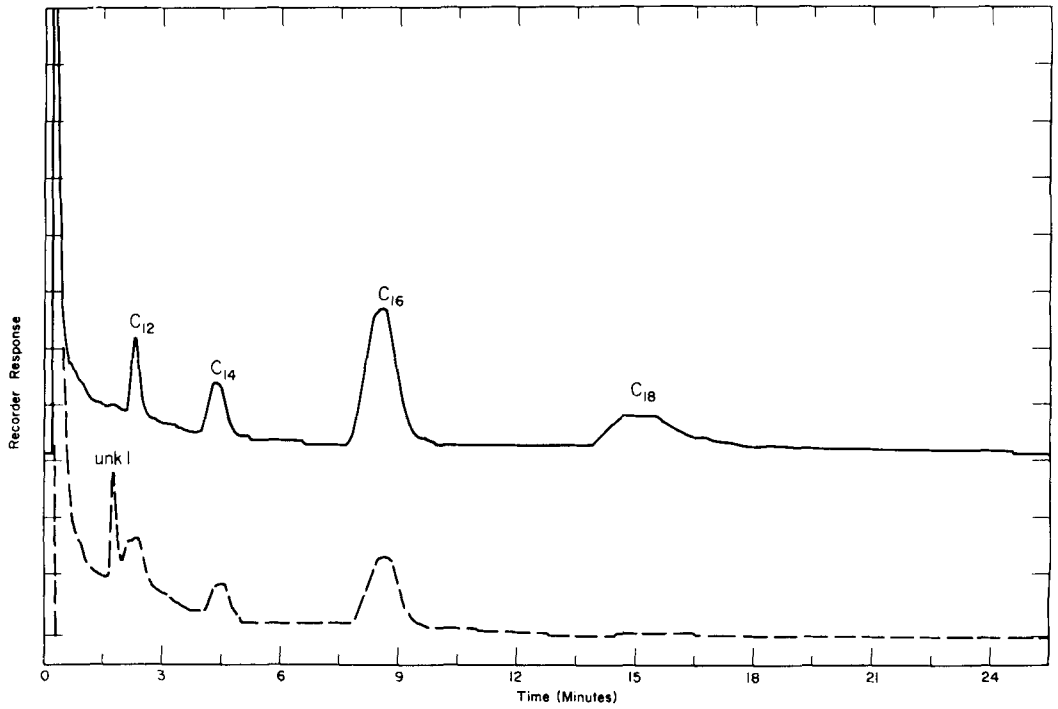

Fig. 3.—Separation of methyl esters of fatty acids in freeze-dried and oven-dried dandelion root at 198°, Summer collection. Samples: ——(B) 8.0 μl. O.D., – –(A) 6.5 μl. F.D.; column packing, silicon on firebrick; column, 72 in. × 0.25 in.; flow rate, 90 ml./min.; temp., 198°; current, 220 mv.

in the Autumn collection which required 6 days to oven-dry as compared with the Spring collection which was dried in 3 days.

Unknown acids Nos. 1, 2, 3, 4, and 6 may possibly be branched-chain, unsaturated, or odd-numbered fatty acids of different chain length. The difference between the quantities of these fatty acids in the oven-dried and freeze-dried samples can also be explained in reference to the amounts of the larger fatty acids present.

The appearance of unknown acids Nos. 5 and 8 only in the freeze-dried samples of the Spring root is of special interest. It was observed that the solutions of methyl esters of fatty acids of the freeze-dried samples were unstable. After a short time, the solutions developed a white precipitate. Consequently, fresh solutions were always used in the gas chromatographic determination of the freeze-dried samples. The solutions of the esters of the oven-dried samples were apparently stable in that they did not show any precipitation over a 12-hr. period. This observation suggests the possibility that unknown acids Nos. 5, 7, and 8 may be highly unsaturated compounds or otherwise unstable molecules which could have been destroyed in the oven-dried samples.

The alteration in the fatty acid distribution, as illustrated by this work, could suggest that other components of this plant are altered by methods used in curing the plant.

SUMMARY AND CONCLUSIONS

1. The fatty acid contents are greatly affected by the temperature and time required for drying dandelion root.

2. Oven-drying does greatly influence the distribution and molecular nature of fatty acid components of dandelion root as compared to freeze-drying.

3. It appears that myristic and stearic acid contents are higher in the freeze-dried than in the oven-dried dandelion root of the Spring collection. Myristic, palmitic, and oleic acids are higher in the freeze-dried than in the oven-dried root of the Autumn collection.

4. In oven-drying process, the Spring and Autumn collected roots show a higher content of linoleic and linolenic acids over the freeze-dried samples, which seems to indicate that synthesis of fatty acids continues in the oven-drying process.

5. It is believed that little degradation occurs in the oven-drying process since, if this did occur, there should be less of these larger fatty acids and a greater percentage of smaller fatty acids.

6. The presence of a greater percentage of small molecular weight fatty acids and a smaller percentage of the larger fatty acids in the freeze-dried samples suggests that synthesis does continue for a time during the oven-drying process.

7. Unknown fatty acids Nos. 2, 3, and 7 are greater in the freeze-dried root of the Spring collection than in the oven-dried samples. Unknown fatty acids Nos. 5, 7, and 8 appear only in the freeze-dried root.

8. Unknown fatty acids Nos. 1, 2, 3, 4, and 6 may possibly be branched-chain, unsaturated, or odd-numbered fatty acids of different chain lengths.

9. Unknown acids Nos. 5, 7, and 8 may possibly be highly unsaturated compounds.

10. The changes occurring in the fatty acid distribution of the root as a result of the two methods of drying indicate that the method of drying a plant material can have a marked effect on these molecules.

Isotonic Solutions XIII

Hemolysis of Red Corpuscles by Various Substances in the Presence of Sodium Chloride

By MARGARET A. SHAW† and WILLIAM J. HUSA

Various compounds which cause hemolysis in the presence of 0.6% sodium chloride were studied in environments of higher concentrations of sodium chloride. An increase in the concentration of sodium chloride reduced the degree of hemolysis produced by a compound in the presence of 0.6% sodium chloride in some instances, but this effect did not occur as a general rule for all compounds. Since 0.1% sodium carbonate did not cause an appreciable discoloration of oxyhemoglobin, it was retained as a standard for total hemolysis in the hemolytic method employed.

PREVIOUS INVESTIGATORS have emphasized the uncertainty associated with the use of physicochemical data to determine whether a solution is isotonic with the blood since methods utilizing colligative properties of solutions ignore the selective permeability of the corpuscular membrane and other pertinent factors. This variation is vividly shown by the fact that some substances cause hemolysis even in the presence of 0.6% sodium chloride which would prevent hemolysis if no other substance were present (1–3).

Compounds studied in this investigation generally exhibited a common property in their behavior toward red blood corpuscles when examined in the presence of 0.6% sodium chloride, *i.e.*, at a certain point, a relatively small change in concentration of the drug generally caused an abrupt increase in the degree of hemolysis. Exceptions to this were procaine hydrochloride and 2-propoxyprocaine hydrochloride.

Marcus and Husa (2) found that solutions of procaine hydrochloride ranging in concentration from 4.00 to 10.00% caused hemolysis in the presence of 0.6% sodium chloride. Using the hematocrit method, Setnikar and Temelcou (4) found that a solution of 5.05% procaine hydrochloride in 0.6% sodium chloride produced hemolysis of rabbit erythrocytes, but hemolysis was prevented when the sodium chloride concentration was increased to 1.3%.

The purpose of the present investigation was to determine by use of the hemolytic method whether the presence of hyperosmotic concentrations of sodium chloride might have general application in preventing the destruction of red blood cells by substances which cause hemolysis in an environment of 0.6% sodium chloride. In addition, a recent report (5) indicated that the alkalinity of 0.1% sodium carbonate solution caused a discoloration of oxyhemoglobin which would invalidate its use as a standard for 100% hemolysis in the hemolytic method. Five hemolyzing solutions were compared in regard to the degree of hemolysis each produced and to determine whether there was any significant change in the color of oxyhemoglobin upon mixing with each hemolyzing solution.

EXPERIMENTAL

Collection of Blood.—The human blood used in various experiments was obtained primarily from the veins of the arms of a 27-year old white female by means of a hypodermic syringe. Blood was taken occasionally from other white volunteers, and a fresh blood sample was utilized for each experiment. Each fresh blood sample was treated in the manner previously described by Grosicki and Husa (6).

Chemicals.—The medicinal chemicals were contributed by the manufacturers. The other chemicals were of C.P. grade with the exception of saponin which was a purified grade.

Preparation of Solutions.—Solutions were prepared by diluting aliquot portions of appropriate stock solutions with triple distilled water.

Quantitative Determination of Per Cent Hemolysis.—Determination of the degree of hemolysis produced by various solutions under examination was accomplished by use of the hemolytic method described by Grosicki and Husa (6). Fragility tests are used to minimize deviations due to the variability of blood when hemolysis is due entirely to osmotic effects. However, no standard method has been established to compensate for the variability of blood when some factor such as an effect on the corpuscular membrane is operative in the presence of 0.6% sodium chloride which would prevent hemolysis if no other compound were present. Consequently, fragility tests offered no advantage in

† Fellow of the American Foundation for Pharmaceutical Education, 1959–1961. Present address: School of Pharmacy, University of North Carolina, Chapel Hill.

the majority of experiments performed in this investigation and were deemed unnecessary in obtaining information which would reveal whether or not the addition of hyperosmotic sodium chloride concentrations would prevent hemolysis by certain compounds which cause hemolysis in the presence of 0.6% sodium chloride. With the elimination of the fragility tests, solutions of sodium chloride alone, corresponding to the sodium chloride concentrations utilized in a particular experiment, were used as controls.

Comparison of Hemolyzing Solutions Producing Approximately Complete Hemolysis.—The hemolyzing solutions tested exhibited no appreciable degree of absorbance *per se*. The hemolytic method was employed to compare the degree of hemolysis elicited by triple distilled water, 0.1% sodium chloride, 0.1% sodium carbonate, 0.01% saponin, and a solution containing 0.1% sodium carbonate and 0.01% saponin. The greatest difference in the average colorimeter readings was 1.3% when per cent hemolysis was calculated on the basis of triple distilled water producing complete hemolysis; this difference was considered to be within experimental error. In other tests, colorimeter readings were determined immediately after mixing each of the hemolyzing solutions with oxyhemoglobin solution prepared by laking red blood cells in triple distilled water. Colorimeter readings were also taken after storage in a refrigerator for 4- and 24-hour periods. Results indicated that no appreciable discoloration of oxyhemoglobin occurred within the time interval required for hemolytic determinations. Consequently, 0.1% sodium carbonate solution was retained as a standard for complete hemolysis in the hemolytic method employed in this investigation.

Reproducibility of Results.—Parallel results and duplicate colorimeter readings were generally obtained when the degree of hemolysis approximated 0 or 100%. However, experimental data associated with concentrations of some compounds producing an intermediate degree of hemolysis exhibited excessive variations, which might be attributed to factors the hemolytic method employed, is incapable of controlling. However, ascertaining the exact percentage of hemolysis produced by the compounds was not essential in determining whether or not the addition of hyperosmotic quantities of sodium chloride would prevent hemolysis produced by the compounds in the presence of 0.6% sodium chloride.

Experiments were conducted to determine whether an uncontrollable factor might be introduced in hemolytic determinations during the time lapse between the addition of blood to the solution under study and the subsequent inversion of the colorimeter tubes to insure thorough mixing. Experiments were performed in which the solutions under study, as well as the 0.85% sodium chloride blank and 0.1% sodium carbonate standards for 100% hemolysis, were treated in the same manner with the exception that one portion of the tubes was shaken immediately after the addition of blood, whereas their counterparts were treated in the usual way. Results indicated that the time lapse between the addition of blood and shaking of the mixture did not account for the variations found in duplicate tubes.

DISCUSSION

Higher concentrations of sodium chloride generally caused a significant reduction in the degree of hemolysis produced by procaine and 2-propoxyprocaine hydrochlorides, ammonium salicylate, and ammonium benzoate in the presence of 0.6% sodium chloride. In most cases, hemolysis was eliminated. However, a smaller inhibitory action was exhibited by solutions of ammonium benzoate. Furthermore, a notable exception was apparent in 4.00% solutions of ammonium benzoate which caused approximately total hemolysis in environments of 0.6, 0.9, 1.2, and 1.5% sodium chloride as indicated in Table I. Absence of hemolysis in procaine hydrochloride solutions ranging in concentration from 4.00 to 10.00% in the presence of 1.3% sodium chloride indicates that the results obtained by Setnikar and Temelcou (4) for rabbit blood also hold true for human blood.

Two trends appeared evident upon examination of the experimental data obtained for pramoxine, benoxinate, and hexylcaine hydrochlorides, and butacaine sulfate. Results generally indicated that additional quantities of sodium chloride inhibited hemolysis somewhat when concentrations of the drug were used such that the degree of hemolysis produced in the presence of 0.6% sodium chloride was low. However, in concentrations of the compound causing degrees of hemolysis ranging from intermediate to essentially complete in 0.6% sodium chloride, the addition of hyperosmotic quantities of sodium chloride did not appear to inhibit hemolysis.

A crystalline precipitate appeared in solutions of several concentrations of butacaine sulfate in 1.2 and 1.5% sodium chloride before the addition of blood. In contrast to the effect produced on butacaine sulfate solutions by increased proportions of sodium chloride, several solutions of pramoxine hydrochloride in some concentrations of sodium chloride exhibited evidence of precipitation after incubation and centrifugation of the blood-salt mixtures. Higher concentrations of sodium chloride appeared to decrease the precipitation until the effect was eliminated as far as visual observation could detect.

Experimental data indicated that phenmetrazine hydrochloride did not behave in a manner similar to any of the other compounds studied in this investigation. As the concentration of sodium chloride was increased, a corresponding augmentation in the degree of hemolysis, compared to that produced in the presence of 0.6% sodium chloride, was effected. The only exception to this trend was exhibited by 5.40% phenmetrazine hydrochloride solutions in environments of 0.6, 0.9, 1.2, and 1.5% sodium chloride; essentially complete hemolysis was elicited in the presence of 0.6% sodium chloride, and increasing the concentration of sodium chloride afforded no apparent change in the degree of hemolysis.

SUMMARY

1. An increase in the concentration of sodium chloride reduced the degree of hemolysis produced by procaine hydrochloride, 2-propoxyprocaine hydrochloride, and ammonium salicylate solutions in an environment of 0.6% sodium chloride. A similar effect was noted in most of the concentrations of ammonium benzoate studied.

2. Increasing the concentration of sodium chloride in solutions of pramoxine, benoxinate, and hexylcaine hydrochlorides, and butacaine sulfate afforded some reduction in the degree of hemolysis produced by the compound in 0.6% sodium chloride in cases where the degree of hemolysis was slight. No reduction in the degree of hemolysis was observed as a result of augmenting the sodium chloride concentration when the compound under examination caused degrees of hemolysis ranging from intermediate to essentially complete in the presence of 0.6% sodium chloride.

3. Higher concentrations of sodium chloride generally increased the degree of hemolysis produced by phenmetrazine hydrochloride solutions in the presence of 0.6% sodium chloride. In the case of 5.40% solutions of phenmetrazine hydrochloride, hemolysis was essentially complete in presence of 0.6, 0.9, 1.2, and 1.5% sodium chloride.

4. No appreciable discoloration of oxyhemoglobin resulted from the presence of 0.1% sodium carbonate. Triple distilled water, 0.1% sodium chloride, 0.1% sodium carbonate, 0.01% saponin, and a solution containing 0.1% sodium carbonate and 0.01% saponin caused the same degree of hemolysis within experimental error.

5. The slight time lapse between the addition of blood to the solution under study and the subsequent shaking of the mixture seemed to produce no appreciable variation in experimental data.

Modification of Physical Properties of Certain Antitussive and Antihistaminic Agents by Formation of N-Cyclohexylsulfamate Salts

By JAMES A. CAMPBELL and JAMES G. SLATER

The N-cyclohexylsulfamic acid salts of four well known therapeutic agents were prepared. Salts of two of the compounds, dextromethorphan and chlorpheniramine, were found to have greatly improved taste and increased solubility. Accelerated aging studies indicate good stability.

PROMINENT among the factors which must be considered in the development of oral dosage forms are those of solubility and taste acceptability. These factors present no great problem provided the drug is to be administered in such dosage forms as capsules or tablets which are designed to be swallowed as a unit. However, in those cases where it is desirable to administer a drug in liquid form, chewable tablet, lozenge, or other such forms, solubility and taste acceptability become factors of prime consideration.

SUMMARY

1. An increase in the concentration of sodium chloride reduced the degree of hemolysis produced by procaine hydrochloride, 2-propoxyprocaine hydrochloride, and ammonium salicylate solutions in an environment of 0.6% sodium chloride. A similar effect was noted in most of the concentrations of ammonium benzoate studied.

2. Increasing the concentration of sodium chloride in solutions of pramoxine, benoxinate, and hexylcaine hydrochlorides, and butacaine sulfate afforded some reduction in the degree of hemolysis produced by the compound in 0.6% sodium chloride in cases where the degree of hemolysis was slight. No reduction in the degree of hemolysis was observed as a result of augmenting the sodium chloride concentration when the compound under examination caused degrees of hemolysis ranging from intermediate to essentially complete in the presence of 0.6% sodium chloride.

3. Higher concentrations of sodium chloride generally increased the degree of hemolysis produced by phenmetrazine hydrochloride solutions in the presence of 0.6% sodium chloride. In the case of 5.40% solutions of phenmetrazine hydrochloride, hemolysis was essentially complete in presence of 0.6, 0.9, 1.2, and 1.5% sodium chloride.

4. No appreciable discoloration of oxyhemoglobin resulted from the presence of 0.1% sodium carbonate. Triple distilled water, 0.1% sodium chloride, 0.1% sodium carbonate, 0.01% saponin, and a solution containing 0.1% sodium carbonate and 0.01% saponin caused the same degree of hemolysis within experimental error.

5. The slight time lapse between the addition of blood to the solution under study and the subsequent shaking of the mixture seemed to produce no appreciable variation in experimental data.

Modification of Physical Properties of Certain Antitussive and Antihistaminic Agents by Formation of N-Cyclohexylsulfamate Salts

By JAMES A. CAMPBELL and JAMES G. SLATER

The N-cyclohexylsulfamic acid salts of four well known therapeutic agents were prepared. Salts of two of the compounds, dextromethorphan and chlorpheniramine, were found to have greatly improved taste and increased solubility. Accelerated aging studies indicate good stability.

PROMINENT among the factors which must be considered in the development of oral dosage forms are those of solubility and taste acceptability. These factors present no great problem provided the drug is to be administered in such dosage forms as capsules or tablets which are designed to be swallowed as a unit. However, in those cases where it is desirable to administer a drug in liquid form, chewable tablet, lozenge, or other such forms, solubility and taste acceptability become factors of prime consideration.

Received April 28, 1961, from the Pharmacy Research Laboratory, Miles Laboratories, Inc., Elkhart, Ind.
Accepted for publication August 18, 1961.
Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.

Some drugs present no taste problem because most people do not find the characteristic taste objectionable. Many drugs, even though moderately distasteful, are acceptable to some people because they are therapeutic agents and are not intended to appeal to the gustatory sense. However, it appears that people, in general, have come to expect and demand palatability in therapeutic agents.

Unpleasant tastes are overcome or improved upon in various ways. The usual method involves the judicious selection and use of additives. Cook (1) noted three factors in successful flavoring of pharmaceuticals: "(*a*) selection of a harmonious flavor, (*b*) effective masking, and (*c*) utilizing the undesirable taste as a base upon which a palatable formulation is built." Entrekin and Becker (2) found that the following would aid in disguising the bitter taste of quinine hydrochloride; adding citric acid, adding sodium chloride to some types of syrups, increasing sugar concentration, and increasing viscosity. In a recent survey of types of flavors used by pharmaceutical manufacturers for improving taste, Wesley (3) divided the flavors into two main categories: (*a*) fruit, and (*b*) nonfruit. It was observed that there was a trend toward the use of fruit flavors with a single flavor being used in 72% of the cases and with a combination being used in 28% of the cases. Pharmaceutical flavors (4) in descending order of frequency of use were found to be cherry, fruit (nonspecific), orange, raspberry, chocolate, and mint.

With the skillful application of masking and flavoring techniques available, one can usually produce an acceptable product provided there are no stringent restrictions on dilution. However, in cases where it is desirable to administer drugs in a rather concentrated form, such as drop dosage, the usual methods of taste control are sometimes inadequate. In such a situation, one must seek other ways of dealing with the taste problem while keeping in mind the solubility limitations.

Conceivably, one might be able to modify the taste characteristics of certain drugs by formation of salts or complexes of the drug which have more acceptable taste characteristics. This might be achieved in either of two ways; the formation of an insoluble compound which would be tasteless (5), or the formation of a soluble salt possessing an improved taste. One obvious disadvantage of the former would be the insolubility which would preclude its use as a solution. On the other hand, the formation of a soluble salt with improved taste is not always easy to achieve.

The objective in the study to be described was the formation of soluble, palatable, stable salts of certain characteristically bitter amine drugs. Four well-known therapeutic agents were chosen for the study: two antitussive agents—noscapine and dextromethorphan; and two antihistaminic agents—thenylpyramine and chlorpheniramine (6). The drugs, in the form of the free bases, were caused to react with N-cyclohexylsulfamic acid to form the corresponding salts.

A preliminary taste evaluation of the resulting salts was performed as follows: Aqueous solutions of the new salts as well as the commonly occurring salts were prepared in 0.004 *M* concentration. The solutions were tasted by a panel of six people. The dextromethorphan and chlorpheniramine salts of N-cyclohexylsulfamic acid were judged to be superior to the original salts (dextromethorphan hydrobromide and chlorpheniramine maleate) by the panel, whereas the new salts of noscapine and thenylpyramine were judged to have no advantage over the original forms. The latter two compounds were not considered further but the dextromethorphan N-cyclohexylsulfamate and chlorpheniramine N-cyclohexylsulfamate were subjected to further investigation.

EXPERIMENTAL

Formation of the Salts

Two different methods for forming the salts were utilized. These will be referred to as Methods A and B.

Method A.—Equivalent quantities of N-cyclohexylsulfamic acid and the free amine base were placed in a round-bottomed flask. Absolute ethanol was added in the proportion of 4 ml. of ethanol to each Gm. of N-cyclohexylsulfamic acid. This mixture was refluxed for a period of 1 hour and then concentrated to approximately one-half its original volume. Approximately three times its volume of ether was added to cool the solution. After precipitation was complete, the precipitate was collected on a filter and dried under vacuum.

Method B.—A slurry of the free base in water was titrated with a 0.1 *N* solution of N-cyclohexylsulfamic acid to the end point using a titrimeter. There was a gradual dissolution of the base as the end point was approached with a complete disappearance at the end point. The solution was evaporated to dryness using a Rinco evaporator at temperatures ranging up to 85°.

Dextromethorphan N-Cyclohexylsulfamate

The compound is a white granular substance. One gram is soluble in 9.7 ml. water. Melting characteristics are as follows: 80° (partial liquefaction), 217–218° (decompn).

Anal.—Calcd. for $C_{18}H_{25}NO \cdot C_6H_{13}NO_3S \cdot H_2O$, M. W. 468.66: N total, 5.99. Found: N total (Kjeldahl), 6.14.

Infrared Spectra.—Infrared spectra of equivalent concentrations of dextromethorphan N-cyclohexyl-

sulfamate and of an equimolar mixture of dextromethorphan and N-cyclohexylsulfamic acid were run in potassium bromide pellets. The spectra are shown in Fig. 1. Certain absorption peaks appeared in the spectrum of the compound but were absent in the spectrum of the reactants. These peaks were found at the following points: 760, 800, 1150, and 1170 cm.$^{-1}$. On the other hand, certain absorption peaks appeared in the spectrum of the mixture but were absent in the spectrum of the compound. These were observed at the following points: 705, 820, 1050, 1220, 1231, 1250, and 3250 cm.$^{-1}$.

Optical Rotation.—The compound was found to have the following optical rotation: $[\alpha]_D^{25} = +28°$ to $+29°$ (2.5% solution in water).

Stability Studies.—Aqueous solutions of the compound were prepared at pH levels of 4, 5, 6, and 7 using phthalate–NaOH and KH_2PO_4–NaOH buffer mixtures. After assay by optical rotation, the solutions were placed in an oven at 50°. The solutions were assayed and inspected at the end of 1 month and 6 months. The results are shown in Table I. From the data it appears that dextromethorphan N-cyclohexylsulfamate in aqueous solution has good stability when maintained at a pH not greater than 4.

TABLE I.—STABILITY OF DEXTROMETHORPHAN N-CYCLOHEXYLSULFAMATE IN AQUEOUS SOLUTION AT 50°

	Original	One Month		Six Months	
pH	% Found	% Found	Appearance	% Found	Appearance
4	2.14	2.13	No change	1.83	Some sediment
5	2.11	1.22	Little sediment	...	Sediment
6	2.09	0.74	Sediment	...	Sediment
7	2.10	0.58	Sediment	...	Sediment

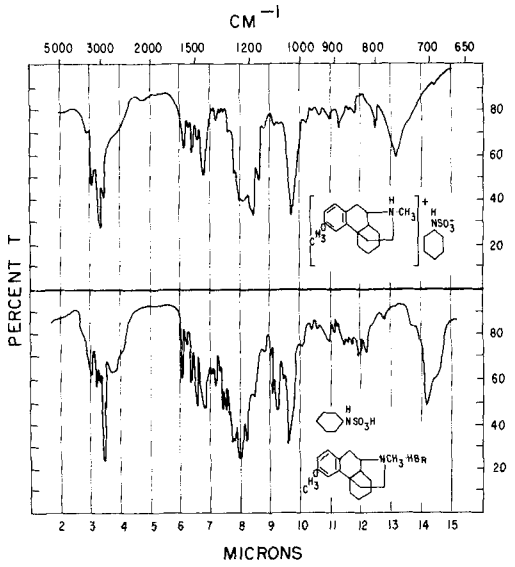

Fig. 1.—Infrared spectra of dextromethorphan N-cyclohexylsulfamate (upper section) and an equimolar mixture of dextromethorphan hydrobromide and N-cyclohexylsulfamic acid (lower section).

Chlorpheniramine N-Cyclohexylsulfamate

This compound appears as a white, or slightly pink crystalline substance. One gram is soluble in 10 Gm. of water. The melting point was found to be 90–95°. It was found to have an absorption maximum at 262 mμ.

Anal.—Calcd. for $C_{16}H_{19}ClN_2 \cdot C_6H_{13}NO_3S$, M.W. 454.04: N total, 9.25; Cl, 7.8. Found: N total (Kjeldahl), 9.27; Cl, 7.73.

Infrared Spectra.—Infrared spectra of equivalent concentrations of chlorpheniramine N-cyclohexylsulfamate and of an equimolar mixture of chlorpheniramine and N-cyclohexylsulfamic acid were run in potassium bromide pellets. The spectra are shown in Fig. 2. Certain absorption peaks appeared in the spectrum of the compound that were absent in the spectrum of the mixture. These peaks can be observed at 940, 1122, and 1550–1560 cm.$^{-1}$. Likewise, certain peaks were found in the spectrum of the mixture that were absent in the spectrum of the compound. These peaks can be observed at 725, 780, 830, 1200, 2700, and 3500 cm.$^{-1}$.

Stability Studies.—Aqueous solutions were prepared in a concentration of approximately 0.4%. The solutions were buffered at pH 4, 5, 6, and 7, respectively. The solutions were assayed by ultraviolet absorption at 262 mμ using a 0.4% chlorpheniramine maleate solution as the standard. After assay, the solutions were placed in an oven at 50°. The solutions were inspected and assayed at the end of 2 months. The results are shown in Table II. From the data contained in Table II it appears that chlorpheniramine N-cyclohexylsulfamate solution possesses good stability when maintained at a pH of 4.

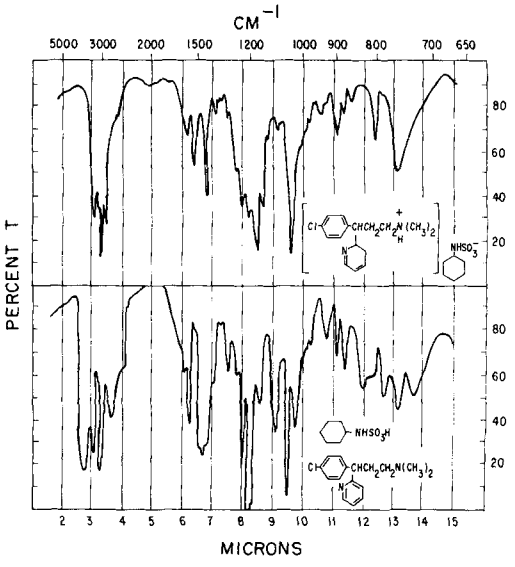

Fig. 2.—Infrared spectra of chlorpheniramine N-cyclohexylsulfamate (upper section) and an equimolar mixture of chlorpheniramine and N-cyclohexylsulfamic acid (lower section).

TABLE II —STABILITY OF CHLORPHENIRAMINE N-CYCLOHEXYLSULFAMATE IN AQUEOUS SOLUTION AT 50° FOR 2 MONTHS

pH	Original, mg./ml.	Two Months— mg./ml.	Appearance	% Loss
4	3.24	3.30	Clear	0
5	4.05	3.46	Clear	15
6	3.65	3.20	Clear	13
7	3.85	2.62	Sediment	32

SUMMARY AND CONCLUSIONS

1. The N-cyclohexylsulfamic acid salts of dextromethorphan and chlorpheniramine were prepared and characterized.

2. The salts were found to have greatly improved bitterness thresholds over that of the commonly occurring salts of the compounds.

3. When submitted to accelerated aging conditions, the compounds appeared to have good stability provided they were maintained at optimum pH levels.

Influence of Kinetin and Gibberellic Acid on the Growth and Alkaloid Patterns in *Datura meteloides*

By DARRYL G. AMBROSE† and LEO A. SCIUCHETTI

Datura meteloides D.C. was administered four weekly-doses of 25 mcg. of kinetin (K) or gibberellic acid (GA). Different growth responses were induced by each treatment. Significant increases in height were noted in plants treated with GA whereas those treated with K were shorter than controls. Considerable increases in dry weights were noted in the GA-treated plants while reductions were observed in K-treated plants. The concentration of alkaloids in the organs of plants treated with GA was markedly reduced but no significant changes occurred with K. The total alkaloid content per plant was less in each of the treated groups but total stem alkaloids were greater in those treated with GA. The per cent of chlorophyll a and b was decreased by GA but increased by K.

PREVIOUS INVESTIGATIONS with kinetin, 6-(furfurylamino)-purine, and gibberellic acid (GA) indicate that these substances induce a profound effect on plant growth. Kinetin (K) was isolated and synthesized in 1955 by Miller, *et al.* (1, 2). This growth regulator has been shown to affect cell division (1, 3), cell enlargement as well as cell division (3, 4), root development (5, 6), shoot formation (7), and seed germination (8–10). Kinetin substituted for the light requirement of *Lemna minor* (11) and caused a modification of sporeling ontogeny in *Marsilea vestita* (12). K-treatment of lupin embryos *in vitro* caused about a twofold increase in alkaloid synthesis (13). Mothes, *et al.*, have shown that K affects nitrogen metabolism (14). Soluble nitrogen compounds in excised tobacco leaves were drawn from other leaf areas or added from the outside by K (14). A review of the literature has indicated that research has not been performed on the effects of K on the growth and alkaloid biogenesis in *Datura meteloides*.

The metabolic effects of GA on many plants (15–17), as well as on some medicinal plants (18), have been well established. The concentration of alkaloids in the plant organs was reduced and stem weight was increased in *Datura stramonium* (18–21), *Atropa belladonna* (19, 20), *Hyoscyamus niger* (22), and tobacco (23, 24). Increased height and variable results on leaftop, and root growth have been reported (18–24).

In view of the fact that K had not been employed on *Datura* species, it was decided to investigate the effect of this substance on the growth pattern, alkaloid formation, and chlorophyll content of *Datura meteloides*. It was further desired to ascertain whether this plant would respond to a GA treatment in a manner similar to that previously reported for *Datura stramonium*, and, also, to observe whether K and GA would induce similar metabolic effects.

EXPERIMENTAL

Procedure.—*Datura meteloides* plants employed in this study were grown under greenhouse conditions. Seeds were germinated in flats containing a soil mixture of two parts of loam and one part of sand. Approximately 50 Gm. of complete organic fertilizer[1] was incorporated into the soil of each flat. On July 5, 1960, 72 14-day-old seedlings were transplanted into individual 1-gallon metal containers that had been filled with the sandy loam mixture. About 5 Gm. of complete fertilizer had been thoroughly mixed into the soil of each container prior to transplantation. The 72 seedlings were placed on eight different benches in the greenhouse. Nine plants were arranged on each bench by use of a randomization table (25). Nine plants each of *Datura tatula*, *Atropa belladonna*, and *Hyoscyamus niger* were also randomly arranged with *Datura meteloides* on each of the eight benches. The other species were being investigated simultaneously by other workers. Each species was labeled according to the following plan for treatment and harvest: three groups of 24 each were designated as controls, K-treated plants, and GA-treated plants; of the 24 plants within each group, eight each were harvested at 0, 2, and 4 weeks. The division of the plant into its morphological parts during each harvest, fresh and dry weight determinations, pulverization, and storage of the powdered material were conducted in a manner described in a previous publication (19).

On July 14 (zero time), the 16 plants for the K group and the corresponding plants of the GA group designated for the last two harvests were treated with a single 25-mcg. dose of the specific growth regulator. Treatments were continued hereafter at weekly intervals. The dose of the chemical was delivered from a micro pipet onto the surface of the youngest unfolding leaf by applying 0.1-ml. portions of the respective aqueous solutions. The GA[2] solution was prepared freshly from a stock alcoholic solution of GA by dilution with distilled water. The K solution was freshly prepared before each treatment by dissolving 2.5 mg. of kinetin in approximately 3 ml. of a stock potassium hydroxide solution having a pH of 11.2. This solution was back titrated with dilute sulfuric acid ($10^{-3}N$) to a pH of 6.5. Then, enough distilled water was added to make 10 ml. At this time, initial height measurements were made on all plants and the first harvest of eight plants from each group was made. Height measurements were taken weekly thereafter.

Growth Effects.—The K-treated plants and the controls resembled each other in habit and were more bushy than the GA-treated plants (Fig. 1). At the final harvest, some of the plants treated with K appeared darker in color than the controls. Typical gibberellin-effects were noted in the GA-treated group, such as greater internodal elongation, increased height, and a spindlier appearance (Fig. 1). The leaves of the GA-treated plants appeared slightly chlorotic initially, whereas the stems demonstrated an apparent chlorosis at the final harvest.

[2] The GA employed in this study was furnished through the courtesy of Dr. Edwin F. Alder, Agricultural Research Center, Eli Lilly and Co., Greenfield, Ind.

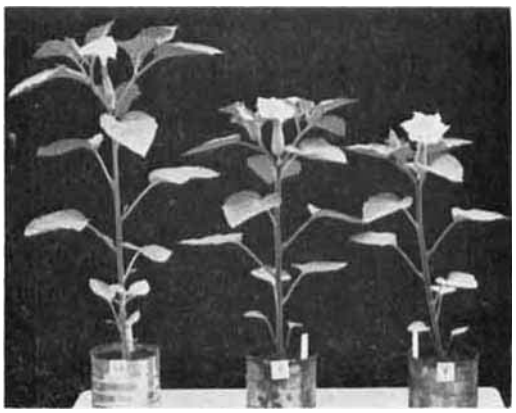

Fig. 1.—Effect of K and GA treatments on the growth of *Datura meteloides*. GA., Gibberellic acid; C, control; K, kinetin. Plants at the final harvest were about 7 weeks old.

Height measurements indicated that plants treated with K were shorter than controls throughout the observation period while the GA-treated plants grew progressively taller (Fig. 2). Treatment with GA induced height increases greater than 40% from the second through fourth weeks.

Fresh and Dry Weights.—The treatment with K caused less growth at the final harvest, as indicated by fresh and dry weight data (Table I). The final dry weights were about 86, 80, and 96% that of controls for leaves-tops, stems, and roots, respectively (Table I). The decreased growth of this group became apparent between the second and fourth weeks. On the other hand, a general favorable response on growth was induced by treatment with GA. The total dry weight per plant of this group attained its maximum gain (about 15%) at the last harvest (Table I). The largest increase in dry weight was noted in the stems. About a 40%

increase in stem weight was noted at the second and fourth weeks. The leaves-tops gained up to 15% in weight during the same period. Only at the final harvest was root dry weight less than controls.

Analysis for Alkaloids.—The alkaloid concentration, calculated as scopolamine, was determined by the Brummett-Sciuchetti method (20). The concentration of alkaloids (mg./Gm.) in the organs of the K-treated plants approximated that of the controls, while the concentration in the GA-treated plants was considerably lower in all plant parts throughout the stages of growth (Fig. 3.). The reductions of about 25% in the leaves-tops and the stems at the second and fourth weeks were considered significant.

Total Plant Alkaloids.—The total alkaloids per plant and per plant organ were obtained by multiplying the dry weight of the plant part by the per cent of alkaloids obtained from the alkaloid analyses and expressing the results in milligrams (Table II). The total alkaloid content generally was markedly reduced in the leaves-tops and stems by the K treatment. The reductions, compared with controls, amounted to about 20% at the final harvest. This was due mainly to decreased growth of these organs. No significant changes occurred in the roots of K-treated plants. Treatment with GA caused about a 20% reduction in the alkaloid content of the leaves-tops at each harvest and about a 15% decrease in the roots at the final harvest. Due to increased stem growth, the GA-treated plants showed gains in total stem alkaloids at each harvest (Table II).

Chlorophyll Content.—The chlorophyll analysis was conducted by a method described by Gjerstad (26). His method was modified by employing dried material, 1-Gm. samples of leaves-tops and 5 Gm. of stems, and using a Soxhlet extraction apparatus. The chlorophyll was completely extracted from the powdered material with a 20% water in acetone solvent. The results of the chlorophyll analysis are shown in Table III. The per cent of chlorophyll a and b in the leaves-tops and stems of the K-treated plants was markedly increased whereas that of the GA-treated plants was reduced considerably (Table III).

DISCUSSION AND CONCLUSIONS

Specific metabolic effects were noted in the plants treated with kinetin. Although the K-treated plants generally appeared similar to the controls in habit, several differences were noted. The treated plants were shorter than controls throughout the observation period and the leaves appeared darker at the final harvest. Growth of the aerial parts was retarded, but this did not occur until a period of time between the second and fourth weeks. The fresh and dry weights of the aerial parts were reduced up to 20% that of the controls at the final harvest. These observations indicate that there was a delayed response to the kinetin. It is altogether possible that a significant reduction in weight would have occurred had this experiment been allowed to continue for a longer period of time. The concentration of alkaloids was not appreciably altered in the plant parts by the K-treatment. The decreased alkaloid content per plant, per leaves-tops, and per stem at the final harvest was due primarily to the adverse effect of kinetin on growth. A most interesting aspect observed from the K-treatment was an increase in the per cent of chlorophyll in the aerial parts. The greatest increase was at the final harvest. This confirms the observations that the leaves generally appeared darker green in color at the final harvest. The fact that the increased per cent of chlorophyll generally directly paralleled the decrease in plant growth, as shown by the dry weight data, might indicate that there was not an increased capacity for chlorophyll synthesis by the K-treated plants; instead, the higher per cent of chlorophyll was probably due to concentration. Future histological work should clarify this phenomenon.

Datura meteloides responded as do other solanaceous plants when treated with GA (18–22). The following characteristic gibberellin-effects were noted: taller and spindlier plants, greater internodal elongation, slight chlorosis of the leaves and stems, significantly increased stem growth, and decreased concentration of alkaloids. Growth was stimulated by GA since increases in dry weights were generally noted throughout the observation period. In spite of a favorable effect on growth, the decreased concentration of alkaloids in the organs resulted in about a 10% reduction in total alkaloid content per plant at the final harvest. The reduced chlorophyll per cent in the aerial parts of the treated plants confirms our observations which were reported previously that GA-treated plants appeared chlorotic (18–20). The decreased chlorophyll per cent in the GA-treated plants is also in agreement with that reported for spearmint (27), but is not in agreement for that reported for peppermint (26) and foxglove (28). In this experiment, as well as the one reported for spearmint (27), the decrease in chlorophyll per cent was accompanied by appreciable increases in growth. This would suggest that the apparent paleness of leaves from gibberellin treatment is most likely due to dilution rather than a direct effect on chlorophyll synthesis.

Kinetin generally induced a different effect than did GA. The following differences were noted (K *vs.* GA): shorter and bushier plants *vs.* taller and spindly plants; decreased growth *vs.* increased growth; no change in alkaloid concentration in the plant organs compared with controls *vs.* appreciable decreases; a delayed response following treatment *vs.* a rapid response. These differences suggest that K and GA possess different modes of action in various metabolic processes involved in plant growth and biosynthesis.

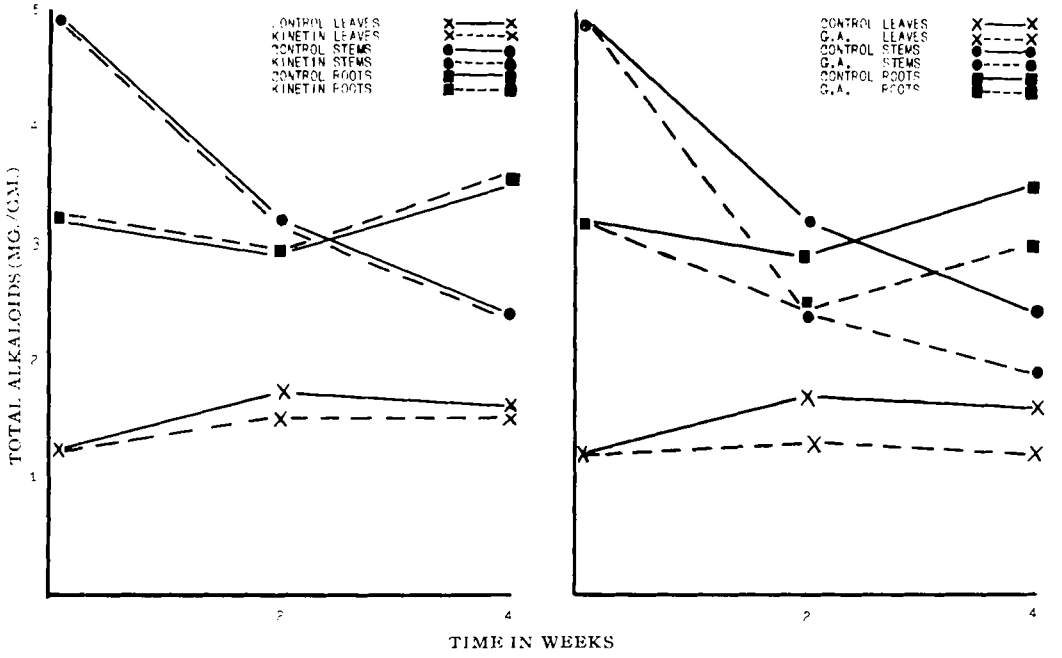

Fig. 3.—Alkaloid pattern of kinetin and gibberellic acid-treated plants. Left, K-treated; right, GA-treated.

Separation and Identification of Sympathomimetic Amines by Gas-Liquid Chromatography

By E. BROCHMANN-HANSSEN and A. BAERHEIM SVENDSEN

A number of commonly used sympathomimetic amines have been subjected to gas chromatographic analysis on low-loaded columns. With the exception of certain isomers, most compounds can be separated on a column of silicone rubber SE-30. Many of the amines investigated react with ketones and the products produce sharp, symmetrical peaks on the gas chromatogram. Ephedrine and pseudoephedrine can be separated and identified on the basis of the difference in the rate of reaction with acetone. Monohydroxyphenols show strong adsorptive effects as the free bases but can readily be gas chromatographed as the acetone derivatives. The dihydroxyphenols are converted to the triacetyl derivatives which are treated with hexamethyldisilazane prior to the gas chromatographic analysis.

OF THE HUNDREDS of sympathomimetic amines which have been synthesized or isolated from natural sources, about 25 find widespread use in medical practice (1). Many methods for their identification have appeared in the literature (2–9). The official products are usually identified by color reactions, precipitation reactions, or on the basis of the melting ranges of the free amines, their salts, or prepared derivatives. Although these methods often lack specificity, they are usually satisfactory when the problem is to confirm the identity of a single compound which is available in sufficient amount. When mixtures of several amines are involved, as is often the case in pharmaceutical preparations, a separation is usually necessary before the components can be identified. In biological work, the problem is further complicated by the limited amounts available and by the presence of amines which are normal products of the animal body or formed by decomposition of biological material. Another complication stems from the fact that the metabolic products of certain sympathomimetic amines are themselves used as drugs (10, 11).

Received March 3, 1962, from the University of California School of Pharmacy, San Francisco.
Accepted for publication April 9, 1962.
This work was supported by a research grant (M-3487) from the National Institutes of Health.

Paper chromatography in combination with the use of several different spray reagents has recently been found to be a valuable method for problems in toxicology involving sympathomimetic amines (12).

In a preliminary communication, the authors showed that a number of widely used sympathomimetic amines could be separated by gas-liquid chromatography (13). The details of this study, which has been extended to include a larger number of compounds, are reported in the present paper.

EXPERIMENTAL

A Barber Colman model 15 gas chromatograph equipped with an argon β-ionization detector (radium 226) was used for the experimental work. The colums were glass U-tubes, 6 to 8 feet in length and having an inner diameter of 3 mm. The solid support materials were Gas-Chrom P, 100 to 140 mesh, and Chromosorb W, 60 to 80 mesh, both of which were washed with concentrated hydrochloric acid and methanolic potassium hydroxide and treated with hexamethyldisilazane (14). The stationary phases were applied by means of a solution in toluene or butanone as described by Horning, *et al.*, (15). The amines were introduced with a Hamilton microliter syringe as 1.0 μl. of a 0.5 to 1.0% solution of the free bases in chloroform, acetone, or butanone. A number of the amines were found to

Paper chromatography in combination with the use of several different spray reagents has recently been found to be a valuable method for problems in toxicology involving sympathomimetic amines (12).

In a preliminary communication, the authors showed that a number of widely used sympathomimetic amines could be separated by gas-liquid chromatography (13). The details of this study, which has been extended to include a larger number of compounds, are reported in the present paper.

EXPERIMENTAL

A Barber Colman model 15 gas chromatograph equipped with an argon β-ionization detector (radium 226) was used for the experimental work. The colums were glass U-tubes, 6 to 8 feet in length and having an inner diameter of 3 mm. The solid support materials were Gas-Chrom P, 100 to 140 mesh, and Chromosorb W, 60 to 80 mesh, both of which were washed with concentrated hydrochloric acid and methanolic potassium hydroxide and treated with hexamethyldisilazane (14). The stationary phases were applied by means of a solution in toluene or butanone as described by Horning, *et al.*, (15). The amines were introduced with a Hamilton microliter syringe as 1.0 μl. of a 0.5 to 1.0% solution of the free bases in chloroform, acetone, or butanone. A number of the amines were found to

react with the ketone solvents to produce reaction products which gave sharp, symmetric peaks on the chromatograms. The catechol amines, epinephrine and levarterenol, were first converted to the triacetyl derivatives (16) and then treated with an excess of hexamethyldisilazane in tetrahydrofuran, either at room temperature overnight or by refluxing for about 2 to 3 hours.

RESULTS AND DISCUSSION

The retention values of 16 sympathomimetic amines and/or their derivatives are listed in Table I. Ephedrine and pseudoephedrine do not separate as the free bases on silicone rubber SE-30, Fig. 1. However, pseudoephedrine reacts relatively rapidly

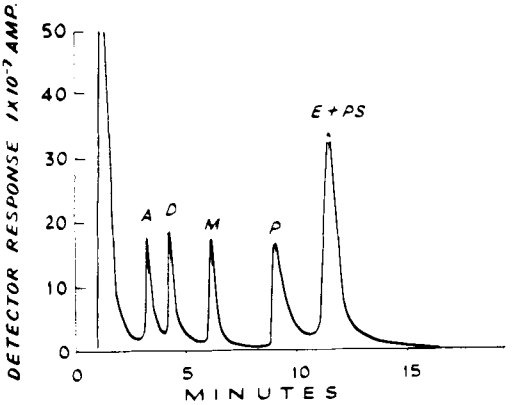

Fig. 1.—Gas chromatogram of six sympathomimetic amines on silicone rubber SE-30, 1.15%. A, amphetamine; D, methamphetamine; M, mephentermine; P, phenylpropanolamine; E, ephedrine; and PS, pseudoephedrine. Operating conditions; *cf.* Table I, footnotes[a], [c].

with acetone, while the reaction between acetone and ephedrine is very slow and incomplete. The reaction rate was studied gas chromatographically on the basis of the peak areas corresponding to the free amine and its ketone derivative. The relative rates of reaction of ephedrine and pseudoephedrine are expressed semiquantitatively in Table II. The two amines could easily be separated and/or identified by preparing an acetone solution and allowing it to stand for 2 to 3 hours prior to the gas chromatographic analysis, Fig. 2. Whereas all

of the primary amines investigated reacted with ketones, this was not the case with all of the secondary amines. The rate of the reaction between phenylpropanolamine and acetone is illustrated in Fig. 3. As would be expected, benzphetamine, being a tertiary amine, gave no reaction with ketones. The reaction between ketones and certain primary amines has been studied by Bergel and Lewis (17, 18). According to these authors, the reaction involves an addition followed by loss of water to form an azomethine. This is accompanied by a dramatic increase in the specific rotation of optically active amines and amino acids. With secondary amines no such loss of water can occur; the reaction is probably a simple addition forming an amino alcohol. Butanone, because of the bulkier ethyl group, reacted more slowly than acetone. Methamphetamine and propylhexedrine had retention times that were very close and could not be separated on the silicone rubber column, but they were separated without difficulty on the more selective fluorosilicone fluid, Fig. 4.

Hydroxyamphetamine could easily be separated from the nonphenolic as well as from the other phenolic amines. Metaraminol could be distinguished from phenylephrine and synephrine on fluorosilicone fluid, but not on silicone rubber, Tables I and III. The isomeric phenylephrine and synephrine could not be separated on either stationary phase.

[a] Ten milligrams of amine was dissolved in 1 ml. of acetone. Heating at 56–57° was carried out under reflux in micro equipment. The solutions were gas chromatographed under conditions described in Table I, footnotes[a, c].

The catechol amines are rather insoluble in most organic solvents and are, furthermore, firmly adsorbed on the low-loaded columns used in this work. Epinephrine and levarterenol were, therefore, converted to the triacetyl derivatives by treatment of an aqueous solution with acetic anhydride and sodium bicarbonate (16). Gas chromatographic analysis of triacetylepinephrine produced three peaks indicating that decomposition had taken place. This decomposition was probably due to the free alcoholic hydroxyl group which in the flash heater caused alcoholysis and transesterification resulting in a mixture of diacetyl-, triacetyl-, and tetraacetylepinephrine. Similar decomposition reactions have been observed by gas chromatography of acetylated morphine (19). Attempts to acetylate epinephrine completely did not entirely eliminate this problem. However, if the secondary alcohol group of triacetylepinephrine was converted to a trimethylsilyl ether, the resulting product gave a single, symmetrical peak. Levarterenol, after acetylation and treatment with hexamethyldisilazane, could be differentiated from epinephrine on the basis of the retention time, Table I.

TABLE III.—RETENTION TIMES OF SOME PHENOLIC AMINES ON FLUOROSILICONE FLUID, QF 1-0065[a]

Compound	—Retention Time, min.— Base[b]	Acetone Deriv.
Metaraminol	...	6.7
Phenylephrine	...	5.7
Synephrine	...	5.7

[a] Column, 6 ft. × 3 mm. i.d.; 2.8% QF 1-0065 (Dow Corning) on Chromosorb, 60–80 mesh; column temp., 138°; inlet pressure 30 lb. p.s.i. [b] No elution peaks were observed for the free amines.

CONCLUSION

With the exception of phenylephrine and synephrine, all the sympathomimetic amines studied could be separated and identified. The reaction with ketones was very useful as a means of separating and identifying certain amines which followed each other very closely as the free bases. The ketone derivatives, furthermore, gave nontailing peaks that should be suitable for quantitative work. Certain phenolic amines were difficult to gas chromatograph on low-loaded columns because of adsorptive effects. The monophenolic amines investigated gave good chromatograms as the ketone derivatives. The catechol amines gave best results by acetylation and treatment with hexamethyldisilazane prior to the gas chromatographic analysis.

Synthesis of Diphenic Acid Derivatives

By WILLIAM D. ROLL† and GUSTAV E. CWALINA

Five new derivatives of diphenic acid were prepared for the purpose of studying their antibacterial, antihyperglycemic, antispasmodic, and/or local anesthetic activity: *o,o'*-bis(2-nitro-1,3-dihydroxypropyl)biphenyl disodium salt; *o,o'*-bis(3-benzoxy-2-benzamido-1-hydroxypropyl)biphenyl; *o,o'*-bis(β-dichloroacetamidoethyl)diphenate; N,N'-bis(benzenesulfonyl)-*o,o'*-diphenoylurea, and *m,m'*-bis(N-carboxymethyl)diphenamide.

VARIOUS types of derivatives of diphenic acid were synthesized for the purpose of making them available for pharmacological testing as possible antibacterial, antihyperglycemic, antispasmodic, and/or local anesthetic agents.

Roberts and Johnson (1) reported that diethylaminoethyl diphenate and diethylaminoethyl imidoester of diphenanilide possessed local anesthetic activity. Case and Koft (2) synthesized a similar compound, diethylaminoethyl 5,5-diaminodiphenate, which had marked local anesthetic activity. A number of substituted amine esters and amides of diphenic acid were prepared by Demers and Jenkins (3) for evaluation as possible antispasmodics and antihistamines. Compound VII of our derivatives contains an amide-ester linkage.

Woolley (4) has suggested that analogs of phenylalanine might function as antimetabolites

Received April 25, 1958, from Purdue University, School of Pharmacy, Lafayette, Ind.
Accepted for publication March 22, 1962.
† Present address: College of Pharmacy, University of Toledo, Toledo, Ohio.

The catechol amines are rather insoluble in most organic solvents and are, furthermore, firmly adsorbed on the low-loaded columns used in this work. Epinephrine and levarterenol were, therefore, converted to the triacetyl derivatives by treatment of an aqueous solution with acetic anhydride and sodium bicarbonate (16). Gas chromatographic analysis of triacetylepinephrine produced three peaks indicating that decomposition had taken place. This decomposition was probably due to the free alcoholic hydroxyl group which in the flash heater caused alcoholysis and transesterification resulting in a mixture of diacetyl-, triacetyl-, and tetraacetylepinephrine. Similar decomposition reactions have been observed by gas chromatography of acetylated morphine (19). Attempts to acetylate epinephrine completely did not entirely eliminate this problem. However, if the secondary alcohol group of triacetylepinephrine was converted to a trimethylsilyl ether, the resulting product gave a single, symmetrical peak. Levarterenol, after acetylation and treatment with hexamethyldisilazane, could be differentiated from epinephrine on the basis of the retention time, Table I.

TABLE III.—RETENTION TIMES OF SOME PHENOLIC AMINES ON FLUOROSILICONE FLUID, QF 1-0065[a]

Compound	—Retention Time, min.— Base[b]	Acetone Deriv.
Metaraminol	...	6.7
Phenylephrine	...	5.7
Synephrine	...	5.7

[a] Column, 6 ft. × 3 mm. i.d.; 2.8% QF 1-0065 (Dow Corning) on Chromosorb, 60–80 mesh; column temp., 138°; inlet pressure 30 lb. p.s.i. [b] No elution peaks were observed for the free amines.

CONCLUSION

With the exception of phenylephrine and synephrine, all the sympathomimetic amines studied could be separated and identified. The reaction with ketones was very useful as a means of separating and identifying certain amines which followed each other very closely as the free bases. The ketone derivatives, furthermore, gave nontailing peaks that should be suitable for quantitative work. Certain phenolic amines were difficult to gas chromatograph on low-loaded columns because of adsorptive effects. The monophenolic amines investigated gave good chromatograms as the ketone derivatives. The catechol amines gave best results by acetylation and treatment with hexamethyldisilazane prior to the gas chromatographic analysis.

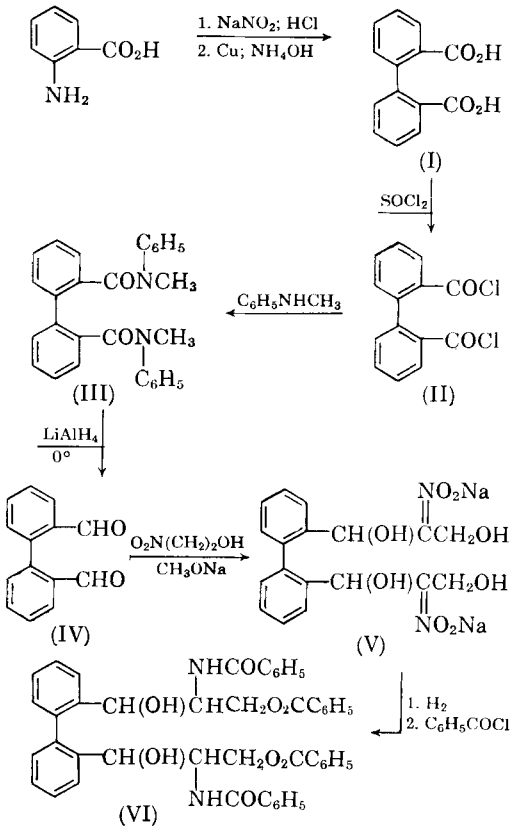
Synthesis of Diphenic Acid Derivatives

By WILLIAM D. ROLL† and GUSTAV E. CWALINA

Five new derivatives of diphenic acid were prepared for the purpose of studying their antibacterial, antihyperglycemic, antispasmodic, and/or local anesthetic activity: *o,o'*-bis(2-nitro-1,3-dihydroxypropyl)biphenyl disodium salt; *o,o'*-bis(3-benzoxy-2-benzamido-1-hydroxypropyl)biphenyl; *o,o'*-bis(β-dichloroacetamidoethyl)diphenate; N,N'-bis(benzenesulfonyl)-*o,o'*-diphenoylurea, and *m,m'*-bis(N-carboxymethyl)diphenamide.

VARIOUS types of derivatives of diphenic acid were synthesized for the purpose of making them available for pharmacological testing as possible antibacterial, antihyperglycemic, antispasmodic, and/or local anesthetic agents.

Roberts and Johnson (1) reported that diethylaminoethyl diphenate and diethylaminoethyl imidoester of diphenanilide possessed local anesthetic activity. Case and Koft (2) synthesized a similar compound, diethylaminoethyl 5,5-diaminodiphenate, which had marked local anesthetic activity. A number of substituted amine esters and amides of diphenic acid were prepared by Demers and Jenkins (3) for evaluation as possible antispasmodics and antihistamines. Compound VII of our derivatives contains an amide-ester linkage.



Woolley (4) has suggested that analogs of phenylalanine might function as antimetabolites

Accepted for publication March 22, 1962.
† Present address: College of Pharmacy, University of Toledo, Toledo, Ohio.

by interfering with the enzymatic transformations which are undergone by an essential metabolite probably related to phenylalanine. Such analogs might inhibit the incorporation of phenylalanine into protein. Structural analogs of the amino acid glycine might also serve as specific inhibitors of protein synthesis. Such compounds may have antibacterial activity since protein synthesis is a process fundamental to the growth of living organisms. Compounds V and VI can be regarded as analogs of phenylalanine, differing from the amino acid in four positions. Compound XI is an amide derivative of glycine. The report (5) of the oral antidiabetic compound tolbutamide[1] stimulated the synthesis of the sulfonylurea derivative of diphenic acid. Compound VIII has structural features similar to tolbutamide.

The synthetic procedure used for the preparation of these compounds may be briefly outlined as follows: *o,o'*-diphenic acid, I, synthesized by the procedure described by Atkinson and Lawler (6), was converted to *o,o'*-diphenoyl chloride, II, (7). In order to introduce an alkanol side chain, the acyl chloride was converted in a step-wise manner to *o,o'*-bis(N-methyl)diphenanilide, III, (8), *o,o'*-diphenaldehyde, IV, (8) and *o,o'*-bis(2-nitro - 1,3 - dihydroxypropyl)biphenyl disodium salt, V. The nitroalcohol was reduced with hydrogen and palladous oxide and isolated as the amide-ester *o,o'*-bis(3-benzoxy-2-benzamido-1-hydroxypropyl)biphenyl, VI.

One ester of diphenic acid was prepared by treating II with β-dichloroacetamidoethanol to form *o,o'*-bis(β-dichloroacetamido-ethyl)diphenate, VII. Two amides of diphenic acid, N,N'-bis(benzenesulfonyl) - *o,o'* - diphenoylurea, VIII, and *m,m'*-bis(N-carboxymethyl)diphenamide, XI, were synthesized by reacting II with benzenesulfonylurea (9) and *m,m'*-diphenic acid, X, with thionyl chloride and glycine.

EXPERIMENTAL

The sequence of synthetic reactions is shown by the diagrams in the text.

***o,o'*-Diphenic Acid, I.**—The procedure used for the synthesis of diphenic acid was that described in "Organic Syntheses" (6).

***o,o'*-Diphenoyl Chloride, II.**—This known compound was prepared from I and thionyl chloride. Yields varied from 89–98% and the product melted at 94–95° (7).

***o,o'*-Bis(N-methyl)diphenanilide, III.**—N-Methylaniline, 30.9 Gm. (0.29 mole), dissolved in 150 ml. of dry benzene, was added in 5-ml. portions over a 1-hr. period to a well stirred solution of 20 Gm. (0.072 mole) of II in 200 ml. of dry benzene. The reaction mixture was stirred for an additional 15 minutes after all of the amine had been added. The reaction mixture, after filtration, was washed with 3 *N* hydrochloric acid until the aqueous phase was colorless and then with distilled water until the aqueous phase was no longer acidic to litmus. The benzene layer was dried over anhydrous sodium sulfate for 24 hours, filtered, and the solvent removed *in vacuo*. The crude residue was recrystallized from acetone-water. The average yield of product (four runs) was 24.2 Gm. (80%); m.p. 160–161° (8).

***o,o'*-Diphenaldehyde, IV.**—In a 1-L. three-neck flask equipped with a mercury-sealed stirrer, a reflux condenser equipped with a calcium chloride tube, and dropping funnel was placed a solution containing 50 Gm. (0.119 mole) of III in 450 ml. of anhydrous tetrahydrofuran. This solution was cooled to 0° and a previously prepared solution containing 2.5 Gm. (0.066 mole) of lithium aluminum hydride in 65 ml. of anhydrous ether was placed in the dropping funnel. The hydride was added dropwise with rapid stirring over a 3-hr. interval. Stirring was continued for 5 additional hours while maintaining the temperature of the reaction mixture at 0°. At the end of this period, the cooling bath was removed and the excess lithium aluminum hydride was decomposed with an ice-cold solution of 5% hydrochloric acid. The reaction mixture was filtered into a separator and extracted with 100 ml. of ether. The ether solution was then washed successively with water, 5% hydrochloric acid, and water. The ether layer was dried over anhydrous sodium sulfate for 24 hours, filtered, and the solvent removed *in vacuo*. The residue weighed 20 Gm.

[1] Marketed as Orinase by The Upjohn Co.

The 2,4-dinitrophenylhydrazone of a portion of the residue was prepared; m.p. 168–169°. The reported (8) melting point is 168°.

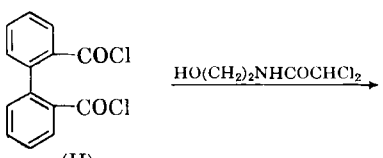
***o,o'*-Bis (2-nitro-1,3-dihydroxypropyl)biphenyl Disodium Salt, V.**—In a 300-ml. round-bottom flask equipped with a mercury-sealed stirrer and 125-ml. dropping funnel, was placed a solution containing 20.0 Gm. (0.095 mole) of IV in 75 ml. of absolute methanol and 18.6 Gm. (0.204 mole) of 2-nitroethanol. The mixture was stirred and cooled to −10°. A freshly prepared solution of sodium methoxide containing 4.4 Gm. (0.190 mole) of sodium in 45 ml. of absolute methanol was cooled to −10° and transferred to the dropping funnel. The base was added in a dropwise manner over 30 minutes. The reaction mixture was stirred for 1 hour after all of the base had been added. The product was filtered, washed first with anhydrous ether, and then with three 10-ml. portions of cold absolute methanol. A yield of 36.5 Gm. (88%) was obtained. A portion of the product was recrystallized from a cold solution of acetone and water and analyzed for sodium (10).

Anal.—Calcd. for $C_{18}H_{18}N_2Na_2O_8$: Na, 10.55. Found: Na, 10.55, 10.56.

***o,o'* - Bis(3 - benzoxy - 2 - benzamido - 1 - hydroxypropyl)biphenyl, VI.**—A 35-Gm. quantity of *o,o'*-bis(2-nitro-1,3-dihydroxypropyl)biphenyl disodium salt, V, was dissolved in 120 ml. of glacial acetic acid in a Parr reduction bottle. Palladous oxide, 1 Gm., was added and the mixture was reduced at 50 p.s.i. for 24 hours. The reaction mixture was filtered and the filtrate heated *in vacuo* at 40°. The residue was dissolved in 250 ml. of water and extracted with ether. The aqueous phase was made strongly alkaline with sodium hydroxide.

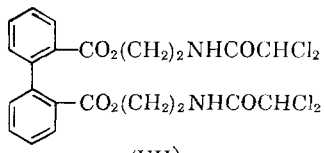
A portion of the strongly basic solution was shaken with 45 Gm. of benzoyl chloride and 100 ml. of chloroform for 20 minutes in a separator. The mixture was allowed to stand for 12 hours. The chloroform layer was drawn off and separated. A white, gummy residue remained which, when stirred repeatedly with fresh portions of dry petroleum ether, solidified to a white crystalline solid. The crude product was recrystallized from ethanol-water yielding 10.5 Gm.; m.p. 85–87°.

Anal.—Calcd. for $C_{46}H_{40}N_2O_8$: N, 3.74; sapon. equiv., 187. Found: N, 3.80, 3.81; sapon. equiv., 173.



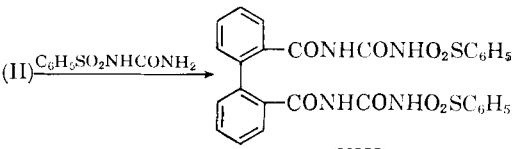
***o,o'* - Bis(β - dichloroacetamidoethyl)diphenate, VII.**—In a 250-ml. Erlenmeyer flask was placed 21.45 Gm. (0.15 mole) of methyl dichloroacetate. To this, with constant shaking, was added 9.15 Gm. (0.15 mole) of β-ethanolamine. The reaction mixture became warm and the heretofore colorless solution became bright red. When it had cooled to room temperature it was transferred to a 400-ml. beaker and allowed to crystallize at room temperature. The product, β-dichloroacetamidoethanol, was filtered and recrystallized from chloroform. It weighed 24.5 Gm. (95%); m.p. 85–86°.

To a cold (0°) well-stirred mixture of 2.79 Gm. (0.01 mole) of II, 50 ml. of dry benzene and 3 ml. of anhydrous pyridine there was added 3.42 Gm. (0.02 mole) of β-dichloroacetamidoethanol obtained above in small portions over a 30-min. period. The reaction mixture was stirred an additional 10 minutes. A heavy gum formed in the bottom of the reaction vessel. The supernatant liquid was decanted and the gum was washed with anhydrous ether. The gum was dissolved in 50 ml. of 95% ethanol and filtered. To the clear, yellow filtrate was added about 1–2 ml. of distilled water with shaking. The flask was allowed to stand overnight. The next day, the pale yellow crystals were removed on a Buchner funnel, dried, and recrystallized from ethanol, yielding 3.85 Gm. (70%) of product; m.p. 111–112°.



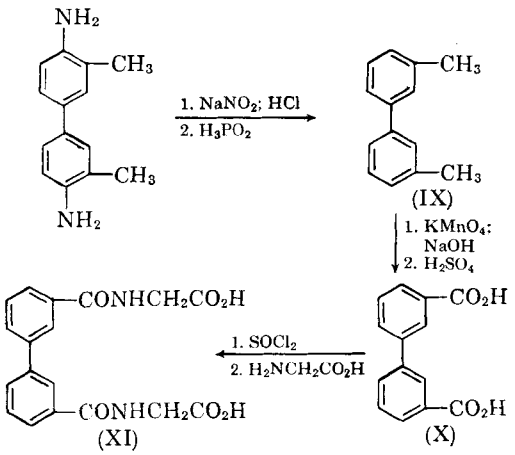
Anal.—Calcd. for $C_{22}H_{20}Cl_4N_2O_6$: N, 5.09; Cl, 25.82. Found: N, 5.08, 5.08; Cl, 25.76, 25.83.

N,N' - Bis(benzenesulfonyl) - *o,o'* - diphenoylurea, VIII.—In a 50-ml. Erlenmeyer flask was placed 1.4 Gm. (0.005 mole) of II and 2.0 Gm. (0.01 mole) of benzenesulfonylurea and the contents were thoroughly mixed. The flask was placed in an oil bath which was heated to and maintained at 130° for 2.5 hours. At this point, the bath temperature was raised to 160° and was kept between 160–170° for 6.5 hours. The flask was removed from the heating bath and allowed to come to room temperature. The crude product was recrystallized from absolute alcohol. A yield of 1.9 Gm. (64%) of product was obtained; m.p. 124–126°.



Anal.—Calcd. for $C_{28}H_{22}N_4O_8S_2$: N, 9.40; S, 10.74. Found: N, 9.28, 9.28; S, 10.57, 10.60.

(II)



(VII)

(VIII)

***m,m'* - Bis(N - carboxymethyl)diphenamide, XI.**—*m,m'*-Bitolyl, IX, was prepared by the method described by Kornblum (11). The yield was 88% and the product distilled at 134–135° (6 mm.). A 4-Gm. quantity (0.022 mole) of IX, 15.8 Gm. (0.1 mole) of potassium permanganate, 2.0 Gm. (0.05 mole) of sodium hydroxide and 420 ml. of water were heated under reflux for a period of 12 hours. At this time, the solution was filtered while still hot and the filtrate carefully acidified by the slow addition of concentrated sulfuric acid. The white precipitate, *m,m'*-diphenic acid, X, after drying, weighed 3.2 Gm. (60%); m.p. 356–358°.

One gram (0.006 mole) of *m,m'*-diphenic acid, X, was refluxed with an excess (25 ml.) of thionyl chloride for 6 hours. The excess thionyl chloride was removed by distillation. The product was washed with successive portions of anhydrous benzene and dried. It weighed 1.2 Gm. One gram (0.004 mole) of the crude product obtained, 0.75

Gm. (0.01 mole) of glycine, and 1.0 Gm. (0.025 mole) of sodium hydroxide in 50 ml. of water were refluxed for 30 minutes. The mixture was cooled and the product precipitated by the slow addition of a 5% solution of hydrochloric acid and recrystallized from ethanol, yielding 1.1 Gm. of product (78.6%); m.p. 204° (decompn.).

Anal.—Calcd. for $C_{18}H_{16}N_2O_6$: N, 7.86. Found: N, 7.88, 7.89.

SUMMARY

Five new derivatives of diphenic acid have been prepared for pharmacological testing as possible antibacterial, antihyperglycemic, antispasmodic, and/or local anesthetic activity: *o,o'* - bis(2-nitro - 1,3 - dihydroxypropyl)biphenyl disodium salt; *o,o'* - bis(3 - benzoxy - 2 - benzamido - 1-hydroxypropyl)biphenyl; *o,o'* - bis(β - dichloroacetamidoethyl)diphenate; N,N' - bis - (benzenesulfonyl) - *o,o* - diphenoylurea, and *m,m'*-bis(N-carboxymethyl)diphenamide.

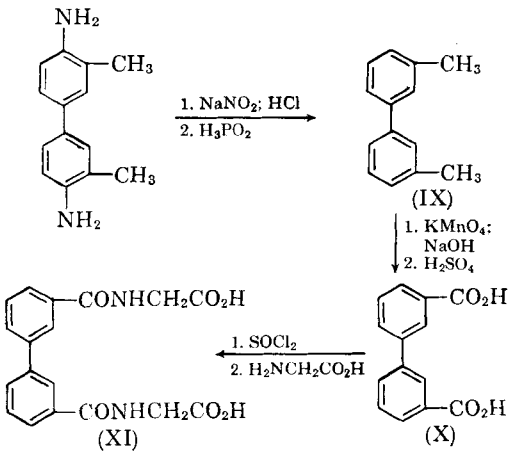
Analysis of Phenobarbital Elixir by an Ion Exchange and Nonaqueous Titration Procedure

By MARTIN I. BLAKE and FREDERICK P. SIEGEL

Phenobarbital elixir is analyzed by passing an aliquot through a strongly basic anion exchange resin. The phenobarbital is eluted from the column with acetic acid in ethanol. After evaporation of the solvent, the residue is dissolved in dimethylformamide and titrated with sodium methoxide in benzene-methanol. Other barbiturate elixirs are assayed similarly. Nonionic components, coloring agents, bases, most salts, and synthetic sweetening agents do not interfere.



THE ANALYSIS of barbiturate salts in a variety of dosage forms by ion exchange and nonaqueous titration was recently reported (1). Application to the assay of elixirs proved unsuccessful. Ion exchange resins have been employed for the isolation of barbiturates (2) and a variety of nonaqueous techniques have been described for determining barbiturates in dosage forms. These have been reviewed in an earlier paper (1). The usual procedure in applying a nonaqueous titration procedure to the analysis of elixirs involves extraction of the barbiturate with an organic solvent prior to titration in a nonaqueous medium.

Potentiometric titration of phenobarbital elixir with silver nitrate was reported by Mattocks and Voshall (3) and later by Bodin (4). Cohen and Lordi (5) developed an amperometric and a potentiometric titration procedure with mercuric ion for analyzing the elixir. A general review of the literature dealing with the analysis of the barbituric acids is presented by Connors (6).

The official assay for phenobarbital elixir is a gravimetric one in which the phenobarbital is extracted with chloroform. High results are usually obtained because of extraction of other chloroform soluble components. This has been noted by several workers (3, 7). In addition, the official assay is tedious and time consuming.

This report describes a procedure in which the phenobarbital is removed from the elixir by

passage through an anion exchange resin. The phenobarbital is eluted from the column with acetic acid in ethanol followed by titration in dimethylformamide with sodium methoxide in benzene-methanol. The assay is applied to other barbiturate elixirs.

EXPERIMENTAL

Preparation of Column.—The strongly basic anionic exchange resin Dowex 2-X8, 50-100 mesh, was used in this study. A suspension in water of about 10 Gm. of the resin was added to a chromatographic column, 1 cm. × 30 cm. The resin column was washed with 100 ml. of distilled water, 100 ml. of 5% sodium hydroxide, and 200 ml. of distilled water. The column was ready for use.

Assay Procedure for Pure Phenobarbital.—Approximately 100 mg. of pure phenobarbital, accurately weighed, was dissolved in 50 ml. of 50% ethanol. The solution was passed through the resin column. This was followed by the addition of 50 ml. of distilled water. The phenobarbital was eluted from the column with a solution of 50% acetic acid in 95% ethanol at a flow rate of 1 ml. per minute. The first 10 ml. of eluate contained no phenobarbital and was discarded. The next 50 ml. of eluate was collected and evaporated to dryness on a steam bath. Five milliliters of distilled water was added and the solution was again evaporated to dryness. This was repeated once. The residue was dissolved in 20 ml. of dimethylformamide and the solution was titrated with 0.1 *N* sodium methoxide in benzene-methanol prepared and standardized as described earlier (8). Titration was effected potentiometrically with a Fisher titrimeter equipped with a calomel and glass electrode system. The end point was determined by plotting millivolts *vs.* volume of titrant. The point of inflection was readily determined from the curve. A blank run was conducted with each series of three determinations. Recovery of phenobarbital was quantitative as indicated by data reported in Table I.

TABLE I.—ANALYSIS OF PHENOBARBITAL ELIXIR

Sample	Phenobarbital Theoretic or Labeled Amount, mg.	Proposed Method, % Recovery[b]	Official Method, % Recovery[c]
Pure phenobarbital	100.0	99.76 ± 0.09[d]	...
Elixir A	100.0[a]	99.12 ± 1.19	100.7
Elixir B	100.0	97.29 ± 0.77	99.5
Elixir C	100.0	96.15 ± 0.78	99.0
Elixir D	100.0	100.96 ± 0.29	104.7

[a] Mg. per 25 ml. [b] Average of at least 5 runs. [c] Average of duplicate runs. [d] Standard deviation.

Phenobarbital Elixir.—Exactly 25 ml. of phenobarbital elixir was transferred by pipet to a 150-ml. beaker. About 25 ml. of distilled water or 50% ethanol was added. This reduced the viscosity of the elixir and permitted a more rapid flow rate through the column. The solution was added to the column. When the last of the solution disappeared below the surface of the resin, distilled water was added to the column. The column was washed with 100-150 ml. of water. The phenobarbital was eluted from the column with 50% acetic acid in 95% ethanol. The eluate was treated as described previously for the pure phenobarbital sample. The data for the analysis of phenobarbital elixir are reported in Table I. Elixirs *A* and *B* represent different batches of phenobarbital elixir prepared in the manufacturing pharmacy of our pharmacy department. Elixirs *C* and *D* were commercial samples.

Other Barbiturate Elixirs.—The proposed assay procedure was applied to the analysis of elixirs containing secobarbital, pentobarbital, and amobarbital. Commonly used commercial varieties of the elixirs were employed in this study. These were treated in the same manner as described for phenobarbital elixir. The data are reported in Table II.

TABLE II.—ANALYSIS OF OTHER BARBITURATE ELIXIRS

Sample	Barbiturate Concn. Labeled Amount, mg.	% Recovery
Secobarbital elixir	110.0[a]	101.86 ± 0.49[c]
Amobarbital elixir	110.0	99.74 ± 0.69
Pentobarbital sodium elixir	91.3[b]	103.83 ± 1.07

[a] Mg. per 25 ml. [b] As pentobarbital. [c] Standard deviation.

DISCUSSION

The shortcomings of the official assay procedure for phenobarbital elixir have been noted here and have been indicated previously by other workers. Although a variety of methods and modifications have been proposed which appear to be superior to the official assay procedure the latter has remained essentially unchanged over the years.

In the technique proposed in the present study, a strongly basic anion exchange resin, quaternary base type, is used to remove the barbiturate from the other components of the elixir. This obviates the tedious and time consuming extraction process used in the official assay and in most of the proposed methods based on nonaqueous titration. The eluent, 50% acetic acid in ethanol, effectively removes the barbiturate from the column. Acetic acid, a stronger acid than the barbiturates, displaces the latter from the resin. Although the barbiturate may be quantitatively recovered from only 30 ml. of eluate, 50 ml. is collected in the assay to ensure complete extraction. Quantitative recoveries are reported for phenobarbital elixir in Table I and for other barbiturate elixirs in Table II. Comparison was made with the official assay for phenobarbital elixir. The data are shown in Table I. It should be noted that somewhat higher results were consistently obtained with the official procedure. This is undoubtedly due to the extraction of chloroform soluble components in addition to the phenobarbital. This was reported earlier by others (3, 7).

The interference by other components in the elixirs was studied. Nonionic ingredients such as sucrose, glycerol, and propylene glycol were readily washed

from the column with water. They appeared in the eluate. The amaranth coloring agent used in phenobarbital elixir did not pass through the column, but concentrated in the upper 0.5 cm. of the resin column. When the resin was to be regenerated, the upper centimeter of the column was removed and discarded. The column was then washed with distilled water, sodium hydroxide solution, and distilled water until the eluate showed pH 5 to 6. The column was ready for a second run. Caramel, the coloring agent used in certain barbiturate elixirs, appeared to be washed completely from the column with water. Barbiturate salts, as pentobarbital sodium in pentobarbital elixir, do not complicate the assay since only the anion is retained by the resin; the cation appears in the eluate. Synthetic sweetening agents as saccharin sodium and cyclamate calcium may be used in commercial barbiturate elixirs. A mixture containing 100 mg. of saccharin and 100 mg. of phenobarbital was titrated in dimethylformamide with sodium methoxide. Differentiation of the two acids was noted. This is shown in Fig. 1, curve *A*; the first inflection is due to saccharin and the second is attributed to phenobarbital. Recovery was quantitative for both components. A mixture of 100 mg. of saccharin sodium and 100 mg. of phenobarbital was dissolved in 50% ethanol and passed through the resin column. The column was eluted with acetic acid in ethanol as described for the barbiturate elixirs. Titration in dimethylformamide with sodium methoxide showed quantitative recovery of the barbiturate. See Fig. 1, curve *B*. Elution of the column with 1 *M* hydrochloric acid in 50% ethanol, evaporation of the solvent, and subsequent nonaqueous titration indicated quantitative recovery of the saccharin. Since acetic acid is a stronger acid than the barbiturates used in this study, but weaker than saccharin, the former and not the latter is displaced from the resin column. Similar results were obtained with cyclamate calcium. Hydrochloric acid, found in pentobarbital elixir, does not interfere since acetic acid will not displace it from the column. Salts, in general, will not interfere unless the anion represents an acid which is weaker than acetic

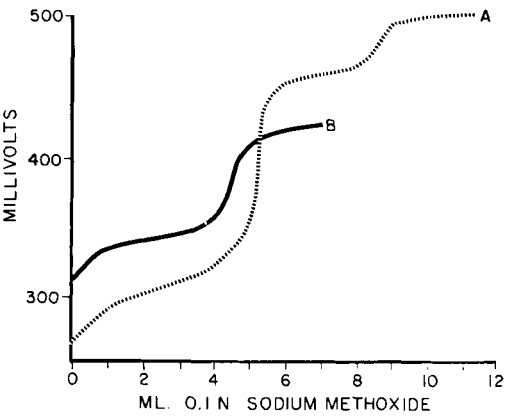

Fig. 1.—Curve *A*, titration of saccharin and phenobarbital mixture; curve *B*, titration of phenobarbital after passage of mixture through resin column.

acid. Even then, it may be possible to differentiate between it and the barbiturate by nonaqueous titration if the two differ significantly in acid strength. Methenamine and bases do not interfere.

The proposed assay procedure is simple, accurate, and less time consuming than the official procedure. It should have wide application. Although it has been used only for elixirs in this study, it should be applicable to other dosage forms and to certain combinations of barbiturates with other agents.

Rheology of Thixotropic Montmorillonite Dispersions I

Changes on Aging of Plain and Polysorbate 80 Containing Dispersions

By GERHARD LEVY

The rheological characteristics of thixotropic montmorillonite dispersions are best defined on the basis of a concept of two different yield values, dynamic and static, in addition to plastic viscosity and thixotropic area. The values of these parameters were determined periodically for 10 weeks after preparation of the dispersions and were found to change at different rates. This shows that evaluation of a single rheological parameter as a function of time is not indicative of the overall rheological changes undergone by these systems. The feasibility of selective modification of certain rheological properties and aging characteristics is demonstrated by the rheograms obtained from montmorillonite dispersions to which polysorbate 80 had been added at the time of preparation.

SYSTEMS capable of isothermal gel to sol transformation upon shaking or shearing, and reversion to a gel upon rest, have considerable utility in pharmacy. Prominent among substances which can produce this property, known as thixotropy, upon dispersion in an appropriate liquid are the clays, particularly those of the montmorillonite group. The present study deals with a characterization of various rheological properties of a widely used member of the montmorillonite group, colloidal magnesium aluminum silicate (MAS), which is a refined product derived from saponite (1). Aqueous dispersions of this material exhibit complex time-dependent flow properties which are complicated further by certain irreversible changes upon aging. It has been found necessary to redefine the concept of yield value as applied to these systems, and to extend the interpretation of the obtained rheograms on the basis of the more recent rheological research results which apparently have not yet been taken into consideration by many pharmaceutical scientists. Of particular interest have been the quantitative and qualitative nature of the irreversible rheological changes of aqueous MAS dispersions upon aging, since it was hoped that subsequent studies in this series could be carried out with dispersions which have attained structural equilibrium. Since both reversible and irreversible changes of montmorillonite clays are related to the surface properties of these materials, it has been found desirable also to investigate the effect of a typical nonionic surface-active agent on the rheological and aging characteristics of the dispersions.

EXPERIMENTAL

Preparation of Dispersions.—Three per cent w/w dispersions of colloidal magnesium aluminum silicate (Veegum)[1] were prepared in 500-Gm. portions by adding 15 Gm. of the clay to 485 ml. of distilled water, and mixing these vigorously for 3 minutes in an Arnold automatic mixer, model No. 15. The individual portions were combined while still hot and agitated with a Brookfield counter-rotating mixer in a 2-gal. beaker at a rheostat setting of 80 for 5 minutes, followed by 25 minutes of agitation at a rheostat setting of 50. The dispersion was then weighed and water lost by evaporation was replaced.

Water at room temperature was used in the preparation of dispersions by the "cold" process, while water heated to 80° was used in the "hot" process.

Polysorbate 80 was added after preparation of the dispersions by the "hot" process and incorporated by mild mixing to prevent foaming.

Storage.—The dispersions were placed in glass jars which were stored in an electric oven at a temperature of 30 ± 1°.

Instrumentation and Methodology.—The Epprecht Rheomat 15[2] was used to obtain the rheograms. This instrument is a rotational viscometer having 15 different shear rate settings for a given measuring system. Changes of shear rate are discontinuous and made manually, but do not require stopping the spindle. All measurements reported in this paper were made at 30°, using the "B" measuring system. The 15 shear rate settings were 3.110, 4.177, 5.496, 7.334, 9.674, 13.94, 18.72, 24.64, 32.87, 43.36, 62.94, 84.51, 111.2, 148.3, and 195.7 sec.$^{-1}$. Each experimental point in Figs. 1–3 represents an average value obtained from three rheograms of different samples of the dispersion. These samples were not returned to the stock dispersion, but discarded after use.

To obtain data for a rheogram, the viscometer cup was filled with an appropriate quantity of the dispersion and the spindle was immersed. Both were then attached to the instrument which was

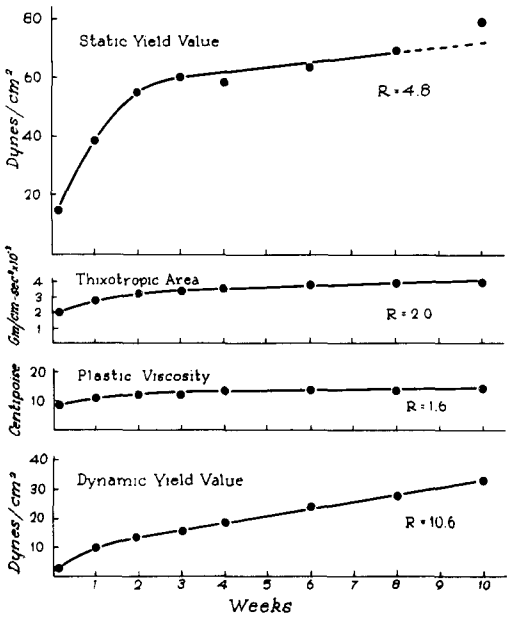

Fig. 1.—Changes in rheological properties of a 3% aqueous dispersion of MAS prepared by the "hot" process, during storage at 30° for 10 weeks.

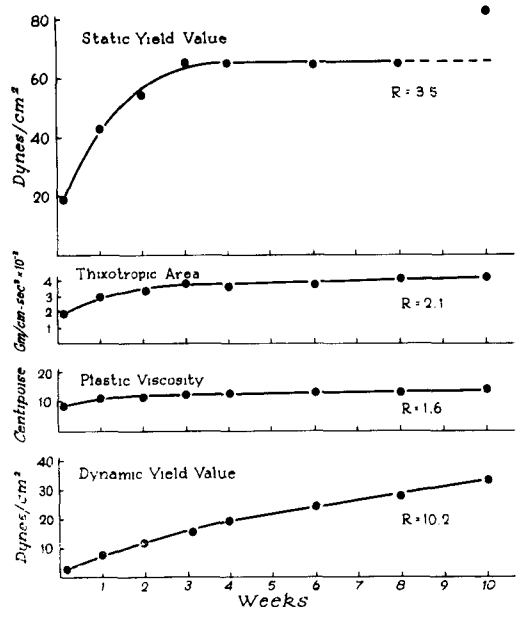

Fig. 2.—Changes in rheological properties of a 3% aqueous dispersion of MAS prepared by the "cold" process, during storage at 30° for 10 weeks.

positioned so that the cup was immersed in a constant temperature water bath set at 30 ± 0.1°. The dispersion was sheared at a rate of 195.7 sec.$^{-1}$ for 5 minutes and then permitted to remain undisturbed for 30 minutes. During this time, the cup was covered with a plexiglas disk to prevent significant evaporation of water from the surface of the dispersion. At the end of the 30-minute period, the viscometer spindle was set in motion at the lowest shear rate. Characteristically, the shear stress indicator exhibited a large excursion as the spindle began to rotate. This maximum torque was noted. Another reading was made 30 seconds after the spindle had been set in motion. The shear rate was then increased to the next setting, and shear stress measured after 30 seconds. Shear rates were increased at 30-sec. intervals until the highest shear rate was reached, then decreased at the same rate to the lowest shear rate. The shear stress data obtained at the various shear rates were used to draw the rheograms.

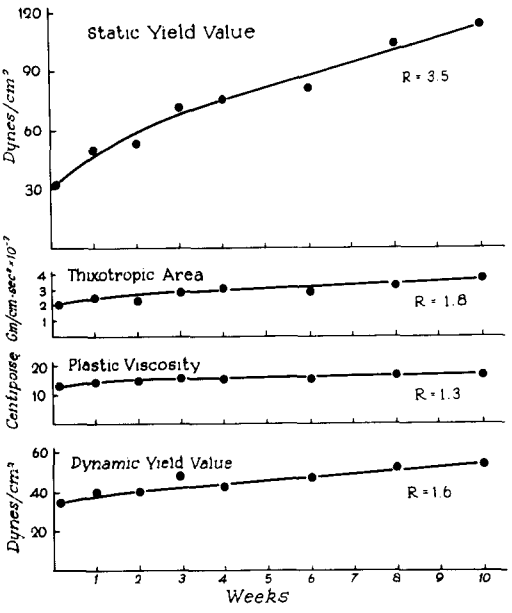

Fig. 3.—Changes in rheological properties of a 3% aqueous dispersion of MAS prepared by the "hot" process and containing 0.1% polysorbate 80, during storage at 30° for 10 weeks.

Yield value corrections were made according to Epprecht (2), using a K_f factor of 0.80, which is based on an R^2/r^2 value of 1.58. Thixotropic areas were determined by means of a compensating polar planimeter from a graph where the shear rate axis represented 7.75 sec.$^{-1}$ per cm. and the shear stress axis 24.9 dynes/cm.^{2} per cm. Accordingly, a thixotropic area of 1 cm.^{2} was equal to 193 Gm./cm. sec.^{3}. The thixotropic area was taken as the area enclosed by the ascending and descending shear rate *vs.* shear stress curves, and the horizontal line connecting the experimental points of both curves at a shear rate of 3.110 sec.$^{-1}$, as shown in Fig. 4.

RESULTS AND DISCUSSION

Flow curves of thixotropic systems are defined usually on the basis of plastic viscosity, thixotropic area, or index, and the value of the shear-stress intercept of the extrapolated linear portion of the down curve at zero shear rate. The latter value is referred to as the yield point or yield value. The rheograms of the MAS dispersions yielded up curves having characteristic shear stress maxima at the

beginning of measurement, followed by shear stress minima at a relatively low shear rate (Fig. 4). The shear stress maxima have been observed only in re-

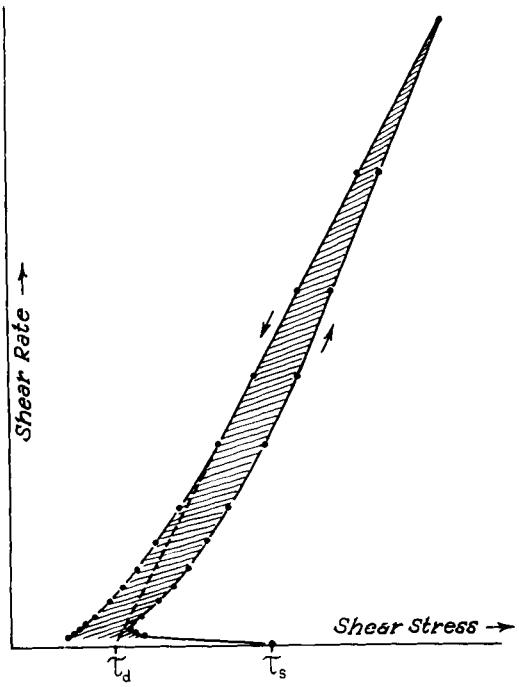

Fig. 4.—Typical rheogram of an aqueous dispersion of MAS. τ_d, dynamic yield value; τ_s, static yield value. Shaded section represents the thixotropic area.

cent years when continuous recording viscometers and more refined and sensitive multiple-point instruments have come into use. However, there is already evidence that these maxima reflect a rheological property of direct pharmaceutical pertinence; for example, it has been found that the persistence of penicillin levels in the blood after administration of procaine penicillin depot preparations is directly related to the value of the initial shear stress maximum of these suspensions (3). Thus, it is desirable to consider the initial shear rate maximum as one of the several rheologic properties which must be measured in order to describe a thixotropic system adequately. This necessitates a redefinition of the concept of yield value as well as a consideration of the significance of the shear stress minimum on the up curve of the rheogram.

Conventional or Dynamic Yield Value.—The shear-stress intercept of the linear portion of the down curve of a rheogram at zero shear rate, referred to conventionally as the yield value, is usually defined as the minimum tangential shearing force necessary to cause flow (4). Experimentally, however, it can be shown that the shearing force necessary to initiate flow of thixotropic montmorillonite dispersions is considerably higher than the conventional yield value. This is reflected by the initial shear stress maximum characteristic of such dispersions. Furthermore, if the conventional yield value really has the meaning assigned to it by the above definition, it should be independent of the maximum shear rate to which the system is exposed in the course of measurement. Such is not the case since the yield value frequently increases upon increasing the top shear rate used in the determination of the flow curve (4, 5). It is well appreciated that the need for some minimum shear stress to initiate the flow of thixotropic systems is predicated upon the presence of a continuous structure whose interparticle bonds must be broken in the process of inducing flow. Thus it should be clear that any measurement based solely on a thixotropic system in flow cannot provide information concerning the shear stress necessary to cause this flow. Upon examination of a typical rheogram, the real significance of the conventional yield value becomes quite clear; it is the energy-input necessary to maintain a constant ratio of shear rate to shear stress (that is, total shear stress minus the yield stress referred to) in a system whose structure has been destroyed, totally or in part, by previous shear (in the course of determining the up curve of the rheogram). Expressed in a different way, the conventional yield value reflects the energy input required to maintain the degree of structural breakdown which exists at the maximum shear rate, just before shear rate is reduced for the determination of the down curve. This is reasonably analogous to the concept of a coefficient of dynamic friction as opposed to the coefficient of static friction of solids. Accordingly, it is proposed that the conventional or Bingham yield value be referred to as the dynamic yield value, unless it can be shown experimentally that this value does not differ from the yield value necessary to cause flow (which would be the case in plastic systems). Apart from the purely mathematical usefulness of quantitating the dynamic yield value, it should also be indicative of the degree to which the internal structure of a system has been destroyed by a given shear stress and duration of shear. At some point, a further increase in shear stress and/or duration should cause no further increase in dynamic yield value; namely, when all the weak secondary bonds between particles have been broken and the dispersed units consist solely of primary particles.

Static Yield Value.—This term evolves as a logical consequence of accepting the concept of a dynamic yield value. It may be defined as the minimum tangential shearing force necessary to initiate flow. Unfortunately, this value is not independent of time. Houwink has pointed out the necessity of including a specification about the rate of increasing shear stress when defining yield value (6).[3] McVean and Mattocks (7) could demonstrate that the static yield value is a function of rate of strain, since it is evident that their rising sphere rheometer measures static rather than dynamic yield value at the "flow" point. The time dependency stems from the viscoelastic and relaxation behavior of most gels. In stating that the force required to break down structure and cause flow of thixotropic suspensions is time-dependent and must be represented by a curve with time as one of the parameters, Dintenfass points out that it is not a case of no flow occurring below a given shear stress value, but rather that the time taken for measurable flow to take place would be abnormally long (8). In addition, the time effect

[3] Within the context of Houwink's discussion it is clear that he was referring to the "static" yield value.

applies also to the rest period of the thixotropic system. In the act of charging the viscometer, structure is destroyed and requires time to rebuild, as indicated by data reported in the following paper (9). Moreover, there are indications that the structural recovery rate is affected by the diameter of the annulus of the viscometer (9). The static yield value is, therefore, far from an absolute value and is related not only to the previous history of the measured material, but also to measurement conditions and instrument characteristics. While the concept of a dynamic and a static yield value has, to the best of our knowledge, not previously been applied experimentally within the strict definition of these terms as presently proposed, it is of interest to note that the idea is not new. A review of the literature has shown that Green and Weltmann suggested these terms in 1946 but evidently did not follow upon their suggestion with experimental data, possibly due to lack of appropriate instrumentation (5).

Shear Stress Minimum.—Prominent in the beginning portion of the up curve of the thixotropic rheogram shown in Fig. 4 is a shear stress minimum, which may occur at shear rates significantly higher than zero. This phenomenon has been explained recently by Enneking (10). He found that the shear stress minimum occurred at higher shear rates when the annular width of the viscometer was increased. As the spindle begins to move (*i.e.*, the point at which static yield value is determined), the measured material flows only at the spindle surface and not throughout the annular space. Upon increasing the spindle velocity, further breakdown of structure occurs and the effective annular distance increases. Since shear rate is inversely proportional to the distance between annular boundaries, the actual shear rate to which the thixotropic material is subjected is decreased, despite the higher speed of rotation of the spindle. Naturally, the shear stress will be less at this lower shear rate. This process continues until flow occurs throughout the space between cup and spindle. At that point, the shear stress minimum is reached and any further increase in spindle r.p.m. reflects a true increase in shear rate and, therefore, requires higher shear stresses. The narrower the annulus, the lower the shear rate at which the stress minimum will occur. Thus, this factor is primarily an instrumental characteristic rather than a property of the material, although the rate of thixotropic breakdown is a contributing factor under the usual nonequilibrium experimental conditions. The experimental points on the up curve of the rheogram between the static yield value and the shear stress minimum have, therefore, no absolute physical meaning since they are plotted on the basis of apparent, but not actual, shear rates.

Rheological Changes of Montmorillonite Dispersions on Aging.—Figure 1 shows the changes in static yield value, thixotropic area, plastic viscosity, and dynamic yield value of a 3% MAS dispersion prepared by the "hot" method during a period of 10 weeks after preparation. Static yield value increased quite rapidly during the first 3 weeks and then leveled off. The R value in the graph is the ratio of the 10-wk. value to the 24-hr. value.[4] For this calculation, the 10-wk. value indicated by the extrapolated curve was used, since the actual experimental points in Figs. 1 and 2 are unusually high and appear to be artifacts. Thixotropic area also increased most rapidly during the first 3 weeks and very slightly from then on. Over the 10-wk. period, the thixotropic area increased only twofold, as opposed to an almost fivefold increase in static yield value. The plastic viscosity exhibited an even smaller change, and essentially reached equilibrium after 4 weeks when it had increased by 60% over the 24-hr. value. This rather small increase is readily understandable if it is assumed that the thixotropic suspension, at the time of measurement of the down curve, consists of individual particles (not necessarily primary particles) suspended in a Newtonian liquid (water). This assumption is reasonable since interparticle bonds have been broken by previous shear and are prevented from reforming as long as the down curve remains linear. As a first approximation, the viscosity of such a liquid should follow the Einstein equation

$$\eta = \eta_0 (1 + 2.5\phi)$$

where η is the viscosity of the suspension, η_0 the viscosity of the medium, and ϕ the volume fraction of the dispersed phase. The latter value would increase somewhat in an aging clay dispersion due to lattice expansion, the degree of this expansion being a function (among others) of the moisture content of the solid clay just prior to use.

Dynamic yield value increased over tenfold during 10 weeks. This is remarkable, especially since the dispersion was agitated quite intensively in the course of preparation. The increase in dynamic yield value signifies that a greater energy input is necessary to prevent structure reformation as the dispersion ages. This may be due to the ultimate dispersion into primary particles of what were originally face-to-face aggregates of numerous clay particles. These primary particles should be capable of individual participation in the formation of the typical scaffolding structure of clay dispersions at rest.

The rheological changes during aging of MAS dispersions prepared by the "cold" method did not differ significantly from those of the dispersions prepared by the "hot" process (Fig. 2). This result was somewhat surprising since the use of heat is generally recommended for the preparation of montmorillonite dispersions. Reference to the literature indicates, however, that another worker also observed only small temperature effects with MAS (11). It may be that the temperature effect is greater when the dispersions are subjected to lower agitation intensities and shorter agitation periods during preparation.

Effect of Polysorbate 80.—The addition of 0.1% polysorbate 80, immediately after preparation, to 3% MAS dispersions prepared by the "hot" method results in a profound modification of flow and aging characteristics (Fig. 3). The static yield value at 24 hours is about 50% higher than in the absence of surfactant. It increases at practically constant rate throughout the 10-wk. period. The thixotropic area is somewhat smaller in the polysorbate 80-containing dispersions. This could be due either to a smaller degree of thixotropy or to a more rapid

[4] This R should not be confused with the coefficient of thixotropic recovery, also designated as R, in the following paper (9)

structural recovery. Subsequent studies described in the following paper (9) indicate that a more rapid structural recovery rate is probably the reason for the smaller thixotropic area. The plastic viscosity is slightly higher in the presence of polysorbate 80. Since polar but otherwise neutral molecules, such as the glycols, are known to be adsorbed between the silicate laminae of montmorillonite clays (12, 13), it is probable that the higher plastic viscosity of polysorbate 80-containing dispersions is due to an increased volume of the dispersed phase caused by lattice expansion upon adsorption of the surfactant. The most significant effect of surfactant was, however, a tenfold increase in dynamic yield value at 24 hours. The subsequent increase upon aging was only 60%, compared with a tenfold increase in the dispersions without surfactant. The presence of polysorbate 80 thus affects, primarily, the dynamic and static yield values, and only slightly the thixotropic area and plastic viscosity of aqueous MAS dispersions. This demonstrates the possibility of a selective modification of certain rheological properties by means of additives capable of modifying the surface properties of montmorillonites. Interpretation of the mechanism of the polysorbate 80 effect is complicated by the fact that the montmorillonite was neither dialyzed nor homoionic. It is known that neutral but polar molecules adsorb on the surface of montmorillonite, orient parallel to that surface, and are capable of displacing hydrogen-bonded water (13). It was found in the course of studies of the adsorption of nonionic aliphatic molecules from aqueous solutions on montmorillonite, that mixtures with high molar adsorption tend to form gels while mixtures with low molar adsorption settle out on standing (14). Of interest, also, are the observations by Samyn that small concentrations of polysorbate 40 increase the apparent viscosity of MAS dispersions but that higher surfactant concentrations reverse this increase (15). It is possible that the surfactant effect is due to partial displacement of inorganic cations from the surface of the clay, although such displacement need not necessarily occur when organic molecules are adsorbed (16). It has been suggested also that surfactant micelles can serve as a locus for the attachment of individual colloidal particles (17). The surfactant may, therefore, have a bridging effect. The high initial yield values and smaller subsequent changes (as compared with those of suspensions without the surfactant) indicate that the lowering of interfacial tension by the surfactant could have increased the rate of dissociation of face-to-face aggregates of the clay. This would make a larger number of particles available for face-to-edge or edge-to-edge association which leads to the scaffolding structure responsible for high yield values. Experiments are currently under way to elucidate the mechanism or mechanisms of the surfactant effect.

CONCLUSIONS

The experimental data show that aqueous dispersions of a representative montmorillonite clay undergo large rheological changes on aging. It has not been possible under our experimental conditions to attain structural equilibrium during 10 weeks of aging at 30°. Other studies in this laboratory indicate that even considerably longer aging periods are inadequate for equilibration of rheological properties of montmorillonite dispersions. The changes in rheological properties of montmorillonite dispersions on aging or due to additives can be characterized adequately only if all the various rheological parameters are determined individually, since they change to different extents. Comparative studies on montmorillonite dispersions must be standardized rigidly with respect to time in order to exclude the aging period as one of the variables. The effect of polysorbate 80 on the rheological and aging properties of MAS dispersions illustrates the feasibility of a relatively selective modification of these properties by means of additives for the purpose of obtaining optimum flow and aging characteristics in a pharmaceutical system.

Rheology of Thixotropic Montmorillonite Dispersions II

Kinetics of Structural Recovery

By GERHARD LEVY

Methodology has been developed to study the kinetics of the structural recovery (build-up) of thixotropic montmorillonite dispersions. The recovery process can be described by means of a coefficient of thixotropic recovery with time, R. Thus: $R = (T_2 - T_1)/(\log t_2 - \log t_1)$, where T_2 and T_1 are the torques necessary to overcome the resistance encountered by a special spindle which is simultaneously rotated and lowered into the dispersion at times t_2 and t_1, respectively, after breakdown of structure by agitation. The effects of aging, concentration, method of preparation (hot process, cold process, ultrasonic treatment), and addition of polysorbate 80, zinc oxide, or glycerin upon structural strength (static yield value) and coefficient of thixotropic recovery have been determined.

THE USEFULNESS of thixotropic systems in pharmacy is based upon their ready conversion from a rigid gel to a fluid sol upon shaking or shearing, and their reversion to the gel state when shaking or shearing is discontinued. The sol to gel transformation or structural recovery is not instantaneous since the particles in random motion are required to approach one another from the proper direction and to overcome an energy barrier before interparticle association can occur. The structural recovery rate of thixotropic systems is probably the most important variable with respect to their pharmaceutical usefulness. For example, if recovery occurs too quickly, thixotropic suspensions will not remain fluid for a sufficient time after agitation to permit pouring. On the other hand, if the time required for structural recovery is too long, the suspended particles will descend to the bottom of the container instead of becoming immobilized within a structural network. This would result in a "stabilized sediment" rather than a well-dispersed, physically stable suspension.

The lack of investigation by pharmaceutical scientists of this important aspect of the rheology of thixotropic systems may be due partly to the long-prevailing misconception regarding the significance of the conventional yield value (1). Usually defined as the minimum tangential force necessary to initiate flow, it has been determined in dynamic systems rather than in static or nonflowing systems. The conventional definition of the term as well as the method used to measure it imply that the yield value remains the same regardless of the amount of shear to which the thixotropic system is subjected. Thus, there would be no reason to assume that yield value will decrease upon shearing and increase during rest, and any logical basis for studying structural recovery rates would be nonexistent.

Redefinition of the conventional yield value as dynamic yield value (which is considered to be indicative of the energy input required to prevent structure reformation), and postulation of a static yield value as the tangential force necessary to break structure to the point of initiating flow (1), provide a logical foundation for a study of thixotropic recovery rates.

Determinations of thixotropic recovery rates require repeated measurements of static yield value in a resting system as a function of resting time. In the early studies of thixotropic phenomena, the so-called "inverted tube method" was most commonly used to determine gelation or setting time (2), and the reciprocal of this value was taken as the rate of gelation (3).

The setting time of a thixotropic system was defined as the time between liquefaction, by mechanical action, and its resetting upon standing at rest. A sample, kept in a test tube, was considered to have set if it did not flow within a minute or so upon turning the tube upside down (4). Apart from various technical difficulties such as the need for a standardized inversion procedure (5), it was soon realized that the setting time is just an arbitrary point on the gel-strength *vs.* time curve, and that it does not reflect any sudden change in slope or other unique characteristic of such a curve (3, 6). It was also found that the diameter

Presented to the Scientific Section, A.Ph.A., Las Vegas meeting, March 1962.
The author acknowledges the technical assistance of J. M. Rutowski.

of the tube had a very large effect on setting time. For example, a bentonite dispersion with a setting time of 30 seconds in a tube of 13 mm. diameter, exhibited a setting time of over 3 hours in a tube having a diameter of 40 mm. (2). The container wall apparently has an organizing effect upon the clay particles, as has been suggested by Houwink (7). This wall effect also limits the usefulness of the standard rotational viscometers for the determination of thixotropic recovery rates, although several investigators have used such instruments to determine what is here defined as static yield value as a function of resting time (8, 9). Evidently these workers did not consider the effect of annular diameter upon thixotropic recovery rate or they felt that this factor was not important relative to the objective of their studies. For pharmaceutical purposes, however, it is desirable to obtain a realistic indication of recovery rates of the material under study when contained in vessels of relatively large diameter. Data to be presented here indicate that recovery rates under these conditions differ by several orders of magnitude from those in which the thixotropic material was situated within a narrow annular space.

A new methodology to determine thixotropic recovery rates, which permits measurements in containers of relatively large diameter where recovery rates become essentially independent of vessel diameter, has been developed for this study. It has also been possible to follow the change in static yield values over long periods of time since the thixotropic material could be stored in regular containers until and during the time of measurement. Apart from a description of the method, this communication deals with a mathematical characterization of the thixotropic recovery process, and a survey of the effect of different preparatory procedures and additives on the static yield value and thixotropic recovery rate of aqueous dispersions of magnesium aluminum silicate (MAS), a representative clay of the montmorillonite group.

EXPERIMENTAL

Preparation of Dispersions.—Dispersions, 3% w/w, of colloidal magnesium aluminum silicate (Veegum)[1] were prepared by adding 15 Gm. of the clay to 485 ml. of distilled water and mixing these vigorously for 3 minutes in an Arnold automatic mixer, model No. 15. The individual portions were combined and agitated with a Brookfield counter-rotating mixer in a 2-gal. beaker at a rheostat setting of 80 for 5 minutes, followed by 25 minutes of agitation at a rheostat setting of 50. The dispersion then was weighed and water lost by evaporation was replaced.

Dispersions of 4, 3.5, and 2.5% concentration were prepared in the same manner as the 3.0% dispersion, except for the necessary changes in amounts of the clay and water.

For dispersions prepared by the "hot" process, the MAS was dispersed in water previously heated to 80°, while water at room temperature was used in the "cold" process. For ultrasonic treatment, 200-ml. portions of dispersion were cooled to 15° and insonated in a General Electric ultrasonic generator, model G 3, at a frequency of 750 kc./sec. for 5 minutes. The temperature of the dispersions did not rise above 25° during insonation. The individual portions of dispersion were subsequently combined. Dispersions containing zinc oxide were prepared in the usual manner, but the zinc oxide was incorporated just 3 days before rheologic measurement, *i.e.*, 9.5 weeks after preparation of the plain dispersion. The zinc oxide was passed through a 60-mesh sieve prior to use.

Polysorbate 80 was added either to the completed dispersion immediately after preparation or it was dissolved in the water prior to addition of the clay.

Glycerin-containing dispersions were prepared by dispersing MAS in water in the usual manner, and adding glycerin just 3 days prior to rheologic measurement, *i.e.*, after 9.5 weeks of aging the plain dispersions.

All dispersions were stored in 8-oz. glass jars (5.5 cm. diameter, 13 cm. height) at room temperature (24 ± 2°). With the exception of the aging experiment (Fig. 3), the dispersions were aged for 10 weeks prior to rheologic evaluation.

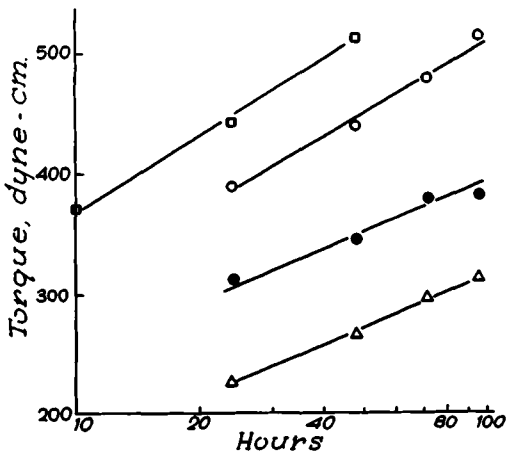

Fig. 1.—Effect of age on static yield value and thixotropic recovery rate of 3.0% MAS dispersions. Δ, 2 Weeks; □, 6 weeks; ○, 11 weeks; ■, 17 weeks.

Instrumentation and Methodology.—The Brookfield Synchro Lectric viscometer, model LVT, mounted on a Brookfield Helipath stand, was used. The spring tension (torque) of the instrument is 673 dyne-cm. at full scale, with a linear relation between

[1] Manufactured by R. T. Vanderbilt Co., New York, N. Y.

scale readings. A No. 5 Helipath spindle, consisting of a 11.4-cm. long stem having a diameter of 0.16 cm. with a 3.6-cm. long, 0.07-cm. diameter crossbar, 0.6 cm. from the end, was used for the measurements. This spindle was rotated at 6 r.p.m. while the platform of the Helipath stand descended at a rate of 2.2 cm. per min. Consequently, the crossbar of the spindle passed through the system being measured in a helical path, continuously contacting a different and previously undisturbed region.

A jar containing 200 ml. of the dispersion was opened carefully in a manner which avoided jarring, and placed on a micro Lab-Jack beneath the viscometer. The instrument was lowered manually until the crossbar of the spindle just touched the dispersion. The Lab-Jack was then raised 1 cm., so that the crossbar was immersed in the dispersion to that distance. Both viscometer and Helipath stand were then switched on, and torque readings were taken at every revolution of the spindle for a total of 16 revolutions. At no time was the spindle stopped or the torque indicator clutch engaged during the period of measurement. The 4th to the 13th readings were averaged and are reported here. Thus, the data represent the structural strength found in the body of the dispersion rather than that found close to the surface or bottom.

To determine structural recovery rate, jars containing the dispersion were placed on a reciprocating shaker with a shaking excursion of 3.8 cm., and shaken at 280 oscillations per min. for exactly 1 minute. The jars then were stored and left undisturbed until time of measurement. Five jars were used at each measurement period, and their average individual readings were averaged to yield the experimental values for the torque *vs.* time plots reported here.

RESULTS AND DISCUSSION

The method used for the determination of structural strength satisfies the requirement for measurement of undisturbed structure, since the crossbar of the inverted T spindle continuously encounters a new region as the spindle descends in the dispersion. The structural resistance met by the spindle is indicated continuously by the instrument pointer in terms of scale units, which can be changed to conventional torque units. The instrumental design does not, however, permit this value to be expressed in terms of dynes/cm.^{2}. Thus, the static yield value determined by the instrument cannot be expressed in conventional units, but this presents no undue disadvantage with respect to the present studies. Since the dispersion can be measured in the container in which it is stored, it is possible to utilize a large number of samples at all time intervals without inconvenience. The reproducibility of the method is high, as indicated by the data shown in Table I, which were selected at random from the total tabulation of experimental results. It is desirable that the rate of application of force by the spindle be high compared with the relaxation time of the system. Reference to the relaxation time of a MAS suspension reported by McVean and Mattocks (10) indicates that this is the case. While it usually is desirable to carry out rate studies at constant temperature, the present studies were made at room temperature since storage of the jars in an oven or water bath would subject the dispersions to vibration and motion. It is known that oscillations and similar slight motion can increase the recovery rate of bentonite dispersions as much as several hundredfold (5), so that it is important not to expose the dispersions to such effects. The usual ambient temperature fluctuations (±2°) did not have a significant effect on the recovery rates of MAS dispersions.

TABLE I.—STATIC YIELD VALUE[a] OF A 3% MAS DISPERSION[b] AT 4 HOURS

Jar No.	Average	Range
1	28.64	28.6–28.7
2	28.40	All readings identical
3	28.79	28.6–29.0
4	28.90	All readings identical
5	29.84	29.8–29.9
Overall	28.9	28.6–29.9

Kinetics of Structural Recovery.—It was found that a linear relationship exists between static yield value of MAS dispersions and the logarithm of resting time (Fig. 2). This linear relationship can be expressed as

$$T = \frac{T_2 - T_1}{\log t_2 - \log t_1} \log t + \text{constant} \quad \text{(Eq. 1)}$$

where T is the torque on the spindle at time t, T_1 the torque at time t_1, and T_2 the torque at time t_2. The structural recovery rate, therefore, is reflected by a coefficient of thixotropic recovery with time, R, which can be defined as

$$R = \frac{T_2 - T_1}{\log t_2 - \log t_1} \quad \text{(Eq. 2)}$$

and is the slope of the line which correlates torque and logarithm of resting time. Differentiation of Eq. 1 yields

$$R' = \frac{dT}{dt} \cdot t \quad \text{(Eq. 3)}$$

where

$$R' = 0.434\,R \quad \text{(Eq. 4)}$$

From Eq. 3 it is evident that the rate of change of torque is inversely proportional to the time and that R' is the proportionality constant.

The definition of R in the above equations is identical with that of Chong and co-workers for a coefficient of increased resistance to shear with time, as applied to the increase in yield value with shearing time of antithixotropic systems (11). Thus it is possible to express the rate of structure formation in thixotropic systems at rest and in antithixotropic systems during shear by means of the same coefficient R. This lends added justification to the term "antithixotropy" as applied by Chong, *et al.*

It would seem reasonable to assume that the structural recovery process ceases after a certain maximum static yield value is attained. The maximum was not reached in the present studies during periods considerably longer than 100 hours. Measurements over even longer periods of time are com-

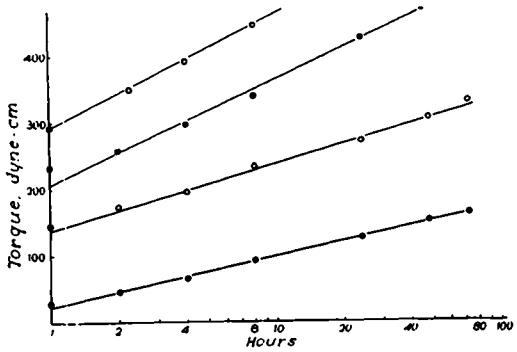

Fig. 2.—Structural recovery of aqueous dispersions of MAS. ●, 2.5%; ○, 3.0%; ■, 3.5%; □, 4.0% w/w.

plicated by the superimposed irreversible rheological changes due to aging, as described in the previous paper (1), which begin to overshadow and distort the now very small changes due to structural recovery. It has also been found that the initial stage of the thixotropic recovery process does not follow the kinetic scheme described. Reference to Figs. 2 and 3 will show that 1-hr. values were occasionally higher than theoretically indicated. Ten-minute values, not reported here, were always much higher than indicated by extrapolation of the straight line. This suggests that structural buildup occurs in two consecutive processes, analogous in part to von Smoluchowski's theory of fast and slow flocculation, for which assumption considerable evidence is available. Hauser and Reed have observed the structural build-up of bentonite dispersions with the ultramicroscope and have found that individual particles first form clusters which subsequently join together to form a continuous network throughout the dispersion (5). This two-step sequence has been observed also in other types of thixotropic dispersions. For example, Voet has found that structure formation in a dispersion of channel black in mineral oil occurred by association (formation of aggregates) followed by reticulation (interlinking of aggregates into a continuous network) (12). The data of Braune and Richter (8) also indicate that the initial rate of structural recovery of bentonite dispersions is higher than the rate in the subsequent

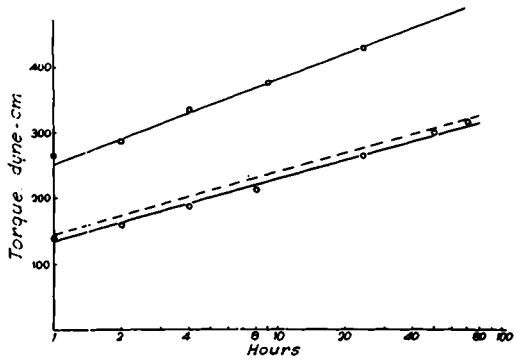

Fig. 3.—Effect of glycerin on static yield value and thixotropic recovery rate of 3% MAS dispersions. – – –, No glycerin; ○, 10% glycerin; □, 30% glycerin.

period. While the present studies deal with the kinetic aspects of structural recovery of MAS dispersions after the first hour of rest, the kinetics of the initial recovery process are currently under investigation and will be dealt with in a subsequent communication.

Effect of Concentration on Structural Recovery Rate.—Figure 4 shows that the logarithm of the coefficient of thixotropic recovery (R) is related linearly to the logarithm of MAS concentration. This relationship takes the form

$$\log R = a \log c + \log K \qquad \text{(Eq. 5)}$$

where c is the concentration of MAS, and a and K are constants. From the slope of the line fitted to the experimental data by the method of least squares, $a = 1.9$. It appears therefore, that

$$R = Kc^2 \qquad \text{(Eq. 6)}$$

since the experimental line deviates only slightly from a slope of 2.

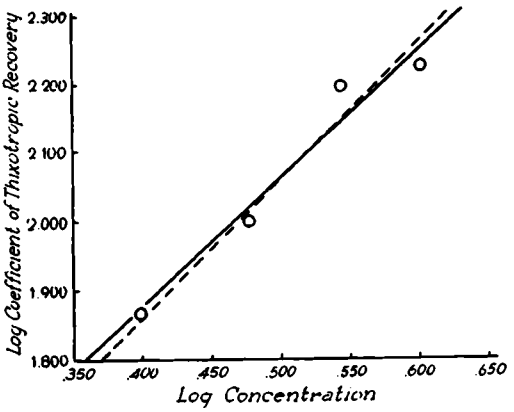

Fig. 4.—Effect of concentration on the coefficient of thixotropic recovery of aqueous dispersions of MAS. ———, Fitted line; - - - -, line with slope 2.

Effect of Aging.—Figure 1 shows the effect of aging on the recovery rate of 3% MAS dispersions prepared by the "hot" method. Both the recovery rate as well as the static yield value at any time during the measurement period increase as the dispersions age. Structural equilibrium had not been reached even after 17 weeks. The magnitude of the rheological changes on aging are, of course, related to the method of preparation of the MAS dispersions, particularly to the duration and intensity of shear to which the dispersions are exposed. The data presented in Fig. 1 were obtained from dispersions prepared from a different lot of MAS than was used in all other experiments reported here. Consequently, the line representing the structural recovery rate of a 10-wk. old dispersion shown in Fig. 2 does not "fit" into the plot and is closer to the 6-wk. line than to the 11-wk. line. This apparent discrepancy is not unusual since it is known that great lot-to-lot variations occur even in a relatively well-defined clay such as the type of MAS used in this study. The data of Samyn, for example, show a more than twofold difference in apparent viscosity between different lots of MAS hydrated for an equal length of time (13).

Method of Preparation.—No attempt has been made to study the effect of numerous manufacturing variables on MAS dispersions, since these have been described by Wood and co-workers (14) and by Simon and co-workers (15). In this study the structural recovery of MAS dispersions prepared by the "hot" method was compared with the recovery of MAS dispersions prepared by the "cold" method, in order to verify the surprisingly small effect of temperature noted in the first part of this investigation (1). The magnitude of the temperature effect again was found to be small (Fig. 5), which is in agreement with our previous results and also with the data reported by Vogt (16). The effect of ultrasonic waves on montmorillonite dispersions had not been studied by the authors cited previously (14, 15) and was, therefore, investigated. Cavitational heating of the dispersions was minimized by precooling and limiting the insonation period to 5 minutes in order to separate the possible temperature effect from the effect due to ultrasonic waves. The results show that ultrasonic treatment can increase the structural strength of MAS, probably due to greater dissociation of face-to-face particle aggregates (Fig. 5). Since the conditions of insonation were chosen arbitrarily, the results should be interpreted only in a qualitative manner.

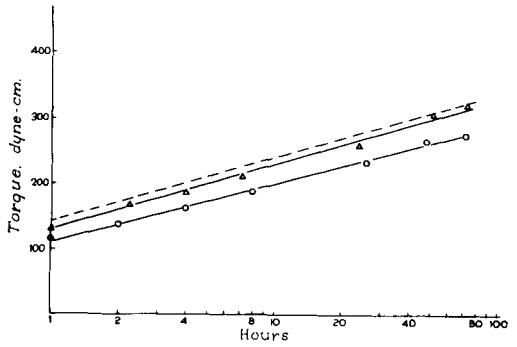

Fig. 5.—Effect of method of preparation on static yield value and thixotropic recovery rate of 3.0% MAS dispersions. O, "Cold" process; Δ, "cold" process and ultrasonic treatment; - - -, "hot" process.

Effect of Additives.—The effect of glycerin on the structural recovery rate and static yield value of MAS dispersions is shown in Fig. 3. In order not to superimpose a possible aging effect, glycerin was added to the MAS dispersions only 3 days prior to measurement, *i.e.*, after 9.5 weeks of aging. Glycerin had no significant effect at a concentration of 10%, but in the presence of 30% glycerin, both recovery rate and static yield value were considerably increased. Since the viscosity of a 30% aqueous glycerin solution is about 2.5 times higher than the viscosity of pure water, it was thought that the structural recovery rate would be lowered by glycerin due to the decreased mobility of dispersed MAS particles in a medium of higher viscosity. Such was not the case and the data suggest an increase in interparticle forces which may overshadow the viscosity effect. It is known that glycerin adsorbs on montmorillonites even from dilute aqueous solutions (17), and it has been suggested recently that the glycerin-bentonite structure differs from the structure of bentonite in water (18). Unfortunately, details of the latter study are not yet available and cannot be considered at this time.

It was of interest to study the effect of polysorbate 80 on MAS dispersions by the present method in view of the profound effect of this surfactant on the nature of the classical rheogram as noted in the first part of this investigation (1). Figure 6 shows the increased recovery rate and static yield value of MAS dispersions upon addition of 0.1% polysorbate 80. The increase in static yield value reflected by increased torques on the inverted T spindle parallels the increase in static yield value as determined with the standard rotational viscometer (1). The higher recovery rate of the dispersions containing the surfactant explains why rheograms of these dispersions had smaller thixotropic areas (1). In order to establish whether the surfactant effect could be enhanced by adding this agent to the medium prior to dispersion of the clay, dispersions of MAS were prepared to which polysorbate 80 was added, either before or after preparation. The more consistent data obtained from dispersions to which the surfactant had been added prior to MAS suggest that such dispersions are more homogeneous with respect to polysorbate 80. The results do not suggest, however, that lowering of interfacial tension during the mechanical dispersion process results in significantly greater lattice expansion or dissociation of face-to-face particle aggregates than lowering of interfacial tension subsequent to preparation of the dispersions.

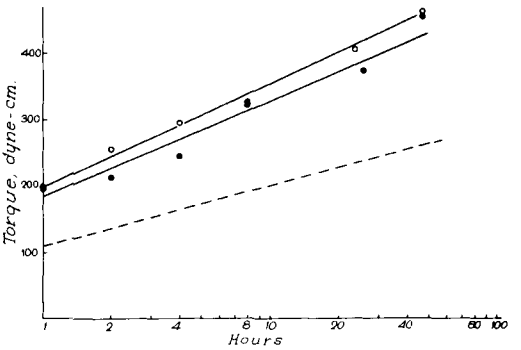

Fig. 6.—Effect of polysorbate 80 on static yield value and thixotropic recovery rate of 3% MAS suspensions. - - -, Prepared by the "cold" method without polysorbate 80; ●, 0.1% polysorbate 80 added after preparation; O, 0.1% polysorbate 80 added before preparation.

The addition of 10% zinc oxide greatly increased the static yield value of a 2.5% MAS dispersion and also increased the recovery rate (Fig. 7). The difference in static yield value is tenfold at 1 hour, and about threefold in 50 hours.[2] Zinc oxide particles are evidently capable of participating in the scaffolding structure of MAS particles in dispersion. While a possible zinc ion effect due to ion exchange cannot be excluded, it was minimized by incorporat-

[2] It must be realized that recovery rate is measured in terms of absolute increase in torque units per unit of time rather than in relative terms. Thus, a dispersion having a low initial static yield value and a low coefficient of thixotropic recovery can exhibit, nevertheless, a greater relative increase in static yield value with time than a dispersion with a higher initial static yield value as well as a higher coefficient of thixotropic recovery

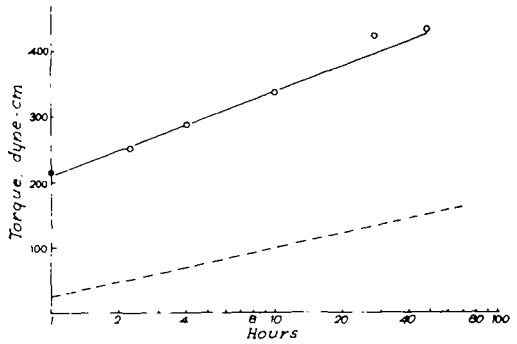

Fig. 7.—Effect of zinc oxide on static yield value and thixotropic recovery rate of 2.5% MAS dispersions. - - -, Plain suspension; O, with 10% zinc oxide.

ing zinc oxide in the aged MAS dispersions only 3 days prior to measurement. The results of this experiment may explain the lack of correlation between certain rheological properties of dispersions of two clays, bentonite and activated attapulgite, and their ability to suspend zinc oxide. Foernzler and co-workers indicate that the suspending ability of these dispersions, as reflected by the sedimentation velocity of zinc oxide, is directly related to the thixotropic area of the clay dispersion without zinc oxide (19). Wood could show subsequently, using the same data, that a similar or better correlation seems to exist between the sedimentation velocity and the reciprocal of yield value (20). Regardless of the treatment of the experimental data, however, the two clays yielded different proportionality constants and, thus, no absolute relationship of yield value or thixotropic area and suspending ability could be shown. While this may be due in part to differences in plastic viscosity as well as recovery rate of the two clays (a variable not considered in the experimental design), it is apparent from the present data that the static yield value of a pure clay dispersion differs greatly from the static yield value of a dispersion containing zinc oxide. Any attempt to correlate rheologic parameters with suspending ability should be based on the rheologic values of the final suspension, and not on those of the pure dispersion containing only the suspending agent.

Automated Dissolution Rate Studies of Capsules and Tablets

By LOUIS C. SCHROETER and JOHN G. WAGNER

Automation of dissolution studies of solid dosage forms has been achieved through the use of a timer-controlled sampling and dilution system which automatically removes filtered samples from the dissolution apparatus, makes reproducible dilutions, and records the absorption of the diluted sample as a function of time. The U.S.P. tablet disintegration apparatus was employed to provide constant, reproducible agitation. Versatility and reliability of the apparatus has been demonstrated by comparing automated dissolution rate results with values obtained by independent, manual analyses. Design requirements and specifications of individual components have been discussed in detail so that other functionally equivalent units may be employed to achieve comparable results with those reported in this study.

Dissolution characteristics of solid dosage forms such as tablets or capsules may be determined by agitating the dosage form in a suitable fluid and periodically assaying the solution for drug content. Reproducible agitation is essential to the test. Widespread availability of the standardized U.S.P. disintegration apparatus (1) makes it ideally suited for providing constant and reproducible agitation of the tablet or capsule since both design and operation of the apparatus are exactly prescribed. Periodic withdrawal of filtered, small aliquots of test fluid provides samples containing varying percentages of dissolved drug. Ultraviolet spectrophotometry serves as a rapid

Automated Dissolution Rate Studies of Capsules and Tablets

By LOUIS C. SCHROETER and JOHN G. WAGNER

Automation of dissolution studies of solid dosage forms has been achieved through the use of a timer-controlled sampling and dilution system which automatically removes filtered samples from the dissolution apparatus, makes reproducible dilutions, and records the absorption of the diluted sample as a function of time. The U.S.P. tablet disintegration apparatus was employed to provide constant, reproducible agitation. Versatility and reliability of the apparatus has been demonstrated by comparing automated dissolution rate results with values obtained by independent, manual analyses. Design requirements and specifications of individual components have been discussed in detail so that other functionally equivalent units may be employed to achieve comparable results with those reported in this study.

Dissolution characteristics of solid dosage forms such as tablets or capsules may be determined by agitating the dosage form in a suitable fluid and periodically assaying the solution for drug content. Reproducible agitation is essential to the test. Widespread availability of the standardized U.S.P. disintegration apparatus (1) makes it ideally suited for providing constant and reproducible agitation of the tablet or capsule since both design and operation of the apparatus are exactly prescribed. Periodic withdrawal of filtered, small aliquots of test fluid provides samples containing varying percentages of dissolved drug. Ultraviolet spectrophotometry serves as a rapid

Accepted for publication January 29, 1962.

and versatile analytical method for determining drug content of most products. Assay of samples removed at various times provides the necessary data for preparing a plot of per cent drug in solution as a function of time.

Automation of the dissolution rate studies provide obvious savings in laboratory man-hours and would permit general use of this concept for designing and controlling superior solid dosage forms on a routine basis. Circulating a filtered sample of test fluid through a spectrophotometer flow cell and automatically recording the change in absorbance as drug goes into solution is the essential feature of this automated process; it provides a plot of per cent drug in solution as a function of time. The schematic diagram of such an arrangement is shown in Fig. 1. Component parts and the applications and limitations of the system will be described in detail. Emphasis will be placed on the functions performed by each component and the specifications necessary to achieve optimum versatility in operation. This permits substitution of different, but operationally equivalent, components which may be available in other laboratories.

DESCRIPTION OF THE AUTOMATED SYSTEM

Agitation of Dosage Form.—The U.S.P. disintegration apparatus and basket-rack assembly (1) provides reliable and reproducible agitation. It was used in all studies and a standard 1-L. beaker was employed as the dissolution vessel. The wire bottom of the basket was brought to within 2.3 ± 0.2 cm. of the bottom of the beaker on the downward stroke. Control of the lower limit appears to be critical since stirring action imparted to granules which have passed through the screen and rest on bottom of beaker is markedly affected by this factor. The test fluid was 37.5 ± 0.2° in all studies.

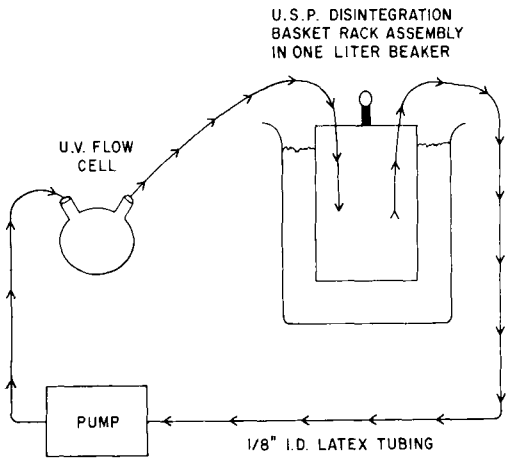

Fig. 1.—Flow pattern for continuous cycling of filtered dissolution fluid through spectrophotometer flow cell.

Filtering and Circulating the Sample.—A filtered sample of test fluid must be rapidly circulated through a spectrophotometer flow cell,[1] such as shown in Fig. 2, and returned to the beaker. Residence time of the sample in the sampling lines must be very short compared to the time required for a significant amount of drug to dissolve. Rapid pumping of the sample at variable speeds may be accomplished with the Sigmamotor model T8 pump[2] which functions by pressing, in sequence, little "fingers" of metal into the tubing, thus effecting a rapidly pulsating flow. This has the particular advantage of avoiding contamination of the fluid by the pump and also avoids hold-up of a large volume of fluid in the pump since the fluid never comes in direct contact with working parts of the pump. Small centrifugal or gear pumps constructed of stainless steel or resistant plastics also may be used if provision is made for controlling pumping rate with a rheostat.

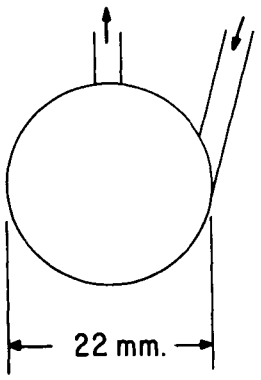

Fig. 2.—Spectrophotometer flow cell.

Filtering of the sample stream may be accomplished by placing a filter of design shown in Fig. 3 into one of the cylinders of the U.S.P. basket-rack assembly. The stainless steel filter tip is made from a 3 × 4 cm. sheet of #100 stainless steel wire cloth rolled into a cylinder with the end closed. This assembly provides reliable sampling of the solution and prevents clogging of the filter. The return stream of filtered solution should be discharged into a different cylinder, but not the cylinder containing the dosage form under test; it should not be discharged into the bottom of the dissolution beaker because this tends to magnify stirring action. Other filtering devices may be used but they should permit high flow rates so that sampling lag time is kept to a minimum. Also, it is desirable that the filter tube be weighted to prevent it from bouncing up in the cylinder and exposing the intake to air. Latex or Tygon tubing of internal diameter 1/8 inch or smaller and of shortest possible lengths should be used in the sampling line to keep sample lag time to a minimum.

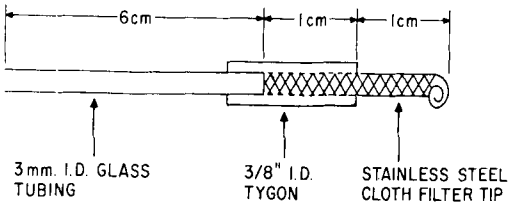

Fig. 3.—Sampling-filter device.

Spectrophotometry.—Automated measurement of the amount of drug in solution may be easily accomplished for those drugs which possess requisite chromophoric groups by automatically recording the change in absorbance of the solution flowing through the spectrophotometer flow cell. Many of the commercially available recording spectrophotometers, such as the Cary model 11, can be set to record absorption at a given wavelength (usually at a point where drug molecule exhibits maximum absorption) as a function of time. This requires no modification of the recording spectrophotometer other than arranging the cell compartment cover to permit entrance of tubing to the flow cell. The recording spectrophotometer may be converted to regular use in less than 30 seconds. However, as a permanent arrangement, the use of such a recording spectrophotometer would commit a versatile and expensive instrument to a specific job function. For this reason, a Beckman model DU spectrophotometer was converted for this specialized purpose.

Conversion of the Beckman DU spectrophotometer to an instrument which will record absorbance as a function of time may be accomplished with the Gilford model 200 optical density converter.[3] This attachment consists of two parts: a photodetector which is fastened to the spectrophotometer in place of the standard detector; and an electronic power supply and converter-amplifier. No modification of the spectrophotometer is necessary; the conversion can be made in minutes and does not impair use of the spectrophotometer for manual, conventional operation. The Beckman DU instrument was chosen for its excellent monochromator system; however, any spectrophotometer having a similar monochromator covering the ultraviolet and visible spectrum from 220 to 800 mμ and having a stabilized light source can be used. Recording can be done on any self-balancing potentiometer recorder with a 50 mv. full-scale sensitivity and a response time of one-half second.

Recording.—A Texas Instrument Servariter recorder model PWS[4] was used in all studies. This recorder has a chart speed selector which permits rapid selection of 10 different chart speeds. Normal range of chart speeds in most studies varied from $^1/_4$ to 2 in. per min.

Intermittent Sampling and Dilution.—Increased versatility of an automated dissolution device may be accomplished with the use of a sampling dilution arrangement shown schematically in Fig. 4. Introduction of a three-way magnetic valve[5] into the sample stream serves as a means of diverting a fixed, small volume of the sample stream into a diluent stream. The valve should have a minimum orifice of $^1/_{16}$ inch so that sample retention is reduced to a minimum. The valve is actuated by a signal from a timer which permits preselection of sampling time and duration of sample stream diversion. Thus, if the flow rate in the sample stream is 1 ml. sec.$^{-1}$, opening the valve for one-half second removes 0.5 ml. of sample. Withdrawal of 10 samples of 0.5-ml. volume from 1 L. of fluid during the course of a dissolution study introduces an overall error of only 0.5%.

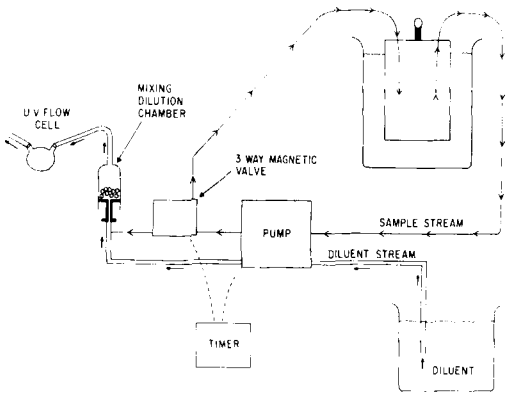

Fig. 4.—Flow pattern of filtered solution when intermittent sampling with dilution employed.

Transport of the diverted sample to the spectrophotometer flow cell may be accomplished by injecting it into a diluent stream flowing at a constant rate. However, streamline flow does not serve for effective mixing (2, 3). Mixing the sample and diluent stream may be accomplished by using a turbulent flow mixing chamber (Fig. 5). It is desirable to have a variable volume mixing chamber to provide requisite control of effective dilution necessary in adjusting absorbances of diluted sample stream between 0.1 and 3.0. It may be advan-

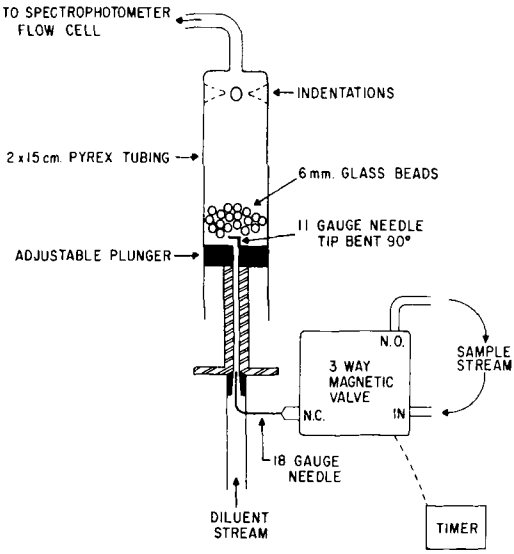

Fig. 5.—Three-way magnetic valve and turbulent flow dilution-mixing chamber for intermittent sampling and dilution of sample stream.

[5] Skinner Electric Valve Div., New Britain, Conn.

tageous to employ fixed volume mixing chambers for studying a series of tablets containing the same amount of drug, *i.e.*, in cases where dilution of sample stream remains constant. Fixed volume mixing chambers can be constructed from ordinary volumetric pipets by cutting off the tubing to within 1 cm. of the body and filling the body with 3- or 4-mm. glass beads. Most reproducible mixing occurs when these are employed in a vertical position with sample and diluent entering the bottom and emerging mixed from the top.

Controlled flow of diluent may be accomplished with a hydrostatic device constructed from a 500-ml. separator modified with a side arm tube (about 5 cm. from top) for overflow. Adjusting height of liquid level permits accurate control of diluent flow. The Sigmamotor pump described above can also be used to pump both the sample stream and the diluent stream simultaneously since it will accommodate tubing on both sides of the "fingers." Different tension adjustments on either side of the pump and the use of larger diameter tubing for the diluent stream permits variable pumping rate selections for both streams. It is not necessary to know the exact dilution factor since all measurements during a dissolution study are relative. However, effective dilution must be reproducible during the course of the study and for comparative studies. Flow rate control may be achieved by periodically checking both the sample and diluent stream with a flow meter.[6]

Timing sequence may be provided by any timer or series of timers which will, at predetermined intervals of from $^1/_2$ to 5 minutes, open for a period from $^1/_2$ to 5 seconds, and then close the three-way solenoid valve. The timer should then automatically reset (recycle) and repeat the sequence. A sequential timer[7] was used to control the operation since it contained six circuits; however, other, less sophisticated timers would be equally satisfactory if they fulfilled the timing requirements. If a Sigmamotor pump is used for pumping both sample and diluent stream, it may be advisable to conserve the diluent, especially when buffers or other color-developing solutions are employed.

Conservation of diluent fluid may be accomplished by intermittent timer-controlled operation of the pumping system. A multiple circuit timer should control the following sequence: (*a*) pump on, 15–20 sec.; (*b*) valve open, $^1/_2$–5 sec.; (*c*) valve shut, 15–30 sec.; (*d*) pump off, 60–300 sec.; (*e*) repeat cycle. Operating the pump for a period of at least five residence times (15 sec.) permits flushing of lines and taking a representative sample from the dissolution vessel. The pump must run a minimum of 15 to 30 sec. after sampling to flush dilution-mixing chamber and spectrophotometer flow cell.

RESULTS AND DISCUSSION

Continuous Monitoring of Dissolution Process.—The schematic arrangement of equipment shown in Fig. 1 was used to follow the dissolution process of a 4-mg. steroid tablet. Complete dissolution of one tablet in 750 ml. of pH 1.35 buffer yielded a solution with an absorbance of 0.21. This low absorbance of the dissolution fluid provided a good test of the sensitivity of the automated procedure for determining dissolution characteristics of dosage forms containing small amounts of drug or drugs with low molar absorptivities. Total volume of sampling lines, filter device, and flow cell was 7.3 ml.; the sample flow rate was 1.34 ml. sec.$^{-1}$. Residence time in the sampling system was 5.4 sec. This can be reduced further by decreasing the volume of the sampling system or increasing flow rate, or both; however, these are upper limits on permissible flow rates. If the flow rate is greater than 2 ml. sec.$^{-1}$, this tends to contribute to the stirring action in the dissolution beaker and results in faster dissolution of the tablet or capsule. A filtered sample stream from the beaker containing drug from one tablet wholly dissolved (100% drug in solution) was pumped through the flow cell and the recorded response adjusted to read 100 units or 100% drug in solution. Sample lines were flushed with pH 1.35 buffer and the test repeated by placing one tablet in the U.S.P. basket-rack assembly immersed in a new beaker containing 750 ml. of pH 1.35 (μ = 0.1) buffer at 37.5°. The dissolution curve produced by the automated procedure is shown in Fig. 6 along with 2 independent individual dissolution rate determinations of other tablets from the same lot.

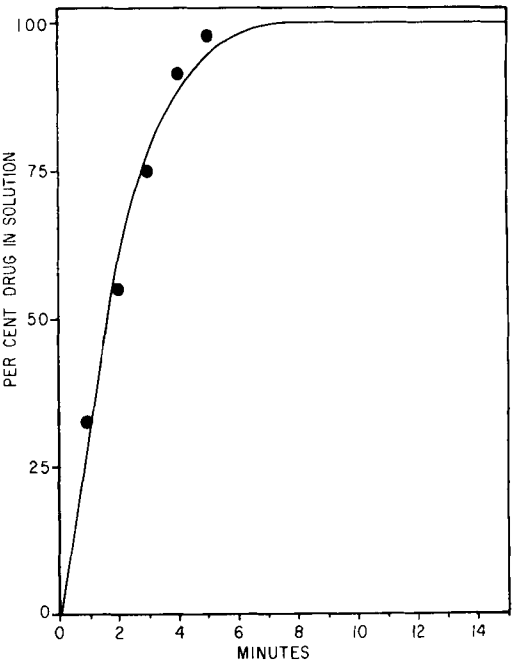

Fig. 6.—Dissolution characteristics of a steroid tablet in 750 ml. buffer (μ 0.1) at 37.5° using U.S.P. disintegration apparatus without disks. Solid line redrawn from curve obtained using automated procedure. Solid circles represent independent assays of tablets from same lot.

The schematic arrangement shown in Fig. 1 serves very well for the accurate monitoring of the dissolution process of this particular steroid tablet. However, it must be emphasized that not all dosage forms contain just the right amount of drug which, when dissolved in about 1 L. of fluid, will yield solutions having absorbance values between 0.1

[6] Flowrator, Fischer and Porter Co., Hatboro, Pa.
[7] Multiflex, Eagle Timer Corp., Moline, Ill.

and 3.0. Many dosage forms contain drugs with high molar absorptivities so that resultant solutions from complete dissolution of the drug have absorbance values of 10 or higher. Thus, with the total volume of fluid set at about 1 L. and the limit of spectrophotometric sensitivity fixed at 0.1 to 3.0 absorbance units, the need for dilution of sample stream becomes evident. The sample stream, once it is diluted, cannot be returned to the test beaker because this would increase the total volume of fluid present. Likewise, the dissolution beaker cannot be constantly sampled nor can the combined withdrawn samples constitute a large volume because this would deplete the fluid in the beaker.

Sampling with Dilution.—A typical "combination of ingredients" tablet containing aspirin, phenacetin, and caffeine was selected to demonstrate automated sampling with dilution. One tablet was dissolved completely in 750 ml. of pH 1.35 buffer (μ = 0.1) by equilibrating at 37.5° for 1 hour. Absorbance of the undiluted solution was 23.6 at the wavelength of maximum absorption which was a composite of the 3 chromophores. This indicated the need for an effective dilution of 20× to give a measurable absorbance. Sample flow rate was regulated to 1 ml. sec.$^{-1}$ and the timer adjusted to send a $^1/_2$ sec. signal (0.5 ml. sample) to the three-way solenoid valve every 1.7 min. Volume of the sampling line and valve was 4.1 ml.; sample lag time was 4.1 sec. The wavelength of the absorption maximum (230 mμ) of the dissolved mixture in pH 1.35 buffer was selected on the monochromator. The recorder was then balanced to give a maximum response to 100 units (100% drug in solution) by manipulating the flow rate of pH 1.35 diluent and adjusting the turbulent flow mixing chamber volume. The sampling system was flushed with pH 1.35 buffer and connected with a new beaker containing 750 ml. of pH 1.35 (μ = 0.1) maintained at 37.5°. One tablet was placed into the U.S.P. disintegration basket assembly and immersed into the buffer solution and agitated at the prescribed rate of 30 cycles per min. Introduction of the tablet into the buffer marked zero time for the process. Reproduction of the curve produced by the recorder is shown in Fig. 7. The heights of the solid vertical lines represent instrumental response or per cent drug in solution. Absorbance of the solution flowing through the cell rapidly returns to zero as the diluted sample is flushed from the cell. The one flow cell serves as a sample cell and as a blank cell since the diluent stream constantly flushes the cell; this assures instrumental reliability of measurements made over long periods. The inherent reliability of the automated system is shown by the close fit of peak heights obtained with the automated procedure to the individual points obtained by an independent method on tablets from the same lot.

Intermittent Circulation with Sampling and Dilution.—A sulfonylurea tablet formulation was used to evaluate the applicability of intermittent fluid circulation followed by sampling with dilution. Two tablets of the sulfonylurea product were dissolved in 750 ml. of pH 7.2 THAM[8] buffer by equilibrating with stirring at 37.5° for 1 hour. Complete solution of the drug content of the tablets corresponds to 100% drug in solution or 1000 mg. of drug dissolved in 750 ml. of buffer. Absorbance of the undiluted solution was 65 at the wavelength of maximum absorption, thus indicating the need for an effective dilution of from 30 to 50×. The sample flow rate was regulated at 1.0 ml. sec.$^{-1}$ and the timer adjusted to start the pump 15 sec. before sending a signal to the valve and to continue pumping 15 sec. after the event. The timer was adjusted to send a 0.5-sec. (0.5-ml. sample) signal to the three-way magnetic valve every 60 sec. Volume of sampling lines and valve was 3.5 ml.; the time required for a sample to complete the circuit from beaker and return was 3.5 sec. Monochromator was adjusted to provide monochromatic radiation at the absorption maximum of the sulfonylurea in pH 7.2 THAM buffer (228 mμ). The recorder was balanced to give a maximum response of 100 units (arbitrarily marked as 1000 mg.) by manipulating the flow rate of diluent and adjusting volume of the mixing chamber. The sampling system was flushed with fresh pH 7.2 THAM buffer and connected with a new beaker containing 750 ml. of pH 7.2 THAM buffer maintained at 37.5°. Two tablets were placed into the U.S.P. disintegration basket-rack assembly and immersed into the buffer solution; this marked zero time on the recorder. Reproduction of the curve obtained from the recorder is shown in Fig. 8. The heights of the solid vertical lines represent instrumental response or per cent drug in solution. Absorbance of the solution rapidly returns to zero as the diluent sample passes through the cell; this serves as a further in-process instrumental check. Analyses of solution composition at various times during the dissolution test by an independent spectrophotometric method served to validate the method.

CONCLUSIONS

Automated dissolution rate studies of solid dosage forms serve as an extremely useful method for controlling the quality of these products. The method is applicable to the evaluation of virtually all tablets, capsules, and granules containing drugs soluble in about 1 L. of dissolution fluid. The total dissolution profile expressed as per cent drug in solution as a function of time may be obtained for these products. However, dosage forms containing drugs not wholly soluble in the dissolution medium may also be evaluated; results are expressed in terms of absolute initial rate of dissolution.

Savings in laboratory man-hours can be enormous if the automated procedure is used regularly to control the quality of solid dosage forms. One investigator working with the automated device can perform the same number of dissolution studies as four technicians working with conventional, manual procedures. Also, the automated procedure uses a modified Beckman DU spectrophotometer in place of a Cary recording spectrophotometer for measuring absorption changes in the solution. This frees the more expensive recording spectrophotometer for other more versatile analytical jobs. The automated device also serves as a useful and versatile analytical tool for automatically re-recording the progress of chemical kinetic reactions which involve changes in absorption of monochromatic light.

Synthesis and Antifungal Evaluation of Some Derivatives of Dialkoxybenzoic and Dialkoxycinnamic Acids

By A. K. KAPADIA† and GAIL A. WIESE

A number of dialkylaminoalkyl esters of dialkoxybenzoic and dialkoxycinnamic acids and their halogenated analogs were prepared. The compounds, in the form of their hydrochloride salts, together with the parent acids were tested *in vitro* against three pathogenic fungi using undecylenic acid and griseofulvin as controls. In general, the results of the tests indicated that most of the compounds had little or no antifungal activity *in vitro*.

IT HAS BEEN shown that fungal diseases in man are a growing health hazard (1). The search for antifungal agents has been in progress for several decades. In reviewing the literature it was noted that there have been few investigations directed toward the study of antifungal activity of the derivatives of dialkoxybenzoic and dialkoxycinnamic acids and their halogenated analogs.

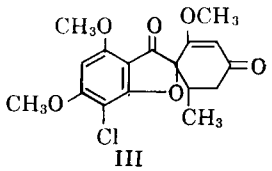
It is interesting to note that the structural fragment I included in this investigation is a

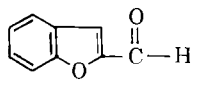


I

position isomer of the structure II present in the

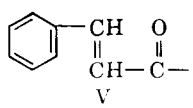
II

griseofulvin molecule III.



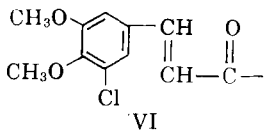
III

MacMillan has shown that the aromatic chlorine substituent in the griseofulvin molecule enhances the antifungal activity of griseofulvin (2).



Woodward, *et al.* (3), have studied the fungicidal properties of various halogens and alkyl substituents on the aromatic ring of phenol *in vitro*. They found that in going from chlorine to bromine to iodine, there was a four to tenfold increase in antifungal activity. Taking these facts into consideration, it was decided that the effect of removal of halogen from the aromatic ring and the interchange of chlorine for bromine and iodine should be studied.

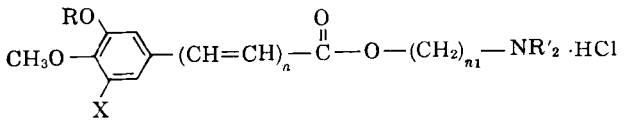
Pan and Wiese (4) found that benzofuran-2-carboxaldehyde (IV) had



IV

significant antifungal activity as compared to undecylenic acid *in vitro*. The cinnamoyl group (V) is present in benzofuran-2-carboxaldehyde (IV).

V



The structural fragment VI was included in this investigation. This is a vinylog of I.

VI

Since dialkylaminoalkyl esters of other acids have shown useful properties (5–8), the dialkylaminoalkyl esters were of interest in this investigation. These alkamine esters were water insoluble, therefore they were converted into the hydrochloride salts. The compounds prepared in this investigation are summarized in Tables I and II.

ANTIFUNGAL EVALUATION

The compounds were tested *in vitro* against *Trichophyton mentagrophytes*, *Trichophyton rubrum*, and *Microsporum gypseum*. The testing procedure was similar to that described by Waters (22), with the exceptions that ethanolic solutions of the compounds and a 7-day incubation period were employed. At the end of the incubation period, the minimum zone of inhibition was measured. The zone of inhibition was the distance between the periphery of the paper disk and the colony growth. Undecylenic acid and griseofulvin were used as controls. Ethyl vanillate and 95% ethanol were also included in this study. The results of this antifungal study are given in Table III. Each value in this table represents an average of two zones of inhibition. Only those compounds which had a zone of inhibition 3 mm. and greater are reported in Table III.

DISCUSSION

The dialkylaminoalcohols used in these studies are readily available. The required acids were synthesized according to the procedures described in the literature with certain modifications.

Raiford and co-workers (12, 14, 15) have reported the synthesis of a number of dialkoxybenzoic acids. Vanillin was first alkylated and subsequently oxidized to the acid with potassium permanganate. We found that oxidizing vanillin to the corresponding vanillic acid and then alkylating it was a more efficient process and gave better yields.

The method of Pearl (8) for preparing vanillic acid (II) from vanillin using silver oxide in an alkaline medium was preferred for the preparation of 5-chlorovanillic acid (V), 5-bromovanillic acid (VIII), and 5-chloro-4-hydroxy-3-ethoxybenzoic acid (XIV).

Veratric acid (III) was synthesized from vanillic acid (II) according to the method used by Fosdick and Starke (23) for preparing 3,4-dimethoxycinnamic acid from ferulic acid. The same procedures were used for preparing 5-chloroveratric acid (VI), 5-bromoveratric acid (IX), and 5-chloro-4-methoxy-3-ethoxybenzoic acid (XV) from their respective aldehydes. Attempts to prepare 5-iodoveratric acid (XII) in this way were unsuccessful. Therefore, the following method was employed: the aldehyde, 5-iodovanillin was first methylated to give 5-iodoveratraldehyde (XI) which was subsequently oxidized to 5-iodoveratric acid (XII) with potassium permanganate. In the case of 5-bromo-4-methoxy-3-ethoxybenzoic acid (XVIII), 3-ethoxy-4-hydroxybenzaldehyde was first oxidized to 3-ethoxy-4-hydroxybenzoic acid (XVI). This compound was brominated yielding 5-bromo-4-hydroxy-3-ethoxybenzoic acid (XVII). Subsequent methylation gave rise to 5-bromo-4-methoxy-3-ethoxybenzoic acid (XVIII).

The compounds, 5-chloro-3,4-dimethoxycinnamic acid (XXI) and 5-bromo-3,4-dimethoxycinnamic acid (XXIV) were synthesized according to the methods of Pearl and Beyer (18) and Fosdick and Starke (23).

The aldehydes, 5-chlorovanillin (IV) and 5-chloro-4-hydroxy-3-ethoxybenzaldehyde (XIII), were obtained by a modification of the method of Menke and Bentley (10). Because of solubility problems, carbon tetrachloride was employed as a solvent instead of chloroform. The compounds, 5-bromovanillin (VII) and 5-iodovanillin (X) were obtained by the methods of McIvor and Pepper (24) and Erdtman (16), respectively.

The alkamine esters were prepared by refluxing the dialkylaminoalcohol in dry benzene with the appropriate acid chloride. The alkamine esters that formed precipitated as the hydrochloride salts.

The results of the antifungal studies, as shown in Table III, indicate that none of the compounds had an antifungal activity comparable to that of the compounds used as controls.

Thin-Layer Chromatography in Drug Analysis I

Identification Procedure for Various Sulfonamides in Pharmaceutical Combinations

By SHELDON KLEIN† and B. T. KHO

A thin-layer chromatographic procedure is described for identifying various sulfonamides when present in pharmaceutical combinations. Successful identification has been accomplished for sulfadiazine, sulfamerazine, sulfamethazine, sulfathiazole, sulfacetamide, sulfanilamide, sulfaquinoxaline, and sodium sulfabromomethazine. The critical effect of water in the solvent system and the use of various detection methods, including fluorescent plates and Ehrlich's and Bratton-Marshall's reagent sprays are described. The procedure can be completed within 2 hours.

SINCE the introduction of thin-layer chromatography (TLC) into pharmaceutical literature by Stahl (1), numerous articles have been published pertaining to drug analysis by use of this technique (2–9). The advantage of TLC over paper chromatography is its speed and ability to withstand corrosive substances for use as spraying agents, such as sulfuric acid for the determination of meprobamate (2). A disadvantage is the difficulty in obtaining reproducible R_f values. This, however, can be overcome by use of standards along with the unknown samples.

The U.S.P. XVI (10) uses a precipitation procedure for its identification of a trisulfapyrimidine combination of sulfadiazine, sulfamerazine, and sulfamethazine. The N.F. XI (11) uses a paper chromatographic separation for the identification of sulfadiazine and sulfamerazine in the presence or absence of sulfacetamide. These are time consuming and tedious to perform. The TLC procedure described in this paper can be done within 2 hours. Wollish, Schmall, and Hawrylyshyn (8) reported a TLC method and approximate R_f values for sulfanilic acid, sulfadiazine, N[1]-(3,4-dimethyl-5-isoxazoyl) sulfanilamide and its acetyl derivative,[1] and 2,4 - dimethoxy - 6 - sulfanilamido - 1,3 - diazine.[2]

The purpose of this paper is to provide, by means of TLC, a relatively rapid systematic separation of commercially available sulfonamide combinations. Using a modification of the solvent system described by Wollish, *et al.* (8), separation and identification of various sulfonamides was accomplished. The influence of the amount of water on the successful separation has also been studied.

EXPERIMENTAL

Primary Preparation of Plates.—The Stahl apparatus[3] and method were used for the preparation of the chromatoplates. Silica gel G,[4] 30 Gm., was placed in a dry 8-oz. mortar.

Preparation of Neutral Plates.—Distilled water, 40 ml., was added while stirring slowly. When the entire mass was of a uniform consistency, an additional 20 ml. of distilled water was added, and the mixture was stirred until uniform.

Preparation of Fluorescent Plates.—Fluorescein, 20 mg., was dissolved in 1.2 ml. of 0.1 *N* sodium hydroxide. Sufficient distilled water was added to make 60 ml. The preparation was then the same as described for the neutral plates, using the fluorescein solution instead of water.

The total stirring time should not exceed 1.5 minutes. The suspension was poured into the applicator and spread immediately over five plates (200 × 200 mm.) or 20 strips (200 × 50 mm.). After air drying for approximately 5 minutes to allow evaporation of excess water, the plates were stored in a desiccator over silica gel. Before use, they were activated at 105° for 30 minutes and set aside to cool. Starting points were marked along an imaginary line 15 mm. from one edge, and a finishing line was drawn 150 mm. from the start.

Standards.—A 10-mg. quantity of each sulfonamide was dissolved in separate 50-ml. portions of acetone. Sulfonamides used were: sulfadiazine (I), sulfamerazine (II), sulfamethazine (III), sulfathiazole (IV), sulfacetamide (V), sulfanilamide (VI), sulfaquinoxaline (VII), and sodium sulfabromomethazine (VIII).

Received February 26, 1962, from the Quality Control Section, Merck Sharp & Dohme, Division of Merck & Co., Inc., Philadelphia, Pa.

Accepted for publication March 8, 1962.

Presented to the Scientific Section, A.PH.A., Las Vegas meeting, March 1962.

The cooperation and encouragement of Dr. L. Paul Sinotte and Mr. Theodore P. Michaels in carrying out this project are gratefully acknowledged. The authors also wish to thank the Technical Services Unit for helpful suggestions, Mr. Karl Wrightman for photography, and Miss Kathleen Smith for her secretarial assistance.

[3] Obtainable from C. Desaga, Heidelberg, Germany, Importer, Brinkmann Instruments Inc., Great Neck, L. I., N. Y.

[4] A standardized mixture of silicic acid and calcium sulfate obtainable from E. Merck, Darmstadt, West Germany; Importers, Brinkmann Instruments Inc., Great Neck, L. I., N. Y.; Terra Chemicals Inc., 500 Fifth Ave., New York 36, N. Y.

Tablet Samples.—A quantity containing approximately 10 mg. of the individual sulfonamide in the largest concentration was added to a 125-ml. glass-stoppered Erlenmeyer flask and extracted with 50 ml. of acetone.

Suspension Samples.—The extraction procedure was the same as that for the tablets except where the products contained interfering ingredients. To these latter samples, 1 ml. of distilled water was added before shaking with the acetone. Cloudy solutions were centrifuged before applying a sample to the plate.

Quantity of Sulfonamide Applied.—A 1-mcg. quantity of sulfonamide was applied to the chromatoplates.

Primary Solvent System.—Chloroform-ethanol-heptane (1:1:1 plus an amount of water depending upon the sulfonamide combination). It was prepared by mixing 66 ml. each of reagent grade chloroform, anhydrous ethanol, and heptane. Anhydrous sodium sulfate was added and the mixture shaken. Before using, sufficient water was added to the decanted solvent to obtain the optimum water percentage. After the addition of water, the level was checked using Karl Fisher reagent.

Concentration of Water.—Table I shows the amounts of water used for various mixtures. Slight variances from the values shown altered the chromatoplates sufficiently to reduce the sensitivity of the procedure.

TABLE I.—AMOUNT OF WATER ADDED TO THE PRIMARY SOLVENT

	Suspected Sulfonamides	Water,[a] %
A	I, II, III, VII, VIII	1.0–1.8 (1.5 optimum)
B	IV	1.2
C	V	1.5–1.8
D	VI	1.5

[a] Per cent water for sulfonamides in A was used when no others were suspected. B, C, and D were used when these sulfonamides appeared in addition to any of those in A.

Spray Reagents.—Aqueous hydrochloric acid, 1*N*, 5% aqueous sodium nitrite, 0.1% alcoholic N-(1-naphthyl)ethylenediamine dihydrochloride (Bratton-Marshall reagent) were used as spray reagents.

Distance Developed.—The chromatoplates were developed over a distance of 150 mm.

Method for Neutral Plates (A).—Samples (5 μl.) and standard solutions (5 μl.) representing each sulfonamide theoretically present in the samples were applied to the plates and dried by a current of air. The developing tanks were allowed to equilibrate at least 3 hours before inserting the chromatoplate. Up to 18 individual samples were applied per plate. When development of 150 mm. was completed, the plates were removed, air dried, and sprayed with 1 *N* hydrochloric acid followed by 5% sodium nitrite.

Any yellow spots representing sulfathiazole or sulfaquinoxaline were marked. The plates were then dried at 100° (usually for less than 5 minutes) until free from excess nitrous acid (when no yellow areas other than those marked could be seen). Coupling with 0.1% N-(1-naphthyl)ethylenediamine dihydrochloride produced reddish-purple spots which were marked and the R_f values calculated. Measurements were made from markings of the leading edge of the spots. The samples were identified by comparison of their R_f values to those of the standards. Development of 200 mm. was also tried on a 200 × 230 mm. plate using a larger developing tank.

Method for Fluorescent Plates (B).—The application of standards and samples, development, and air drying were identical to the procedure described for the neutral plates. Instead of the spray reagents, a short wave U.V. lamp (257 mμ) was used to observe the separation of the components, and the dark nonfluorescent spots were then marked. A summary of R_f ranges for the various sulfonamides tested is shown in Table II.

Figures 1 and 2 show typical, developed neutral chromatoplates of commercial products and standards using 1.2 and 1.5% water in the solvent system.

TABLE II.—APPROXIMATE R_f VALUES AND RANGES OBTAINED FOR VARIOUS SULFONAMIDES[a]

Sulfonamide	Av. R_f	Std. Deviation	Exptl. Ranges
Sulfacetamide	0.42	0.03	0.36–0.47
Sulfadiazine	0.47	0.03	0.43–0.53
Sulfathiazole	0.50	0.03	0.47–0.60
Sulfanilamide	0.53	0.02	0.48–0.57
Sulfamerazine	0.57	0.03	0.53–0.64
Sulfamethazine	0.64	0.04	0.59–0.72
Sulfaquinoxaline	0.66	0.05	0.62–0.75
Sodium sulfabromomethazine	0.77	0.04	0.70–0.83

[a] Data accumulated from 12 or more plates, using 1.5% water in the solvent system. In 1.2% water, the values for all except sulfacetamide, sulfathiazole, and sulfanilamide are reduced by at least 0.05.

RESULTS AND DISCUSSION

Procedure A.—Using the proper concentration of water, the sulfonamides, except VII, were sufficiently separated to allow identification by observation of the developed spot. Though the R_f value for VII closely approximated that for III, it was readily differentiated from the other by its yellow diazotization product. The identification of IV, if overlapped, was also possible due to its yellow diazotization product. Close observation of freshly sprayed spots showed IV to have a brown tint, V a red tint, and the others to be reddish-purple. On standing the colors faded.

The development of 200 mm. gave more distinct separation but did not justify the increased development time. Table III shows the various types of pharmaceutical combinations tested. The other components present did not interfere with the procedure.

Procedure B.—Though the total time consumed was reduced by the elimination of the spraying procedure, the sensitivity was also reduced. This was overcome by increasing the amount of sample applied to the plate. To increase the visibility of the samples, the diazotization and coupling can be carried out on the fluorescent plate. The reddish spots are then clearly visible on the yellow background.

Experimental plates were developed in solvent

systems containing various amounts of water. The water concentration was critical in the separation of sulfathiazole and sulfanilamide from the others. When these two were not present, an optimum range existed whereby the spots were sufficiently separated to allow easy identification.

A water concentration of 1.2% was found to be optimum for the separation of sulfathiazole from sulfadiazine, and 1.5% water was found to be optimum for the separation of sulfanilamide from sulfamerazine. Higher concentrations (1.8%) caused an overlapping of sulfanilamide and sulfadiazine; lower concentrations (1.2%) caused sulfanilamide to overlap the sulfamerazine. Sulfacetamide showed the best separation at a water level between 1.5 and 1.8%, though no overlapping occurred at the other levels tested.

Greater concentrations of water gave further movements for certain compounds but decreased the separation areas. A weakening of the adsorptive property of the silica gel G on some of the compounds by the water caused the increased movements. An anhydrous solvent system gave less separation, overlapping, and more tailing.

For the preliminary investigation of an unknown mixture, it is recommended that duplicate plates be prepared. One plate should be developed in the

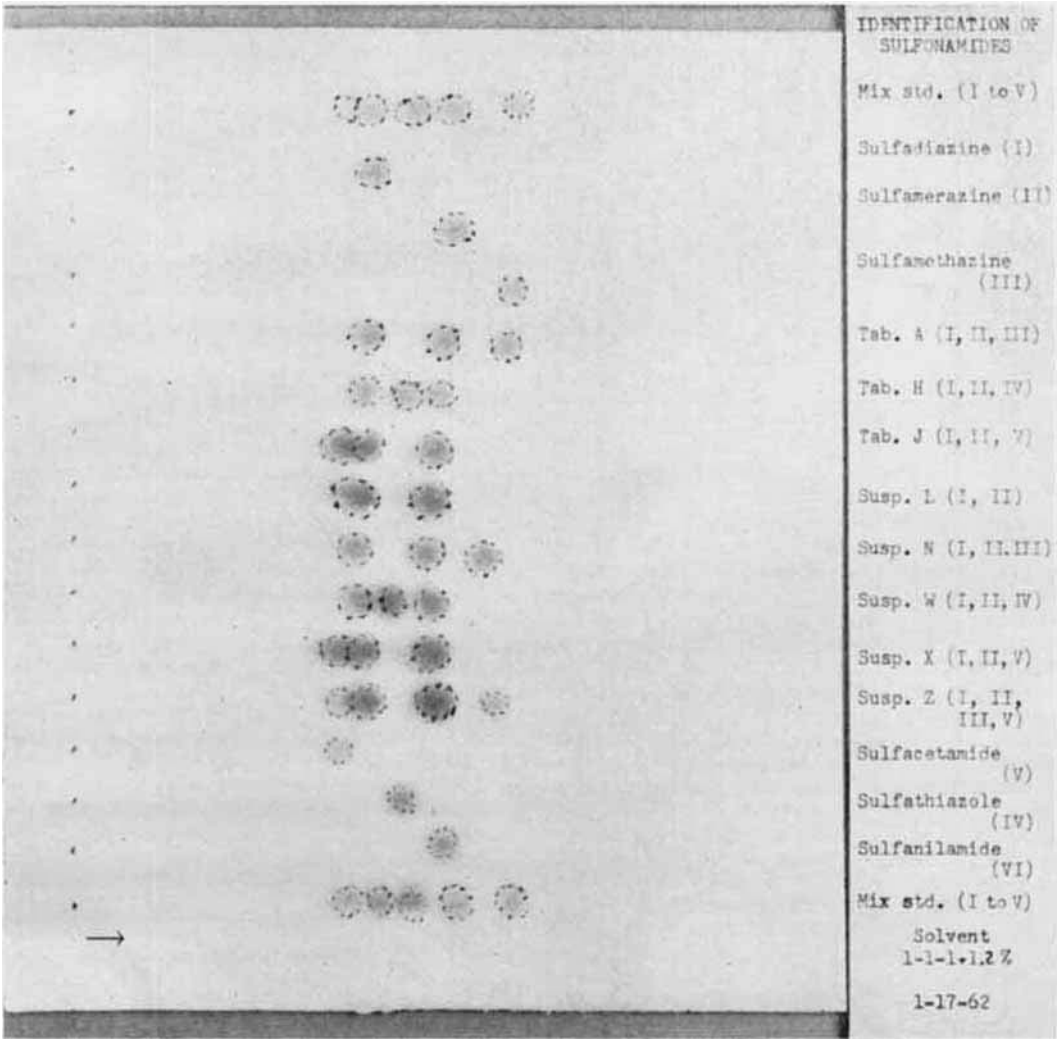

Fig. 1.—Thin-layer chromatographic separation of pharmaceutical combinations. Solvent: chloroform-heptane-ethanol (1:1:1 + 1.2% water).

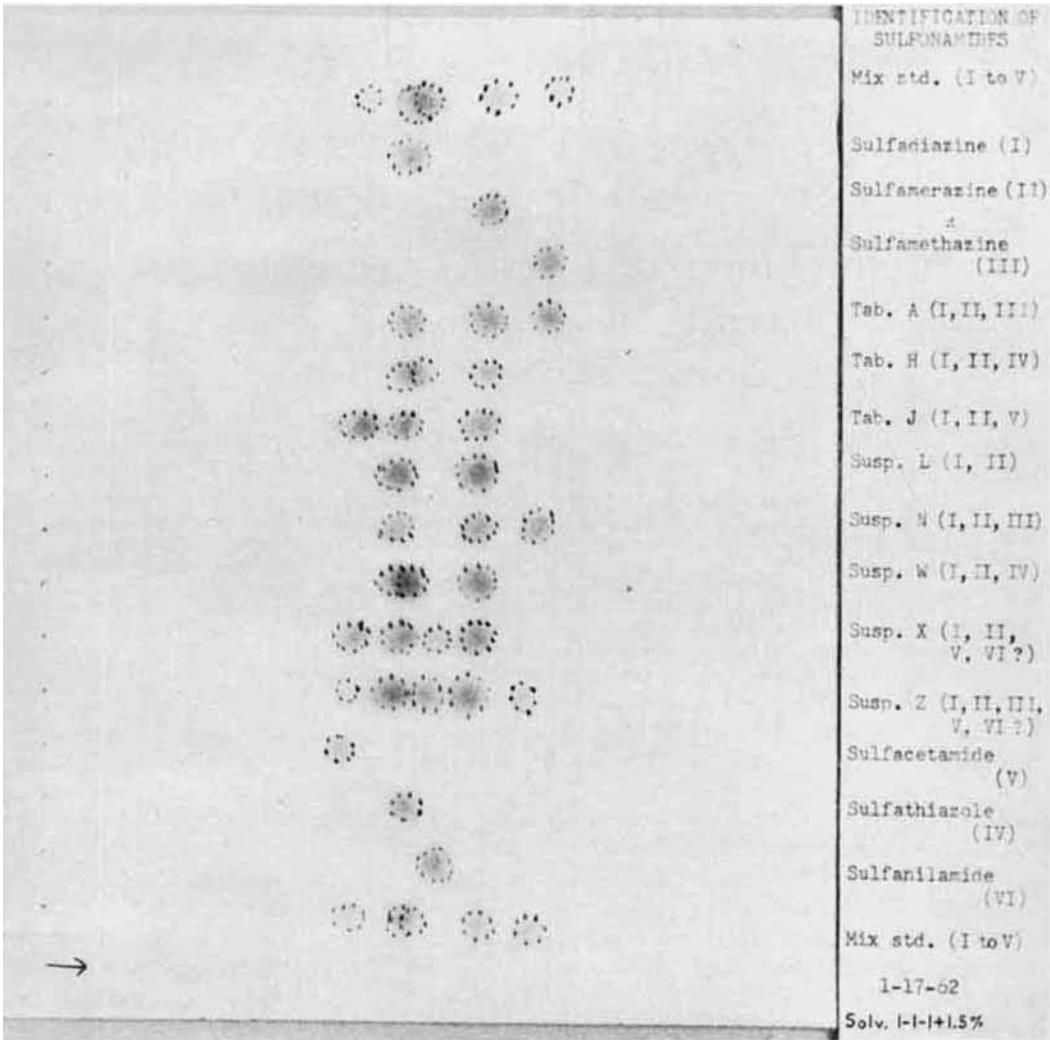

Fig. 2.—Thin-layer chromatographic separation of pharmaceutical combinations. Solvent: chloroform-heptane-ethanol (1:1:1 + 1.5% water).

solvent system containing 1.2% water and the other in the 1.5% water solvent system.

Ehrlich's reagent (*p*-dimethylaminobenzaldehyde, 1% in acidified ethanol) was tried as a replacement for the Bratton-Marshall reagent. Though it was less time consuming, the differentiation of VIII from III and the presence of IV, if overlapped, were not possible. Also, the outlines of the individual spots were not as distinct as those produced by using the Bratton-Marshall reagent.

Due to the uncertainty of reproducing R_f values from one plate to another, it is important to use standards along with the samples.

SUMMARY

1. A thin-layer chromatographic procedure for the identification of various sulfonamides individually and in combination has been developed.

2. Successful separation of mixtures containing the following sulfonamides has been obtained: sulfadiazine, sulfamerazine, sulfamethazine, sulfathiazole, sulfacetamide, sulfanilamide, sulfaquinoxaline, and sodium sulfabromomethazine.

3. The identification of the following has been made when present in pharmaceutical combinations: sulfadiazine, sulfamerazine, sulfamethazine, sulfathiazole, sulfacetamide, and sulfanilamide.

4. The concentration of water is critical for obtaining satisfactory separations of sulfathiazole and sulfanilamide from the other sulfonamides tested.

Composition of Gum Turpentines from Twenty-Two Species of Pines Grown in New Zealand

By ALLETTE L. WILLIAMS and M. H. BANNISTER†

Vapor-phase chromatography, following steam distillation, has provided an effective means of identifying many components of the gum turpentines of oleoresins from 22 *Pinus* species, with the probable exception of the sesquiterpenes and some trace constituents. With the improved injection instruments, it has been possible to analyze samples as small as 0.5 Gm., thus allowing the study of very low-yielding or small trees. This work confirms the specific differences previously reported for the major constituents, with two notable exceptions, *P. muricata* and *P. montezumae*. The results suggest the existence of two varieties of *P. muricata*, distinguishable by a wide difference in turpentine composition.

THE GENUS *Pinus*, as described by botanists, comprises about 100 species, several of which are divided into subspecies or varieties. The chemical composition of the gum turpentine (*i.e.*, the volatile fraction of the oleoresin obtained by wounding the sapwood) has been reported for 92 species and 2 varieties, as summarized by Mirov (1). This work, requiring oleoresin samples of the order of 500 Gm., was done in the main by fractional distillation of the turpentine, followed by determination of the densities, optical rotations, and refractive indexes of the fractions, and finally by the preparation of crystalline derivatives. It was limited by the inadequate methods for isolating and identifying many of the individual compounds which occur only in trace amounts. Physical methods such as vapor-phase chromatography and infrared spectroscopy have simplified the study of turpentine composition, and have the great advantage of being applicable to very small samples. With vapor-phase chromatography alone, however, the comparison of retention volumes depends on the availability of pure reference compounds. Purified samples of terpenes are not readily available and their preparation is often difficult and time-consuming, especially when the compounds occur only as trace quantities. Nevertheless, the value of vapor-phase chromatography in the terpene field has already been recognized and the technique has been used by many workers (1–6).

A satisfactory vapor-phase-chromatography technique for studying the turpentine composition of *P. radiata*, *P. attenuata*, and hybrids between these two species has been developed (7). While extending this work to study individual variation in *P. radiata* (8) we decided to try the technique on a number of other species of pines grown in New Zealand. This would not only test the efficiency of the method for analyzing more complex turpentines, but would also provide a comparison between species grown in New Zealand and elsewhere.

EXPERIMENTAL

Method of Sampling.—All the oleoresin samples except one were collected from single trees growing in or near the New Zealand Forest Service Arboretum at Whakarewarewa, near Rotorua, in February 1961. The remaining sample was collected from a single tree of *P. muricata* on Huckleberry Hill, near Monterey, Calif., in 1960. Holes, 2.5 cm. in diameter, were bored into the sapwood and close-fitting tubes were inserted. With this method the oleoresin had minimum contact with the outside air, and the time required to collect the sample was usually 1 or 2 days, and in no case more than 7 days. The oleoresin samples were tightly

Composition of Gum Turpentines from Twenty-Two Species of Pines Grown in New Zealand

By ALLETTE L. WILLIAMS and M. H. BANNISTER†

Vapor-phase chromatography, following steam distillation, has provided an effective means of identifying many components of the gum turpentines of oleoresins from 22 *Pinus* species, with the probable exception of the sesquiterpenes and some trace constituents. With the improved injection instruments, it has been possible to analyze samples as small as 0.5 Gm., thus allowing the study of very low-yielding or small trees. This work confirms the specific differences previously reported for the major constituents, with two notable exceptions, *P. muricata* and *P. montezumae*. The results suggest the existence of two varieties of *P. muricata*, distinguishable by a wide difference in turpentine composition.

THE GENUS *Pinus*, as described by botanists, comprises about 100 species, several of which are divided into subspecies or varieties. The chemical composition of the gum turpentine (*i.e.*, the volatile fraction of the oleoresin obtained by wounding the sapwood) has been reported for 92 species and 2 varieties, as summarized by Mirov (1). This work, requiring oleoresin samples of the order of 500 Gm., was done in the main by fractional distillation of the turpentine, followed by determination of the densities, optical rotations, and refractive indexes of the fractions, and finally by the preparation of crystalline derivatives. It was limited by the inadequate methods for isolating and identifying many of the individual compounds which occur only in trace amounts. Physical methods such as vapor-phase chromatography and infrared spectroscopy have simplified the study of turpentine composition, and have the great advantage of being applicable to very small samples. With vapor-phase chromatography alone, however, the comparison of retention volumes depends on the availability of pure reference compounds. Purified samples of terpenes are not readily available and their preparation is often difficult and time-consuming, especially when the compounds occur only as trace quantities. Nevertheless, the value of vapor-phase chromatography in the terpene field has already been recognized and the technique has been used by many workers (1–6).

A satisfactory vapor-phase-chromatography technique for studying the turpentine composition of *P. radiata*, *P. attenuata*, and hybrids between these two species has been developed (7). While extending this work to study individual variation in *P. radiata* (8) we decided to try the technique on a number of other species of pines grown in New Zealand. This would not only test the efficiency of the method for analyzing more complex turpentines, but would also provide a comparison between species grown in New Zealand and elsewhere.

[a] Values expressed as weight per cent; *t* indicates < 1%. [b] Samples analyzed directly after distillation at 120° and helium flow rate 21 ml./min.

stoppered and stored at about 0° whenever possible until required for analysis.

Analysis.—The oleoresin samples (20 Gm. or less) were steam-distilled at atmospheric pressure and the distillates (400 ml.) collected in ice-cooled flasks. The distillation time was about 40 minutes. The yields of the steam-volatile fractions, except from the very small samples, are given in Table I. When steam distilling the smaller oleoresin samples (*i.e.*, less than 2 Gm.) the distillate was collected in a narrow-bore syphoning tube, designed so that the steam-volatiles could be sampled directly. The turpentine samples were stored at 0° between analyses.

The steam-volatiles were chromatographed on a Perkin-Elmer vapor fractometer, model 154C, in conjunction with a Leeds and Northrup Speedomax type G recorder. Columns 1 M. in length and 4–5 mm. in diameter were packed with the following materials: 20% di-isodecylphthalate on Celite 545 (Johns-Manville); 23% squalane (May and Baker) on Celite 545; 11% squalane (May and Baker) on Celite 545; 20% silicone oil DC-200 on Celite 545; 18% polyethylene glycol (Carbowax 1500) on Chromosorb R (60–80 mesh); and 15% silicone oil (May and Baker) on Chromosorb R. The columns were tested at temperatures from 80 to 120° and with various helium flow rates. The most satisfactory overall separation of the constituents of the turpentines was obtained with a column of di-isodecylphthalate on Celite 545 at a temperature of 80° and a helium flow rate of 116 ml./min. The majority of the samples were analyzed under these conditions.

A Hamilton microliter syringe (0–10 μl.) was used to inject most samples into the gas stream. For the remaining oleoresin samples (*i.e.*, 0.5–1 Gm.) which produced only trace amounts of turpentine, a Perkin-Elmer microdipper (1 μl.) was used. The volume of steam-volatiles analyzed was varied from 0.4 to 1 μl., depending on the number of constituents present and their proportions. Each analysis was run in duplicate and the mean values reported to the nearest 0.5%. The areas under the peaks were determined with a planimeter, as some peaks were incompletely resolved, and areas of less than 1% of the sum of the peak areas were quoted as trace quantities.

Relative retention ratios using α-pinene as the reference were determined for authentic samples of known turpentine constituents with the di-isodecylphthalate/Celite column at 80°, and also with the silicone oil DC-200/Celite column at 80° as a check. The identities of the individual components of the turpentines being investigated were established by comparison with these ratios, which are given in Table II. Two minor constituents present in the turpentines have not been identified.

The turpentines were initially analyzed immediately after distillation on a di-isodecylphthalate/Celite column (1 M.) at 120° with flow rate of 21 ml./min. Limonene, β-phellandrene, *p*-cymene, and *n*-undecane peaks were not distinguishable at this temperature but were more satisfactorily resolved at a lower temperature of 80°. β-Pinene and β-myrcene were also separated at this temperature. The analyses were therefore repeated at a temperature of 80° and a flow rate of 116 ml./min. approximately 2 months after steam distillation. The compositions (weight percentages) of the steam-volatiles determined under these conditions are listed in Table I. As the analyses of *P. banksiana*, *P. contorta*, and *P. muricata* (A) could not be repeated at 80° owing to insufficient samples, the compositions of these species determined at 120° are reported. In the case of *P. coulteri*, the compositions found at both 120 and 80° are given.

Typical chromatograms, shown in Figs. 1, 2, and 3, were obtained under the following conditions: length of column, 1 M.; internal diameter of column, 4 mm.; column packing, 20% di-isodecylphthalate on Celite 545; temperature, 80°; helium flow rate, 116 ml./min.; recorder range, 8.

DISCUSSION

In this study it has been assumed that the mole responses of the constituents to the thermal conductivity cell detector are identical and, therefore, that the area under each peak is proportional to the mole per cent of that component. Jamieson (9), however, has shown that this assumption does not hold strictly when nitrogen is used as the carrier gas, and it is probable that small differences in the mole responses of the terpenes would also be found with helium. In a further investigation we propose to purify samples of the various constituents by preparative-scale gas chromatography and to determine their mole responses using helium as the carrier gas. It is expected that the necessary correction factors will be quite small. The purified terpenes will also be used to obtain optical rotation data.

We have also assumed that isomerization, polymerization, or decomposition of the turpentine constituents did not occur on the column di-isodecylphthalate on Celite 545. The catalytic effects of the supporting materials on terpenes have been discussed by many workers and Celite has been considered to be fairly satisfactory (2, 4, 5). However, Matsuura, *et. al.* (6), preferred crushed crystallized quartz which had been previously treated with nitric acid. In the present work, samples α- and β-pinenes chromatographed on a column of silicone oil (May and Baker) on Chromosorb R gave more than one peak, suggesting that the supporting medium or liquid phase was suspect. No

Table II.—Relative Retention Ratios for Terpene Hydrocarbons and Related Compounds at 80°

Compound	Relative Retention Ratios: Di-isodecylphthalate	Relative Retention Ratios: Silicone oil DC-200
n-Heptane	0.14	0.18
n-Octane	0.29	0.38
n-Nonane	0.64	0.79
α-Pinene	1.00	1.00
Camphene	1.21	1.07
β-Pinene	1.54	1.33
β-Myrcene	1.78	1.42
Δ^3-Carene	1.94	1.64
α-Phellandrene	2.08	1.56
Limonene	2.48	1.87
β-Phellandrene	2.63	1.85
p-Cymene	2.94	1.74
n-Undecane	3.12	3.40

such effect was detected when the pure compounds were chromatographed on a silicone oil DC 200/ Celite 545 column.

Although it has already been shown in the hybridism studies involving *P. radiata* and *P. attenuata* (8) that the ratio of the α-pinene to β-pinene content is not affected by ultraviolet light, storage time, or by distillation, this has not been established for the other terpenes encountered in these investigations. No doubt the paraffin hydrocarbons are unaffected. α- and β-Phellandrenes are known to be rather unstable compounds and to polymerize readily. This was demonstrated by the marked decrease in the β-phellandrene content of *P. coulteri* observed when the analysis of the turpentine was repeated at 80° after storage at 0° in the dark for 2 months. Hence, the composition of the volatile fraction of *P. coulteri* determined at 80° and without allowance for the polymerized phellandrene should be disregarded. Although the β-phellandrene content of *P. patula* was not affected during the same storage period, a similar decrease in the β-phellandrene content was subsequently shown. Polymerization of β-phellandrene probably also occurred during steam distillation, as suggested by Mirov (10) in his study of *P. coulteri*. He showed that polymerization was greatly decreased by distilling the turpentine under reduced pressure.

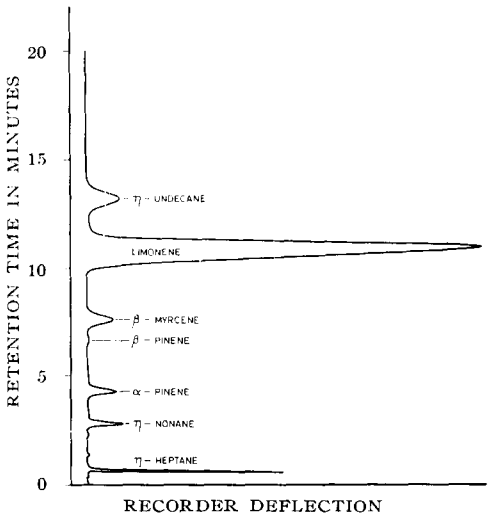

Fig. 1.—Chromatogram of turpentine from *P. torreyana*.

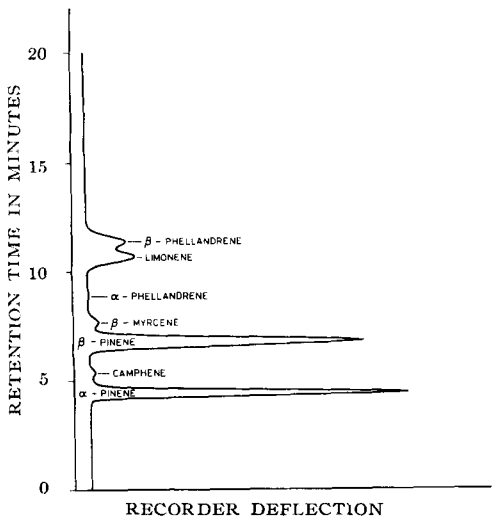

Fig. 2.—Chromatogram of turpentine from *P. rigida*.

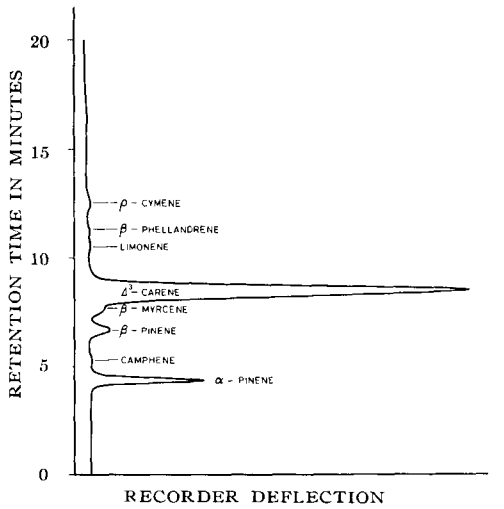

Fig. 3.—Chromatogram of turpentine from *P. muricata* (B).

The possibility of changes in the turpentine composition during collection of the oleoresin sample cannot be overlooked. Although precautions were taken during the sampling operation, these were probably not entirely adequate in preventing some changes in the less stable turpentine constituents.

An unidentified compound in concentration from 1 to 7% (relative retention ratio 3.00 at 120°) was detected in the turpentines of *P. coulteri*, *P. ponderosa*, *P. contorta*, *P. patula*, *P. montezumae*, and *P. muricata* (samples A, B, C, D) when chromatographed immediately after distillation at 120°. This compound was apparently degraded on standing.

In view of these considerations the compositions of the turpentines given in Table I cannot be assumed to be identical with those in the living trees.

A comparison of the results given in Table I with those already published suggests that high-boiling constituents, such as the sesquiterpenes, were not detected. While we have reduced the possibility of changes in the turpentine caused through prolonged steam distillation, it is probable that the high-boiling constituents have remained in the rosin fraction of the oleoresin. Distillation of the oleoresin under reduced pressure is necessary to isolate all the volatile components (1). On the other hand, it is possible that in chromatographing the turpentines at the low temperature of 80°, the high-boiling constituents have remained on the column.

β-Myrcene appears to be more widely distributed in the genus *Pinus* than was hitherto thought. Mirov (1) notes that its presence has been recorded in eight species including *P. nigra* (11), *P. ponderosa* (12–16), *P. taeda* (17), and *P. halepensis* (18). While *P. coulteri* was found to contain 18% β-pinene when chromatographed at 120° (Table I), the analysis of this sample at 80°, even though it is not entirely reliable, suggests that probably the greater proportion of this 18% would have been myrcene. The ease of polymerization of β-myrcene noted by McGimpsey and Murray (19) in the study of *Podocarpus spicatus* (matai) could perhaps account for the fact that myrcene has seldom been found in pines.

The occurrence of β-phellandrene and camphene in small amounts is also more widespread than was supposed (1). α-Pinene, not detected previously in *P. pinea* and *P. torreyana*, has been found in the New Zealand specimens of these species.

We have tentatively identified *p*-cymene in *P. sabiniana*, *P. luchuensis*, *P. ponderosa*, *P. montezumae*, *P. thunbergii*, and *P. muricata* (samples B, C, D). This compound has previously been reported only in *P. sylvestris* (20) and *P. taeda* (11). α-Phellandrene has also been tentatively identified in *P. patula*, *P. rigida*, and *P. jeffreyi*.

Two or more of the paraffin hydrocarbons *n*-octane, *n*-nonane, and *n*-undecane have been tentatively identified in each of the turpentines containing *n*-heptane, *P. jeffreyi*, *P. torreyana*, *P. coulteri*, and *P. sabiniana*.

Refinements in the experimental procedure such as the use of capillary columns, the extremely sensitive ionization detectors, temperature programming, or preliminary separation and concentration of fractions of the turpentines, could establish the existence of further components.

Botanical Aspects

In comparing the results with those summarized by Mirov (1) we find, in general, a close agreement, at least for the major constituents. This was to be expected, because Mirov (1, 21) has found that there is little variation throughout the growing season within the individual tree, and that apparently the composition of the turpentine is affected little, if at all, by variations in the habitat. He has concluded that composition of turpentine is a stable, "genetically fixed character."

On the other hand, it was also to be expected that our results would differ, in some ways, from those already published. Some differences may have resulted from variation in the methods of collection and analysis. Others may have arisen from genetic variation between groups of trees, or between individual trees, within a species. Little is known about variation of turpentine composition within species, but the evidence (1) suggests that some species are nearly uniform (*e.g.*, *P. merkusii*), whereas others are very heterogeneous (*e.g.*, *P. ponderosa*). There is, therefore, quite a high probability that our results, most of which represent only one individual tree per species, would include some which deviate markedly from the values reported previously. In particular, we wish to discuss three species which evidently vary widely in turpentine composition.

P. ponderosa.—This species has a wide geographic distribution, and has become genetically differentiated into a number of morphological and physiological forms. Analyses by Mirov and coworkers (12–16) of turpentines from 12 widely separate localities within its natural range, and another analysis by Goldblatt and Burgdahl (22) have revealed consistently high percentages of Δ^3-carene and, generally, of β-pinene. But there is a wide variation, both in the proportions of the major constituents and in the occurrence and percentages of the minor constituents. Our result falls well within this range of variation, and, in so far as it is comparable with Mirov's data, it suggests a close kinship between the New Zealand tree and the *P. ponderosa* of southwest Idaho or California.

P. montezumae.—This name is applied to a complex assortment of populations, most of which are found in Mexico. Martinez (23) has formally divided the complex into two varieties and one form. Two independent analyses by Iriarte (24) and Mirov (13*a*) of samples collected near Uruapan, Michoacan, agreed in finding α-pinene to constitute 96–98% of the turpentine. For a sample from Chiapas, Iloff and Mirov (25) reported the composition: 72% α-pinene, 7% limonene, 8% heptane, and 8% longifolene. Mirov (1) has concluded that these results may represent two distinct varieties, or two distinct species, or possibly one species in Michoacan and a swarm of interspecific hybrids in Chiapas.

Our results might suggest that the New Zealand sample came from *P. ponderosa* rather than from *P. montezumae*, but this seems unlikely. In its morphological characters, the tree in question is much more like *P. pseudostrobus* than *P. ponderosa*, and it might well be *P. montezumae* var. *lindleyi* Loudon. Further work on the turpentine composition of *P. montezumae* and related species is needed.

P. muricata.—Our sample A of this species contained about 86% of Δ^3-carene (Table I). It was collected on Huckleberry Hill, near Monterey, Calif. Mirov (26) had previously analyzed a sample collected near Fort Bragg, about 350 km. north of Monterey, and found the turpentine to consist almost entirely of α-pinene (98–99%). Some unpublished work by Mirov indicated that the turpentine of the Fort Bragg population might differ considerably in its optical rotation from that of the Huckleberry Hill population (27). Our result for the Huckleberry Hill sample was open to various interpretations, and as a check we sampled four trees growing near Rotorua.

Three of these belonged to a group which, from their circumstances and morphological characters, were judged to be very closely related to one another. The uniformity of their turpentines supports this judgment (Table I, samples B, C, and D). The fourth tree (sample E) was an isolated specimen, some 8 km. away. It differed considerably in morphological character from the others and yielded turpentine essentially the same as that of the Fort Bragg trees sampled by Mirov (26). Although only superficial observations have been made on the morphology of these four trees and of *P. muricata* elsewhere in New Zealand, we suggest that the data may represent a taxonomic discontinuity in *P. muricata*, two groups being distinguishable as follows: (*a*) somewhat squat, bushy trees with hemispherical crowns when grown in the open; dense green foliage; extremely spiny cones; and turpen-

tine predominantly of Δ^3-carene; (*b*) generally taller trees with conical crowns; foliage distinctly bluish, the needles thicker than in (*a*); cones with the apophyses more rounded on the outer side and generally less spiny than in (*a*); and turpentine predominantly α-pinene.

Unfortunately, the lineage of the New Zealand specimens cannot be traced back to a known provenance in California. Nevertheless, the scheme suggested not only fits the chemical facts so far, but also agrees closely with the morphological work of Duffield (27). His conclusion was that the mainland populations of *P. muricata* could well be divided into two varieties, one of which, including the Huckleberry Hill population and the typical form near San Luis Obispo, stretched from the Annapolis area southward, while the other, including the Fort Bragg population, stretched from Annapolis northward.

Further close collaboration between botanists and chemists studying this species is highly desirable; particularly useful would be a detailed population analysis in the Annapolis area where, according to Duffield (27), the trees show a morphological transition between the typical variety and the northern one.

Amino Ketones: Kinetics of *In Vitro* Antibacterial Activity

By SHU-SING CHENG†, SIGURDUR JONSSON‡, and FRED T. SEMENIUK

α- and β-Amino ketone analogs of amino acids were tested *in vitro* against *Escherichia coli, Staphylococcus aureus, Pseudomonas aeruginosa, Bacillus anthracis, Saccharomyces cerevisiae,* and *Candida* spp. by serial broth dilution and agar diffusion methods and found to be active as growth-inhibitors at concentration levels which varied with the test culture. The study of the growth curve of a test bacterium in a liquid medium with and without the presence of the drug provides an accurate means for the *in vitro* evaluation of the antibacterial activity of potential chemotherapeutic agents. It serves also as a means for studying the dynamics as well as the mode of antibacterial action. Since the generation time and the numbers of generations of microbial growth occur before stationary phase can be calculated, the inhibitory activity of different drugs may be compared on this basis.

THE growth-inhibitory activity of β-amino ketone analogs of β-alanine against *Escherichia coli* and *Staphylococcus aureus* has been reported recently (1). This leads to speculation that α-amino ketone analogs of α-amino acids might possess similar activity. This study was then undertaken in order to investigate the potential antimicrobial action of these two categories of amino ketone analogs of amino acids.

Received April 28, 1961, from the School of Pharmacy, University of North Carolina, Chapel Hill.
Accepted for publication March 27, 1962.
Presented to the Scientific Section, A.PH.A., Chicago meeting, April 1961.
Abstracted in part from a thesis submitted by Shu-Sing Cheng to the Graduate School of the University of North Carolina in partial fulfillment of the requirements for the degree of Doctor of Philosophy.
† Recipient of 1961 Lunsford Richardson Pharmacy Award. Present address: Department of Chemistry, Clark University, Worcester, Mass.
‡ Deceased.

PROCEDURES AND RESULTS

There are three general methods for determining drug sensitivity of bacteria currently in use: the serial broth dilution, agar diffusion, and agar plate dilution methods. For the *in vitro* evaluation of antimicrobial activity of amino ketone hydrochlorides, the first two methods were selected.

Agar Diffusion Method.—*Staphylococcus aureus*, *Bacillus anthracis*, and *Pseudomonas aeruginosa* were used as test organisms. Stock culture was maintained on slants of peptone-casein agar and transferred to fresh slants about once a week. The assay plates and inocula were prepared according

tine predominantly of Δ^3-carene; (*b*) generally taller trees with conical crowns; foliage distinctly bluish, the needles thicker than in (*a*); cones with the apophyses more rounded on the outer side and generally less spiny than in (*a*); and turpentine predominantly α-pinene.

Unfortunately, the lineage of the New Zealand specimens cannot be traced back to a known provenance in California. Nevertheless, the scheme suggested not only fits the chemical facts so far, but also agrees closely with the morphological work of Duffield (27). His conclusion was that the mainland populations of *P. muricata* could well be divided into two varieties, one of which, including the Huckleberry Hill population and the typical form near San Luis Obispo, stretched from the Annapolis area southward, while the other, including the Fort Bragg population, stretched from Annapolis northward.

Further close collaboration between botanists and chemists studying this species is highly desirable; particularly useful would be a detailed population analysis in the Annapolis area where, according to Duffield (27), the trees show a morphological transition between the typical variety and the northern one.

2-Amino-1-indanone	16	22	10	18

[a] See references (1) and (7) for the preparation of these compounds.

to U.S.P. XV method for penicillin microbial assay (2). The medicated disk method was used instead of cylinder-plate method. Peptone agar and peptone-casein agar were used for preparing the supporting agar layer and seeding layer, respectively.

The medicated paper disks were gently placed on the surface of the inoculated agar plate. For reference, sulfanilamide (5 mg.), sodium sulfamerazine (3 mg.), and sodium sulfapyridine (3 mg.) were included. In the case of sulfanilamide, the drug was placed directly on the surface of the inoculated agar plate without using the paper disk. All the plates were incubated at 37° for 16 to 18 hours, after which the growth responses were examined and the diameters of the clear zones of growth inhibition were measured on a bacterial colony counter. The results are summarized in Table I. 2-Amino-1-indanone hydrochloride exhibited a rose-red inhibitory zone on the surface of agar plate inoculated with *B. anthracis*, whereas phenyl aminomethyl ketone and *p*-tolyl aminomethyl ketone hydrochlorides each exhibited a rose-red inhibitory zone with a surrounding zone of growth-stimulation when tested under the same conditions. *o*-Tolyl aminomethyl ketone and 3,4-dimethylphenyl aminomethyl ketone hydrochlorides each showed yellow to brownish inhibitory zone surrounded by a zone of growth-stimulation when tested against *B. anthracis* and *P. aeruginosa*.

Of the 17 compounds tested, 2-amino-1-indanone and *n*-heptyl β-aminoethyl ketone hydrochlorides (2 mg. each) exhibited the widest zones of inhibition against the growth of *B. anthracis*. Sulfanilamide (5 mg.) produced very slight or no inhibition on the test organisms. Sodium sulfapyridine (3 mg.) and sodium sulfamerazine (3 mg.) were inactive.

Serial Broth Dilution Method.—*Escherichia coli* ATCC 8739, *Staphylococcus aureus* ATCC 6538 P, *Saccharomyces cerevisiae*, *Candida albicans*, and *Candida krusei* were used as test organisms. Stock cultures of *E. coli* and *Staphylococcus aureus* were maintained on trypticase-soy agar slant, while the stock cultures of yeast and fungi were maintained on Sabouraud dextrose agar slants. The culture media used in the test were a synthetic liquid medium (3) for *E. coli;* nutrient broth for *Staphylococcus aureus;* and Sabouraud liquid medium for *Saccharomyces cerevisiae*, *Candida albicans*, and *Candida krusei*.

The inocula were prepared from 18- to 24-hr. bacterial broth cultures or from 3-day fungus and yeast broth cultures. For broth cultures, the test organisms were transferred into the appropriate liquid medium and incubated at 37° for bacteria, and 30° for yeast and fungi. One drop (0.05 ml.) of 1:100 dilution of the broth culture in sterile distilled water was used to inoculate the medium. Viable cell counts were made from the serial dilutions of these inocula by the pour-plate method for bacteria, and by the surface-spreading method for yeast and fungi.

The stock solutions of amino ketone hydrochlorides were prepared by dissolving the drug in sterile distilled water to make a concentration of 5000 mcg./ml., and were sterilized by filtering through a Millipore filter.

For the conduct of the test, 10 15-ml. test tubes, each containing 5 ml. of the sterilized double-strength broth, were divided into duplicate series. A 1-ml. quantity of the stock solution of amino ketone hydrochloride was added to the first tube; 0.5 ml. of the same solution was added to the second; 0.5 ml. of a 1:2 and 1:4 dilution of the stock solution, respectively, was added to the third and fourth. The volume was made up to 10 ml. in each tube. The final concentration of the amino ketone hydrochloride in each tube was 500, 250, 125, 62.5, and 0 mcg. per ml., respectively. The last tube, without drug, served as organism growth control. Each tube was inoculated with 1 drop of a 1:100 dilution of the broth culture. Incubation was at 37° overnight for the bacteria, and at 30° for 3 days for yeast and fungi. The tubes were examined for growth inhibition of the organism at the end of each incubation period. The least amount of drug resulting in complete inhibition of growth was recorded as minimum inhibitory concentration. The results are summarized in Table II.

Mode of Antibacterial Action.—In order to investigate the mode of antibacterial action, a study of the growth curve of the test organism in a liquid medium, with and without the presence of drug, was then performed. The results are shown in Figs. 2 and 3 for the response of *Staphylococcus aureus* toward *o*-tolyl aminomethyl ketone and *n*-heptyl β-aminoethyl ketone hydrochlorides, respectively. The growth curve was based on viable cell counts obtained by the pour-plate technique.

Examination of the control growth curve Ia (the curve resulting from the growth of *Staphylococcus aureus* in the absence of drug) in Figs. 2 and 3 reveals that the curves follow the pattern of a typical growth curve of bacterium as shown in Fig. 1, except for the lack of a lag phase. This is explainable by the active physiological state of the bacterial cells (19-hr. culture).

In Fig. 2, curves IIa, IIIa, and IVa record the growth response of 14,600 cells of *Staphylococcus aureus* in nutrient broth in the presence of 125, 250, and 1000 mcg. of *o*-tolyl aminomethyl ketone hydrochloride per ml. of culture medium. Curves IIa and IIIa indicate that, at drug concentrations of 125 mcg. and 250 mcg./ml., 14,600 cells from the inoculum multiply by four to five generations to reach a final population of 3×10^5 cells, 8 hr. and 36 min. after inoculation and reach the stationary phase. The calculation involves solving the equation $b = a \times 2^n$, where b is the number of cells of the final population, a is the number of cells introduced into the medium from the inoculum, n is the number of generations by which the initial number of cells multiply to yield the final population (4). The calculation is shown as follows

$$b = a \times 2^n$$

$$n = \frac{\log_{10} b - \log_{10} a}{\log_{10} 2}$$

$$= \frac{\log_{10} 3 \times 10^5 - \log_{10} 14{,}600}{\log_{10} 2}$$

$$= 4.368 \text{ generations}$$

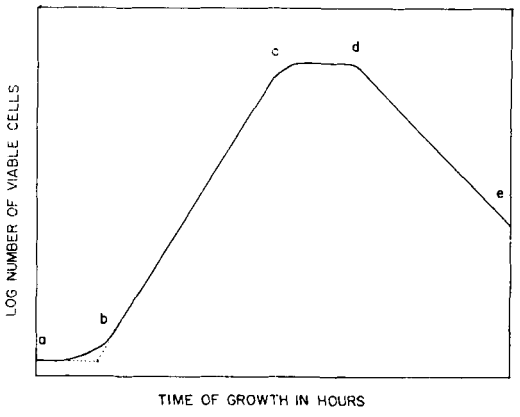

Fig. 1.—Typical growth curve of bacteria.

In contrast to curves IIa and IIIa, Ia indicates that, in the absence of drug, 14,600 cells continue the multiplication for 20.32 generations to yield a final population of 192×10^8 cells before the phase of decline is reached at 8 hr. and 36 min. after the inoculation was made

$$n = \frac{\log_{10} 192 \times 10^8 - \log_{10} 14{,}600}{\log_{10} 2}$$

$$= 20.32 \text{ generations}$$

On the other hand, as shown by curve IVa, representing a drug concentration of 1000 mcg./ml., 14,600 cells of *Staphylococcus aureus* did not increase in number, but decreased logarithmically even after brief contact with the drug. Eighty-eight minutes after inoculation and contact with the drug, the population dropped to 9000 cells, contrasting with the respective figures of 105×10^3, 213×10^3, and 696×10^3 cells in the presence of 250, 125, and 0 mcg. of *o*-tolyl aminomethyl ketone hydrochloride/ml. of culture medium, respectively. In the logarithmic phase, the curve IVa has a negative slope of −0.00239 in comparison with +0.00973, +0.01322, and +0.0197 for curves IIIa, IIa, and Ia, at respective drug concentrations of 250, 125,

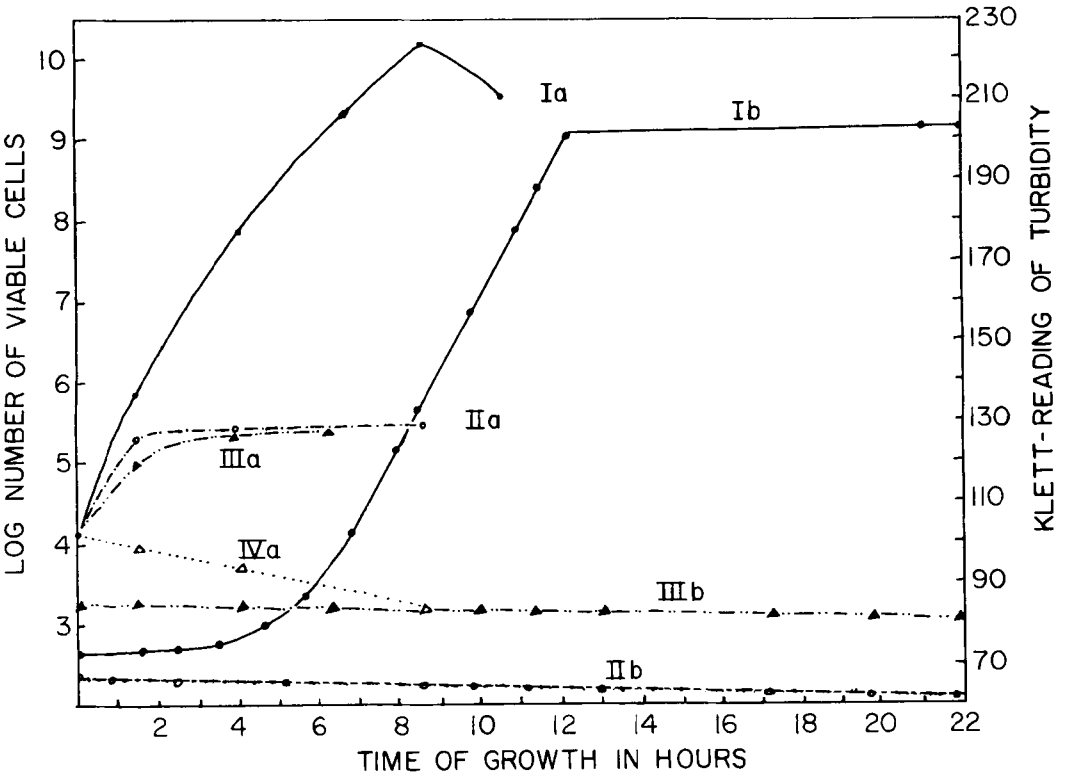

Fig. 2.—Growth response of *Staphylococcus aureus* toward *o*-tolyl aminomethyl ketone hydrochloride.

and 0 mcg./ml. of culture medium. The slopes of the straight lines represent the growth rate, R, during the logarithmic growth. They are simply calculated by solving the equation for logarithmic growth in terms of the variables of the growth curve

$$R = \frac{\log_{10} b_2 - \log_{10} b_1}{t_2 - t_1}$$

where t_2 and t_1 is the time at which the culture has viable cell count of b_2 and b_1, respectively. The data were taken from Table III at the end of 88 min. of incubation. The positive value of R represents the growth rate, whereas the negative value of R represents the death rate. From growth rate, the generation time, g, can be calculated by solving the following equation

$$b = a \times 2^n$$

$$\log_{10} b = \log_{10} a + n \log_{10} 2$$

$$\log_{10} b = \log_{10} a + \frac{t}{g} \log_{10} 2$$

$$\log_{10} b = \log_{10} a + \frac{0.301}{g} t$$

then

$$\text{slope} = R = \frac{0.301}{g}$$

and

$$g = \frac{0.301}{R}$$

TABLE III.—GROWTH RESPONSE OF *Staphylococcus aureus* TOWARD *o*-TOLYL AMINOMETHYL KETONE HYDROCHLORIDE IN NUTRIENT BROTH

Growth Time	Calculated Log No. Viable Cell/30 ml. —Drug Concentration mcg./ml. Medium— 0	125	250	1000
Zero (Inoculation)	4.1644	4.1644	4.1644	4.1644
1 hr. 28 min.	5.8426	5.3284	5.0212	3.9542
4 hr. 3 min.	7.9258	5.4771	5.4771	...
6 hr. 20 min.	8.9484	...	...	...
8 hr. 36 min.	10.2833	...	...	...
10 hr. 23 min.	9.4771	...	...	...

The averaged generation time calculated for cultures in the presence of *o*-tolylaminomethylketone hydrochloride at concentration of 0, 125, and 250 mcg./ml. is 15.78, 22.77, and 30.94 min., respectively. The elongation in generation time due to the presence of drug indicates the bacteriostatic effect of *o*-tolyl aminomethyl ketone hydrochloride.

Curve IVa reveals the bactericidal action of *o*-tolyl aminomethyl ketone hydrochloride at concentration of 1000 mcg./ml. The rate constant, k of the bactericidal action at this concentration is equal to 0.05726 min.$^{-1}$. This is calculated from the equation for logarithmic order of death (5)

$$k = \frac{2.303}{t} \log_{10} \frac{a}{b}$$

where a is the initial population and b is the final number of bacteria after contact with the drug for time period t. The death rate follows the rate of a

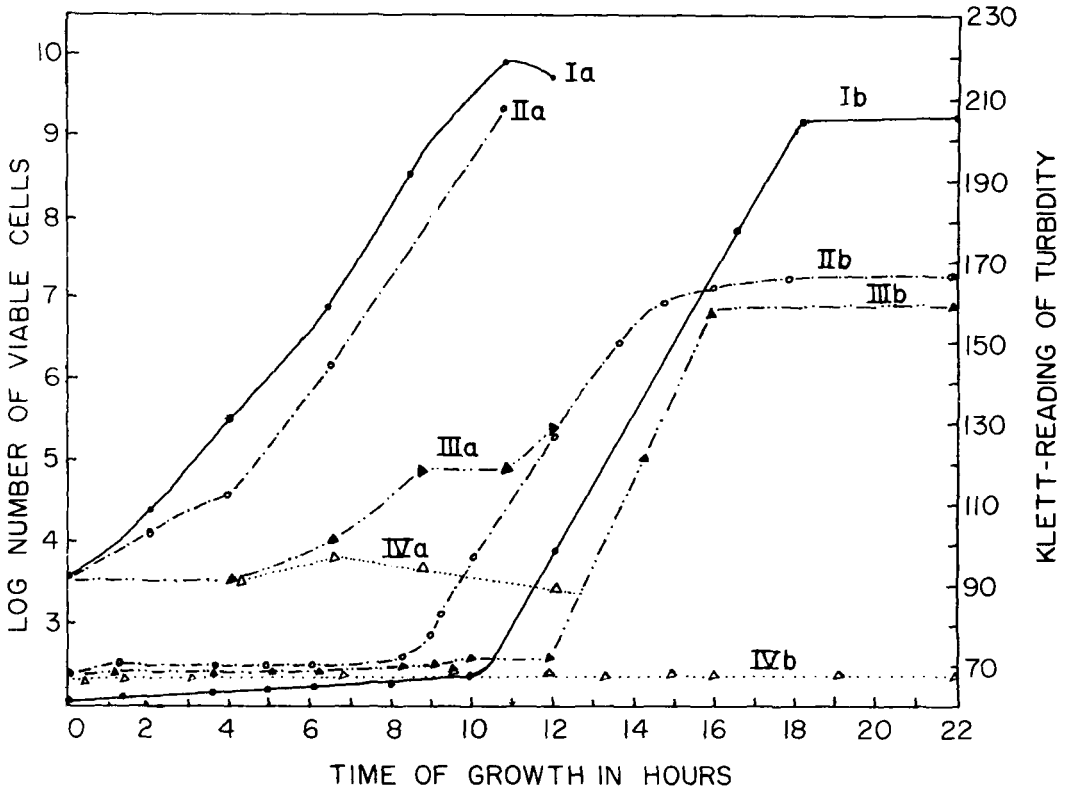

Fig. 3.—Growth response of *Staphylococcus aureus* toward *n*-heptyl β-aminoethyl ketone hydrochloride.

first-order reaction, which is usually observed for many bactericidals (6). It is still an open question whether this implies a simple inhibition of the rate of a single reaction sequence or is merely a coincidence.

From the mathematical treatment, it is obvious that *o*-tolyl aminomethyl ketone hydrochloride acts as a bacteriostat at low concentrations (*ca.* 250 mcg./ml.), and as a bactericide at higher concentrations (*ca.* 1000 mcg./ml.). This conclusion is true also for *n*-heptyl β-aminoethyl ketone hydrochloride, an amino ketone analog of β-alanine. The growth curves in Fig. 3 confirm this statement. In the above experiment, the growth responses were checked also by the turbidity reading of the culture. The turbidity curves are plotted in Figs. 2 and 3 and are designated with subscript *b*, in contrast to the use of subscript *a* for the viable population curve resulting from colony counting.

In order to investigate the mechanism by which β-aminoethyl ketone hydrochlorides act as antibacterial agents, an inhibition-reversal study with β-alanine and calcium L-pantothenate was performed. The results show that at inhibitor: metabolite molar ratio of 1.101:1 or 11.48:1, neither β-alanine nor calcium L-pantothenate possess any reversal activity in antagonizing the growth-inhibitory effect of *n*-heptyl β-aminoethyl ketone hydrochloride against *E. coli*.

DISCUSSION

The reversal of the growth-inhibitory effect of a compound by a structurally or biochemically related metabolite implies that the inhibitor in question prevents growth by interfering with a biochemical pathway involving that metabolite. The preliminary experiment on the inhibition-reversal study of *n*-heptyl β-aminoethyl ketone hydrochloride by either β-alanine or calcium pantothenate failed to demonstrate the antagonism at an inhibitor:metabolite molar ratio of 1.101:1 or 11.48:1 against *E. coli*. At a molar ratio of 0.805:1 glycine also failed to nullify the growth-inhibition of an amino ketone analog of glycine on a glycine dependent organism. These facts suggest that amino ketone analogs of amino acids may be valuable chemotherapeutic agents, and they may warrant further study.

In contrast to α-aminomethanesulfonic acid, the amino ketone analogs of glycine prepared for this work (7) are active in growth-inhibition against *E. coli* at concentration levels of *ca.* 1×10^{-3} mole. α-Aminomethanesulfonic acid has been found to be a glycine antagonist on test systems such as: the bacteriophage of *E. coli* (8), vaccina virus (9), and of different species of bacteria (10), but is not active against *E. coli* (11). This implies that amino ketones

[a] Initial population, 14.6×10^3 cells of *Staphylococcus aureus* 6538P; culture medium, nutrient broth; incubation temperature, 37°. Data are average figures calculated for the first 88 min. of incubation.

may be more reliable than amino sulfonic acids as growth inhibitors when they are structurally related to natural amino acids. The observations that amino ketone analogs, $H_2NCH_2CH_2COR$, of β-alanine inhibit the growth of many microorganisms, whereas taurine, $H_2NCH_2CH_2SO_3H$, the amino sulfonic acid analog of β-alanine, functions as an essential metabolite in vertebrates and invertebrates have lent support to this viewpoint.

The study of the growth curve of *Staphylococcus aureus* in liquid medium, with and without the presence of drug, reveals the pattern of growth-inhibition. Two types of response to an inhibitor have been observed for *o*-tolyl aminomethyl ketone and *n*-heptyl β-aminoethyl ketone hydrochloride, respectively; these are referred to as types A and B. In type A, the plot of log viable cell count against time is linear up to 88 min. after inoculation, as shown by curves Ia, IIa, and IIIa in Fig. 2. This linear relationship is in agreement with the exponential growth law. The growth rate of a test bacterium is reduced by amino ketone hydrochloride; the degree of depression increases with increase in concentration of drug. Type A growth response of *Staphylococcus aureus* toward *o*-tolyl aminomethyl ketone hydrochloride corresponds to the type 1 response described by Moore and Boylen (12) for *E. coli* toward 5-bromouracil; while type B growth response of *Staphylococcus aureus* to *n*-heptyl β-aminoethyl ketone hydrochloride is equivalent to type 3 growth response of *E. coli* toward pyridine-3-sulfonic acid.

The study of the growth curves of test bacteria suggests an accurate method for evaluating the *in vitro* antibacterial activity of drugs with mathematical implication. It serves also, as a means for studying the kinetics as well as the mode of antibacterial action, and may be generally applicable in the screening of antimicrobial agents.

Antienzymes to α- and β-Amylase

By J. J. STOCK and H. D. SANDERS†

Studies on the antigenicity of an α- and a β-amylase have been made. The use of incomplete Freund's adjuvant enhanced the amount of enzyme-neutralizing antibody formed by rabbits to active α-amylase (*Bacillus subtilis*), whereas, under similar conditions, the adjuvant did not enhance antienzyme formation to active β-amylase (barley). The use of this adjuvant prolonged the duration of antibody level produced by both of these enzymes. Acid-inactivated α-amylase was found to produce a circulating antibody in rabbits which will neutralize its homologous active enzyme. It is suggested that the determinant groups on this enzyme, which are responsible for antibody production, are not necessarily the same groupings responsible for activity on substrate.

COMPARATIVELY FEW observations of antibodies to α- and β-amylase have been reported. Sevag (1) has demonstrated that the antienzyme to malt amylase is specific in its enzyme-neutralizing capacity and will not neutralize the activity of an α-amylase. Furthermore, inactivated malt amylase was shown to be nonantigenic in the sense that sera from animals inoculated with this material possessed no antienzyme capacity. Recently, Nomura and Wada (2) have obtained rabbit antiserum against the amylase of *B. subtilis*. Also, Wada (3) has shown that the presence of heat-denatured Taka-α-amylase did not inhibit reaction between this active enzyme and its antibody.

No observations appear to have been made concerning the effect of an adjuvant on the antigenicity of these enzymes, or of any attempt to investigate the serologic relationship of an antienzyme to inactivated α-amylase. It was hoped that an investigation of this nature would help provide more knowledge concerning the molecular groupings of these enzymes which are responsible for activity on substrates and those which are responsible for antigenic activity, as well as the immunospecificity of these antigens when injected into rabbits over a comparatively long period of immunization. Previous investigators (4–9) have shown a diminution in specificity of an antiserum following a prolonged immunization period with various antigens.

MATERIALS AND METHODS

Antigenic Materials.—The α-amylase used in this investigation was obtained from a bacterial source (*Bacillus subtilis*) and the β-amylase was derived from barley; both of these materials were obtained commercially.[1]

Assay for Enzyme Activity.—Glycogen, $[\alpha]_D^{20} = +196$ to 197°, containing no reducing sugars, was the substrate used to demonstrate enzymic activity.[1] The assay method was that of Somogyi (10) for the determination of reducing sugars, as modified by Nelson (11) and Somogyi (12). All measurements for the concentration of reducing sugars, released from the substrate through enzymic activity at 37° for 15 minutes at a pH of 5.3, were made using a Bausch & Lomb Spectronic 20 at a wavelength of 510 mμ (13).

Serologic Tests.—A method for the indirect determination of antienzyme concentration through a modification of the Nelson-Somogyi procedure was performed as described elsewhere (13). The values reported for the reciprocal of serum dilutions represent the dilution of antibody, at the time of sampling recorded, which neutralized the enzymatic activity of the standard enzyme preparation used. It was found that naturally occurring amylase in rabbit sera at dilutions of 1:25 or higher would not affect assay results.

Adjuvant.—Incomplete paraffin-oil adjuvant, described by Freund (14), was prepared to contain 2 parts of paraffin oil (Marcol GX),[2] 1 part of Falba, and 2 parts of the desired concentration of enzyme. The incorporation of the amylases with the adjuvant base and the control tests have been reported elsewhere (13).

Sera.—All rabbits were bled by ear vein puncture, and the sera were preserved at −20°. No preservative was added to these sera.

Immunization.—Those rabbits which were immunized with the enzyme incorporated in the adjuvant base were injected subcutaneously in the scapular region over a period of 78 days. Each group of rabbits was immunized on the basis of equal amounts of total nitrogen. On this basis, 0.027 mg. nitrogen/mg. (± 0.002) of enzymic material promoted the same degree of hydrolysis of substrate, whether it was α- or β-amylase. Where amylase was used as an antigenic agent without the use of incomplete Freund's adjuvant, it was injected in the form of a sterile saline solution every 4 days, either intravenously or subcutaneously, depending on the experiment. The total amount of nitrogen injected was adjusted to be the same at the end of successive

8-day periods for each group of rabbits during the first 44 days of the immunization period. After this time, further injections were made as shown in Figs. 1 and 2. Blood was collected from the animals at the intervals indicated in the graphs. All assays for antibody content were made at the conclusion of each immunization schedule.

Inactivation of α- and β-Amylase.—α-Amylase was inactivated according to a modification of the method used by Kneen, Sandstedt, and Hollenbeck (15) and as previously reported (13). Irreversible inactivation of this enzyme took place at a pH of 3.0 when held at 37° for 10 minutes in a 0.02 *M* biphthalate-hydrochloric acid buffer. According to previous findings (13), this method of acid inactivation could not be employed with β-amylase. Therefore, β-amylase in 0.02 *M* phosphate buffer of pH 7.2 was inactivated at a temperature of 55° after 30 minutes.

EXPERIMENTAL AND RESULTS

Route of Antigen Injection.—Using active β-amylase without adjuvant and on the basis of equal amounts of total nitrogen injected, the route of injection, whether it be subcutaneous or intravenous, does not appear to influence antienzyme formation in rabbits. These observations were made using a total of 11 animals.

Effect of Incomplete Freund's Adjuvant on the Antigenicity of α- and β-Amylase.—The rate of appearance of antibodies in the circulation was determined at various times during the immunization schedule and the findings are reported in Figs. 1 and 2. No enhancement in antienzyme formation to β-amylase was found using this adjuvant. Several rabbits from two distinct sources of albino New Zealand breeding stock of both sexes and weighing approximately 2.5 Kg. were used without success in attempts to obtain higher antienzyme titers. On the other hand a potentiation of approximately 10 times in antibody production was observed when α-amylase was used with the adjuvant. Antienzyme production to both antigens was maintained for a prolonged duration with the use of this adjuvant. (See Figs. 1 and 2 at the times of 54 and 100 days.)

Antigenicity of Active and Inactive Amylases.—As illustrated in Figs. 1 and 2, the α-amylase used is a comparatively good antigenic agent as compared to β-amylase derived from barley. β-Amylase inactivated by a mild heating, and using incomplete Freund's adjuvant does not produce detectable circulating antienzymes in rabbits. On the basis of total nitrogen injected, inactivated α-amylase has been shown to produce antienzymes in as high a titer as does the active form of the enzyme when incorporated into this adjuvant. This acid-inactivated α-amylase produced antienzymes which neutralized the activity of its homologous active enzyme on glycogen. Therefore, it appears that the determinant groups on this enzyme responsible for antibody production may not be the same groupings which are responsible for activity on substrate. Cross-neutralization tests with antienzymes to all antigenic agents used showed no apparent inhibition of activity on substrate, even though these antibodies had been produced after a comparatively intensive and prolonged schedule of immunization.

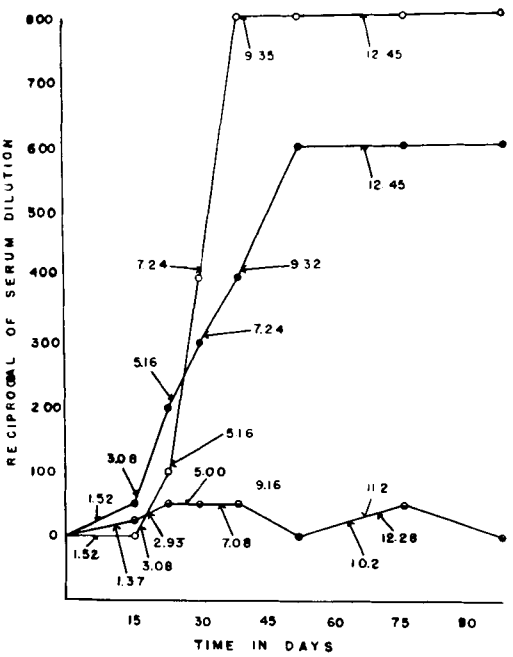

Fig. 1.—Inhibition of α-amylase by homologous antisera. The reciprocal of the antisera dilutions to α-amylase represents the median of the values obtained for each group of animals. Test bleedings were made just prior to injections as designated by points on the graphs. Numbers record cumulative amounts of total N injected at designated times. Despite the comparatively small number of animals used here, there was a consistent difference in the response of each group, and this was significant. DISCUSSION

The objective of this investigation was not a comparison of the antigenicity of α-amylase with that of β-amylase, as the origin of the materials used was from divergent sources. Also, we have made no assumption that these materials are to be considered as representative of this class of enzymes as our findings may not be similar to those which may be obtained with the use of other preparations. According to our findings, Sevag's observations concerning the immunospecificity of the antienzyme to β-amylase and its inability to neutralize the activity of an α-amylase, and the lack of antigenicity of inactivated β-amylase have been confirmed.

In this investigation we have shown that α-amylase from *Bacillus subtilis* is a better antigenic agent than β-amylase (barley) in the production of circulating antibodies in rabbits. Also, the enzymatically inactive form of this amylase is as good an antigen as the active α-amylase and will neutralize its activity.

Little and Caldwell (16, 17) have shown that the activity of α-amylase on a substrate requires that the primary amino groups be free, that tyrosine groups are not essential, and that sulfhydryl groups may be lacking entirely. Weill and Caldwell (18) have

reported that with β-amylase, primary amino groups are not essential for activity, whereas tyrosine and sulfhydryl groups are necessary. It may be surmised that these differences between the molecular structures of the two enzymes or the presence or absence of certain groups on the molecule of active β-amylase may help contribute to its comparatively poor antigenicity. According to our observations, the factors which lend themselves to acidic inactivation of α-amylase and its heat stability are not the same with β-amylase, as this enzyme is comparatively thermolabile (13).

Despite the fact that Little and Caldwell (16, 17) carried out their analyses on an α-amylase originating from pancreas, and the α-amylase used in this work was from a bacterial source, and that α-amylases from different sources may vary in characteristics such as stability, pH optima, etc., it is accepted generally that α-amylases do not differ with respect to their specific action on substrate, but only in their affinities for substrate (19).

McGeachin and Reynolds (20) have demonstrated that hog pancreatic and human salivary amylases are antigenic and that their respective antibodies have amylase-inhibiting properties. They have reported that the enzymatic site of these amylases is part of or located close to the antigenic site and is blocked or covered by the large antibody molecules. Using amylase of *B. subtilis*, Wada and Nomura (21) found that the neutralization reaction by antibody was inhibited by the presence of substrate or certain of its degradation products. They suggested that there may be a competitive relationship between substrate and antibody for combination at the same portion of the enzyme surface. Although the antigen-antibody interaction may mask enzymatically active sites, according to our observations, the activity site of α-amylase (*B. subtilis*) for substrate may be destroyed, but the antigenic site remains unaltered.

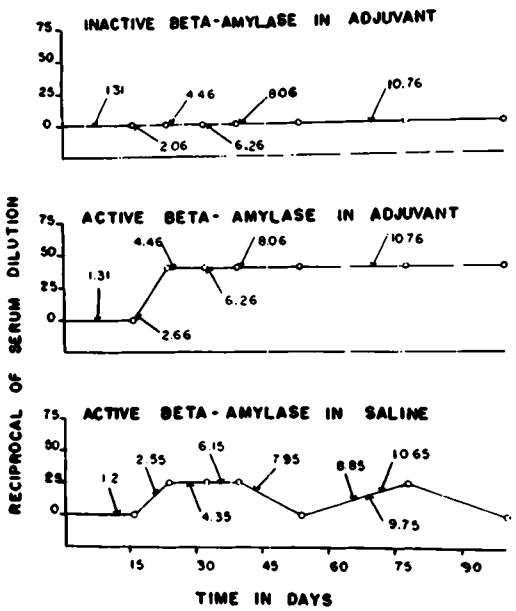

Fig. 2.—Inhibition of β-amylase by homologous antisera. The reciprocal of the dilutions of antisera to β-amylase represents the median of the values obtained for each group of animals. Test bleedings were made just prior to injections as designated by points on the graphs. Numbers record cumulative amounts of total N injected at designated times. Inactive β-amylase in adjuvant, 12 animals; active β-amylase in adjuvant, 7 animals; active β-amylase in saline, 11 animals.

In this work, we have shown that the inactivation of α-amylase by acidification does not decrease its antigenicity for rabbits, and according to Little and Caldwell's observations (16, 17), it appears that free primary amino groups on the α-amylase molecule acting as an antigen are not essential to its ability to produce antibody. To the authors' knowledge, the exact mechanism of acid inactivation for this molecule is not known, however, the addition of acid to a protein may alter its structure. Thus, the active site of an enzyme could be destroyed but its antigenic groups may remain unaltered. Since α-amylase activity is lost irreversibly by this method of inactivation, it is suggested that the amino groups are not free, and that this altered molecule either now possesses steric hindrance with substrate or the charges on groups active with substrate have been neutralized.

Although a comparatively intensive and prolonged immunization schedule with all antigenic materials was used, no demonstration of alteration in antienzyme specificity was observed. Recent work on the serology of various mammalian amylase antigens incorporated in incomplete Freund's adjuvant employed as few injections as necessary to avoid the possibility of decreased antibody specificity (20). The inactivated α-amylase used showed no ability to produce a neutralizing antibody against β-amylase (barley). Therefore, alteration of this α-amylase through acid inactivation apparently does not alter its structure sufficiently to promote this modification in its antigenic specificity.

Belladonna Alkaloid Analysis by Partition Column Chromatography

By RALPH S. SANTORO and ANDREW R. MATZ

A sharp separation of total belladonna alkaloids (atropine, hyoscyamine, and scopolamine) from chlorpheniramine[1] and phenylpropanolamine[2] was effected by partition column chromatography which permitted the colorimetric determination of the total belladonna alkaloids. The column utilized a stationary phase of pH 7.0 buffer with moving phases of 1:1 cyclohexane-carbon tetrachloride for removal of the chlorpheniramine, and chloroform for the elution of the alkaloids. Phenylpropanolamine was retained on the column. The method was applied to pharmaceutical formulations containing the belladonna alkaloids in combination with chlorpheniramine maleate and phenylpropanolamine hydrochloride.

THE SOLANACEOUS alkaloids, atropine, hyoscyamine, and scopolamine, the well known parasympatholytic agents, have been the subject of intensive investigation evidenced by the body of literature that has grown about these substances. Analysis and/or assay methods have also been extensively reported. The two colorimetric methods most common to the reported assay procedures and used for the actual determination of the separated alkaloids are the Vitali-Morin reaction, in which a violet color is produced from the condensation of aromatic nitro-groups with acetone in the presence of potassium hydroxide (1–5), and the formation of an alkaloid or tertiary amine complex with sulfonic acid indicators (6–13). Conditions which affect the precision and accuracy of results are also discussed in the above references. These methods have been successfully adapted to the *in vivo* and *in vitro* determination of total alkaloid content.

More recently, methods have appeared in which paper chromatography has been employed for the resolution of the solanaceous alkaloids into their separate components, followed by quantitative determination with the above, or other appropriate methods (14–18). It should be mentioned that determinations using means other than color development have been used, *e.g.*, polarographic (19) and infrared (20), where conditions possible for their use were present.

The particular method chosen for the determination is governed in part by such factors as the accuracy and precision required; amount of constituent present coupled with the sensitivity of the assay method; the form encountered, *i.e.*, crude extract, purified chemical, or pharmaceutical formulation; and the amount and nature of interfering substances. However, the problem of the actual determination many times does not resolve itself into a consideration of method advantage, but into a more basic consideration: achievement of a satisfactory separation from interfering substances so that a quantitative determination can be made.

This paper describes a method in which the total belladonna alkaloids, hyoscyamine sulfate, scopolamine hydrobromide, and atropine sulfate, were separated by partition column chromatography from a pharmaceutical preparation containing chlorpheniramine maleate and phenylpropanolamine hydrochloride. The total alkaloids were then determined colorimetrically with methyl orange as the complexing agent.

EXPERIMENTAL

Reagents.—Cyclohexane, practical grade, b.p. 71–81°.

Chloroform and carbon tetrachloride, reagent grade.

Celite (Hy-Flo Supercel, Johns-Manville Co.).

Buffer solution pH 5.6. Dissolve 27.22 Gm. of potassium dihydrogen phosphate, reagent grade, in 1 L. of distilled water and adjust to pH 5.6 with 0.1 *N* sodium hydroxide.

Methyl orange reagent. Saturate 1 L. of pH 5.6 buffer with approximately 2 Gm. of methyl orange, reagent grade, and filter through Whatman No. 1 filter paper. Extract the filtrate repeatedly with chloroform until the chloroform layer is colorless.

Buffer solution pH 7.0. Dissolve 5.42 Gm. of sodium dihydrogen phosphate, reagent monohydrate, and 16.36 Gm. of dibasic sodium phosphate, reagent heptahydrate, in 1 L. of distilled water and adjust to pH 7.0 with either 0.1 *N* hydrochloric acid or 0.1 *N* sodium hydroxide.

Standard solutions of alkaloids. Dry samples of hyoscyamine sulfate N.F., atropine sulfate U.S.P., and scopolamine hydrobromide U.S.P. overnight at 105°. Store the dried chemicals in a desiccator.

Stock standard. Weigh 0.869 Gm. of hyoscyamine sulfate, 0.175 Gm. of atropine sulfate, and

Received July 28, 1961, from Smith Kline & French Laboratories, Philadelphia 1, Pa.

Accepted for publication March 14, 1962.

The authors wish to acknowledge the assistance of Joseph J. Fitzpatrick and E. Lee Haines who contributed to the experimental part of this paper. We also wish to express our gratitude to Joseph Carpenter, Mary Maculate, and Martin De Porres for their guidance and help.

[1] 2-[*p*-Chloro-α-(2-dimethylamino-ethyl)benzyl]pyridine.

[2] α-(1-Aminoethyl)benzyl alcohol.

0.092 Gm. of scopolamine hydrobromide into a 100-ml. volumetric flask. Dissolve and dilute to volume with pH 5.6 buffer.

Intermediate working standard. Dilute 10 ml. of the stock standard to 500 ml. with pH 5.6 buffer.

Working standards. Dilute 12.5- and 25-ml. aliquots of the intermediate working standard to 100 ml. with pH 5.6 buffer. These standards represent 0.140 mg./5 ml. and 0.285 mg./5 ml. belladonna alkaloids.

Apparatus.—Klett-Summerson photoelectric colorimeter.

Chromatographic column. Approximately 19 mm. × 350 mm. with adapter equipped with a stopcock for controlling rate of flow (Ace Glass catalog No. 6261).

Rinco rotating evaporator.

Preparation of the Calibration Curve.—Transfer a 5.00-ml. aliquot of each of the two working standards to 125-ml. separators. To a third separator, transfer a 5.00-ml. aliquot of pH 5.6 buffer to serve as a reagent blank. Add 3.00 ml. of methyl orange reagent from a pipet to each funnel. Extract with 5–15-ml. portions of chloroform, collecting the chloroform extracts in a 100-ml. volumetric flask containing 15 ml. of 95% ethanol, through a pledget of cotton previously wet with chloroform. When 1-min. shake-outs are used, the chloroform layer should be essentially colorless by the fifth shake-out.

Read the color intensity of each of the standards on the Klett-Summerson photoelectric photometer, using a No. 42 filter and pH 5.6 buffer as the zero. Subtract the reagent blank from the readings obtained, and calculate the standard factor for each of the two standards by dividing the standard weight by the corrected reading. Take the average of the two. Each factor should not vary more than ±3% from the average factor.

The standard factor should be calculated daily or whenever new buffer is used.

Assay Procedure.—Accurately weigh a finely ground portion of the sample containing 0.5 to 0.7 mg. of total alkaloids into a 2-oz. mortar, add 1 ml. pH 7.0 buffer, and grind until a uniform slurry is obtained. Add 3 Gm. of Celite and 2 ml. of pH 7.0 buffer to the slurry. Regrind until the Celite is uniformly wet and homogeneous in texture.

In a second 2-oz. mortar, prepare an additional 3 Gm. of Celite by adding 3 ml. of pH 7.0 buffer and grinding until the physical appearance is as described above. Place a small mat of glass wool in the bottom of a glass chromatographic column. Transfer about 2.5 Gm. of the prepared Celite into the column and tamp firmly, but gently, with a suitable length of wood dowling.

Transfer all of the Celite containing the sample into the column: first, by scraping the mortar with a metal spatula after the loose bulk has been transferred, and adding the scrapings to the column; second, by adding the remaining Celite from the second mortar into the sample mortar, grinding the Celite around the bottom and sides of the mortar, and adding the grindings to the column as described in the initial step above. Retamp the column until the outside walls have a uniform porosity. Cap the column with a mat of glass wool.

Elute the column with 100 ml. of a mixture of 1:1 carbon tetrachloride and cyclohexane. After about 10 ml. of the mixture has been collected, stop the flow of solvent and allow the column to equilibrate for 15 minutes, then continue until elution has ceased. Discard the mixture. Add 80 ml. of chloroform to the column and collect the eluant in a 100-ml. flat-bottom boiling flask with a standard taper 24/40 ground-glass neck. Vacuum evaporate the collected chloroform to dryness, using a rotating evaporator at room temperature. Pipet 10 ml. of pH 5.6 buffer into the flask and heat gently on a steam bath until solution of the residue is effected.

Transfer a 4-ml. aliquot of this solution into a 125-ml. separator and proceed as directed above under preparation of the calibration curve, beginning with the addition of the methyl orange reagent. Run a second 4-ml. aliquot as the sample blank using 3.00 ml. of pH 5.6 buffer in place of the methyl orange reagent. Run a reagent blank using 4.00 ml. of pH 5.6 buffer in place of the sample. Calculate the total alkaloids by

$$\frac{[\text{Klett reading} - (\text{sample blank} + \text{reagent blank})] \times \text{standard factor} \times 100}{\text{sample weight (Gm.)} \times 4} =$$

mg. total belladonna alkaloids/Gm.

Modified Vitali Method.—The use of methyl orange for the colorimetric determination was adequate since the concentration of alkaloids in the samples was relatively large. The sensitivity of the methyl orange method can be improved by reconcentrating the extracted indicator into acid (21), but because the Vitali-Morin reaction has a greater sensitivity, its use would be indicated in samples containing a concentration of alkaloids below the sensitivity of normal indicator methods. Calibration curves on the mixed alkaloids were run by the modified Vitali method (2), and Beer's law adherence was obtained down to 0.023 mg. (Fig. 1).

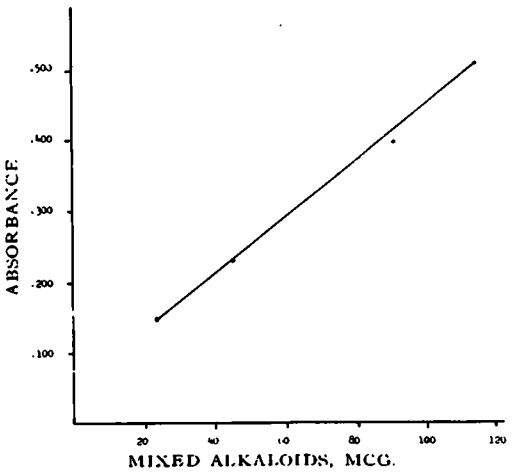

Fig. 1.—Modified Vitali method calibration curve of mixed alkaloids.

RESULTS AND DISCUSSION

Solvent partition experiments were run on hyoscyamine sulfate, chlorpheniramine maleate, and phenylpropanolamine hydrochloride at various pH conditions by equilibrating a known amount of chemical between equal volumes of the two phases. The amount remaining in the buffer phase was then determined by ultraviolet absorption. These experiments indicated that the conditions optimum to the separation of chlorpheniramine from hyoscyamine were extraction with cyclohexane at a pH of 7.0 (Table I). With the use of pH 7.6 buffer, 87% of the chlorpheniramine was extracted into the cyclohexane, but a loss of 3% hyoscyamine was encountered. Below pH 7.0, the extractability of both substances dropped markedly.

A suitable solvent extraction method was developed in which the chlorpheniramine was first removed by multiple extractions with cyclohexane from pH 7.0 buffer, followed by extraction of the alkaloids with chloroform. However, the results were uniformly high due to traces of chlorpheniramine remaining in the buffer phase, and increasing the number and volume of cyclohexane extractions served to reduce, but not eliminate, the positive error.

The distribution coefficient K for chlorpheniramine was calculated from

$$K = \frac{w_1/v}{(w - w_1)l} \qquad \text{(Eq. 1)}$$

where v is the volume in ml. of pH 7.0 buffer (phase I), w is the weight in Gm. of dissolved substance extracted with l ml. of cyclohexane (phase II), and w_1 is the solute remaining in phase I after the extraction (22). The chlorpheniramine remaining in the buffer after any given number of extractions is then

$$W_n = w\left(\frac{Kv}{Kv + l}\right)^n \qquad \text{(Eq. 2)}$$

Since the reaction of methyl orange is a molecular ratio of 1:1 in compounds having one basic amine function (23), the estimated error due to chlorpheniramine in the methyl orange reaction can be expressed as

$$E = \frac{w_n}{w_a} \times \frac{MW_1}{MW_2} \qquad \text{(Eq. 3)}$$

where w_a is the weight of alkaloids originally present with an average molecular weight of MW_1, and MW_2 is the molecular weight of chlorpheniramine maleate. From the data (Table I), K for chlorpheniramine maleate is 0.449, and calculating the estimated error after six extractions yields 10.5%. Beyond this number of extractions, simple solvent separation

was not only impractical, but showed a significant loss of hyoscyamine on known solutions due to the systemic errors inherent in the type of separation.

In order to extract the buffer exhaustively and effect the complete removal of chlorpheniramine, the technique of partition column chromatography was utilized for the separation. Recovery of the mixed alkaloids was quantitative in the presence of chlorpheniramine maleate and phenylpropanolamine hydrochloride present in the same ratio theoretically found in the samples (Table II). The mixed alkaloids in this study are susceptible to hydrolysis to form tropine, epoxy tropine, and tropic acid. Tropine and epoxy tropine react with methyl orange in the same fashion as the intact alkaloids; tropic acid does not react nor interfere with the determination.

The hydrolytic products were tested through the procedure with the result that the methyl orange blank and the hydrolysis product readings were the same. It was concluded that the degradation products were retained on the column and the method could be used as a stability procedure. The method was applied to samples of various pharmaceutical formulas for initial assay and stability determinations. The results from these experiments are listed in Table III.

Although cyclohexane was initially selected for the removal of chlorpheniramine, the mixture of cyclohexane and carbon tetrachloride was developed as the eluting solvent for two reasons: (*a*) cyclohexane caused a slower elution than desired, and (*b*) it did not remove many of the wax excipients normally associated with pharmaceutical formulations. The subsequent elution with chloroform extracted these excipients along with the alkaloids and caused hard waxy residues after the chloroform evaporation which tended to occlude the alkaloids in the pH 5.6 buffer solution.

The solvent mixture overcame the difficulties experienced with cyclohexane. The use of carbon tetrachloride itself as the eluting agent would be ideal from the standpoint of chlorpheniramine and wax removal, but the alkaloids also partition. Assays in which carbon tetrachloride was used gave low results, and decreasing the volume in an attempt to prevent the loss gave high and erratic results. The mixture selected, along with the two-stage feature of the column, accomplished a sharp separation with little interfering residue from the chloroform step.

It was found that the precision of the results was improved by equilibrating the column before each elution. The equilibration consisted of stopping the flow of eluant after 5–10 ml. had been collected and allowing the column to stand 15–20 minutes before elution was recommenced. This procedure was followed for both elutions. Time limitation necessitated the stopping of many assays during the elution with cyclohexane-carbon tetrachloride and the columns were allowed to stand overnight without affecting the results. Another advantage observed with equilibration and associated with the first elution was the further diminution of waxy residues in the chloroform eluate. Samples which were not finely ground before being incorporated in the column showed inconsistent results even with prolonged equilibration times, and indicated that equilibration was not a substitute for a properly prepared sample.

SUMMARY

A column partition separation of the total belladonna alkaloids, hyoscyamine sulfate, atropine sulfate, and scopolamine hydrobromide, from chlorpheniramine maleate and phenylpropanolamine hydrochloride is described in which the stationary phase is pH 7.0 buffer and the moving phases are 1:1 cyclohexane-carbon tetrachloride, for the removal of chlorpheniramine, and chloroform for the elution of the alkaloids. Phenylpropanolamine does not elute with either solvent system.

The total alkaloids were determined colorimetrically using methyl orange as the complexing agent. A modified Vitali procedure is recommended for determinations in which the alkaloid content is below the sensitivity of indicator methods.

Factors governing the selection of column partition chromatography as the method of separation, choice of the eluting solvents, advantage of equilibration, and necessity for proper sample preparation are also discussed.

Interaction of Carrageenan and Other Hydrocolloids with Alkaloids II

Equilibrium Dialysis Studies

By HORACE D. GRAHAM and LINNIE B. THOMAS†

The extent of binding of the alkaloids, quinine hydrochloride, hyoscyamine hydrochloride, caffeine, and theophylline by the hydrocolloids carrageenan, furcellaran, sodium carboxymethylcellulose, gum tragacanth, sodium alginate, pectin, locust bean gum, and gum acacia was studied. Data were obtained employing varying pH levels of the reaction system and temperatures of 4, 27, and 37°. A Langmuir-type plot of the data to obtain the limiting binding capacity of the hydrocolloids at infinitely high concentrations of the alkaloids, indicates that quinine hydrochloride was bound to the greatest extent by most of the hydrocolloids used. The order of binding was as follows: carrageenan > sodium carboxymethylcellulose > furcellaran > sodium alginate. Locust bean gum, pectin, gum tragacanth, and gum acacia bound this alkaloid considerably less. Approximately the same trend was exhibited with hyoscyamine hydrochloride, whereas caffeine and theophylline were bound to a much smaller, but nonetheless significant, extent than the other alkaloids tested.

IN A PREVIOUS communication, Graham and Thomas (1) demonstrated that several natural and some synthetic hydrocolloids are precipitated by alkaloids of different classes. However, in some cases, no visible precipitation was noted although, on a structural basis, significant interactions could have occurred. Such subtle reactions can be studied best by equilibrium dialysis, a technique which has been used extensively to elucidate interactions between proteins and other substances (2, 3), between anionic polysaccharides and detergents (4), and for studying several other reactions (5–13).

This report summarizes the data obtained from studies on the interaction of several alkaloids with hydrocolloids which are commonly used in pharmaceutical and food formulations. Evidence has been obtained that, even in cases where no visible turbidity was evident, considerable binding of the alkaloids by the hydrocolloids occurred.

EXPERIMENTAL

Materials

Alkaloids.—Quinine hydrochloride (2%), hyoscyamine hydrochloride (1%), caffeine (1%), and theophylline (0.5%).

All samples were prepared in double distilled water. Where necessary, solution was accomplished by gentle heating in a water bath. Representative alkaloids were selected on the basis of the following characteristics: Quinine hydrochloride: this alkaloid reacts strongly with most hydrocolloids producing visible turbidity in most cases. Hyoscyamine hydrochloride: at low concentrations, this alkaloid produces little or no visible turbidity when mixed with the hydrocolloids used (1); however, at high concentrations (2–4%) ready precipitation occurs, especially with some of the sulfated hydrocolloids. Caffeine and theophylline: these alkaloids do not produce visible turbidity with any of the hydrocolloids used.

Hydrocolloids.—These are listed in Table I. All samples were prepared and dialyzed as previously described (1). All calculations are expressed on a dry weight basis. The moisture content of each hydrocolloid was determined by drying each sample to constant weight in a vacuum oven at 80°.

Equipment

Beckman DU spectrophotometer, Beckman pH meter, model G, 30-ml. Pyrex, glass-stoppered test tubes, 50-ml. acid buret, Burrell wrist-action shaker, refrigerated room at 4°, dialysis membrane—27/32 dialysis tubing, seamless cellulose, Fisher Scientific Co.

Procedure

Preparation of the Dialysis Bags.—Twelve-inch strips of the dialysis membrane were cut with as much uniformity as possible and 12-in. lengths of string were used to tie the bags. The strips of dialysis membrane and string were thoroughly washed in tap water, soaked in, and finally rinsed several times with distilled water. Dialysis bags were constructed by tying one end as tightly as possible, placing the hydrocolloid dispersion in the bag and then tying the open end securely.

Dialysis and Determination of the Amount of Alkaloid Bound by the Hydrocolloids.—The experimental regimen was essentially that employed by Klotz, *et al.* (12), and more recently by Patel and Kostenbauder (10). A 25-ml. quantity of the stock solution containing 10–1000 mg. of the particular hydrocolloid was placed in the dialysis bag, the open end was tied securely, and the bag placed in a wide-

Gum acacia	47.0	26.0	16.0	18.6

mouth bottle containing 75 ml. of the particular alkaloid. The bottles were placed on a Burrell wrist-action shaker and reaction allowed to take place for 36 hours, an interval sufficient for the attainment of equilibrium. Experiments conducted using 300-ml. Erlenmeyer flasks, 50 ml. of the hydrocolloid dispersion, and 50 ml. of outside solution gave essentially similar results. However, the use of wide-mouth bottles as described offers the possibility of keeping the bathing fluid in better contact with the bag surface. Moreover, during the shaking, such bottles are less subject to breaking as was experienced with the flasks in some instances.

At the end of the reaction period, the outside solution was poured into a 100-ml. volumetric flask and the contents made up to volume with double distilled water. One milliliter of this solution was then used for determination of the free alkaloid in the solution on the outside of the dialysis bag. In several instances, the solution inside the dialysis bag was also analyzed for its content of both free and total alkaloid. In such cases, the solution was also accurately made up to volume. A control, which differed from the primary bag only in that the former contained distilled water instead of hydrocolloid, was included. This permitted corrections for any alkaloid bound by the dialysis membrane.

The amount of alkaloid bound by a given quantity of hydrocolloid was calculated by subtracting the sum of the free alkaloid in the system and the alkaloid bound by the bag from the total amount of alkaloid added.

Methods Used in Determining the Amount of Free Alkaloid

Routinely, the amount of free alkaloid was determined by the colorimetric dichromate-sulfuric acid method of Graham and Thomas (14). Essentially, the procedure is as follows: 1 ml. of the solution to be assayed is placed in a Pyrex, ground glass-stoppered test tube, 1 ml. of a 5% solution of potassium dichromate is added, and the mixture is incubated for 5 minutes in a constant temperature water bath at 30°. At the end of this incubation period, 8 ml. of concentrated sulfuric acid is added, the tube is swirled gently to mix the contents well, and then placed in an ice water bath for 20 minutes. Duplicate control tubes containing all ingredients except the alkaloid are included and are treated similarly. The color developed is measured at 650 mμ with a Coleman Universal spectrophotometer, model 14, or with a Beckman DU spectrophotometer, and the amount of alkaloid present determined by reference to a standard curve.

Since the alkaloids used absorb strongly in the ultraviolet region, the concentration of alkaloid in the solutions both inside and outside the dialysis bag, after dilution with distilled water, was determined, in some cases by ultraviolet spectrophotometry using the Beckman DU spectrophotometer. Quinine hydrochloride was determined at 331 mμ (9), caffeine at 272 mμ (15), and theophylline at 276 mμ (16).

Under the experimental conditions employed, excellent agreement was obtained whether the concentration of alkaloid was determined only in the solution outside the dialysis bag or both in the solution inside and outside of the dialysis bag. Similar excellence in agreement of values obtained by analyzing both the solution inside the dialysis bag and the solution outside the dialysis bag, has been noted by Patel and Kostenbauder (10) and by Ehrenpreis (3). Additionally, as seen from Table II, good agreement in results were obtained by both the colorimetric dichromate-sulfuric acid method and the ultraviolet absorbance method. In view of these facts, the dichromate-sulfuric acid method was used routinely.

Equilibrium Dialysis Calculations

Essentially, the method of calculation and the assumptions involved are similar to those outlined by Patel and Kostenbauder (10) in their studies on the binding of parahydroxybenzoic acid esters by Tween 80. In principle, the thin semipermeable

TABLE II.- AMOUNT OF ALKALOIDS BOUND BY HYDROCOLLOIDS AT 27° AS DETERMINED BY THE DICHROMATE-SULFURIC ACID (DS) METHOD AND BY THE ULTRAVIOLET (UV) SPECTROPHOTOMETRIC METHOD

Hydrocolloid	μm. of Alkaloid Bound per Gm. of Hydrocolloid at 27°: Quinine Hydrochloride DS Method	Quinine Hydrochloride UV Method	Caffeine DS Method	Caffeine UV Method	Theophylline DS Method	Theophylline UV Method

membrane permits free passage of the alkaloid but not of the hydrocolloid. The alkaloid placed on the outside of the bag will diffuse inwardly to react with the hydrocolloid placed on the inside of the bag. At equilibrium, the activity of the alkaloid will be equal on both sides of the membrane. For a sufficiently dilute solution it can be assumed that the concentration of the alkaloid on both sides of the membrane will be essentially the same. Therefore, if the macromolecule is placed on one side of the membrane and the concentration of alkaloid on the opposite side is determined, it becomes possible to determine the amount of free or unbound alkaloid in equilibrium with the hydrocolloid. The procedure employed is outlined symbolically: let A_t = total alkaloid added; let A_b = alkaloid actually bound by the hydrocolloid; let A_m = alkaloid bound by membrane; let $A_{f.o.}$ = free alkaloid outside of bag; let $A_{f.i.}$ = free alkaloid inside of bag = $A_{f.o.}$ Then, $2A_{f.o.}$ = total free alkaloid in system. Then $A_b = A_t - (2A_{f.o.} + A_m)$. In these calculations, the Donnan effects were neglected.

Influence of Temperature and pH on the Binding Process

In order to characterize the reactions more thoroughly, the influence of temperature and pH on the binding of alkaloids by the hydrocolloids was investigated.

A constant quantity of the particular hydrocolloid was allowed to equilibrate for 36 hours against an excess of each alkaloid according to the general procedure at 4, 27, and 37°. For the experiments at 4°, all reagents were preincubated at this temperature; the dialysis systems were set up and removal of aliquots for determination of the free alkaloid on the outside was done in the cold room. This precluded any experimental errors due to temperature changes which would result through removal of the flasks from the cold room.

Possible variations in the extent of binding at 27° caused by differences in the pH of the system were investigated by dialyzing 200 mg. of each hydrocolloid against an excess of each alkaloid. The alkaloids and hydrocolloids were suspended in 0.02 *N* phosphate buffers of varying pH levels. At the end of the dialysis period, the pH of the solutions inside the bag and outside the bag was checked with a Beckman model G pH meter. Quinine hydrochloride precipitates readily in the presence of salts, hence the quinine hydrochloride system was not investigated.

RESULTS AND DISCUSSION

Estimation of the Degree of Binding from the Equilibrium Dialysis Data.—Variations in the degree of binding of the various alkaloids by the hydrocolloids are shown in Table I and Fig. 1. The limiting or maximum binding capacity per unit of hydrocolloid at infinitely high levels of the alkaloids was ascertained by plotting the reciprocal of the amount of alkaloid bound per mg. of hydrocolloid (i/y) *vs.* the reciprocal of the amount of free alkaloid present (i/x). The y intercept is the reciprocal of the limiting quantity of the alkaloid bound per mg. of hydrocolloid. This approach has been used extensively by Kennon and Higuchi (9) and Patel and Kostenbauder (10) in studying the interaction of drugs with polyelectrolytes.

Figure 2 is a plot of the amount of alkaloid bound *vs.* the free alkaloid in the system at 27° in aqueous solutions. Carrageenan, carboxymethylcellulose, furcellaran, sodium alginate, and pectin bound quinine hydrochloride and hyoscyamine hydrochloride to a considerably greater extent than gum tragacanth, locust bean gum, and gum acacia. The so-called xanthine alkaloids, caffeine and theophylline, when mixed with the hydrocolloids used, produced no turbidity whatsoever. However, as shown by Fig. 2 and Table I, binding occurred. In defense of this observation, the work of Guttman and Athalye (17) may be cited. Here, quite stable complexes were formed between riboflavin and caffeine and theophylline. They postulated that the imidazole ring of the xanthine nucleus must be strongly involved. As in their studies, it may be postulated that although hydrogen bonding could possibly provide a primary linkage between the interactants, reinforcement by secondary van der Waals interactions involving other parts of the molecule could also have occurred. Studies on interactions of xanthine molecules with bovine serum albumin by Eichman, *et al.* (18), also indicate the capability of complex formation by caffeine and theophylline with organic molecules.

It is evident that the complexes formed by caffeine and theophylline with the hydrocolloids used are weaker than those complexes formed by quinine hydrochloride and hyoscyamine hydro-

chloride with the same hydrocolloids. This is particularly so with carrageenan, furcellaran, sodium carboxymethylcellulose, sodium alginate, and pectin, in which cases the interaction is primarily a salt formation.

Between 4° and 27°, the amount of each alkaloid bound by the hydrocolloids varies slightly. However, at 37° considerably greater binding was exhibited between the alkaloids quinine hydrochloride and hyoscyamine hydrochloride and the hydrocolloids carrageenan and sodium carboxymethylcellulose. See Table III. The increased binding at the higher temperatures could be due to a weakening of the sodium gegenion field around the polymer so that more drug-polymer interaction occurs. The reaction may be a complex one and besides ionic interactions, hydrogen bonding and secondary van der Waals interactions may occur. However, if van der Waals forces were the only or main factor involved, increased temperature would cause a decrease in interactions.

The interaction with caffeine and theophylline showed less variation with temperature within the range of 4–37°. This probably reflects the weak interactions which occurred as contrasted with quinine hydrochloride and hyoscyamine hydrochloride.

As seen from Table IV, the pH of the system had no marked effect on the extent of binding of the alkaloids by carrageenan. However, beyond either

extreme, the stability of the hydrocolloid and, perhaps of the alkaloid, must be taken into serious consideration. Carboxymethylcellulose, in particular, would be relatively more severely affected than the sulfated hydrocolloids like carrageenan and furcellaran. At pH levels of about 3.0 or below, the ionization of sodium carboxymethylcellulose would be severely repressed and the hydrocolloid would precipitate (19). Data obtained at pH 3.0 for sodium carboxymethylcellulose may therefore be somewhat equivocal. As previously stated, studies in buffer solutions are complicated by precipitation of certain alkaloids, for example, quinine hydrochloride. Such side reactions, even if not visible, must not be ignored.

These studies bear significantly upon the problems which may arise when alkaloids and hydrocolloids are both incorporated into pharmaceutical and other preparations. Where rapid effects are required, the concentration of "free alkaloid" in the system and not the total alkaloid, is important. However, in many areas of nutritional (20) and pharmaceutical (21, 22) therapy, gradual or sustained release of the medicinal or nutritional constituent is desirable. Economy and convenience are two of the many advantages claimed for such sustained release. In this respect, hydrocolloids incorporated into the dosage forms may enhance the desired properties. Alternate effects, such as the inactivation of antimicrobial and other agents, could also be caused by the presence of such hydrocolloids as carrageenan and carboxymethylcellulose, as suggested by Eisman, *et al.* (23).

If binding data are available, it will be possible to approximate and perhaps determine the required concentration of a particular alkaloid or alkaloid-like agent necessary for eliciting a particular physiological function in the presence of specific hydrocolloids incorporated into the medicating mixture for emulsifying or other effects. Wagner (22), in an excellent review entitled "Biopharmaceutics: Absorption Aspects," paid critical attention to the interaction effects of adjuvants, such as gum acacia, when they are used in tablets and other preparations. Alterations in the surface area of the drug, if in solid forms, and inhibition of absorption through formation of a less soluble compound were cited as possibilities. The opposite of these effects may also be possible, hence the significance of such interactions in formulation work should not be overlooked.

Relationship between *In Vitro* Dissolution Rates, Solubilities, and LT_{50}'s in Mice of Some Salts of Benzphetamine and Etryptamine

By W. MOROZOWICH, T. CHULSKI, W. E. HAMLIN, P. M. JONES, J. I. NORTHAM, A. PURMALIS, and J. G. WAGNER

Salt formation of benzphetamine and etryptamine as a potential means of obtaining sustained release and/or prolonged action was studied by measuring the median lethal time (LT_{50}) in mice and its relationship to *in vitro* dissolution rates and solubilities. Both the LT_{50} and LD_{50} increase as the *in vitro* dissolution rate, determined at pH 7.2, decreases. An empirical relationship was found between the LT_{50} and the *in vitro* dissolution rate at pH 7.2. The experimental data suggest that salt formation is a potentially useful means of approaching development of sustained- or prolonged-action dosage forms of certain drugs.

THE PURPOSES of this study were: (*a*) to investigate salt formation as a means of obtaining sustained release and/or prolonged action, and (*b*) to investigate relationships between toxicity data and *in vitro* dissolution rates and solubilities. The relative toxicities of a series of salts of a drug reflect the rate of absorption providing the salt-forming agents are relatively nontoxic. When absorption is rate-limited by dissolution of the salt in the gastrointestinal tract, as will be the case with slowly soluble salts, the toxicity of a slowly dissolving salt will most probably be lower than that of a more rapidly dissolving salt. A similar concept was applied by Nelson (1) in which the clinical effects noticed with various theophylline salts were explained on the basis of dissolution rates. Becker and Swift (2) showed that sustained-release properties of drug resinates could be evaluated by observing the median lethal time of death (LT_{50}) of the drug resinate. Greater sustained or slow release of drug provided an increased LT_{50} and an increased LD_{50} resulting from slower absorption. *In vitro* release of drug from other resinates (2, 3) and from sustained-release capsules[1] (4) was found to correlate with toxicity and blood levels in animals. Shenoy, Grice, and Campbell (5) found the determination of the LD_{50} of a sustained-release formulation to be a very useful method of assessing sustained-release preparations; however, the limitation of the method was the inability to distinguish between sustained and/or slow release and nonavailability of drug. They found that supposed sustained-release products which failed to show sustained release by means of urinary excretion studies in human subjects also showed no sustained release in LT_{50} studies in animals.

The compounds selected for this study were etryptamine[2] and benzphetamine,[3] both of which are basic amino compounds with apparent pKa values in water of 8.8 and 9.3, respectively. Both amine bases have low water solubilities but form highly soluble hydrochlorides.

EXPERIMENTAL

Preparation of Salts.—Salts of the amine drugs were prepared by (*a*) the reaction of the amine hydrochloride with an alkali salt of an acid in aqueous or aqueous-organic solvent mixtures, or by (*b*) reaction of the amine base with a free acid in an appropriate solvent. Elemental analysis and equivalent weight confirmed the stoichiometry of the salt.

Determination of LT_{50} and LD_{50}.—Each salt was ground to a fine powder in a mortar, suspended in 1.0% carboxymethylcellulose by means of a tissue grinder, and intubated orally into ten starved mice. The amount of salt administered was equivalent to that amount which just produced 100% death in an acute toxicity study. In the benzphetamine series it was that quantity equivalent to 400 mg./Kg. benzphetamine hydrochloride, whereas in the etryptamine series it was that quantity equivalent to 124 mg./Kg. etryptamine acetate. The death time of each animal was recorded to the nearest minute.

The LT_{50} was estimated as the time midway between the times to death of the fifth and sixth animals. This method is an alternative to that in which the intersection of the 50 percentile point with a plot of cumulative percentage mortality on log-probability graph paper is taken as the LT_{50} (2–5). This method was chosen since many sets of such mortality data are not truly log-normally distributed.

Determination of *in vitro* Dissolution Rates and Solubilities.—The solubilities were determined by: (*a*) equilibration of excess compound with water for

[2] Etryptamine (Monase, as the acetate) is 3-(2-aminobutyl)indole.

[3] Benzphetamine (Didrex, as the hydrochloride) is (+)N-benzyl-N, α-dimethylphenethylamine.

24 hours at room temperature and determination of the amount in solution, or by (*b*) visual observation of the amount which just dissolves upon equilibration as above.

The dissolution rates were determined by the hanging pellet method of Nelson (6). The pellets were 13 mm. in diameter and were compressed at 20,000 p.s.i. The dissolution medium was 500 ml. of 0.1 *N* hydrochloric acid or 0.2 *M* tris(hydroxymethyl) aminomethane solution adjusted to pH 7.2 with hydrochloric acid and maintained at 37°.

RESULTS AND DISCUSSION

Tables I and II show the various salts of benzphetamine and etryptamine, respectively, arranged in order of increasing LT_{50}. The cumulative death data used in determining the LT_{50} are shown in Tables III and IV. Inspection of Tables I and II shows that the *in vitro* dissolution rates determined at pH 7.2 correlate much better with LT_{50} than do either the water solubilities or dissolution rates determined at pH 1. There is poor correlation of water solubility with dissolution rate, probably because the water solubility is an equilibrium condition at an uncontrolled pH whereas the dissolution rate is a dynamic property dependent upon many factors (7). The polygalacturonate salt of benzphetamine is an example of a salt with a very high water solubility but low dissolution rates. An accurate determination of the solubility of this salt was hindered by the high viscosity of the resultant solution. The seeming anomalously low dissolution rates of this salt are probably due to the high viscosity of the diffusion layer.

Some salts, notably the 8-nitrotheophyllinates, diliturates, bis-methylene-salicylates, and pamoates showed unusual pellet dissolution at pH 1.0. It was found that a layer of the insoluble acid, resulting from hydrolysis of the salt, was formed on the surface of the pellet while the protonated amine diffused through this barrier.

Only a few of the LD_{50}'s were determined (Table I). However, for those available there appears to be a qualitative relationship between LD_{50}, LT_{50}, and dissolution rates at pH 7.2; both the LT_{50} and LD_{50} increase as the dissolution rate decreases. It appears then that one should always use the most rapidly dissolving salt or other form of a drug in determining the intrinsic acute LD_{50} of the drug; conversely, the apparent acute toxicity may be decreased by employing a slowly dissolving form of the drug.

When the LT_{50} of each salt was plotted against the *in vitro* dissolution rate, determined at pH 7.2,

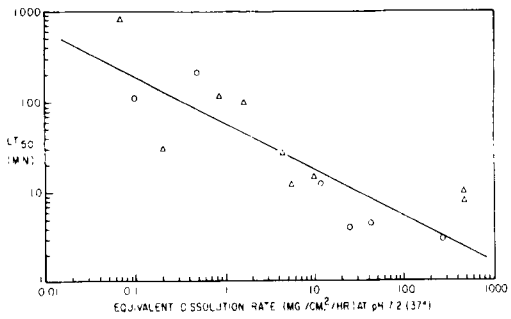

Fig. 1.—A plot of LT_{50} in mice against equivalent dissolution rate at pH 7.2 for etryptamine and benzphetamine salts. Δ, Benzphetamine salts; O, etryptamine salts.

on log-log graph paper, the points appeared to be linearly distributed. Estimation of the least squares regression line indicated the slope of the line was approximately −0.5. Figure 1 is such a plot with the solid line having a slope of −0.5. It follows that for the salts studied, the LT_{50} is inversely related to the square root of the equivalent *in vitro* dissolution rate determined at pH 7.2. This treatment is similar to that of Sturtevant, *et al.* (4), in which linear relationships were found between the logarithm of ΔLT_{50} and the logarithm of the *in vitro* release rates of various sustained-release amphetamine bead preparations.

SUMMARY AND CONCLUSIONS

1. Series of salts of benzphetamine and etryptamine were prepared.

2. The water solubility, *in vitro* dissolution rates determined in aqueous media having a pH of 1.0 and 7.2, and the median lethal time of death (LT_{50}) were determined for each salt. The LD_{50} (mice) of five of the benzphetamine salts, following oral administration, were also determined.

3. The experimental data show that the times to death of mice following a lethal dose and the LD_{50}'s of the various salts are related to the rates of dissolution of the salts as determined by a standardized *in vitro* test.

4. Regression analysis indicated that the LT_{50} is inversely related to the square root of the equivalent *in vitro* rate of dissolution determined at pH 7.2 for the salts studied.

5. The water solubilities and the *in vitro* rates of dissolution determined at pH 1.0 did not correlate nearly as well with the toxicity data as did the *in vitro* rates of dissolution determined at pH 7.2.

Excretion Patterns of Phenothiazine-S^{35} Compounds in Rats

Effect of Change in Structure on Metabolism

By THOMAS L. FLANAGAN, JACK H. NEWMAN, ALFRED R. MAASS, and EDWARD J. VAN LOON

The excretion patterns of five S^{35}-labeled phenothiazines were compared in rats following the oral administration of pharmacologically active doses. Substitution in the 2 position in the phenothiazine ring did not have any apparent effect upon the S^{35} excretion pattern. Differences in the structure of the side chain did have an effect upon the mode of S^{35} excretion. The urinary S^{35} excretion decreased and the fecal S^{35} excretion correspondingly increased as the side-chain structure was changed from 3-dimethylaminopropyl to 3-dimethylamino-2-methylpropyl to 4-methyl-1-piperazinylpropyl. At a dosage level of 9.0 mg. of free base/Kg. in rats, the urinary S^{35} excretion following the oral administration of compound II [2-chloro-10-(3-dimethylaminopropyl)phenothiazine-S^{35} hydrochloride] was twice as great as the urinary S^{35} excretion following the oral administration of compound III [10-[3-(4-methyl-1-piperazinyl)-propyl]-2-trifluoromethylphenothiazine-S^{35} dihydrochloride]. The former compound contained a chlorine atom in the 2 position of the phenothiazine nucleus, while the latter contained a trifluoromethyl grouping at this position. The increased dosage level (9.0 mg. of free base/Kg.) did not appreciably change the S^{35} excretion pattern of compound IV [10-(3-dimethylamino-2-methylpropyl)phenothiazine-S^{35} tartrate] and compound V [10-(3-dimethylamino-2-methylpropyl)-2-trifluoromethylphenothiazine-S^{35} hydrochloride].

ALTHOUGH there are reports in the literature on the urinary excretion pattern of chlorpromazine [2-chloro-10-(3-dimethylaminopropyl)-phenothiazine hydrochloride] there are few comparative studies of the excretion patterns of various phenothiazines. Christensen and Wase (1), using mice as the experimental animals, were the first to report on the urinary and fecal excretion of chlorpromazine-S^{35}. In a preliminary communication Fyodorov and Shnol (2) reported that, following the oral administration of chlorpromazine-S^{35} (aminazine-S^{35}) to rats, 16–17% of the radioactivity was excreted in the urine while approximately 76% was excreted in the feces. In other communications Fyodorov (3, 4) reported on the fate of three phenothiazine compounds in the organism: aminazine-S^{35}, promazine-S^{35}, and chlormeprazine-S^{35}. In his studies with aminazine-S^{35}, Fyodorov found a high concentration of radioactivity in the bile following oral administration. He reported (5) that a large part of the aminazine did not enter into the general blood stream but circulates in a closed circuit: intestine, portal vein, liver, bile, and back to the intestine being eliminated gradually in the feces.

In our laboratories it was shown that, following the intraduodenal administration of chlorpromazine to anesthetized dogs, the bile contained a high percentage of the drug and its metabolites (6). In similar experiments in dogs with three S^{35}-labeled phenothiazines, it was found that the phenothiazines were excreted in large but varying amounts *via* the biliary route. In light of these results it was decided to study the excretion patterns of five phenothiazine-S^{35} compounds in normal rats to see what effect changes in nucleus substitution and/or in the side chain would have upon urinary and fecal excretion following oral administration. Because of the large biliary excretion of the phenothiazines, it was recognized that the fecal pattern of each drug would not be a measure of unabsorbed drug but rather an indication of the amount of phenothiazine entering into the closed circuit system.

The structures of the phenothiazine-S^{35} compounds utilized are shown in Fig. 1.

Fig. 1.—Structures and nomenclature of phenothiazine-S^{35} compounds used in the studies.

EXPERIMENTAL

Preparation of S^{35} Phenothiazines

The phenothiazine-S^{35} compounds were prepared in this laboratory by Dr. D. W. Blackburn (7).

Dosage

Study 1.—Five groups of male, albino rats, 10 rats per group, averaging between 250 to 300 Gm., were used. Each group received a single oral dose of a solution of a labeled drug by stomach tube. In the initial study the drugs were administered at dosage levels (Table I) based upon the pharmacologically active dose, *i.e.*, the dose that blocks avoidance response. The rats were fasted overnight prior to drug administration. Immediately following drug administration, each animal was placed in an individual metabolism cage. Food and water were allowed *ad libitum*. Urine and fecal collections were made at 24-hour intervals for 96 hours. Each day the animals were transferred to clean cages.

Study 2.—The purpose of the second study was to compare the excretion pattern of phenothiazine-S^{35} compounds in nonfasted rats with that of fasted rats. Three of the labeled drugs were administered by stomach tube to groups of nonfasted rats at the same dosage levels as study 1. After administration, the study was completed as described under study 1. However, only the radioactivity of the urine specimens was determined.

Study 3.—To compare the effect of drug administration at the same dosage level upon excretion, the five labeled phenothiazines were administered by stomach tube to groups of 10 rats at a dosage level of 9.0 mg. of free base content of drug per Kg. of body weight. The animals were not fasted and the experiment was completed as described in study 2.

Oxidation and Counting Procedures

The urine specimens were made to volume and a suitable aliquot was counted in a Packard Tricarb liquid scintillation spectrometer, model 314 X, using a phosphor system which contained 80 Gm. of naphthalene and 5 Gm. of 2,5-diphenyl-oxazole dissolved in a mixture of toluene, 1,4-dioxane, and absolute alcohol (1:1:0.6) in a 1 L. volume.

Each 24-hour fecal collection was placed in a 100-ml. Kjeldahl flask containing 4–5 glass beads and 50 ml. of 8 *N* nitric acid. The fecal samples were soaked overnight and then digested to remove all carbonaceous material. The samples were evaporated to 5 ml. or less and cooled to room temperature. Nine milliliters of a digestion mixture consisting of 1:1 8 *N* nitric acid and perchloric acid (60% Baker's analyzed reagent) was added to each sample and digestion continued until bumping occurred. If the digest was not clear, an additional 3 ml. of the digestion mixture was added and the digestion continued until a clear solution was obtained.

After cooling, the contents of the flasks were transferred to 150-ml. beakers and the pH of the solutions adjusted to 3.0 with alkali. The $S^{35}O_4$

was precipitated as $BaS^{35}O_4$ with 5% barium chloride solution in the usual manner. Subsequently the precipitates were filtered, dried, weighed, and counted on a gas flow counter having a micromil window (Nuclear-Chicago 192). The samples were corrected to infinite thinness. In all the studies only total radioactivity was measured. As stated previously, fasted and nonfasted rats were used in separate experiments.

DISCUSSION AND RESULTS

The urinary and fecal S^{35} excretion values obtained on the experimental animals following the administration of a pharmacologically active dose of each drug are given in Table I. The urinary S^{35} excretion in fasted and nonfasted animals was similar for each compound following the adminstration of compounds I, III, and V (Table I). However, slightly higher recoveries were obtained in the nonfasted animals over a 96-hour collection period. In the first two studies in which the animals were administered the pharmacologically active dose of drug, the average urinary recoveries of the S^{35} compounds fell into three ranges: (*a*) The highest S^{35} average recovery (38–43%) was obtained from compound I which had a dimethylaminopropyl side chain. (*b*) The lowest average urinary S^{35} recoveries, 13 and 10%, were obtained with compounds II and III, respectively, which have a 4-methyl-1-piperazinyl propyl side chain. (*c*) The urinary S^{35} excretion of the two compounds which have a dimethylamino-2-methylpropyl side chain, compounds IV and V, was intermediate, 27 and 20%, respectively.

In the comparison of compounds II with III and IV with V, the data show that the S^{35} compound which was administered at the higher dosage level (Table I) gave the higher S^{35} concentration in urine. Because of the difference in dosage levels, no attempts were made to correlate the differences in the urinary S^{35} excretion based upon substitution in the 2 position of the phenothiazine ring.

The fecal S^{35} excretion patterns also fell into three ranges as shown in Table I, and they were exactly opposite to the urinary S^{35} patterns. The fecal excretion of compounds IV and V was 82 and 71%, respectively. This 11% difference was significant at the $P = 0.01$ level ($t = 4.15$). However, no correlation was made of this difference because there was a difference in dosage level, and the respective compounds were excreted to the extent of 62 and 60% in the first 24 hours.

When the fecal S^{35} excretion data were compared from the two sets of compounds which have an identical ring structure and differ only in substitution in the side chain, compounds I with II and compounds V with III, it was seen that the two compounds which contain a 4-methyl-1-piperazinyl propyl side chain (II and III) were primarily excreted in the feces.

In the third study the five phenothiazines were administered at the same dosage level of free base (9 mg./Kg.) to nonfasted rats. When the dose of compound II was increased from 5 mg. of compound/Kg. to 14.6 mg./Kg. (equivalent to 3.1 and 9.0 mg. of free base/Kg., respectively), the urinary S^{35} excretion was increased from 13 to 27% based

upon the administered dose of drug. A threefold increase in dose caused a twofold increase in urinary S^{35} output (Table II). An eightfold increase in the dose of compound III caused only a slight increase in the urinary S^{35} excretion of this compound.

The difference in structure between compounds II and III other than the salt form is in the substitution in the 2 position in the phenothiazine nucleus; compound II contains a chlorine atom, while compound III contains the trifluoromethyl grouping. This was the only case in which substitution in the 2 position of the nucleus appeared to have an effect upon the excretion pattern.

Although the dosages of compounds IV and V were increased two- and fourfold, respectively, the urinary S^{35} excretion of these compounds was increased only slightly (Table II). The increase in urinary S^{35} excretion following the increase in dose of compound II was similar to that obtained with promazine-S^{35}, 10-(3-dimethylaminopropyl) phenothiazine hydrochloride. Fyodorov (3), following the oral administration of promazine-S^{35} to rats at dosage levels of 12–20 mg./Kg., reported that the urine contained 40% of the administered S^{35} activity. At dosage levels of 50 mg./Kg. of promazine-S^{35} to rats intragastrically by stomach tube, Walkenstein and Seifter (8) reported that approximately 65% of the S^{35} dose was excreted in the urine. Compound I (chlorpromazine-S^{35}) was administered at only one dosage level due to a limited supply of this compound.

Relation of Cathartic Activity to Structural Modifications of Ricinoleic Acid of Castor Oil

By M. S. MASRI, L. A. GOLDBLATT, F. DeEDS, and G. O. KOHLER

Castor oil and certain of its derivatives were tested in rats to elucidate the specific structural configuration of castor oil responsible for its cathartic action. The results indicate that the hydroxyl function on carbon-12 and the double bond between carbons 9 and 10 of the ricinoleic acid moiety are essential for the cathartic action, as evidenced by the loss of activity upon either masking of the hydroxyl group or hydrogenation of the double bond. On the other hand, the naturally occurring *cis* configuration of the double bond is not essential for this action, as evidenced by the retention of the activity upon elaidinization to the *trans* configuration.

CASTOR OIL, which is obtained from the seeds of *Ricinus communis*, consists mainly of the triglycerides of an unsaturated hydroxy fatty acid, ricinoleic acid, having the formula $C_{17}H_{32}$-(OH)COOH. Castor oil acts as a cathartic for man although considerable amounts may be absorbed and utilized when fed as part of the diet of many animals. Paul and McCay (1) reported 92.1% utilization by rabbits and 99% utilization by sheep when castor oil was fed to the extent of 6%. Stewart and Sinclair (2) fed adult rats a diet containing 48.4% castor oil and found that the oil was readily metabolized with no evidence of catharsis. Perkins, *et al.* (3), recently reported that weanling rats fed 10% triricinolein "gained as much weight as those fed corn oil (10%) diets" and found (private communication) no indication of catharsis.

Since ricinoleic acid differs from oleic acid, generally considered to be the most plentiful as well as the most widely distributed of all fatty acids in natural fats, only in having a hydroxyl group at carbon-12, it was of interest to investigate the effect of chemical modifications of the functional groups of ricinoleic acid upon the cathartic activity. The modifications planned included esterification of the hydroxyl group, hydrogenation of the double bond, and elaidinization, that is, conversion of the naturally occurring *cis* to the *trans* isomer. Materials tested included castor oil and the hydrogenated, elaidinized and acetylated oil. Castor oil, although it is predominantly the triglyceride of ricinoleic acid, is not a single chemical compound. Therefore, the investigation was extended to include highly purified methyl ricinoleate and its elaidinized, hydrogenated, and acetylated derivatives. The structural formulas for these four compounds are given in Fig. 1.

EXPERIMENTAL

Material and methods.—Castor oil grade AA,

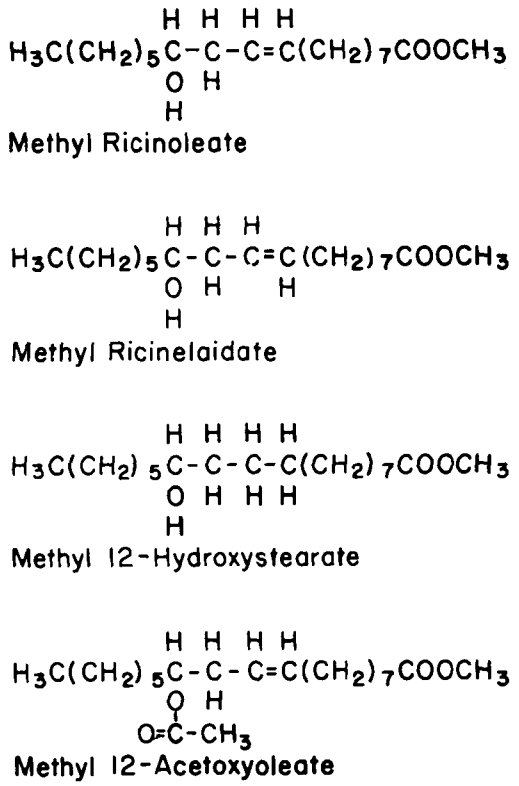

Fig. 1.—Formulas of methyl esters tested.

hydroxyl value 165, a commerical product,[1] was employed.

Hydrogenated Castor Oil.—Fifty grams of castor oil in 250 ml. ethanol was hydrogenated in the presence of 0.3 Gm. of platinum dioxide at a pressure of 55–39 p.s.i. gauge in a Parr hydrogenator. After 5 hours the theoretical amount of hydrogen had been taken up and absorption of hydrogen ceased. Hydrogenation was begun at room temperature of 24° and the temperature rose spontaneously to 29°. However, as the hydrogenation progressed the saturated product began to crystallize from the solution and it was necessary to raise the temperature by external heating to above 50° to keep the product in solution. After hydrogenation was discontinued the catalyst was filtered off and the solvent removed with a rotary evaporator at reduced pressure at a temperature below 70°. The hydrogenated oil, obtained in practically quantitative yield as an almost colorless white solid, melted at 83.5° to 85.2°.

Elaidinized Castor Oil.—Castor oil was elaidinized with a relatively small quantity of nitrite-nitric acid solution as the isomerization agent essentially according to the procedure of McCutchon, *et al.* (4), for the elaidinization of methyl ricinoleate. *To 150 Gm. castor oil maintained at 60°* was added with rapid stirring (magnetic stirrer) 10 ml. of 2 *M* sodium nitrite and 6.7 ml. of 6 *M* nitric acid. The heating and stirring was continued for 4 hours, after which the mixture was poured into 500 ml. of hot distilled water contained in a separator. The water layer was drawn off and the elaidinized oil washed again with 500 ml. hot distilled water. The oil, which was orange-brown in color and solidified below 50°, was then extracted with 500 ml. of a mixture of ethyl ether and Skellysolve F (1:1). The solution was dried with sodium sulfate and decolorized by percolating through a 200-Gm. column of alumina previously wetted with ether-Skellysolve F. The colorless eluate was evaporated to dryness at reduced pressure. The waxy, nearly colorless product melted at 48.9° to 51.0° and showed characteristic absorption in the infrared region at 10.3 μ indicating about 80% conversion of the *cis* olefinic unsaturation to the *trans* (elaidinized) configuration.

Methyl Ricinoleate.—This ester was obtained by alcoholysis of castor oil, followed by fractional distillation of the crude esters according to the procedure of Swern and Jordan (5) and purified further by low temperature crystallization. A heart cut of the distillate which was already better than 98% pure, α_D^{26} + 4.68°,[2] was further purified by fractional crystallization from Skellysolve F-acetone. One hundred and fifty grams of methyl ricinoleate was dissolved in a mixture of 250 ml. Skellysolve F and 50 ml. acetone and cooled to −30°. An impure first crop, α_D^{26} + 4.57°, amounting to 12 Gm. was thus obtained. The filtrate was then cooled to −36° whereby a second crop amounting to 83 Gm. was obtained, α_D^{26} + 4.70°. A third crop obtained at −50° was again somewhat impure, α_D^{26} + 4.65°. Recrystallization of a portion of the second crop did not increase its optical activity and this material, liquid at room temperature, was used in the biological tests.

Ricinoleic Acid.—Ricinoleic acid was prepared by saponification of purified methyl ricinoleate, α_D^{26} + 4.68°, essentially according to the procedure of McCutchon, *et al.* (4).

Anal. Calcd. for $C_{18}H_{34}O_3$: Acid value and hydroxyl value 187.9. Found: acid value 183.2; hydroxyl value 181.3.

Methyl Ricinelaidate.—Methyl ricinoleate was elaidinized with a small quantity of nitrite-nitric acid solution as the isomerization agent and purified by crystallization from Skellysolve F-acetone followed by decolorization with carbon and recrystallization from acetone-water (4). The product thus obtained melted at 29.2° to 30.8°. The magnitude of the characteristic absorption in the infrared region at 10.3 μ indicated quantitative conversion of the *cis* to the *trans* configuration in the purified product.

Methyl 12-Hydroxystearate.—Methyl ricinoleate was hydrogenated in the same manner previously described for the hydrogenation of castor oil except that no external heating was required since the product remained in solution at all times. Using 50 Gm. methyl ricinoleate, 250 ml. 95% ethanol, and 0.2 Gm. platinum oxide at a pressure of 50–30 p.s.i. the calculated amount of hydrogen was absorbed in about 2 hours at 30° but shaking under hydrogen was continued for another hour. The catalyst was then filtered off and the product allowed to crystallize at −2° overnight. The precipitate was collected and recrystallized from

[1] We are indebted to the Baker Castor Oil Co. for a generous supply of castor oil.

[2] Rotations reported are those observed in a 10-cm. tube.

methanol, 5 ml. per Gm. at 2°. The product thus obtained was a white crystalline solid, m.p. 56.4° to 57.6°.

Methyl 12-Acetoxyoleate.—Methyl ricinoleate was acetylated by treating 62.4 Gm. (0.2 mole) of the ester with 320 ml. of an acetic anhydride-pyridine mixture (1:3) in a 1-L. round-bottom flask which was fitted with a reflux condenser and thermometer. The mixture was stirred and heated to 100° and maintained at this temperature for 2 hours. After cooling to 75°, 300 ml. of water was added, and the mixture was stirred rapidly at this temperature for 15 minutes. It was then cooled to room temperature, transferred to a separator, and extracted with 400 ml. of ether. The ether extract was washed four times with 500-ml. portions of 3 *M* hydrochloric acid, after which it was dried over anhydrous sodium sulfate. The recovered product was fractionally distilled at reduced pressure. The main fraction, 40 Gm. distilling at 154° at 0.23 mm., had $\alpha_D^{26} + 23.01°$. This liquid distillate was used for the biological tests.

Acetylated Castor Oil.—Castor oil (hydroxyl value 165) was acetylated in the same manner as methyl ricinoleate. The crude reaction product was extracted with ether and washed and dried but was not distilled. The 3.3 hydroxyl value of the product indicated that 98% of the hydroxyl groups originally present in the oil had been acetylated.

Biological Tests.—Young adult male albino rats from a colony maintained in our laboratory since 1931 were used. The rats were fed a diet previously described (6). For the determination of cathartic activity, the rats were fasted overnight but allowed free access to water. In the morning they were lightly anesthetized with ether and stomach-tubed with the test substances. Samples which are solid at room temperature were warmed and given in the melted state with or without warm corn oil as a diluent to overcome their tendency to crystallize at body temperature. The relatively high melting point of hydrogenated castor oil, in particular, necessitated the use of a relatively large volume of corn oil. Two pellets weighing about 15 Gm. of a commercial ration for rats and a water bottle were supplied immediately after stomach-tubing. The rats were housed individually in hanging-wire cages with soft tissue paper spread underneath. The bottom of each cage was 9.5″ × 8″ made from 2-mesh, 16-gauge galvanized wire cloth which allowed the feces to drop freely on the paper. The number of wet feces produced in 24 hours was taken as an index of catharsis (7). Feces were scored wet when they were so fluid as to be unformed and produced distinct brown stains on the tissue paper surrounding them. Also, wet feces, when allowed to dry, could not be brushed off without tearing the paper. When catharsis was evident almost all the wet feces were usually produced within a few hours of stomach-tubing and occasionally it was necessary to replace the tissue papers with fresh ones in order to facilitate counting of the wet feces. In one experiment in which castor oil constituted 10% of the diet, weanling instead of adult rats were used. They were observed for growth and catharsis over a period of 5 weeks. For this experiment the diet with the following percentage composition was employed: corn meal 53, sucrose 10, casein 17, salt mixture U.S.P. XIV 4, corn oil 4, adequate vitamin mixture triturated in dextrose 2, and castor oil 10.

Table I.—Cathartic Action of Test Substances in Rats

Material Stomach-Tubed	No. of Rats	Body wt., Gm. Mean ± S.E.	Wet Feces/Rat Mean	Wet Feces/Rat S.D.

Corn oil (control) 2.0 ml.	10	202 ± 4	1.3	2.2
Corn oil (control) 3.5 ml.	8	216 ± 9	3.3	2.8

[a] With 1.5 ml. corn oil. [b] With 3.0 ml. corn oil.

RESULTS AND DISCUSSION

The results obtained with stomach-tubed samples are shown in Table I. It is evident that castor oil, elaidinized castor oil, methyl ricinoleate, methyl ricinelaidate, and ricinoleic acid all produced catharsis under our conditions. On the other hand, hydrogenated castor oil, acetylated castor oil, methyl 12-hydroxystearate, and methyl 12-acetoxyoleate were without cathartic action. The apparent slight cathartic activity of the sample of acetylated castor oil tested may be due to its slight content of incompletely acetylated oil. It should be emphasized that the number of wet feces given in Table I represent only a rough but measurable index of the degree of catharsis. Although the individual wet feces differed with respect to size and degree of wetness, each was assigned the same numerical value of one. The subjective appraisal is therefore also important, and a strict statistical comparison of the numbers of wet feces is not intended. However, it should be stated that the subjective appraisal of the individual tests paralleled the conclusions to be drawn from the numerical values.

In the feeding experiment in which 10 four-week-old male rats were fed *ad libitum* the diet containing 10% castor oil for approximately 5 weeks, no catharsis was observed and growth was comparable to that obtained with a similar control group in which the castor oil was replaced by corn oil. The mean weight and its standard error of the rats receiving castor oil was 42.2 ± 0.6 Gm. at the start and 155.6 ± 4.6 Gm. at the end of the experiment.

The corresponding means for the control group were 42.2 ± 0.5 Gm. and 160.5 ± 4.1 Gm., respectively.

Gross examination at autopsy showed no abnormalites. Histopathological examination of the perirenal fat also showed no abnormalities.

The results indicate that either saturation of the double bond or masking of the hydroxyl group of the hydroxy-double bond system of ricinoleic acid nullifies the cathartic action. On the other hand, neither isomerization of the double bond from the *cis* to the *trans* configuration, nor conversion of the neutral triglyceride to the methyl ester or to the free acid, appears to affect the cathartic action to an appreciable extent. The fact that the highly purified (distilled and crystallized) methyl ricinoleate is very effective militates against the possibility that the cathartic action of castor oil may be due to a trace contaminant.

The quite different results obtained when castor oil was given to fasted rats by stomach tube or as a part of the diet is striking. In the latter case no catharsis was observed, although the daily food intake toward the end of the feeding experiment provided well over 1 Gm. of castor oil per rat. This is in agreement with the observations of others, *e.g.*, Stewart and Sinclair (2) found that no catharsis occurred even when castor oil was included in the diets of rats at levels as high as 48.4%. There is no ready explanation for this difference. The reported use of castor oil as an article of the diet in China (8), presumably without untoward effects, may be related to this phenomenon. It is noteworthy that when used as a cathartic, castor oil is usually taken on an empty stomach (9).

Water Vapor Sorption and Diffusion through Hard Gelatin Capsules

By W. A. STRICKLAND, Jr., and MARTHA MOSS

Gelatin contains appreciable amounts of water under normal environmental conditions. This water may be transferred to a hygroscopic powder contained in a gelatin capsule. This report describes a study of this water transfer and of the diffusion of water vapor through gelatin capsules.

THE TWO-PIECE hard gelatin capsule is a convenient single dose medicine container that prevents ill taste on swallowing and promptly dissolves on reaching the stomach. The development of high speed filling equipment and the availability of well made, low cost capsules has prompted renewed interest in capsules as a dosage form. Capsules are made from refined animal gelatin and may contain very small amounts of other substances such as dyes or preservatives; however, the physical properties of hard gelatin capsules are essentially the properties of the gelatin from which they were made. Gelatin normally contains 9 to 12% water, but the water content can vary from about 4 to about 16%, depending on the environment. It is conceivable that the water content of normal capsules may exercise a deleterious effect on the capsule content provided it can be transferred. In addition, atmospheric water vapor may diffuse through capsules if the content is hygroscopic. Gelatin cannot be completely dehydrated by normal desiccating procedures and, if low water content is achieved, the capsules become brittle and fracture easily; conversely, greater than normal water content causes

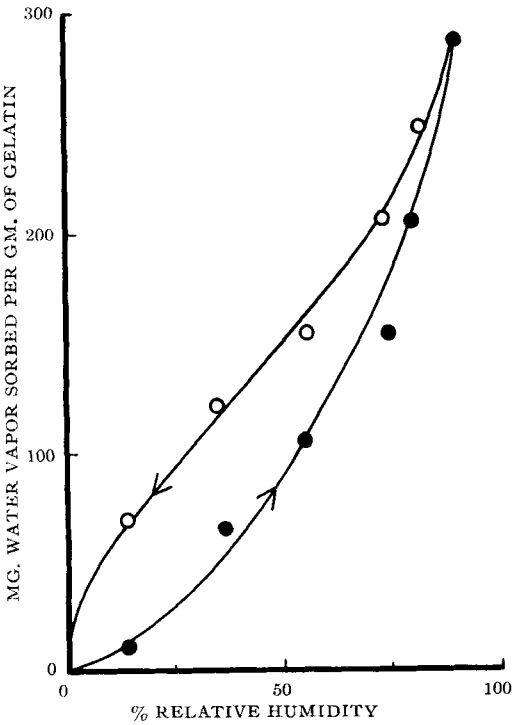

Fig. 1.—Typical sorption-desorption isotherm of crushed gelatin capsules in relative humidity chamber showing pronounced hysteresis of the desorption portion (open points) of the curve.

sticking and ultimate softening of capsules (1, 2).

This communication describes a study of water vapor transfer from capsules to hygroscopic powders and vice versa, and an apparatus used to study rate of water diffusion through gelatin capsules with typical results to show its application. A single lot of size 00 capsules (Parke, Davis and Co., Lot No. G5210-20) was used throughout this study.

EXPERIMENTAL

Sorption and Desorption of Water Vapor by Gelatin.—Isotherms showing the sorption and desorption of water vapor by gelatin were determined in relative humidity chambers by changing the relative humidity by increments at weekly intervals, as previously described (3), at 24°. Figure 1 shows a typical isotherm using crushed gelatin capsules (8 mesh) prepared by drying to constant weight over concentrated sulfuric acid. While the shape of the curve is subject to some variance with different gelatins, invariably there is pronounced hysteresis of the desorption portion of the curve. Perhaps the hysteresis is due to failure to achieve equilibrium, but it is reproducible and, therefore, significant in this work because desorption characteristics govern the availability of water for absorption by hygroscopic materials enclosed in capsules.

Water Vapor Transfer from Gelatin to Hygroscopic Medicinal Powders.—Transfer of water vapor from gelatin to hygroscopic powders, and vice versa, was studied by placing approximately 5 Gm. of accurately weighed samples of crushed gelatin capsules (8 mesh) and of hygroscopic powders (60 to 100 mesh) in aluminum foil dishes, about 5 cm. diameter, and bringing them to constant weight in relative humidity chambers maintained at the desired relative humidity by saturated salt solutions (4). Pairs of samples, one of gelatin and one of a hygroscopic powder, were placed in well closed containers of 1 L. capacity for 1 week at 21 ± 2°, after which time the gain or loss of sample weight was found by weighing. Table I gives typical data found in one such study.

Rate of Water Diffusion through the Capsule Wall.—The apparatus shown in Fig. 2 was devised to study rate of water diffusion through the capsule wall. Nitrogen gas, bubbled through a column of water to saturate it with water vapor, was passed through an equilibrating tube, then into the sample chamber at a constant rate of approximately 50 ml. per minute. The quartz helix springs, previously described (3), employed to determine the gain or loss of weight of sample capsules gravimetrically, had a maximum capacity of 2 Gm. at an extension of

A, Water reservoir through which nitrogen was bubbled to saturate the gas; B, empty tube to assure temperature equilibrium and precise vapor saturation; C, sample chamber with sample capsules suspended from quartz springs; D, flow meter. The entire apparatus was immersed in a water bath maintained at 24 ± 0.2°.

TABLE I.—VAPOR PHASE TRANSFER OF WATER BETWEEN CRUSHED GELATIN CAPSULES AND PENTOBARBITAL SODIUM POWDER, U.S.P.

Material	Weight of Samples at Equilibrium (% Relative Humidity)	Wt. after 1 Week in Closed Containers (21°)	Net Gain or Loss, Gm.[a]
Pentobarbital sodium	4.9789 (0)	5.0380	+0.0925
Gelatin (8 mesh)	4.5047 (72)	4.4210	−0.0837
Pentobarbital sodium	5.1541 (72)	5.0426	−0.1115
Gelatin (8 mesh)	4.2911 (0)	4.4789	+0.1878

[a] The difference in gain and loss is accounted for by the atmospheric water vapor present and the end point relative humidity in the liter container.

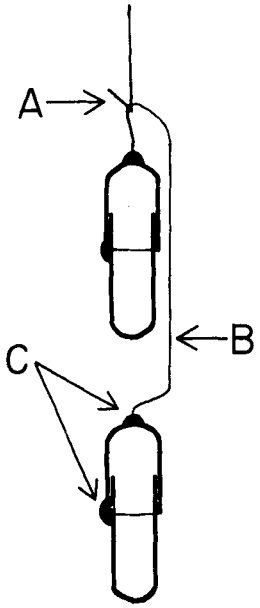

Fig. 3.—Pairs of capsules suspended from the lower hook of quartz spring, A; a small wire, B, was attached to capsules by spots of melted gelatin, C.

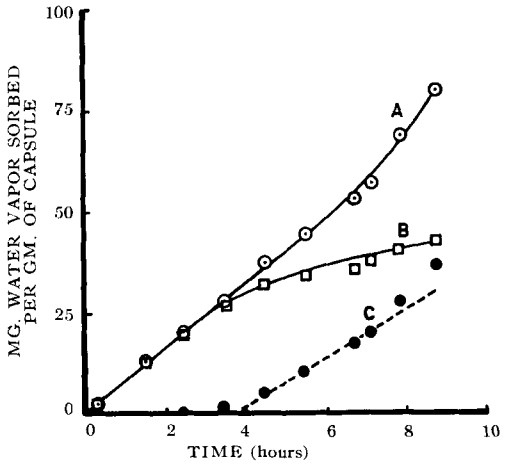

Fig. 4.—The result of a typical determination of water vapor diffusion through gelatin capsules. The weight gain, per Gm., of unfilled capsules, B, subtracted from the weight gain of starch filled capsules, A, yields the lag time of diffusion, C.

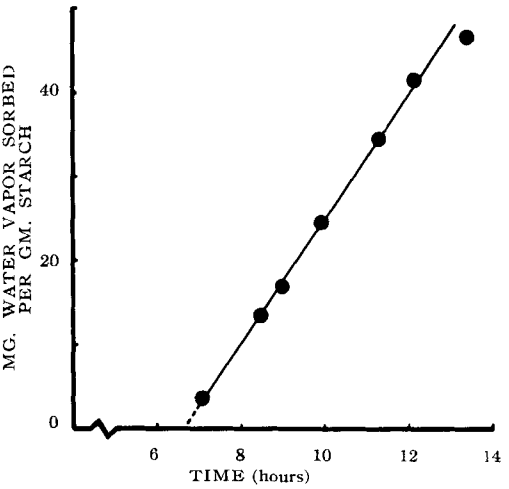

Fig. 5.—The lag in diffusion of water vapor through gelatin capsules filled with dried corn starch and coated with stearic acid.

approximately 1 cm. for each 51 mg. added weight. A cathetometer reading to 0.01 cm. was used to determine spring extension.

Sample capsules were suspended in pairs (Fig. 3) from the lower hook of the quartz spring. Capsules employed in this study weighed about 0.120 Gm. each and had a capacity of about 0.50 Gm. corn starch. After the larger section of the capsule was filled with a dried hygroscopic powder, the two parts of the capsule were gently pushed together and a spot of melted gelatin placed on the juncture to prevent the two sections from coming apart during experimental procedures. Glass beads were placed in the blank capsules to give a total weight near that of powder-filled capsules. Pairs of capsules were attached to a small wire, as shown in Fig. 3, then the assembled capsules were placed in a desiccator for 1 week or more and dried to constant weight prior to use. Figure 4 gives the results obtained when empty capsules and corn starch-filled capsules were placed in the apparatus and weight gain *vs.* time was determined. The time lag for water penetration through the capsule wall was about 4 ± 1 hours. Hygroscopic powders other than starch were used to fill capsules and yielded essentially the same results. Figure 5 depicts the results of determining the diffusion rate of water through capsules coated with stearic acid prepared by immersing capsules in a 2% carbon tetrachloride solution of stearic acid. The capsules appeared to be incompletely coated on visual inspection, which may account for the less than expected increase in lag time.

On occasion, primary softening or melting of capsule content at the juncture of the capsules was noted; however, in most determinations it appeared as if the juncture formed a good seal and the water

vapor diffused rather uniformly through the entire surface of the capsule.

CONCLUSIONS

The water content of gelatin capsules may be subject to desorption in the presence of hygroscopic materials. Relative hygroscopicity of the gelatin capsules and the filling materials determines the direction of vapor phase transfer of water in the closed capsule system. Gelatin capsules offer little protection to a hygroscopic content from atmospheric water vapor. Certain coatings may enhance this protective function, and the extent of protection may be evaluated in terms of prolonged diffusion lag time.

Determination of Calcium Carbonate Moisture Content by a Radioisotope Technique

By MEI CHEN SCHNEITER†, WAYNE V. KESSLER, and JOHN E. CHRISTIAN

The transmission of beta particles through calcium carbonate samples with different moisture contents was studied. It was found that the transmission was linearly related to the moisture content.

IN MANY pharmaceutical manufacturing processes the moisture content of various materials is important. Conventional methods for moisture analysis are time consuming and delay further processing and subsequent production steps. Thus, a definite need exists for a rapid, simple method for moisture analysis. The objective of this investigation was to study the feasibility of determining the moisture content of pharmaceutical products using the beta-particle transmission technique. Although this technique has been used for determining the moisture content of certain materials such as wood (1) and paper (2), no reference to its use for moisture analysis of pharmaceutical products has been reported.

Calcium carbonate was selected for this study because it is a component of many pharmaceutical products. The transmission of the beta particles from a SrY-90 source through calcium carbonate samples with known moisture contents was measured. It was found that the transmission was linearly related to the moisture content.

Accepted for publication March 16, 1962.
† Fellow of the American Foundation for Pharmaceutical Education and recipient of scholarships from the Kappa Kappa Gamma Fraternity and the Purdue Chapter of Mortar Board. Present Address: Purdue Alumni Assoc., Memorial Union Building, Purdue University, West Lafayette, Ind.
This work was performed in part under contract with the Division of Isotopes Development, United States Atomic Energy Commission, Contract No. AT(11-1)-737.

EXPERIMENTAL

Radiation Counting Equipment and Radioactive Source.—A conventional decade scaler, a Geiger-Müller tube with a 1.4 mg./cm.^{2} end window, and a lead shield with a Lucite tube mount were used for the counter. The radioactive source was a $^3/_{16}$-in. diameter deposit of SrY-90 in the center of a $1^1/_4$-in. aluminum planchet having five concentric circular grooves on the bottom. The activity of the deposit was 218,000 c.p.m. at a distance of 2.4 cm. from the detector window. The deposit was covered with a thin coat of label glaze. The planchet was attached to an aluminum planchet holder which, in turn, was placed in the Lucite tube mount of the lead shield.

Preparation and Measurement of Samples.—Stock samples of wetted calcium carbonate were prepared from calcium carbonate powder (A.R. grade) and distilled water. For each stock sample, 100 Gm. of calcium carbonate was mixed with the

vapor diffused rather uniformly through the entire surface of the capsule.

CONCLUSIONS

The water content of gelatin capsules may be subject to desorption in the presence of hygroscopic materials. Relative hygroscopicity of the gelatin capsules and the filling materials determines the direction of vapor phase transfer of water in the closed capsule system. Gelatin capsules offer little protection to a hygroscopic content from atmospheric water vapor. Certain coatings may enhance this protective function, and the extent of protection may be evaluated in terms of prolonged diffusion lag time.

EXPERIMENTAL

Radiation Counting Equipment and Radioactive Source.—A conventional decade scaler, a Geiger-Müller tube with a 1.4 mg./cm.^{2} end window, and a lead shield with a Lucite tube mount were used for the counter. The radioactive source was a $^3/_{16}$-in. diameter deposit of SrY-90 in the center of a $1^1/_4$-in. aluminum planchet having five concentric circular grooves on the bottom. The activity of the deposit was 218,000 c.p.m. at a distance of 2.4 cm. from the detector window. The deposit was covered with a thin coat of label glaze. The planchet was attached to an aluminum planchet holder which, in turn, was placed in the Lucite tube mount of the lead shield.

Preparation and Measurement of Samples.—Stock samples of wetted calcium carbonate were prepared from calcium carbonate powder (A.R. grade) and distilled water. For each stock sample, 100 Gm. of calcium carbonate was mixed with the

calculated amount of water with a mechanical mixer. The samples were stored in screw-cap glass jars and the actual moisture contents were determined by gravimetric analysis using 2- to 3-Gm. samples dried to constant weight in weighing bottles at 100°.

Preliminary experimentation showed that the sample layer must be as uniformly dense as possible in order to get reproducible results. Slugs having convex surfaces were made from the stock samples with a 1-in. diameter punch and die set and a Carver laboratory press. The appropriate weight of sample, determined from a mass absorption curve, was added to the die, and a pressure of 5000 pounds was gradually applied to the sample. The moisture content of the slugs was limited to a range of 0.5–10%, since below 0.5% the powder was too dry to press into slugs and above 10% water droplets were pressed out of the powder. Each slug was placed in a geometrically reproducible position over the SrY-90 source under the Geiger-Müller tube in the lead shield. The distance from the top of the slug to the thin window of the tube was 1.8 cm. The beta-particle transmission was determined during 2 minutes.

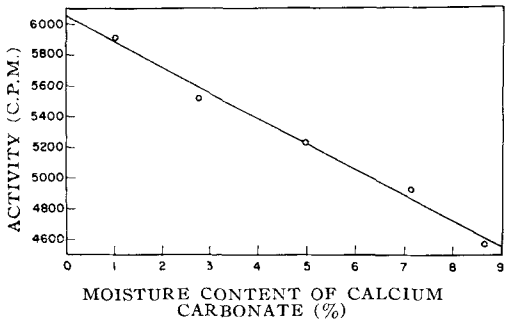

Fig. 1.—SrY-90 beta-particle transmission through wetted calcium carbonate using a constant dry sample weight.

RESULTS

Five stock samples with moisture contents ranging from 1.04 to 8.65% were studied using a constant dry-sample weight of 2.75 Gm. The beta-particle transmissions of four slugs from each stock sample were measured and the average transmission was calculated. The moisture contents and average transmissions of the five stock samples were: 1.04%, 5,913 ± 131 c.p.m.; 2.79%, 5,521 ± 73 c.p.m.; 4.97%, 5,229 ± 47 c.p.m.; 7.13%, 4,930 ± 61 c.p.m.; and 8.65%, 4,568 ± 72 c.p.m. Figure 1 is a least squares plot of these data.

Four stock samples with moisture contents ranging from 1.04 to 7.13% were studied using a constant wet-sample weight of 2.89 Gm. The beta-particle transmissions of four slugs from each stock sample were measured and the average transmission was calculated. The moisture contents and average transmissions of the four stock samples were: 1.04%, 4,857 ± 88 c.p.m.; 2.79%, 5,033 ± 88 c.p.m.; 4.97%, 5,162 ± 41 c.p.m.; 7.13%, 5,294 ± 41 c.p.m. Figure 2 is a least squares plot of these data.

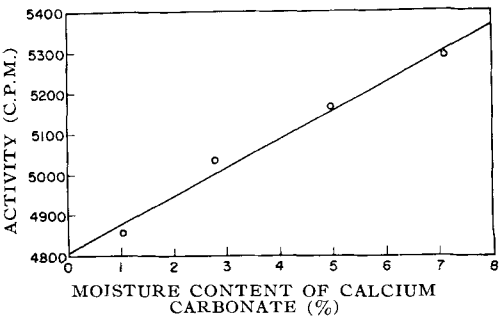

Fig. 2.—SrY-90 beta-particle transmission through wetted calcium carbonate using a constant wet sample weight.

DISCUSSION

The precision of the determinations could be improved by reducing the counting error. The standard deviations of the four determinations for each moisture content range from ±0.80 to ±2.21%. However, the expected counting error for the 2-min. counts is about 1%. The counting error could be reduced by either taking longer counts or using a more intense beta source. If a more intense beta source is used, a scintillation counter with an anthracene crystal would be desirable to avoid coincidence corrections.

The beta-particle transmission technique should be useful in routine moisture analyses of materials when moisture content is the only variable. Calibration curves relating beta-particle transmission to moisture content would be required for each material.

Effects of Stimulants on Rotarod Performance of Mice

By N. PLOTNIKOFF†, D. REINKE, and J. FITZLOFF

This study has demonstrated that amphetamine and pheniprazine increased performance time of mice on the rotating rod, whereas the effects of caffeine were questionable.

SEVERAL reports in the literature have suggested that various stimulant drugs have differential effects on various motor coordination tasks. Studies in lower animals appeared to be limited and it seemed of interest to evaluate the effects of various stimulant drugs on motor coordination. The present study will attempt to describe the effects of a group of stimulants on the performance of mice on a rotating rod, a test originally reported by Dunham and Miya (1).

METHODS

The apparatus originally reported by Dunham and Miya (1) was modified in the following manner: the rod consisting of a 1-in. wooden dowel was divided into 10 equal spaces of 3.5 inches by plastic disks of 8 inches diameter. The rod is operated by a kymograph motor (Gorell and Gorell Monodrum) which has an adjustable speed. One end of the wooden dowel was fitted into the kymograph drive shaft and the other into a ball bearing (1 inch) supported by a vertical wooden support.

The actual testing procedure consisted of (*a*) training all animals by placing them on the rotarod for 6 minutes, (*b*) injecting the animals with drugs by the intraperitoneal route, and (*c*) 30 minutes following injection, observing the performance of the animals on the rotarod for 1 hour, or until they fell off.

RESULTS

Studies on control mice consisted of performance evaluation at three different rotarod speeds. The results are shown in Table I.

TABLE I.—PERFORMANCE TIME *vs.* SPEED

Rotarod Speed, r.p.m.	No. of Groups of Mice[a]	Average Performance Time ± S.E., min.
A 29.28	10	24.5 ± 3.0
B 18.30	5	28.9 ± 4.1
C 11.44	16	30.2 ± 2.2

[a] Ten mice per group.

Although the mean performance times of the mice at the three speeds did not appear to differ significantly, gross differences in behavior were noted. The animals tested at the A speed were observed to have difficulty keeping up with the speed of the rod while those tested at the C speed spent a great deal of time in exploratory behavior. Thus, mice dropping off the rotarod at the A speed may be said to do so from failure to "keep up" with the rod, while those tested at the C speed dropped off primarily because of errors in exploratory behavior—attempts to climb or lean against the plastic disk dividers and/or side excursions on the rod itself. The behavior of the mice tested at the B speed resembled those tested at the A speed.

The effects of amphetamine on performance time were evaluated on three different rotarod speeds, A, B, and C. The results are shown in Table II.

The data shown would indicate that there is a dose response relationship with the use of amphetamine at the three speeds. The estimated doses effective in enhancing performance in 50% of the animals (ED_{50}) were found to be 2.8 ± 0.4 mg./Kg. for the A speed, 1.9 ± 0.4 mg./Kg. for the B speed, and 5.1 ± 0.5 mg./Kg. for the C speed ("estimated" ED_{50} only, since upper ratio was 1.48 at 5.0 mg./Kg.). Thus, there is no apparent difference (by inspection of means and standard errors) between the effects of amphetamine on A and B speeds; however, the agent is less active at the C speed.

The effects of pheniprazine also were evaluated at the three speeds and the results are shown in Table III.

Significant increases in mean performance time with the use of pheniprazine were observed in all three speeds. However, at the C speed the agent was seemingly ineffective 30 minutes after administration (standard error limits compared to controls) but had a pronounced effect at 2 hours. The estimated ED_{50} doses are 6.0 ± 0.8 mg./Kg. for the A speed, 7.0 ± 1.3 mg./Kg. for the B speed, and 6.5 ± 0.8 mg./Kg. for the C speed.

Caffeine was also evaluated at the three speeds and the results are shown in Table IV.

There was no significant improvement in the performance of mice treated with caffeine at any speed tested.

DISCUSSION

The present investigation has demonstrated that the stimulants, amphetamine and pheniprazine, enhance the performance of mice on the rotarod, whereas caffeine was found to be inactive or to have a questionable effect.

It is debatable whether this enhancement is due to a decrease in errors of judgment in movement or an actual improvement in muscular coordination. Thus, control animals tested at the C speed exhibited exploratory behavior while those tested at the A and B speeds did so to a much smaller extent.

Following medication, the animals appeared to concentrate to a greater extent on maintaining pace with the rotating rod and spent less time in exploratory behavior. Several reports indicate that amphetamine reduces errors in the performance of

Identification Test for Tolbutamide and Chlorpropamide

By BERTON E. BALLARD and EINO NELSON

To date no simple and rapid identification test for tolbutamide or chlorpropamide is available, although more elaborate qualitative and quantitative methods of detecting and determining the compounds have been proposed (1–12). The qualitative test presented here is based on a "spot" test discussed by Feigl (13) for the detection of methenamine.

PROCEDURE

To a 100-mg. sample of each of the drugs listed in Table I, 100 mg. of powdered zinc and 100 mg. of granular ammonium chloride were added and intimately mixed in a mortar. The powder mixture of each drug was transferred to an 8-in. Pyrex test tube. Test papers were made by dipping Whatman No. 5 filter paper into a 2% solution of 2,4-dinitrochlorobenzene dissolved in ethyl ether. The paper was dried, passed through the vapors of concentrated ammonium hydroxide, and cut into squares large enough to completely cover the test tube opening.

The identification test for the compounds consisted of placing the square of test paper over the tube opening and putting the tube in a Slaco tube heater (Hallikainen Instruments, Berkeley, Calif.) preset at 150 ± 1° for exactly 10 minutes. The paper was held tightly in place by resting a small Pyrex beaker on top of it during the heating period. A yellow circular stain on the part of the paper over the tube orifice at the end of the heating period indicated a positive result for a particular compound. The lower limits of the method for the detection of tolbutamide and chlorpropamide under these conditions were determined by keeping the weights of zinc powder and ammonium chloride constant and decreasing the quantity of added sulfonylurea until a definite yellow paper color was seen at the end of 35 minutes.

Tolbutamide, chlorpropamide, methenamine, and sulfisoxazole all gave color reactions on the paper within the 10-min. time period. The yellow color of the first three substances on paper was the one expected for the reaction between a volatile amine and 2,4-dinitrochlorobenzene, while the brown color seen with sulfisoxazole was atypical and due to the staining of the paper by colored distillation products.

The method could detect 0.4 mg. of either tolbutamide or chlorpropamide after 35 minutes of heating.

Table I.—Drugs to which Powdered Zinc and Granular Ammonium Chloride Were Added to Make Test

	Official or Common Name[a]	Results
1.	Aprobarbital	−

15.	Tolbutamide	+

[a] 1. 5-Allyl-5-isopropylbarbituric acid; 2. 5,5-diethylbarbituric acid; 4. 1-propyl-3-(*p*-chloro-benzenesulfonyl)-urea; 6. formin or hexamethylenetetramine; 7. 5-ethyl-5-(1-methylbutyl)barbituric acid; 8. 5-ethyl-5-phenylbarbituric acid; 9. N¹-acetylsulfanilamide sodium; 10. N¹-Guanylsulfanilamide; 11. N¹-(4,6-dimethyl-2-pyrimidinyl)sulfanilamide; 12. N¹-(5-methyl-1,3,4-thiadiazol-2-yl)sulfanilamide; 13. N¹-(3,4-dimethyl-5-isoxazolyl)-sulfanilamide; 14. 5-ethyl-5-(1-methylbutyl-)2-thiobarbituric acid; 15. 1-butyl-3-(*p*-tolylsulfonyl)urea. [b] Brown tint to paper due to volatile decomposition products.

DISCUSSION

The pyrolysis reaction here probably involves first the liberation of hydrogen chloride from the heated ammonium chloride-zinc dust mixture, which then causes cleavage of the substituted sulfonylurea. An amine is liberated as a decomposition product. If ammonium chloride is omitted from the procedure, the development of the yellow ring is greatly delayed. The identification test described here is also suitable for qualitative detection of the hypoglycemic agents in commercially available tablets.

Colorimetric Determination of Salicylic Acid

By JOSEPH D. DeMARCO and ARNOLD D. MARCUS

DURING a study of the stability of various salicylic acid derivatives, it was necessary to follow the decomposition reactions by determining the free salicylic acid produced. Because of various interferences, direct ultraviolet determination appeared impractical. It seemed advisable, therefore, to attempt to make use of the well-known ferric ion-salicylic acid reaction.

Two recent reports concerning the stability of aspirin describe modifications of the A.O.A.C. procedure (1) for salicylic acid. These reports concern the use of ferric alum reagent in reaction systems containing 50% ethanol (2) and the same color developing material in aqueous solutions adjusted to pH 2.63 (3). Both modifications appeared unsatisfactory for our need because of the very low concentrations of salicylic acid used. The resulting low absorbance values, on an instrument such as the Beckman model DU spectrophotometer, appeared to allow too great a chance for inaccuracy and imprecision.

Since it seemed probable that the low concentrations of salicylic acid (1–2 mg./100 ml.) were used in an effort to maintain fidelity to Beer's law, we were interested in determining if the method could be improved to permit use of higher concentrations of salicylic acid. The following summarizes our studies concerning the effect of ethanol concentration and the relative usefulness of ferric chloride as compared to ferric alum.

EXPERIMENTAL

Reagents.—Salicylic acid U.S.P.; absolute ethanol, reagent; ferric chloride hexahydrate, Merck reagent; ferric alum, Merck reagent.

Procedure.—Standard solutions of salicylic acid were prepared using absolute ethanol as the solvent. Aliquots of these solutions were then transferred to 100-ml. volumetric flasks, the desired amounts of the ferric chloride or ferric alum solutions were added along with additional ethanol, when desired or necessary, and the solution brought to 100 ml. After 15 minutes the color was read at 532 mμ against a suitable reagent blank. All readings were made on a Beckman model DU spectrophotometer using the tungsten lamp.

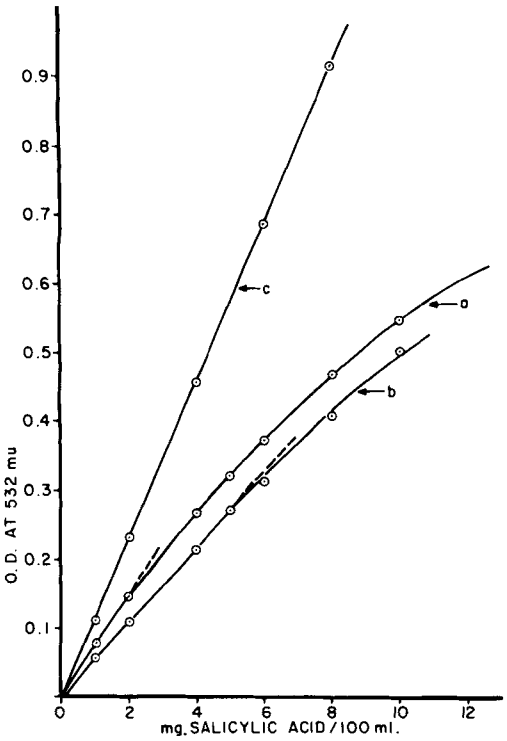

Fig. 1.—Plots showing the effect of ethanol and ferric alum concentration on the iron-salicylate reaction; 5 ml. ferric chloride (1%) in 50% ethanol system.

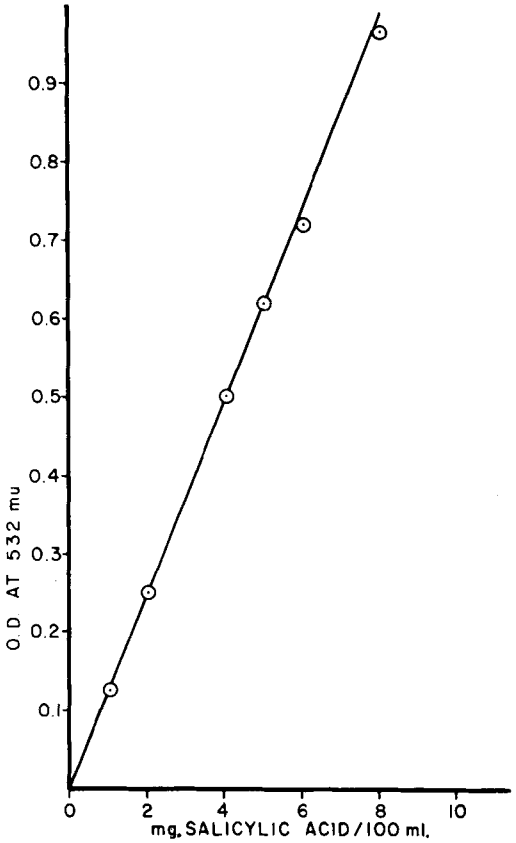

Fig. 2.—Plot showing the value of ferric chloride in gaining adherence to Beer's law despite a high ethanol concentration; 5 ml. ferric chloride (1%) in 50% ethanol system.

Received January 15, 1962, from the Pharmaceutical Research Department, Merck Sharp and Dohme Research Laboratories, West Point, Pa.
Accepted for publication February 15, 1962.

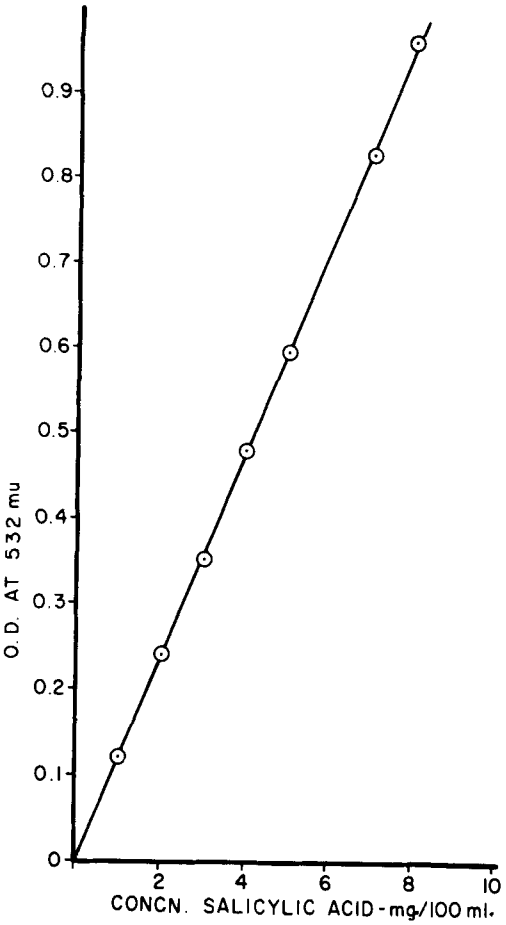

Fig. 3.—Plot showing ferric chloride to be only barely affected by ethanol concentration in the color reaction with salicylate (compare with Fig. 2); 5 ml. of 1% ferric chloride in 10% ethanol system.

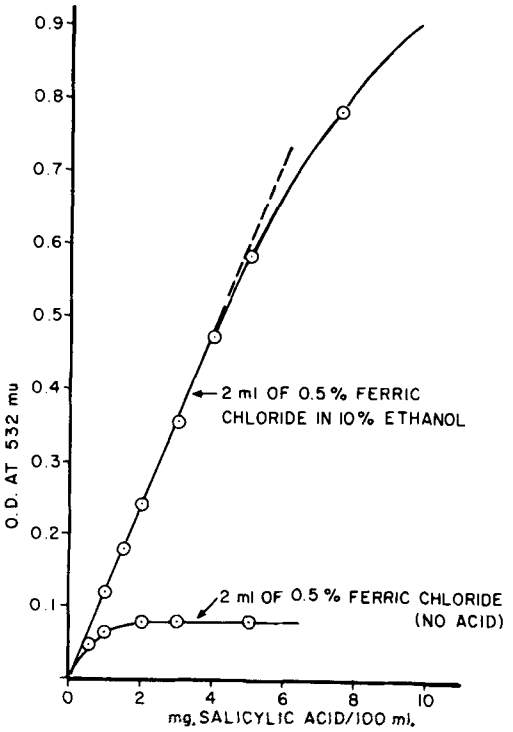

Fig. 4.—Plots showing the importance of suitably high concentrations of acid for good development of the iron-salicylate color.

DISCUSSION

As shown in Fig. 1, curve A, the use of 2 ml. of a 2% solution of ferric alum in a system containing 50% ethanol gives but limited adherence to Beer's law. Somewhat greater fidelity is achieved by increasing the amount of reagent added to 5 ml. per 100 ml. of reaction mixture (curve B). The best adherence to linearity is obtained, however, when the ferric alum reagent is maintained at 5 ml. and the ethanol concentration is reduced to 10% of the final volume (curve C). Indeed, this last modification provided not only good linearity but apparently increased the efficiency of the reagent considerably. By increasing the amount of ferric alum and reducing the alcohol concentration, sufficiently high concentrations of salicylic acid can be used so that absorbance readings in the region of maximum accuracy and precision are easily attainable.

Since some studies might require the use of sufficient ethanol to make the use of ferric alum undesirable, we studied the usefulness of ferric chloride to develop the characteristic color. This material is given as an alternate for ferric alum in the A.O.A.C. method (1). Solutions containing 0.5 and 1.0% ferric chloride in 0.1 *N* hydrochloric acid were used for color development.

As shown in Fig. 2, the use of 5 ml. of 1.0% ferric chloride in a system containing 50% ethanol provided good adherence to Beer's law. By reducing the ethanol concentration to 10%, linearity is extended to higher concentrations of salicylic acid. This is demonstrated in Fig. 3.

When the 1.0% solution of ferric chloride is replaced with a 0.5% solution, Beer's law is obeyed up to a concentration of 5 mg. of salicylic acid per 100 ml., as in Fig. 4. Although this is useful from a practical viewpoint, the use of a 1.0% solution of ferric chloride seems preferable.

The lower curve in Fig. 4, obtained with a 0.5% aqueous solution of ferric chloride (no added acid) convincingly demonstrates the necessity of an acid system for suitable color development.

CONCLUSION

On the basis of these studies, it may be concluded that ferric chloride is preferred to ferric alum as a reagent for the colorimetric determination of salicylic acid. If the latter must be used, the ethanol concentration should be kept to a minimum. In either case, preparation of the reagent in acid solution is mandatory for proper color development.

Synthesis of Salicylamide Sulfate and its Effect on Calcium Ion Solubility

By WILLIAM O. FOYE, RONALD N. DUVALL, MONTGOMERY H. TALBOT, and ROBERT H. ZAIM

Salicylamide sulfate has been synthesized and found to be chromatographically identical to a metabolic product appearing in the urine of patients on salicylamide therapy. This compound, when incubated with suspensions of calcium hydroxide, was found to increase the aqueous solubility of calcium ion beyond that expected from a salt effect alone. An explanation of the effect of salicylamide in halting calcium stone growth has been suggested.

SALICYLAMIDE SULFATE (I), commonly referred to as an "ethereal" sulfate but actually a sulfate ester, has been postulated as a metabolite of salicylamide in humans. Litter, *et al.* (1), claimed that 36% of the drug was excreted by humans as the sulfate without giving experimental details, and Becher, *et al.* (2), showed that a metabolite of salicylamide from humans liberated sulfate after hydrolysis. Foye, *et al.* (3), also hydrolyzed the urines collected from stone-formers and found that a metabolite, supposed to be the sulfate according to Becher's procedure, liberated both salicylamide and sulfate in the hydrolysate. Quantitative determinations on the urines of a large number of stone-forming patients gave an average "ethereal" sulfate excretion of 31% of the salicylamide ingested. Mandel, *et al.* (4), did not detect the sulfate among the metabolites of salicylamide from three cancer patients, but possibly their countercurrent extraction procedure was too lengthy to obtain the sulfate unhydrolyzed.

Salicylamide sulfate has not previously been isolated. To identify positively that the sulfate measured quantitatively in human urines was salicylamide sulfate, the compound has now been synthesized and shown to be chromatographically identical with the urinary product. Although the substance did not migrate with the solvent systems used, the faintly flourescent spot it gave on paper chromatograms did not appear in the urines of the patients in the absence of salicylamide ingestion. A supply of this compound was also required to determine the extent of any solubilization it might exert on calcium ion, since salicylamide ingestion has been found to halt calcium stone growth in a number of stone-formers (5).

The procedure of Burkhardt (6) for preparing the sulfate of phenol using dimethylaniline and potassium pyrosulfate was attempted for the synthesis of salicylamide sulfate, but the major product was dimethylaniline-*m*-sulfonic acid. Baumann's procedure (7) for the preparation of salicylic acid sulfate (no per cent yield was mentioned), however, was adapted to the present synthesis, and the potassium salt of salicylamide sulfate was obtained in low yield. The low yield is not surprising when it is considered that the compound was prepared in an aqueous medium and is readily hydrolyzable. The compound was found to be quite hygroscopic and unstable when exposed to air for any length of time, which probably accounts for the discrepancy in the analytical value for carbon. The product was chromatographically homogeneous, however, and showed no evidence of contamination with salicylamide or other salicylic acid derivatives. Attempts to prepare salicylamide sulfate under nonaqueous conditions were unsuccessful.

Solubility determinations were made in water for calcium hydroxide in the presence of salicylamide sulfate, as well as with sodium chloride, measurements being made up to 3 hours, when hydrolysis of the salicylamide sulfate becomes noticeable. A definite increase in the solubility of calcium hydroxide was noted beyond that to be expected from the salt effect alone (see Table I). Examination of the data in Table I reveals an apparent increase with time in the solubility of calcium hydroxide when in the presence of salicylamide sulfate. This could be due to slow formation of a calcium ion salicylamide sulfate complex, but is more likely the result of experimental variation or error. The same may be said for the apparent decrease in solubility of calcium hydroxide in water or in the presence of sodium chloride.

It appears likely that a so-called weak salt or complex is formed between salicylamide sulfate and

Supported in part by a grant (A-1914) awarded by the National Institute of Arthritis and Metabolic Diseases, Bethesda, Md.

calcium ion, which could explain the halt in calcium stone growth observed in stone-formers when taking salicylamide daily. While the increase in solubilization is small [molar concentrations of salicylamide sulfate were used which approximate those to be expected in urines from the amount of salicylamide (2–3.6 Gm.) ingested by stone-formers on this therapy], it is sufficient to explain the failure of existing stones to accumulate the few mg. of calcium salts per day that ordinarily deposit in the kidneys of stone-forming patients.

I

EXPERIMENTAL

Potassium Salicylamide Sulfate.—Salicylamide (20 Gm., 0.146 mole) was dissolved in 40 ml. of distilled water containing 16 Gm. (0.285 mole) of potassium hydroxide. Finely powdered potassium pyrosulfate (34 Gm., 0.134 mole), previously heated to 350–400°, was added slowly, with stirring. The mixture was stirred for 6 hours at a temperature of 60–70°, and the pH was maintained between 8 and 9 by the addition of saturated potassium hydroxide solution.

The mixture was then shaken with 50 ml. of 95% ethanol and filtered. After cooling, the mixture was treated with 150–200 ml. of ether, with shaking. The aqueous layer was separated and neutralized to pH 7 by the dropwise addition of glacial acetic acid. Precipitated salicylamide was removed, and the filtrate was evaporated to dryness by means of a current of dry air. Absolute ethanol (200 ml.) was added to the residue, and a white, powdery product was filtered, washed with absolute ethanol, and air-dried for a few hours before being stored in a desiccator. The yield was 1.42 Gm. of product which softened at 145–150° and melted at 220–230°.

Anal.[1]—Calcd. for $C_7H_6KNO_5S$: C, 32.93; H, 2.37; S, 12.56. Found: C, 31.70; H, 2.35; S, 12.76.

The compound is extremely soluble in water and insoluble in absolute ethanol. Its aqueous solution has a nearly neutral pH and gave a violet color with ferric chloride T.S. only after hydrolysis with dilute hydrochloric acid. It gave no precipitate with barium chloride solution and dilute hydrochloric acid until the solution was heated for a few minutes. The barium sulfate was isolated, weighed, and the percentage of sulfur calculated. The total sulfur present was thus shown to be sulfate ester.

The compound gave a positive flame test for potassium. It is unstable in air at room temperature. An aqueous solution showed the same faintly fluorescent spot on a paper chromatogram, which did not migrate in the solvent system used, 1-butanol saturated with 3 *N* ammonia, as was obtained in the urines of patients on salicylamide therapy, but not in the absence of salicylamide ingestion. Hydrolysis of the material liberated salicylamide and sulfate ion.

Solubility Determinations.—Test tubes containing 50 ml. of distilled water with excess calcium hydroxide, and either 50 ml. of salicylamide sulfate solution (the appropriate concentration of the potassium salt neutralized with hydrochloric acid), or 50 ml. of sodium chloride solution of the appropriate normality were mechanically stirred in a constant temperature bath at 37°. Aliquots, 2 ml., were withdrawn at the indicated times by means of a pipet whose tip was covered with filter paper. From each aliquot, 1 ml. was used to determine calcium ion by a modification of the method of Hawk, Oser, and Summerson (8) (the calcium oxalate was centrifuged rather than filtered, and was washed with 20% ammonia water instead of distilled water) and 1 ml. was used to determine inorganic sulfate. The latter determinations showed no significant hydrolysis of the ethereal sulfate during the course of the experiment. For longer periods of time, appreciable hydrolysis of the salicylamide sulfate was observed, which prevented the determination of solubility products under equilibrium conditions.

[1] Carbon-hydrogen analysis was done by Carol K. Fitz, Needham, Mass.

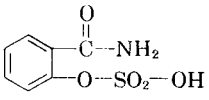
Digitoxin Antagonism by Visnadin



By D. D. VARONOS, P. C. VOUKYDES, and G. C. NIKITOPOULOU

Visnadin, a lactone derived from bishop's weed, has been found to have marked antidotal properties in animals poisoned with digitoxin. It increases survival on acute and chronic administration of the glycoside, prevents the appearance of bradycardia, and reverses cardiac arrhythmias.

DIGITALIS glycosides probably have the smallest margin of safety of any of our commonly used drugs and they appear to have resisted all attempts at improvement in this respect by chemical modification. A less desirable alternative would be to have available a reliable antidote, but this has not yet been found. Recently, a naturally occurring lactone, visnadin (1), has been introduced in Europe for the treatment of the anginal syndrome (2) and has been shown by Smith, *et al.* (1), to have 10 times

The mixture was then shaken with 50 ml. of 95% ethanol and filtered. After cooling, the mixture was treated with 150–200 ml. of ether, with shaking. The aqueous layer was separated and neutralized to pH 7 by the dropwise addition of glacial acetic acid. Precipitated salicylamide was removed, and the filtrate was evaporated to dryness by means of a current of dry air. Absolute ethanol (200 ml.) was added to the residue, and a white, powdery product was filtered, washed with absolute ethanol, and air-dried for a few hours before being stored in a desiccator. The yield was 1.42 Gm. of product which softened at 145–150° and melted at 220–230°.

Anal.[1]—Calcd. for $C_7H_6KNO_5S$: C, 32.93; H, 2.37; S, 12.56. Found: C, 31.70; H, 2.35; S, 12.76.

The compound is extremely soluble in water and insoluble in absolute ethanol. Its aqueous solution has a nearly neutral pH and gave a violet color with ferric chloride T.S. only after hydrolysis with dilute hydrochloric acid. It gave no precipitate with barium chloride solution and dilute hydrochloric acid until the solution was heated for a few minutes. The barium sulfate was isolated, weighed, and the percentage of sulfur calculated. The total sulfur present was thus shown to be sulfate ester.

The compound gave a positive flame test for potassium. It is unstable in air at room temperature. An aqueous solution showed the same faintly fluorescent spot on a paper chromatogram, which did not migrate in the solvent system used, 1-butanol saturated with 3 *N* ammonia, as was obtained in the urines of patients on salicylamide therapy, but not in the absence of salicylamide ingestion. Hydrolysis of the material liberated salicylamide and sulfate ion.

Solubility Determinations.—Test tubes containing 50 ml. of distilled water with excess calcium hydroxide, and either 50 ml. of salicylamide sulfate solution (the appropriate concentration of the potassium salt neutralized with hydrochloric acid), or 50 ml. of sodium chloride solution of the appropriate normality were mechanically stirred in a constant temperature bath at 37°. Aliquots, 2 ml., were withdrawn at the indicated times by means of a pipet whose tip was covered with filter paper. From each aliquot, 1 ml. was used to determine calcium ion by a modification of the method of Hawk, Oser, and Summerson (8) (the calcium oxalate was centrifuged rather than filtered, and was washed with 20% ammonia water instead of distilled water) and 1 ml. was used to determine inorganic sulfate. The latter determinations showed no significant hydrolysis of the ethereal sulfate during the course of the experiment. For longer periods of time, appreciable hydrolysis of the salicylamide sulfate was observed, which prevented the determination of solubility products under equilibrium conditions.

[1] Carbon-hydrogen analysis was done by Carol K. Fitz, Needham, Mass.

Digitoxin Antagonism by Visnadin

By D. D. VARONOS, P. C. VOUKYDES, and G. C. NIKITOPOULOU

Visnadin, a lactone derived from bishop's weed, has been found to have marked antidotal properties in animals poisoned with digitoxin. It increases survival on acute and chronic administration of the glycoside, prevents the appearance of bradycardia, and reverses cardiac arrhythmias.

DIGITALIS glycosides probably have the smallest margin of safety of any of our commonly used drugs and they appear to have resisted all attempts at improvement in this respect by chemical modification. A less desirable alternative would be to have available a reliable antidote, but this has not yet been found. Recently, a naturally occurring lactone, visnadin (1), has been introduced in Europe for the treatment of the anginal syndrome (2) and has been shown by Smith, *et al.* (1), to have 10 times

Received March 2, 1962 from the Department of Physiology, Medical School, University of Athens, Athens, Greece.
Accepted for publication March 20, 1962.

the activity of khellin and four times that of papaverine as a coronary vasodilator (2). Since this drug will inevitably be used in digitalized patients, it seemed desirable to study its pharmacologic relationship to the glycosides.

METHODS AND RESULTS

The effect of visnadin was studied first on the acute LD_{50} of digitoxin in adult male, albino mice. Digitoxin was administered by subcutaneous injection using 10 animals for each dose level. The LD_{50} was calculated by the method of Miller and Tainter (3). Two mice of approximately equal weight were assigned to each cage. After several hours fasting, they were given a mixture of one-half of their usual daily food intake mixed intimately with the appropriate dose of visnadin. In this way, the dose was entirely consumed. Fresh food was given 12 hours later and any unconsumed portion removed from the cages after 4 hours. Finally the digitoxin was injected after another 4 hours. The results are given in Table I from which it appears that visnadin at the maximum feasible oral dose raised the LD_{50} of digitoxin approximately 70%.

TABLE I.—EFFECT OF VISNADIN ON THE LETHAL DOSE OF DIGITOXIN IN THE MOUSE

Dose of Visnadin, mg./Kg.	LD_{50} of Digitoxin ± S.E., mg./Kg.
0	14.4 ± 0.48
150	18.2 ± 0.79
300	24.4 ± 0.78
ca. 450[a]	24.2 ± 1.03

[a] Food-drug mixture not entirely consumed.

Visnadin was also found to modify the lethal dose of digitoxin on chronic administration in the mouse. Digitoxin was given subcutaneously at a dose of 2.5 mg./Kg. daily for 2 days and then 3.5 mg./Kg. daily until death occurred. One group of 10 mice received digitoxin only, while a second group of 10 were given the same dose of digitoxin and, simultaneously, 400 mg./Kg. of visnadin in the food as in the preceding experiments. The control group survived for an average of 9.3 days and the visnadin-treated group for an average of 12.8 days. The mean lethal doses were 25 and 35 mg./Kg. for control and treated group, respectively.

Digitoxin was administered daily by subcutaneous injection to adult albino rats with and without the addition of visnadin to the feed by a technique similar to that described above. Electrocardiograms were taken daily before the dose of digitoxin was given. The duration of the cardiac cycle was measured and the data are given in Table II. It is clear that visnadin strongly inhibited the development of bradycardia due to digitoxin.

DISCUSSION

The mechanism of the antagonistic action of visnadin on the toxicity of the cardiac glycosides is not known. It may possibly be related to its coronary vasodilator action since Lee (4) and Reiter (5) have reported that the positive inotropic action of the glycosides is followed by a deficiency of oxygen in the heart muscle. However, both visnadin and the digitalis glycosides contain unsaturated lactone rings and have certain other structural similarities, so that competitive antagonism must also be considered. Several unrelated lactones have been reported to have antidigitalis glycoside activity (6, 7), although results of other workers do not absolutely agree with this view (8). Nevertheless, it must be considered that the lactones of the cardiac glycosides, except scillaren, are furane forms, while the visnadin lactone belongs to the pyrane form.

It seems clear that visnadin merits further study as to mechanism of action and clinical application because of its great potential value in controlling the action of the digitalis glycosides in the treatment of heart disease.

TABLE II.—EFFECT OF VISNADIN ON BRADYCARDIA PRODUCED BY DIGITOXIN IN THE RAT

Time	Cardiac Cycle Duration, sec., + mean of 10 animals ± S.E. Group I Digitoxin, 2.5 mg./Kg. per day, s.c.	Group II Digitoxin, *ibid.*, plus Visnadin, 200 mg./Kg. per day, oral	Probability of Difference between Means Due to Random Sampling[a]
Control	0.138 ± 0.0040	0.139 ± 0.0039	0.8
Digitoxin started			
1st Day	0.170 ± 0.0039	0.168 ± 0.0037	0.8
Visnadin started			
2nd Day	0.183 ± 0.0032	0.158 ± 0.0039	0.001
3rd Day	0.198 ± 0.0035	0.149 ± 0.0046	0.001
4th Day	0.210 ± 0.0049	0.147 ± 0.0048	0.001
5th Day	Death	0.160 ± 0.0041

Communications

Riboflavin Marker in Drug Products

Sir:

In patients receiving long-term therapy, a simple procedure is desirable for determining whether or not the patients are actually taking their prescribed medication. This might be done by including, in the dosage form, a marker which is easily detectable in the urine. Riboflavin has been suggested for this purpose by several investigators. This communication reports a brief examination of the use of riboflavin in this manner.

Control urine samples were collected from three human subjects on uncontrolled diets. Three milligrams of riboflavin was then administered to each subject. Urine samples were again collected after 3 hours.

Two subjects collected control urine samples prior to receiving orally, on different days, 3 mg. riboflavin plus one of the following drugs: 10 mg. chlorpromazine, 5 mg. prochlorperazine, 1 mg. trifluoperazine, 10 mg. thioridazine, and 5 mg. tranylcypromine. Urine samples were collected 3 hours after the subject had received the drug plus riboflavin.

The urine samples were observed in transparent flint glass bottles under the following conditions: In a darkroom, the urine samples were illuminated with a Black-Ray Model B-100 long-wave ultraviolet lamp.[1] The control urine samples exhibited a light blue fluorescence. The other urine samples exhibited a milky white fluorescence with distinct yellow at the sides of the bottle. Riboflavin in water shows a very intense yellow fluorescence under these conditions.

The control and test urine samples did not look appreciably different under normal illumination; however, under long-wave ultraviolet light they were easily distinguishable. Urine samples from subjects receiving riboflavin alone or riboflavin plus drug were indistinguishable.

For subjects receiving these, and possibly other drugs, three or four times daily, this amount of a riboflavin marker per dose seems more than sufficient to aid in establishing that the prescribed medication is actually being taken by simple periodic urine checks.

The Ciba Collection of Medical Illustrations. Vol. 3, Digestive System. Part 2, Lower Digestive Tract. Prepared by FRANK H. NETTER. Ciba Pharmaceutical Co., Summit, N. J., 1962. xi + 243 pp. 24 × 30.5 cm. Price $15.

The second part of volume 3 in this exceptional series of informative art and comment includes seven sections under the headings: Development of the digestive tract, Anatomy of the abdomen, Anatomy of the lower digestive tract, Functional and diagnostic aspects of the lower digestive tract, Diseases of the lower digestive tract, Diseases and injuries of the abdominal cavity, and Hernias. References to the text in the sections (VIII–XIV) and a general subject index are appended.

Steroid Drugs. By NORMAN APPLEZWEIG. The Blakiston Division, McGraw-Hill Book Company, Inc., 330 West 42nd St., New York 36, N. Y., 1962. xv + 742 pp. 15 × 22.5 cm. Price $25.

This one volume reference book on steroid drugs written by one of the pioneers in steroid research and development is divided into four parts: history and background of steroid product development, production processes, steroids in drug therapy, and biologically active steroids. Summaries of progress developments are presented via production flow sheets, process data, charts showing relation of structure to function, and tables of compounds having similar biological activity. This volume also includes a catalog of over 1800 biologically active steroids coded according to their structure which enables the reader to determine whether a structural alteration of a basic steroid has been attempted and the effect of the alteration on its biological activity.

Biochemical Preparations. Vol. 9. Edited by MINOR J. COON. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1962. ix + 149 pp. 14.5 × 22.5 cm. Price $6.95.

This volume contains methods for the preparation of: N-Acetylneuraminlactose, P^{32}-Labeled adenosine 5′-phosphate and deoxycytidine 5′-phosphate, 5-Benzyloxyindole, Enzymatic synthesis of (+)-citramalic acid, Chemical synthesis and resolution of (±)-citramalic acid, Coenzyme Q_{10}, 2-Deoxy-D-ribose 5-phosphate, Reduced diphosphopyridine nucleotide (DPNH) oxidase, D-Glucosamine 6-phosphoric acid and D-mannosamine 6-phosphoric acid, Glutamate-asparate transaminase, γ-Glutamyl-L-cysteine from glutathione, L-α-Glycerylphosphorylcholine, Carboxyl-C^{14}-labeled 3-hydroxyanthranilic acid, D(-)- and L(+)-β-Hydroxybutyric acids, *threo*-γ-Hydroxy-L-glutamic acid, *threo*-γ-Hydroxy-DL-glutamic acid, Carbonyl-C^{14}-labeled 3-hydroxy-DL-kynurenine, Hydroxylapatite for protein chromatography, Hydroxypyruvic acid and lithium hydroxypyruvate, 5-Hydroxy-DL-tryptophan, L-*myo*-Inositol 1-phosphate, Malic dehydrogenase from rat liver, *p*-Nitrophenyl carbobenzoxyglycinate, Oleic acid, Enzymatic synthesis of oleic, linoleic, and linolenic esters of cholesterol, Enzymatic synthesis of ribo- and deoxyribonucleoside 5′-triphosphates, Sphingosine, and Tobacco mosaic virus. A subject index is appended.

Medical Abbreviations. Compiled by the SPECIAL STUDIES COMMITTEE OF THE MICHIGAN OCCUPATIONAL THERAPY ASSOC. Michigan Occupational Therapy Assoc., Occupational Therapy, Dept. of Physical Medicine and Rehabilitation, University Hospital, Ann Arbor, Mich., 1961. v + 241 pp. 11 × 15 cm. Price $2.25.

A paper bound cross reference dictionary compiled from lists of abbreviations obtained from medical centers in an attempt to provide a handbook looking toward the standardization of medical abbreviations.

Practical Neurochemistry. By HENRY MCILWAIN and RICHARD RODNIGHT. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. vii + 296 pp. 15.5 × 23.5 cm. Price $10.50.

Those concerned with neural systems in chemical, biochemical, physiological, pharmacological, or pathological study should find useful information in this book. Practical teaching, demonstrating, and research on the mammalian nervous system are the authors' background for this textbook for undergraduate and graduate students in medicine and science.

Progress in Drug Research. Vol. 3. Edited by ERNST JUCKER. John Wiley & Sons, Inc., Interscience Division, 440 Park Ave. South, New York 16, N. Y., 1962. 563 pp. 16.5 × 24 cm. Price $23.50.

Included in this third annual volume are (in contributed language): Les derives organiques du fluor d′ interet pharmacologique, Structure-activity relationship in certain anthelmintics, Recent research in the field of 5-hydroxytryptamine and related indolealkylamines, Uber neue Arzneimittel, A pharmacological approach to allergy, Krebswirksame Antibiotika aus Actinomyceten. A general subject index is appended.

Biological Alkylating Agents. By W. C. J. Ross. Butterworth Inc., 7235 Wisconsin Ave., Washington 14, D. C., 1962. xi + 232 pp. 13.5 × 22 cm. Price $10.50.

Chemical compounds capable or acting as alkylating agents under certain physiological conditions are considered in this book. The subtitle of the book "Fundamental Chemistry and the Design of Compounds for Selective Toxicity" indicates the direction of the scope of the text which is divided into two parts. Part 1 reviews the chemical reactivity of the compounds, and Part 2 discusses attempts which have been made to produce agents with selective toxicity toward cancer cells.

Textbook of Biochemistry. 8th ed. By BENJAMIN HARROW and ABRAHAM MAZUR. W. B. Saunders Company, West Washington Square, Philadelphia 5, Pa., 1962. vi + 651 pp. 15.5 × 23 cm. Price $7.75.

This is a current revision of a textbook on biochemistry and contains chapters on the chemistry of the tissues, hormones, immunochemistry, and chemotherapy as well as others. It carries numerous illustrations, chemical formulas, graphs, and diagrams to assist the student in understanding the subjects presented.

The Ciba Collection of Medical Illustrations. Vol. 3, Digestive System. Part 2, Lower Digestive Tract. Prepared by FRANK H. NETTER. Ciba Pharmaceutical Co., Summit, N. J., 1962. xi + 243 pp. 24 × 30.5 cm. Price $15.

The second part of volume 3 in this exceptional series of informative art and comment includes seven sections under the headings: Development of the digestive tract, Anatomy of the abdomen, Anatomy of the lower digestive tract, Functional and diagnostic aspects of the lower digestive tract, Diseases of the lower digestive tract, Diseases and injuries of the abdominal cavity, and Hernias. References to the text in the sections (VIII–XIV) and a general subject index are appended.

Steroid Drugs. By NORMAN APPLEZWEIG. The Blakiston Division, McGraw-Hill Book Company, Inc., 330 West 42nd St., New York 36, N. Y., 1962. xv + 742 pp. 15 × 22.5 cm. Price $25.

This one volume reference book on steroid drugs written by one of the pioneers in steroid research and development is divided into four parts: history and background of steroid product development, production processes, steroids in drug therapy, and biologically active steroids. Summaries of progress developments are presented via production flow sheets, process data, charts showing relation of structure to function, and tables of compounds having similar biological activity. This volume also includes a catalog of over 1800 biologically active steroids coded according to their structure which enables the reader to determine whether a structural alteration of a basic steroid has been attempted and the effect of the alteration on its biological activity.

Biochemical Preparations. Vol. 9. Edited by MINOR J. COON. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1962. ix + 149 pp. 14.5 × 22.5 cm. Price $6.95.

This volume contains methods for the preparation of: N-Acetylneuraminlactose, P^{32}-Labeled adenosine 5′-phosphate and deoxycytidine 5′-phosphate, 5-Benzyloxyindole, Enzymatic synthesis of (+)-citramalic acid, Chemical synthesis and resolution of (±)-citramalic acid, Coenzyme Q_{10}, 2-Deoxy-D-ribose 5-phosphate, Reduced diphosphopyridine nucleotide (DPNH) oxidase, D-Glucosamine 6-phosphoric acid and D-mannosamine 6-phosphoric acid, Glutamate-asparate transaminase, γ-Glutamyl-L-cysteine from glutathione, L-α-Glycerylphosphorylcholine, Carboxyl-C^{14}-labeled 3-hydroxyanthranilic acid, D(-)- and L(+)-β-Hydroxybutyric acids, *threo*-γ-Hydroxy-L-glutamic acid, *threo*-γ-Hydroxy-DL-glutamic acid, Carbonyl-C^{14}-labeled 3-hydroxy-DL-kynurenine, Hydroxylapatite for protein chromatography, Hydroxypyruvic acid and lithium hydroxypyruvate, 5-Hydroxy-DL-tryptophan, L-*myo*-Inositol 1-phosphate, Malic dehydrogenase from rat liver, *p*-Nitrophenyl carbobenzoxyglycinate, Oleic acid, Enzymatic synthesis of oleic, linoleic, and linolenic esters of cholesterol, Enzymatic synthesis of ribo- and deoxyribonucleoside 5′-triphosphates, Sphingosine, and Tobacco mosaic virus. A subject index is appended.

Medical Abbreviations. Compiled by the SPECIAL STUDIES COMMITTEE OF THE MICHIGAN OCCUPATIONAL THERAPY ASSOC. Michigan Occupational Therapy Assoc., Occupational Therapy, Dept. of Physical Medicine and Rehabilitation, University Hospital, Ann Arbor, Mich., 1961. v + 241 pp. 11 × 15 cm. Price $2.25.

A paper bound cross reference dictionary compiled from lists of abbreviations obtained from medical centers in an attempt to provide a handbook looking toward the standardization of medical abbreviations.

Practical Neurochemistry. By HENRY MCILWAIN and RICHARD RODNIGHT. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. vii + 296 pp. 15.5 × 23.5 cm. Price $10.50.

Those concerned with neural systems in chemical, biochemical, physiological, pharmacological, or pathological study should find useful information in this book. Practical teaching, demonstrating, and research on the mammalian nervous system are the authors' background for this textbook for undergraduate and graduate students in medicine and science.

Progress in Drug Research. Vol. 3. Edited by ERNST JUCKER. John Wiley & Sons, Inc., Interscience Division, 440 Park Ave. South, New York 16, N. Y., 1962. 563 pp. 16.5 × 24 cm. Price $23.50.

Included in this third annual volume are (in contributed language): Les derives organiques du fluor d′ interet pharmacologique, Structure-activity relationship in certain anthelmintics, Recent research in the field of 5-hydroxytryptamine and related indolealkylamines, Uber neue Arzneimittel, A pharmacological approach to allergy, Krebswirksame Antibiotika aus Actinomyceten. A general subject index is appended.

Biological Alkylating Agents. By W. C. J. Ross. Butterworth Inc., 7235 Wisconsin Ave., Washington 14, D. C., 1962. xi + 232 pp. 13.5 × 22 cm. Price $10.50.

Chemical compounds capable or acting as alkylating agents under certain physiological conditions are considered in this book. The subtitle of the book "Fundamental Chemistry and the Design of Compounds for Selective Toxicity" indicates the direction of the scope of the text which is divided into two parts. Part 1 reviews the chemical reactivity of the compounds, and Part 2 discusses attempts which have been made to produce agents with selective toxicity toward cancer cells.

Textbook of Biochemistry. 8th ed. By BENJAMIN HARROW and ABRAHAM MAZUR. W. B. Saunders Company, West Washington Square, Philadelphia 5, Pa., 1962. vi + 651 pp. 15.5 × 23 cm. Price $7.75.

This is a current revision of a textbook on biochemistry and contains chapters on the chemistry of the tissues, hormones, immunochemistry, and chemotherapy as well as others. It carries numerous illustrations, chemical formulas, graphs, and diagrams to assist the student in understanding the subjects presented.

The Ciba Collection of Medical Illustrations. Vol. 3, Digestive System. Part 2, Lower Digestive Tract. Prepared by FRANK H. NETTER. Ciba Pharmaceutical Co., Summit, N. J., 1962. xi + 243 pp. 24 × 30.5 cm. Price $15.

The second part of volume 3 in this exceptional series of informative art and comment includes seven sections under the headings: Development of the digestive tract, Anatomy of the abdomen, Anatomy of the lower digestive tract, Functional and diagnostic aspects of the lower digestive tract, Diseases of the lower digestive tract, Diseases and injuries of the abdominal cavity, and Hernias. References to the text in the sections (VIII–XIV) and a general subject index are appended.

Steroid Drugs. By NORMAN APPLEZWEIG. The Blakiston Division, McGraw-Hill Book Company, Inc., 330 West 42nd St., New York 36, N. Y., 1962. xv + 742 pp. 15 × 22.5 cm. Price $25.

This one volume reference book on steroid drugs written by one of the pioneers in steroid research and development is divided into four parts: history and background of steroid product development, production processes, steroids in drug therapy, and biologically active steroids. Summaries of progress developments are presented via production flow sheets, process data, charts showing relation of structure to function, and tables of compounds having similar biological activity. Summaries of progress developments are presented via production flow sheets, process data, charts showing relation of structure to function, and tables of compounds having similar biological activity. This volume also includes a catalog of over 1800 biologically active steroids coded according to their structure which enables the reader to determine whether a structural alteration of a basic steroid has been attempted and the effect of the alteration on its biological activity.

Biochemical Preparations. Vol. 9. Edited by MINOR J. COON. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1962. ix + 149 pp. 14.5 × 22.5 cm. Price $6.95.

This volume contains methods for the preparation of: N-Acetylneuraminlactose, P^{32}-Labeled adenosine 5′-phosphate and deoxycytidine 5′-phosphate, 5-Benzyloxyindole, Enzymatic synthesis of (+)-citramalic acid, Chemical synthesis and resolution of (±)-citramalic acid, Coenzyme Q_{10}, 2-Deoxy-D-ribose 5-phosphate, Reduced diphosphopyridine nucleotide (DPNH) oxidase, D-Glucosamine 6-phosphoric acid and D-mannosamine 6-phosphoric acid, Glutamate-asparate transaminase, γ-Glutamyl-L-cysteine from glutathione, L-α-Glycerylphosphorylcholine, Carboxyl-C^{14}-labeled 3-hydroxyanthranilic acid, D(-)- and L(+)-β-Hydroxybutyric acids, *threo*-γ-Hydroxy-L-glutamic acid, *threo*-γ-Hydroxy-DL-glutamic acid, Carbonyl-C^{14}-labeled 3-hydroxy-DL-kynurenine, Hydroxylapatite for protein chromatography, Hydroxypyruvic acid and lithium hydroxypyruvate, 5-Hydroxy-DL-tryptophan, L-*myo*-Inositol 1-phosphate, Malic dehydrogenase from rat liver, *p*-Nitrophenyl carbobenzoxyglycinate, Oleic acid, Enzymatic synthesis of oleic, linoleic, and linolenic esters of cholesterol, Enzymatic synthesis of ribo- and deoxyribonucleoside 5′-triphosphates, Sphingosine, and Tobacco mosaic virus. A subject index is appended.

Medical Abbreviations. Compiled by the SPECIAL STUDIES COMMITTEE OF THE MICHIGAN OCCUPATIONAL THERAPY ASSOC. Michigan Occupational Therapy Assoc., Occupational Therapy, Dept. of Physical Medicine and Rehabilitation, University Hospital, Ann Arbor, Mich., 1961. v + 241 pp. 11 × 15 cm. Price $2.25.

A paper bound cross reference dictionary compiled from lists of abbreviations obtained from medical centers in an attempt to provide a handbook looking toward the standardization of medical abbreviations.

Practical Neurochemistry. By HENRY MCILWAIN and RICHARD RODNIGHT. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. vii + 296 pp. 15.5 × 23.5 cm. Price $10.50.

Those concerned with neural systems in chemical, biochemical, physiological, pharmacological, or pathological study should find useful information in this book. Practical teaching, demonstrating, and research on the mammalian nervous system are the authors' background for this textbook for undergraduate and graduate students in medicine and science.

Progress in Drug Research. Vol. 3. Edited by ERNST JUCKER. John Wiley & Sons, Inc., Interscience Division, 440 Park Ave. South, New York 16, N. Y., 1962. 563 pp. 16.5 × 24 cm. Price $23.50.

Included in this third annual volume are (in contributed language): Les derives organiques du fluor d′ interet pharmacologique, Structure-activity relationship in certain anthelmintics, Recent research in the field of 5-hydroxytryptamine and related indolealkylamines, Uber neue Arzneimittel, A pharmacological approach to allergy, Krebswirksame Antibiotika aus Actinomyceten. A general subject index is appended.

Biological Alkylating Agents. By W. C. J. Ross. Butterworth Inc., 7235 Wisconsin Ave., Washington 14, D. C., 1962. xi + 232 pp. 13.5 × 22 cm. Price $10.50.

Chemical compounds capable or acting as alkylating agents under certain physiological conditions are considered in this book. The subtitle of the book "Fundamental Chemistry and the Design of Compounds for Selective Toxicity" indicates the direction of the scope of the text which is divided into two parts. Part 1 reviews the chemical reactivity of the compounds, and Part 2 discusses attempts which have been made to produce agents with selective toxicity toward cancer cells.

Textbook of Biochemistry. 8th ed. By BENJAMIN HARROW and ABRAHAM MAZUR. W. B. Saunders Company, West Washington Square, Philadelphia 5, Pa., 1962. vi + 651 pp. 15.5 × 23 cm. Price $7.75.

This is a current revision of a textbook on biochemistry and contains chapters on the chemistry of the tissues, hormones, immunochemistry, and chemotherapy as well as others. It carries numerous illustrations, chemical formulas, graphs, and diagrams to assist the student in understanding the subjects presented.

The Ciba Collection of Medical Illustrations. Vol. 3, Digestive System. Part 2, Lower Digestive Tract. Prepared by FRANK H. NETTER. Ciba Pharmaceutical Co., Summit, N. J., 1962. xi + 243 pp. 24 × 30.5 cm. Price $15.

The second part of volume 3 in this exceptional series of informative art and comment includes seven sections under the headings: Development of the digestive tract, Anatomy of the abdomen, Anatomy of the lower digestive tract, Functional and diagnostic aspects of the lower digestive tract, Diseases of the lower digestive tract, Diseases and injuries of the abdominal cavity, and Hernias. References to the text in the sections (VIII–XIV) and a general subject index are appended.

Steroid Drugs. By NORMAN APPLEZWEIG. The Blakiston Division, McGraw-Hill Book Company, Inc., 330 West 42nd St., New York 36, N. Y., 1962. xv + 742 pp. 15 × 22.5 cm. Price $25.

This one volume reference book on steroid drugs written by one of the pioneers in steroid research and development is divided into four parts: history and background of steroid product development, production processes, steroids in drug therapy, and biologically active steroids. Summaries of progress developments are presented via production flow sheets, process data, charts showing relation of structure to function, and tables of compounds having similar biological activity. This volume also includes a catalog of over 1800 biologically active steroids coded according to their structure which enables the reader to determine whether a structural alteration of a basic steroid has been attempted and the effect of the alteration on its biological activity.

Biochemical Preparations. Vol. 9. Edited by MINOR J. COON. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1962. ix + 149 pp. 14.5 × 22.5 cm. Price $6.95.

This volume contains methods for the preparation of: N-Acetylneuraminlactose, P^{32}-Labeled adenosine 5′-phosphate and deoxycytidine 5′-phosphate, 5-Benzyloxyindole, Enzymatic synthesis of (+)-citramalic acid, Chemical synthesis and resolution of (±)-citramalic acid, Coenzyme Q_{10}, 2-Deoxy-D-ribose 5-phosphate, Reduced diphosphopyridine nucleotide (DPNH) oxidase, D-Glucosamine 6-phosphoric acid and D-mannosamine 6-phosphoric acid, Glutamate-asparate transaminase, γ-Glutamyl-L-cysteine from glutathione, L-α-Glycerylphosphorylcholine, Carboxyl-C^{14}-labeled 3-hydroxyanthranilic acid, D(-)- and L(+)-β-Hydroxybutyric acids, *threo*-γ-Hydroxy-L-glutamic acid, *threo*-γ-Hydroxy-DL-glutamic acid, Carbonyl-C^{14}-labeled 3-hydroxy-DL-kynurenine, Hydroxylapatite for protein chromatography, Hydroxypyruvic acid and lithium hydroxypyruvate, 5-Hydroxy-DL-tryptophan, L-*myo*-Inositol 1-phosphate, Malic dehydrogenase from rat liver, *p*-Nitrophenyl carbobenzoxyglycinate, Oleic acid, Enzymatic synthesis of oleic, linoleic, and linolenic esters of cholesterol, Enzymatic synthesis of ribo- and deoxyribonucleoside 5′-triphosphates, Sphingosine, and Tobacco mosaic virus. A subject index is appended.

Medical Abbreviations. Compiled by the SPECIAL STUDIES COMMITTEE OF THE MICHIGAN OCCUPATIONAL THERAPY ASSOC. Michigan Occupational Therapy Assoc., Occupational Therapy, Dept. of Physical Medicine and Rehabilitation, University Hospital, Ann Arbor, Mich., 1961. v + 241 pp. 11 × 15 cm. Price $2.25.

A paper bound cross reference dictionary compiled from lists of abbreviations obtained from medical centers in an attempt to provide a handbook looking toward the standardization of medical abbreviations.

Practical Neurochemistry. By HENRY MCILWAIN and RICHARD RODNIGHT. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. vii + 296 pp. 15.5 × 23.5 cm. Price $10.50.

Those concerned with neural systems in chemical, biochemical, physiological, pharmacological, or pathological study should find useful information in this book. Practical teaching, demonstrating, and research on the mammalian nervous system are the authors' background for this textbook for undergraduate and graduate students in medicine and science.

Progress in Drug Research. Vol. 3. Edited by ERNST JUCKER. John Wiley & Sons, Inc., Interscience Division, 440 Park Ave. South, New York 16, N. Y., 1962. 563 pp. 16.5 × 24 cm. Price $23.50.

Included in this third annual volume are (in contributed language): Les derives organiques du fluor d′ interet pharmacologique, Structure-activity relationship in certain anthelmintics, Recent research in the field of 5-hydroxytryptamine and related indolealkylamines, Uber neue Arzneimittel, A pharmacological approach to allergy, Krebswirksame Antibiotika aus Actinomyceten. A general subject index is appended.

Biological Alkylating Agents. By W. C. J. Ross. Butterworth Inc., 7235 Wisconsin Ave., Washington 14, D. C., 1962. xi + 232 pp. 13.5 × 22 cm. Price $10.50.

Chemical compounds capable or acting as alkylating agents under certain physiological conditions are considered in this book. Review Article

Gas Chromatography and Its Application to Pharmaceutical Analysis

By E. BROCHMANN-HANSSEN

THE INTRODUCTION of chromatography as an analytical tool is generally attributed to Tswett (1) who coined the term chromatographic adsorption analysis. In principle, there appears to be no restriction on the nature of the mobile and the stationary phases in chromatography, nor on the types of equilibria involved. This was first recognized by Martin and co-workers (2, 3) who used a liquid adsorbed on a solid support as the stationary phase. The solid support might be a finely powdered inert material, such as diatomaceous earth, starch, or glass beads, or it might be sheets or strips of filter paper. In either case, separation took place by a partitioning of the solutes between two immiscible phases. In their first report on the partition chromatographic method, published in 1941, Martin and Synge (2) pointed out that the moving phase need not be a liquid, but might just as well be a gas. In fact, they even discussed the advantages that such a system might have. At the time nobody seemed to realize the tremendous significance of this suggestion, and the idea lay dormant for about 10 years until Martin, this time in cooperation with James, proceeded to work out the experimental technique. Their first paper on gas-liquid chromatography was published in 1952 (4). Actually, the principle of gas chromatography had been used for a long time for the separation of gases by means of a solid adsorbant (5, 6). However, it was the introduction of gas-liquid chromatography by James and Martin which led to the widespread acceptance of gas chromatography in general as an analytical technique. Gas-solid chromatography has remained the standard method for separation of permanent gases and low molecular weight hydrocarbons, while gas-liquid chromatography has become the method of choice for separation, identification, and quantitative determination of a wide variety of complex mixtures. The transition from gas-solid to gas-liquid chromatography is often gradual (7, 8) and, with the low concentrations of liquid phases now commonly used for separation of high boiling compounds, adsorption phenomena and the tailing which results are often difficult to eliminate.

The main advantages of gas chromatography over other modifications of chromatography, in fact over all other separation procedures, are speed, sensitivity, and versatility. The low viscosity of the mobile phase permits a high rate of flow and a fast equilibration between the thin film of liquid and the gas. As a consequence, separation can become very rapid. In many instances half a dozen or more substances may be separated in a matter of a few seconds. The sensitivity of the new ionization detectors is of the order of 10^{-12} Gm. per ml. of gas; 0.01 mcg. or even less can often be detected. A wide variety of stationary liquid phases, from nonpolar to very polar materials, are available for separation of a multitude of substances. Although essentially an analytical technique, gram quantities of very pure

Received from the School of Pharmacy, University of California Medical Center, San Francisco 22.
Supported in part by Grant M-3487 from the National Institutes of Health, Bethesda, Md.

materials can be isolated from high capacity columns.

LITERATURE

In spite of its recent origin, the literature on gas chromatography is already very extensive. More than 1600 papers were published in 1961 alone (9). In addition to the well-known abstracting periodicals dealing with chemical and related literature, two abstracting services devoted exclusively to gas chromatography are available (10, 11). Numerous review articles (9, 12–23), monographs (24, 25), and books (26–31) have been published. Papers presented at national and international symposia on gas chromatography have been collected and published in book form. The purpose of the present review is to present some of the fundamental aspects of gas chromatography in general and to deal in somewhat greater detail with its analytical applications with special emphasis on pharmaceutical analysis.

THEORETICAL PRINCIPLES

In gas-liquid chromatography, one is mainly concerned with the interactions between the solutes and the stationary liquid. There is only one liquid solution to be considered rather than two, as in liquid-liquid chromatography. This relative simplicity, coupled with the speed and reproducibility of gas chromatographic separations, has greatly stimulated an interest in the theoretical aspects of chromatography. Two approaches have been used to explain the various phenomena affecting retention, efficiency, and resolution. The "plate theory," first introduced by Martin and Synge (2) for liquid-liquid partition chromatography and developed further by Glueckauf (32), treats the chromatographic column as a discontinuous system analogous to a distillation column, involving a series of equilibria or theoretical plates. The "rate theory" (33–35) regards the chromatographic column as a continuous medium in which diffusion phenomena and mass transfer are taken into account. A thorough discussion of the theory of gas chromatography is beyond the scope of this review. The reader is referred to the original literature and to the several books and review articles on the subject.

Retention.—When vapors from a sample enter a gas chromatographic column they are retarded by the stationary phase and travel more slowly than the carrier gas itself. The rate at which each solute travels through the column depends, among other things, on its partition coefficient between the stationary liquid and the gas or, in other words, upon its vapor pressure above its solution in the liquid. The volume of gas passing through the column from the time of application of the sample to the emergence of the peak maximum is called the retention volume, V_R

$$V_R = t_R F_c \qquad \text{(Eq. 1)}$$

where t_R is the retention time measured from the time of sample injection to the appearance of the peak maximum, and F_c is the flow rate of the carrier gas measured at the outlet pressure and at the temperature of the column. The compressibility of the gas causes its linear velocity to increase along the length of the column due to a drop in pressure from the inlet to the outlet. The corrected retention volume, V_R^o, is calculated by introducing a correction factor, f, for the pressure drop in the column (4)

$$V_R^o = f V_R = f\, t_R F_c \qquad \text{(Eq. 2)}$$

where $f = {}^3/_2[(p_i/p_o)^2-1]/[(p_i/p_o)^3-1]$, p_i and p_o being the carrier gas pressure at the inlet and the outlet, respectively. Correction should also be made for the "dead volume" or "gas holdup" of the column, V_G^o. V_G^o may be estimated (36, 37) from the retention time of homologous compounds or measured as the corrected retention volume of a gas which will not be adsorbed by the column liquid, such as air

$$V_N = V_R^o - V_G^o = f\, t\, F_c \qquad \text{(Eq. 3)}$$

where V_N is the net retention volume, corrected for the pressure drop of the column, and t is the net retention time measured as the time between the air peak and the peak for the component being analyzed.

A fundamental equation relating the corrected retention volume to the partition coefficient and the amount of stationary liquid in the column is given by

$$V_R^o = V_G^o + K V_L = V_G^o + Kw/\rho \qquad \text{(Eq. 4)}$$

where K is the partition coefficient, V_L is the volume and ρ the density of the stationary liquid, both at the column temperature, and w is the weight of the liquid phase in the column. In order to obtain an expression for the retention volume that would be independent of the amount of liquid phase, Littlewood, Phillips, and Price (38) introduced the symbol, V_g, usually referred to as the specific retention volume. It is the net retention volume per gram of liquid phase reduced to standard temperature and pressure

$$V_g = 273\, V_N/Tw = 273\, K/T\rho \qquad \text{(Eq. 5)}$$

where T is the column temperature in °K.

Equation 4, relating the corrected retention volume to the product of the partition coefficient and the volume of stationary liquid, does not account for the changes in elution sequence which sometimes occur with changes in the concentration of liquid phase on the column. Martin (39) suggested that such changes, which are especially predominant with highly polar liquid phases, are due to adsorption of the solute on the surface of the liquid. He has modified Eq. 4 to include this phenomenon.

Column Efficiency.—The efficiency of a gas chromatographic column may, in the same way as a distillation column, be described in terms of its number of theoretical plates and calculated from the chromatogram by the expression

$$n = 16\,(t_R/b)^2 \qquad \text{(Eq. 6)}$$

where b is the base (in the same units as t_R) of the triangle formed by the tangents through the inflection points of the peak. The length of the column required to establish the equivalent of one equilibration between the gas phase and the stationary liquid is called "the height equivalent to a theoretical plate" (HETP). This value is obtained from the total number of plates (n) and the length of the column (l)

$$\text{HETP} = l/n \qquad \text{(Eq. 7)}$$

In linear, nonideal chromatography, such as gas-liquid chromatography, and in the absence of adsorptive effects, the peaks are symmetrical or nearly so, approximating a Gaussian distribution curve. However, the bands tend to broaden as they move down the column and the longer the retention time of a solute, the wider the emerging peak. This band broadening which reduces the efficiency of the column is due to several factors involving diffusion phenomena and resistance to mass transfer. Van Deemter, Zuiderweg, and Klinkenberg (34) have expressed the relationships as follows

$$\text{HETP} = A + B/u + Cu \qquad \text{(Eq. 8)}$$

or more fully

$$\text{HETP} = 2\lambda d_p + \frac{2\gamma D_{\text{gas}}}{u} + \frac{8}{\pi^2} \cdot \frac{K'}{(1+K')^2} \cdot \frac{d_f^2 u}{D_{\text{liq}}} \qquad \text{(Eq. 9)}$$

where λ is the statistical irregularity of the packing, d_p is the particle diameter of the support, D_{gas} and D_{liq} denote the molecular diffusion in the gas and the liquid phases, respectively, u is the average linear gas velocity of the carrier gas, γ is the labyrinth factor or tortuosity constant of the paths in the column, K' represents the product of the partition coefficient, K, and the ratio of the liquid volume to the gas volume of the column, and d_f is the mean diameter of the liquid film on the support.

The term A, referred to as "eddy diffusion," is due to the irregularities of stream paths in a porous medium. Van Deemter, *et al.* (34), found it to be independent of flow rate. It can be reduced by careful packing and by using uniform particle size of small diameter (40, 41). B represents molecular diffusion which is inversely proportional to the gas velocity, and C is concerned with resistance to mass transfer, expressing the lack of equilibration between the two phases. The effects of these factors are illustrated in Fig. 1 in which HETP is plotted against the average linear velocity of the carrier gas. The van Deemter equation has been widely discussed and there is general agreement that it presents a reasonably good picture of the conditions responsible for the spreading of chromatographic zones. However, recent work by several investigators has indicated a need for an additional term or terms similar to the C term, dealing with resistance to mass transfer in the gas phase (42, 43). The A term has also been the subject of much speculation and controversy (44, 45).

As expressed in the van Deemter equation and by several investigators, the apparent column efficiency is affected by the nature, flow rate, and pressure gradient (46, 47) of the carrier gas, the particle size of the support and the density of the

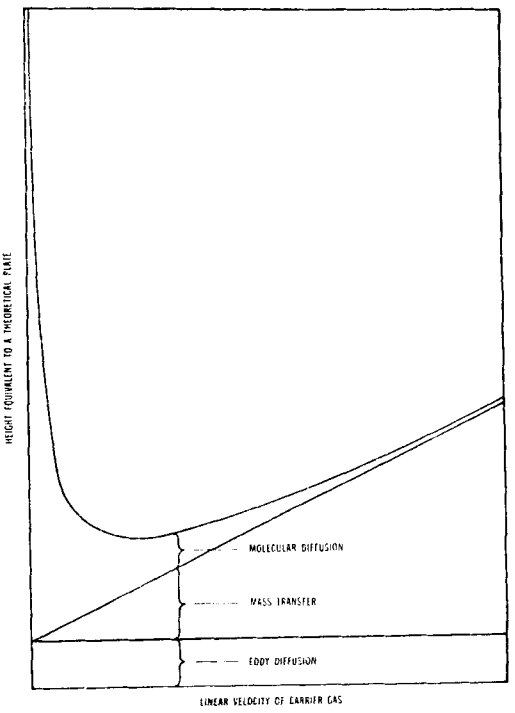

Fig. 1.—Effect of gas velocity on HETP. [After T. Johns (258); courtesy of Beckman Instruments.]

packing, the amount and type of liquid phase (49–51), the size and type of sample (40, 48), the column temperature (49, 50), the length of the column, and the conditions of sample introduction (51, 52). The response time and volume of the detection system are also important considerations (53, 54). Most packed gas chromatographic columns in use today have efficiencies of the order of 500 to 1000 theoretical plates per foot although much greater efficiency can be attained (41, 55). Golay (56) has suggested a "performance index" as a measure of column efficiency and has calculated on a theoretical basis the performance index for an ideal gas chromatographic column. From the difference between this theoretical value and those found in practice, he concludes that there is much room for improvement in basic column design.

Selectivity.—The relative position of the peaks in a gas chromatogram depends upon the relative vapor pressures of the solutes above the liquid phase in the column. The separation of two components in a mixture may, therefore, be expressed as the ratio of the partition coefficients or of the net retention volumes

$$\alpha_{1,2} = \frac{K_2}{K_1} = \frac{\gamma_1^o p_1^o}{\gamma_2^o p_2^o} = \frac{V_{N2}}{V_{N1}} \qquad \text{(Eq. 10)}$$

where α is the relative volatility of substances 1 and 2, γ_1^o and γ_2^o are the activity coefficients, of the solutes in the solvent at infinite dilution, and p_1^o and p_2^o are the vapor pressures of the pure substances.

Where there is little interaction between the solutes and the liquid phase, or where the solute-solvent interactions are of the same magnitude as the interaction between the solute molecules, gas chromatographic separation takes place largely according to the boiling points of the pure substances (57). Such stationary phases are nonselective. Nonpolar liquids, such as saturated hydrocarbons and alkylsilicones, belong to this group. Selectivity increases rapidly with increasing polarity due to the various cohesive forces operating between the solute and the liquid phase. A selective phase is one which will cause separation of substances which have the same boiling points but are of different molecular types (58–60). If $p_1^o = p_2^o$, Eq. 10 becomes

$$\alpha_{1,2} = \frac{\gamma_1^o}{\gamma_2^o} \qquad \text{(Eq. 11)}$$

This ratio has been referred to as the selectivity coefficient (58, 59). Hydrogen bonding plays a very important role in the solute-solvent interaction on polar liquid phases. This was clearly shown by James (61) in the separation of primary, secondary, and tertiary amines. On a nonpolar stationary liquid, the amines emerged in the order of increasing molecular weights, namely in the order of primary, secondary, and tertiary amines. On a very polar column the sequence was reversed, which is the order of increasing hydrogen bonding.

Permanent or induced dipoles in the solute will give rise to interaction with polarizable groups in the solvent and can be used for separation on selective stationary liquids (57). Formation of weak complexes has also been exploited as a means of increasing selectivity (62).

Resolution.—Resolution of closely related compounds in a mixture depends both on the efficiency of the column and on the relative volatility of the solutes in the stationary liquid. The relationship between column efficiency and resolving power has been studied by many workers (32, 55, 63–66).

An important parameter for effective separation is the ratio between the dead volume of the column, V_G^o, and the net retention volume of the solute, V_N. With a reduction in the amount of stationary phase on the column, the plate number often increases while the degree of separation decreases for components with a given relative volatility. This is, at least partly, compensated for by the lower temperature required with lightly loaded columns resulting in increased relative volatility (67). Purnell (55, 63) has defined a separation factor, S, which measures the ability of a chromatographic column to achieve a particular separation

$$S = 36\,[\alpha/(\alpha - 1)]^2 \qquad \text{(Eq. 12)}$$

From S the number of theoretical plates required for separation of two components, for which the relative volatility is known, can be calculated

$$n = 36\,[\alpha/(\alpha - 1)]^2[1 + 2\,(V_G^o/V_N) + (V_G^o/V_N)^2] \qquad \text{(Eq. 13)}$$

Purnell (55) showed that compounds with an α value of 1.15 will be completely separated on a column having 1500 theoretical plates if V_G^o is negligible, whereas, 40,000 plates are required if the ratio V_G^o/V_N is 10.

RECENT ADVANCES IN INSTRUMENTATION AND TECHNIQUES

Detectors.—There has been considerable development in the field of detectors for gas chromatography since James and Martin (4) analyzed eluted acids by a titration procedure. Although the workhorse among detectors for many years has been the katharometer, this de-

tector cell does not possess the sensitivity necessary for the small sample sizes commonly used with high molecular weight compounds and with capillary columns. In 1958, Lovelock (68, 69) described a β-ray ionization detector which was extremely sensitive, and it has since become very popular for gas chromatography in the biochemical field. Argon is used as a carrier gas and is bombarded by α- or β-rays from a radioactive source inside the detector cell. This produces some argon ions and electrons which are accelerated by a high electric field of about 1000 v., reaching velocities sufficient to excite a large number of argon atoms to their metastable state. These excited species normally revert to ground state by emission of electromagnetic radiation. However, if they undergo collision with a molecule having an ionization potential below 11.6 e.v., the metastable argon gives up its excitation energy, thereby causing ionization of the colliding molecule. The ionization current produced in the electric field is amplified and recorded.

Another detector which is extensively used, both because of its high sensitivity, linearity of response, small volume, and simplicity of design is the hydrogen flame ionization detector developed by McWilliam and Dewar (70). The effluent from the column is mixed with hydrogen and fed through a jet where the gas is burned. Ions are formed in the flame by a mechanism of chemi-ionization (71). These are attracted to a collector electrode, thus producing an ionization current which is amplified and recorded.

Other detectors of interest include those based on electron capture (69, 72, 73), thermionic emission (74), and glow discharge (75).

The Column.—From Eq. 4 it is apparent that the retention volume is very much dependent on the amount of stationary liquid in the column. When columns with liquid loadings of the order of 0.5 to 3% are used, instead of the usual 15 to 30%, it becomes possible to decrease substantially retention volumes for compounds of low volatility. By taking advantage of the high sensitivity of the ionization detectors, the sample size can be reduced to such an extent that it will vaporize rapidly into the gas stream at temperatures which are 100 to 200° below the boiling points of the components. At the same time, improvements in instrument design and a greater variety of thermostable stationary phases have extended the range of application to high column temperatures.

An important development in gas chromatographic columns was initiated by Golay (76, 77) who proposed to use capillary tubing coated on the inner surface with the stationary phase instead of packed columns. These capillary columns, which are usually made from stainless steel, glass, or nylon tubing, range in length from 50 to several hundred feet. Efficiencies approaching a million theoretical plates have been achieved, but this is not directly comparable with the efficiencies of packed columns. The performance of coated capillary columns with respect to speed, column efficiency, and resolution has been thoroughly studied by Desty and co-workers (78–80). Purnell (55, 63) has shown that analyses performed with very long capillary columns of up to one-half million plates can be closely reproduced by a 7-ft. packed column of 5000 plates in about one-hundredth the time. Capillary columns have very low capacities and rarely operate efficiently if the quantity of any single component to be separated exceeds 10^{-7} Gm. A sample splitting device between the injection port and the column is, therefore, essential. There is still considerable controversy regarding the relative merits of packed columns and capillary columns. Undoubtedly, both types have their strengths and weaknesses. Although capillary columns have gained considerable popularity for separation of closely related compounds, especially in the petrochemical field, it is unlikely that they will replace the packed columns completely for analytical gas chromatography.

Tailing.—When polar materials are gas chromatographed on a nonpolar liquid phase, tailing can often cause considerable problems. It will distort the symmetry of the peaks, interfere with clean-cut separation, and make quantitative analysis very difficult. This is especially true if the concentration of liquid phase is low. The reason for this tailing effect is that most solid support materials are not completely inert, but contain active spots which cause adsorption. When adsorption takes place, the retention time is much influenced by the sample size. Large samples cause an earlier appearance of the front accompanied by a peak broadening. This has been attributed to a Langmuir adsorption isotherm which has reached the saturation limit (81). The effects of the solid support material on the retention volumes have been studied by Scholz and Brandt (82), Bens (83), Weinstein (84), and others. Adsorptive effects are due to weak van der Waals forces and strong hydrogen bonding forces, caused mainly by the presence of free hydroxyl groups on the support material. Several methods of deactivation have, therefore, aimed at removing the hydroxyl groups by reaction with dichlorodimethyl silane (85, 86), hexamethyldisilazane (81, 82), or by methylation (*cf.* 82).

Ormerod and Scott (87) have reported that silver coating of firebrick drastically reduces adsorptive effects. Others have added small amounts of fatty acids (4, 88), their salts (89), or various surface-active agents (81, 90, 91). These tend to deactivate hydrogen bonding sites, spread the stationary phase over the surface of the support, and possibly act as a "glue" to span the interface between the liquid and the solid (91). Addition of small amounts of a very polar stationary liquid to a nonpolar liquid will markedly reduce tailing without changing the retention values (81, 88, 92).

Temperature Programing.—Because of the band broadening factors expressed in the van Deemter equation, the peaks of a normal isothermal gas chromatogram become wider and lower as the retention time increases. Furthermore, it is possible for high boiling components to go undetected because of very long retention times (93–95). By increasing the temperature during the run of a chromatogram, it is possible to separate rapidly a mixture of components boiling over a wide range of temperature, and all solutes emerge as sharp, well-defined peaks of nearly the same shape (Fig. 2). With a linear temperature rise, each solute is eluted at a characteristic retention volume in the same way as for isothermal gas chromatography (96). The theoretical aspects of temperature-programed gas chromatography have been discussed by Giddings (97) and Said (98). Many commercial instruments have incorporated the feature of temperature programing. Dual column systems are sometimes used in order to maintain a stable base line by canceling the effects of increased column bleeding at higher temperatures (99).

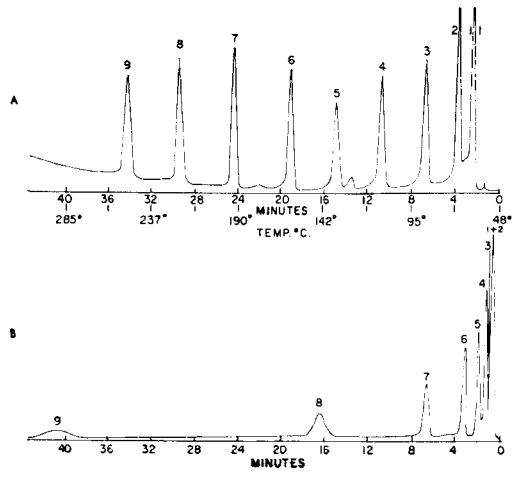

Fig. 2.—Gas chromatography of alcohols. A, temperature programing; B, isothermal gas chromatography at 165° of (*1*) methanol, (*2*) ethanol, (*3*) 1-propanol, (*4*) 1-butanol, (*5*) 1-pentanol, (*6*) cyclohexanol, (*7*) 1-octanol, (*8*) 1-decanol, and (*9*) 1-dodecanol. Sample Pyrolysis.—Organic substances, upon heating, undergo various decomposition reactions, the mechanism of which depends upon the structure of the molecules. Although the pyrolysis reactions are often extremely complex, they are reproducible under constant conditions. Pyrolysis has been used in conjunction with gas chromatography by several investigators (100–111) both for qualitative and quantitative analysis. The principle is simple. The product to be studied is applied to a filament which is placed in the stream of carrier gas. The filament is heated at a predetermined temperature for a few seconds by means of an electric current, and the pyrolysis products are carried by the gas stream to the column for separation. The method is particularly suited for analysis of polymers which, at a certain temperature, depolymerize to give the original monomers (111). However, numerous other compounds have been analyzed by this method, including amino acids, barbiturates, alkaloids, and steroids.

APPLICATIONS

Qualitative Analysis.—Identification of components in a mixture by gas chromatography is most frequently based on retention data which are related to the R_f value commonly used in paper chromatography. A comparison of the retention volumes (or times) of the unknown constituents with those of known compounds will often suffice to identify the former. However, the retention volumes are dependent on experimental conditions, many of which cannot be easily reproduced. It has, therefore, been recommended that retention data be reported in absolute units, such as specific retention volumes or partition coefficients. Somewhat simpler, from an experimental point of view, is the use of relative retention volumes (or times), where the effects of operating parameters are considerably reduced, depending mainly on the nature of the stationary phase and on the column temperature. The relative retention values are expressed by

$$r_{1,2} = \frac{V_{N1}}{V_{N2}} = \frac{V_{g1}}{V_{g2}} = \frac{V'_{R1}}{V'_{R2}} = \frac{t_1}{t_2} \quad \text{(Eq. 14)}$$

where the subscripts 1 and 2 stand for the sample component and the standard, respectively, V'_R is the net uncorrected retention volume, and t is the net retention time measured from the air peak to the sample peak.

Several modifications of this principle have been proposed. Evans and Smith (112), using a primary standard (*n*-nonane) and one or more internal standards, express the retention of the unknown relative to that of *n*-nonane as follows

$$R_{X9} = R_{XN} \cdot R_{N9} \qquad \text{(Eq. 15)}$$

where R_{X9} is the retention of the unknown relative to *n*-nonane, R_{XN} is its retention relative to the internal standard, and R_{N9} is the retention of the internal standard relative to *n*-nonane. Two internal standards are used whenever possible, one emerging on either side of the unknown, and the mean R_{X9} value is determined.

A closely related method is used by Kovats (113–116), who calculates a "retention index" on the basis of two reference standards.

The logarithm of the net retention volume of a substance is proportional to the free energy of solution of the solute molecules in the stationary phase. The free energy of solution is an approximately additive function of the groups constituting the molecule. Therefore, if the logarithm of the net retention volume (or relative retention volume) is plotted against some increasing property, such as the number of carbon atoms in a homologous series, a straight line is obtained. The slope of this line depends on the nature of the stationary phase (61, 117, 118).

In a complex mixture, there is always the possibility of two or more substances having the same retention characteristics on a particular column. This uncertainty with respect to separation and identification can be greatly reduced by making use of two or more columns of different polarity. Many methods are based on this principle. Lewis, Patton, and Kaye (119) used homologous series plots in which the logarithms of the elution times obtained on a nonpolar column were plotted against those obtained on a polar column. James (25) used log plots of the relative retention volumes for two stationary phases as a means of characterizing fatty acids. Brown (120) proposed a three-column method, basing the identification of the components of brown coal tar on the retention data measured with three different types of stationary liquids: a nonpolar liquid, an electron donor, and an electron acceptor. He defined an "affinity fraction," A, of the substance to be identified for each phase as

$$A_1 = r_1/(r_1 + r_2 + r_3)$$

where r_1, r_2, and r_3 are the retention volumes (or times) on the three stationary liquids under controlled conditions. The affinity fractions of a given substance in the three liquids were plotted on a triangular graph.

Because of the efforts required to achieve positive identification of complex mixtures solely on the basis of retention characteristics, many investigators have preferred to use gas chromatography in combination with chemical reactions or auxilliary instrumentation.

Walsh and Merritt (121) used a combination of retention volume and functional group analysis for the identification of chromatographic peaks. The functional group classification was accomplished by means of a stream splitting device attached to the exit tube from a thermal conductivity cell. As each chromatographic peak passed through the detector, the gas stream was split and the vapor collected in a set of reagents. A similar procedure was used by Dubois and Monkman (122). Various other chemical reactions, both before and after chromatographic separation, have been proposed for identification purposes (123, 124).

The combination of a gas chromatograph and a time-of-flight mass spectrometer is extremely useful for rapid and positive identification of complex mixtures. The mass spectra of the components can be scanned and recorded simultaneously with the running of the chromatograph (125, 126). The input system to the spectrometer can be designed so as to trap the sample from the column, letting it leak into the spectrometer long enough to allow the analog output system to record the spectrum.

Identification of gas chromatographic peaks by means of infrared or ultraviolet spectrophotometry is also extensively used (127–134). The fractions may be collected in a solvent or in solid potassium bromide and the appropriate analyses made, or a continuous scanning of the gaseous eluate may be carried out.

Another means of identification which is likely to become increasingly important is to use a combination of a selective and a nonselective detector. The electron capture detector is a selective detector having a high degree of specificity for halogenated compounds as well as for conjugated carbonyls and organometals (72, 135). Hydrocarbons, alcohols, amines, ketones, etc., produce virtually no response. Varadi (136) has developed an ionization detector which gives both qualitative and quantitative information. It is composed of a thermionic ionization detector unit for quantitative determination combined with a radio-frequency m/e analyzer, where the characteristic mass number of the gas component can be

determined. The signals from both detector parts are amplified and recorded on separate recorders.

Quantitative Analysis.—With a differential detector in combination with a potentiometric strip chart recorder, the substances appear as peaks having the dimensions of (millivolts) (time). The areas of these peaks are related to the concentration of component vapor in the carrier gas. The factor for converting peak area into weight varies with the detection system, the carrier gas, and the component to be determined. For accurate work, the detector response must be linear over a reasonable range of vapor concentration in the carrier gas. Accuracy and precision also depend on the sensitivity and stability of the detector and amplifier, on the method of sample application, and, in the case of capillary columns, on the linearity of the stream splitting system. Gas samples can be applied to the column with great accuracy by means of a gas sampling valve. For liquids and solids the problem is not nearly as simple, and many attempts have been made to develop reproducible sampling techniques. With the small samples required for very high boiling materials, especially in conjunction with ionization detectors and capillary columns, a simple syringe technique is commonly used although the sample size cannot be accurately reproduced. This usually requires an internal standard for calibration. A known amount of a reference substance is added to the sample and the mixture chromatographed. The composition of the sample is obtained from a standard curve based on chromatograms of several accurately known mixtures of the standard and the sample components. Two or more internal standards should be used if the sample contains substances with a wide range of boiling points (137).

Another method frequently used is referred to as internal normalization. If the detector response is approximately equal for all the components in a mixture, the total area under all the peaks is normalized to 100% and each peak calculated as a percentage of the total. If the detector response is markedly different for the different constituents in the sample, and this is usually the case, correction factors must be applied to each peak before they are added and proportioned.

Various methods have been proposed for the measurement of peak area. The simplest method which still gives reasonably good results when the peaks are symmetrical and well separated is triangulation, in which the area is assumed to be equal to the area of the triangle formed by the tangents through the points of inflection and the peak base. Greater precision can be achieved by means of a planimeter, although measurement errors for small peaks can be considerable. Besides, the method is slow and subject to operator fatigue. Based on the fact that gas chromatographic peaks, in the absence of adsorptive effects, closely approximate a Gaussian distribution curve, Bartlet and Smith (138) calculated peak areas from the peak height and the standard deviation for the curve by the formula

$$A = h\sigma\sqrt{2\pi} = 2.507\ h\sigma \qquad \text{(Eq. 16)}$$

where A is the area, h is the peak height, and σ the standard deviation for the normal distribution curve corresponding to the peak (= one-half peak width at 0.607 h).

The most accurate estimation of peak area may be obtained by a number of integrators based on analog or digital computation. A widely used type of analog computor is the ball and disk integrator which is relatively simple and inexpensive. It has an inherent accuracy within ±0.1% of full scale, and with proper care and operation a high degree of precision may be achieved (139). Recorder-integrator errors in gas chromatography area measurements have been studied by Orr (140). A formula has been developed to correct for these errors. With careful work, quantitative analysis by means of gas chromatography can give a high degree of precision and accuracy. This has been shown by many workers, but perhaps most clearly by Evans and Scott (141). Based on 110 consecutive determinations, the overall spread was 1%, the coefficient of variation 0.23%, and the 95% confidence limits ±0.35%. This compares very favorably with most instrumental methods of analysis.

Although gas chromatographic columns should be chosen so as to produce optimal separation, a complete resolution cannot always be obtained. Quantitative analysis may be made even if the peaks are overlapping. The problems involved and the methods used to overcome them have been discussed by several investigators (138, 142, 143).

ANALYSIS OF COMPOUNDS OF PHARMACEUTICAL INTEREST

It is only natural that the early applications of gas chromatography to pharmaceutical analysis have been concerned with very volatile

materials, such as anesthetic gases (144), alcohols, and other solvents, including water (145–149), nitroglycerin (145), essential oils, and their constituents (145, 150–155). In fact, gas chromatography has been a great impetus to the study of essential oils and perfumes, as well as the flavor and aroma substances present in food and beverages (156, 157). Because of the complex nature of these materials, no satisfactory method for a thorough, objective analysis was available until gas chromatography was developed. It is now possible, in a short time, to identify a volatile oil on the basis of the retention data and peak ratios of the chromatogram, and the components can be determined quantitatively. The method can also be used to detect adulterations and even to determine the geographical origin of the oil (158).

Gas chromatography has been used for monitoring the concentration of anesthetics in the patient's breath during the course of an operation (159) and to determine the absorption, distribution, and elimination of diethyl ether (160–162). Ether and chloroform, as well as various essential oil constituents, have been determined quantitatively in a variety of pharmaceutical preparations (150, 152, 163, 164).

Gas chromatography was developed in connection with the separation of organic acids, and a tremendous amount of work has been done in biochemical research involving studies of fatty acids and lipids and their metabolism in man and animals. The fatty acids are usually converted to the methyl esters by one of several methods (165) although the free acids may also be gas chromatographed (4, 166–168). Various polyesters are particularly selective for separation and identification of fatty acid esters (169, 170). The specific distribution of fatty acids in the glycerides of vegetable fats has been studied by means of gas chromatography (171) which promises to be an exceptionally useful method for quality control of fats and oils, including identification, detection of adulteration, and misbranding (172), and determination of the amounts of free fatty acids present (173). More recently it has been shown that the triglycerides may be gas chromatographed directly (174–176). Whether this method will prove to be more valuable than the standard procedure based on the fatty acid methyl esters still remains to be seen.

The resin components of marihuana (*Cannabis sativa*) have been separated by Kingston and Kirk (177) and by Farmilo and Davis (178). In addition to the major component, cannabinol, a large number of smaller peaks illustrate the complex nature of this material. The method appears to be of value for determination of the origin of seized marihuana.

Although aliphatic amines were among the first substances gas chromatographed by James (61), it is only recently that the method has been applied to pharmaceutically important amines. Brochmann-Hanssen and Svendsen (179, 180) have gas chromatographed a number of commonly used sympathomimetic amines on silicone rubber SE-30 and achieved excellent separation in most instances. The reaction between amines and ketones is useful for identification purposes and to separate certain isomers, such as ephedrine and pseudoephedrine. The catechol amines, epinephrine and norepinephrine, have been gas chromatographed after treatment of the triacetyl derivatives with hexamethyldisilazane.

Fales and Pisano (181) have also separated a number of biologically important amines including histamine, seratonine, tyramine, and some sympathomimetics.

In a recent publication Parker, Fontan, and Kirk (182) reported gas chromatographic separation and identification of a large number of tranquilizers, including phenothiazine derivatives, diphenylmethane derivatives, butanediols, propanediols, and others. No peaks were observed after application of rauwolfia alkaloids. Occasionally, following storage of some of the tranquilizers, new small secondary peaks appeared which increased in height with the passage of time. This suggested a possible application of the method to quality control during manufacture.

Gas chromatography of phenothiazine derivatives has also been reported by Anders and Mannering (183).

During the past year, the barbiturates and some related substances have been successfully gas chromatographed on various stationary liquids in low concentration (184–186). Not all compounds can be separated on the same column, but by using two columns, one with a nonpolar phase such as Apiezon L and one with a moderately polar polyester, a large number of possible combinations can easily be separated. The method has been used for identification of pharmaceutical preparations and for the study of the metabolism and excretion of barbiturates in humans (186, 187). The partial transformation of phenobarbital to *p*-hydroxyphenobarbital, and the demethylation of N-methyl substituted barbituric acid derivatives have been confirmed

by means of gas chromatography.

Stainier and Gloesener (188) have analyzed certain ester alkaloids and related synthetic drugs by hydrolysis and gas chromatography of the liberated alcohols. However, such pretreatment is usually not necessary. The volatile tobacco alkaloids can easily be gas chromatographed, as was shown by Quin (189–191) in 1958. More surprising is the fact that many alkaloids of high molecular weights and relatively low stability can be gas chromatographed as such. This was first demonstrated by Lloyd, *et al.* (192), who gas chromatographed 45 different alkaloids on low-loaded columns of silicone rubber SE-30. In this way, strychnine was separated from brucine, quinine from cinchonine, and the various major alkaloids in opium were separated from one another. Eddy, *et al.* (193), used this method for the determination of the geographical origin of opium. Brochmann-Hanssen and Svendsen (194) also applied gas chromatography to the separation and study of alkaloids in several crude drugs. Alkaloidal salts were gas chromatographed directly without prior isolation of the base. The salts dissociated in the flash heater which was maintained at about 325°, and the alkaloids were eluted as the free bases. The decompositions sometimes observed when certain alkaloids were subjected to gas chromatography were discussed (194).

Few classes of drugs are of greater importance than the steroids. Therefore, when it was shown in 1960 (195, 196) that steroids could be analyzed by gas chromatography with little or no decomposition, this created a tremendous interest among biochemists and pharmaceutical chemists. A new tool had become available for research in this area, and during the last two years an impressive amount of work has been done with it, particularly by Horning and his co-workers. Silicone rubber SE-30, the more polar and more selective fluorosilicone fluid QF 1-0065 (197), and various heat-stable polyesters (198, 199) have been found to be satisfactory stationary phases for gas chromatography of steroids. The method has been applied to corticosteroids (200, 201), androgens (199, 202), estrogens (202, 203), steroidal amines (204), sapogenins (205), cholesterol (86, 196), bile acids (86, 202), vitamin D (207), etc.

Synthetic estrogens, such as diethylstilbestrol, have been estimated in extracts of tissue, feces, and urine (208).

Several attempts have been made over the years to separate mixtures of amino acids by gas chromatography. The amino acids are not sufficiently volatile to be gas chromatographed directly, but may be converted to volatile products by various reactions. These include oxidation to aldehydes (209, 210), reaction of the amino group with acetic anhydride or trifluoroacetic anhydride followed by esterification of the carboxyl group (211–215), or treatment with hexamethyldisilazane (216). Pisano, *et al.* (217), have gas chromatographed the phenylthiohydantoin and the dinitrophenyl derivatives of amino acids.

The best results so far appear to have been obtained by Johnson, *et al.* (215, 218), who have separated a large number of amino acids as the *n*-amyl esters of the N-acetylamino acids. The method has been applied to hydrolysates of peptides and proteins (218).

Carbohydrates, including mono-, di-, and trisaccharides, as well as simple glycosides, have been gas chromatographed, either as the methyl ethers (219–223), the acetates (224–226), or the trimethylsilyl ethers (227). Using a column of fluorosilicone fluid QF 1-0065, Horning, *et al.* (226), separated the tetraacetates of α- and β-glucose. No separation was achieved with the less selective silicone rubber SE-30.

SPECIAL PROBLEMS IN PHARMACEUTICAL ANALYSIS

Determination of Purity.—An important aspect of pharmaceutical analysis is concerned with the identification and determination of trace impurities, and gas chromatography is excellently suited for this purpose. Bennett, *et al.* (228), have determined trace amounts of impurities in various solvents with a reproducibility of better than 2% for well-resolved peaks. Figure 3 illustrates the importance of instrument sensitivity. Chromatograms I and II are typical runs obtained with conventional equipment. Runs III and IV were made at a one hundred-fold increase in sensitivity. The total concentration of impurities in the cyclohexane sample was 0.3% and could not be detected by infrared analysis. Maruyama and Seno (229) determined trace amounts of methanol in ethanol and reported a detection limit of 0.005%. Impurities in chloroform have been studied by Gloesener (230). An interesting report by Iguchi, *et al.* (231), describes the application of gas chromatography to the determination of trace amounts of arsenic. The sample is reduced with zinc and acid, and the arsine is gas chromatographed with hydrogen as the carrier gas. As little as 1 mcg. could be detected, while the limit for quantitative determination was 4 mcg.

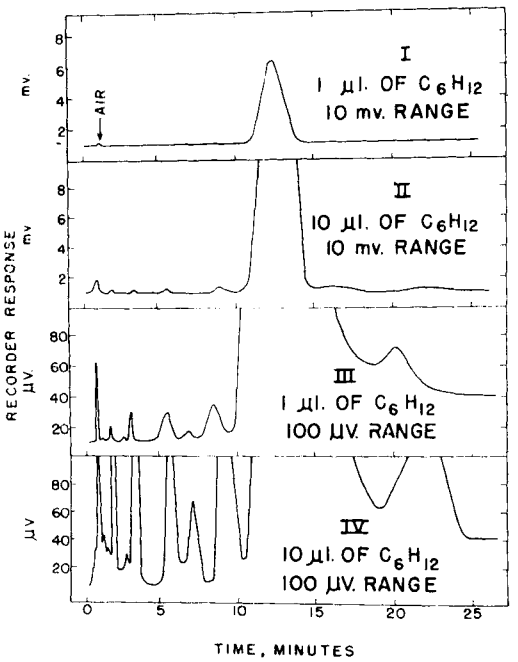

Fig. 3.—Chromatograms of cyclohexane at 10 mv. and 100-µv. full-scale sensitivity ranges. [After C. E. Bennett, *et al.* (228); courtesy of *Analytical Chemistry*.]

Using a column of toluene on granular Teflon and a temperature of −78°, Bergmann and Martin (232) separated bromide and chloride as the hydrogen halides. The sample was added to 70% sulfuric acid, whereby the halide ions were converted to the covalent hydrogen halides which were collected in a nitrogen trap and then gas chromatographed. Concentrations down to 0.01 p.p.m. in water could be detected. The method also permitted easy determination of trace amounts of chloride in bromide, a difficult analysis by other methods.

Much work has been done in the field of pesticide residues on fruits and vegetables. The electron capture detector is excellent for analysis of chlorinated pesticides because it permits determination of submicrogram amounts of the pesticides in the presence of a considerable excess of coextracted material (233). Coulson, *et al.* (234), used a coulometric detection system for quantitative analysis of halogenated pesticide residues.

A concentration technique is frequently needed in order to eliminate interference from other components in the sample (235, 236). Hornstein, *et al.* (173), determined the free fatty acids in fat emulsions by adsorption on an anionic exchange resin, esterification of the acids on the resin by means of methanol and hydrochloric acid, and gas chromatography of the isolated methyl esters. Trace components in an essential oil were determined after all polar matrix compounds had been removed by adsorption on silica gel (237).

Elemental Analysis.—Rapid methods have been developed for determination of carbon and hydrogen by means of gas-solid chromatography (238, 239). The organic sample is burned in a stream of oxygen, and the resulting carbon dioxide and water vapor are passed through a calcium carbide tube which converts the water to acetylene. The gases are concentrated in a freeze trap and then vaporized and swept into the chromatographic system by the carrier gas. The method is claimed to be very precise (0.5% for carbon and 0.1% for hydrogen) and more rapid than conventional methods. The time of analysis is about 20 minutes for a single determination and about 10 minutes each for a continuous series of analyses including area measurements (238). Vogel and Quattrone (240) have modified the method somewhat. Using gas-liquid chromatography with dodecyl phthalate as the stationary liquid and oxygen as the carrier gas, they eliminated the need for isolating the products of combustion from the combustion atmosphere.

Direct gas chromatographic analysis of oxygen in organic compounds has been reported by Goetz (241) and by Suchanec (242). Oxygen is converted to carbon monoxide at high temperatures by means of charcoal (241) or a platinum-carbon mixture (242). Suchanec reports a standard deviation of ±0.17%. Gas chromatographic methods are also available for determination of organically bound nitrogen (243) and sulfur (244).

Determination of Surface Area.—Surface area and particle size determinations are often of considerable importance in studies related to formulation of pharmaceutical dosage forms. This is a field in which gas chromatography has been particularly useful. In 1958 Nelsen and Eggertsen (245) described a method for determination of surface area based on adsorption chromatography.

The column packing is the sample whose surface area is to be determined and the mobile gas is a mixture of a suitable adsorbate (nitrogen) and an inert gas (helium). A known mixture of nitrogen and helium is passed through the sample in a U-shaped tube, the effluent being monitored by a thermal conductivity detection system. When a stable base line is obtained, the sample tube is immersed in liquid nitrogen. The sudden cooling causes absorption of nitrogen

and a corresponding negative peak on the recorder chart. After the equilibrium condition is established again, as indicated by the return of the recorder pen to the base line, the coolant is removed, causing desorption of nitrogen from the sample and a positive peak on the chart. Both peak areas are of the same size, being a function of the amount of nitrogen absorbed by the sample, and may be used for surface area measurements by either an absolute or a comparative method. Modifications of this method have been described by Roth and Ellwood (246) and by Stock (247).

Separation of Isomers.—A problem which has intrigued pharmaceutical chemists for a long time is the separation of isomers, particularly optical isomers.

Partial separation of racemic mixtures has been reported by means of an optically active stationary liquid such as *d*-tartaric acid ethyl ester (248). However, best results seem to have been achieved so far by converting the optical isomers to diastereomeric derivatives prior to the gas chromatographic analysis. In this way, Casanova and Corey (249) separated the optical isomers of camphor as ketals prepared from D(-)-2,3-butanediol. The choice of liquid stationary phase was very critical, as was also shown in the separation of the four stereoisomeric racemates of menthol. Using Hyprose SP-80 [octakis (2-hydroxypropyl) sucrose] and a 12-ft. column, Moore and Kossay (250) were able to determine quantitatively menthol, isomenthol, neomenthol, and neoisomenthol obtained by catalytic hydrogenation of thymol. The amounts of the various isomers in peppermint oil can also be determined (158, 251). Optical isomers are not separated by this procedure.

Bates, *et al.* (252), have isolated and characterized the four stereoisomeric farnesols on a 5-ft. column containing 20% of polyethylene glycol 20M. The isomers of ionone and methylionone have likewise been separated by gas chromatography (253, 254). One may expect considerable work in this field in the future, particularly in regard to high molecular weight drugs.

Process Control.—Chemical analyses for process control must be rapid and dependable, and the instrumentation must be rugged and preferably suitable for automatic operation. Gas chromatography satisfies most of these requirements, and during the last few years it has become an important tool for monitoring chemical reactions. The method is not continuous in the strict sense, since the separation does require a definite time. However, it can be made automatic in that it is carried out according to a predetermined schedule without manual operation. The instrument itself samples the stream, passes the sample through the column, and records the components as they emerge (255–260). High speed chromatography is especially important for this type of application. Several commercial instruments for process analysis are available.

Miscellaneous Applications.—Gas chromatography has been a valuable aid in the determination of structures of organic molecules, particularly in conjunction with pyrolysis or other degradation reactions. Formyl and acetyl groups in digitalis glycosides have been identified by gas chromatography after transesterification with methanol (261, 262). Lloyd, *et al.* (263), used the method to determine the position of aromatic methoxyl groups in alkaloids related to powelline, while Cox (264) identified the side chains of steroids by pyrolysis followed by gas chromatography. Others have been able to use gas chromatographic techniques for determination of the amino acid sequence in proteins (265) and the arrangement of fatty acids in triglycerides (171). Dhont (108) has made a systematic study of the correlation between structure and the pyrolysis products of organic compounds.

Because of its speed and selectivity, the gas chromatographic method is well suited for the study of reaction mechanisms and reaction kinetics, both with regard to the synthesis of drugs, their *in vitro* deterioration (266), and their biotransformation. The effects of experimental parameters on the yield of a synthetic procedure may be readily evaluated and optimum conditions established.

CONCLUSIONS

No attempt has been made to exhaust completely the existing literature with reference to the applications of gas chromatography to pharmaceutical and related analysis. However, it should be apparent that the method has become a powerful tool for research as well as routine analytical work. The use of gas chromatography for high molecular weight compounds of low volatility, a very recent adaptation, has greatly stimulated interest among pharmaceutical chemists, since the vast majority of drugs fall in this category. It is important to realize that many chemical substances which are quite unstable even at

room temperature in the presence of air and moisture, frequently hold up very well in the vapor state in the inert atmosphere of a gas chromatographic column. Where the substance to be analyzed is unstable at the elevated temperature required for volatilization, stable, volatile derivatives can often be prepared, or the pyrolysis technique may be applied.

The pharmaceutical industry is making use of gas chromatography on a rapidly increasing scale and it is not unreasonable to assume that the method may be recognized by the official compendia in the near future.

Substituted Heterocyclic Thioureas I

Antitubercular Activity

By ARTHUR C. GLASSER and RICHARD M. DOUGHTY

A series of substituted 2-pyridyl and 4-(1-phenyl-2,3-dimethyl)-5-pyrazolone thioureas have been synthesized and tested for their antitubercular activity against *Mycobacterium tuberculosis* in Dubos medium. The minimum inhibitory concentrations of the compounds studied ranged from 10 mg. per 100 ml. to 0.16 mg. per 100 ml.

THIOUREA and its simple derivatives have been shown to have a limited tuberculostatic activity (1). *p*-Aminophenyl alkyl ethers also have a definite inhibitory effect (2), and when the two classes of compounds are combined through N-substituted thioureas this activity is enhanced (3–7). The tuberculostatic activity of the thioureas has been reviewed by Schroeder (8). This study is concerned with the influence on tuberculostatic activity by the substitution of the thiourea molecule with heterocyclic rings such as 2-pyridyl- or 4-(1-phenyl-2, 3-dimethyl)-5-pyrazolone in conjunction with alkyl or *p*-alkoxyphenyl substitution. The 1-*p*-alkoxy-

phenyl-3-(2-pyridyl) thioureas have been investigated (5). With our observation of the activity of the 1-*n*-octyl-3-(2-pyridyl) thiourea it was decided to investigate the other members of the 2-pyridyl series along with the 5-pyrazolone series.

The *in vitro* determination of the tuberculostatic activity was carried out using the virulent H37Rv strain of *M. tuberculosis* grown on Dubos medium with added Tween 80 and beef serum. A comparison of the biological activities as seen from Table I shows the inhibitory concentrations range in activity from a low value of 10 mg./100 ml. to an upper limit of 0.16 mg./100 ml. Maximum activity of the 2-pyridyl series rests in the phenyl and *n*-octyl derivatives, while maximum for the 5-pyrazolone series is shown by the isopropoxyphenyl derivative. In the *p*-alkoxyphenyl derivatives the increased activity of the lower alkyl chains is in keeping with observations made on the 4,4′-dialkoxythiocarbanilides (9).

Synthesis of the thioureas involved the reaction of 2-aminopyridine or 4-aminoantipyrine with the appropriate isothiocyanate in absolute alcohol or thiophene free benzene (10). The alkyl isothiocyanates were prepared by the general method of Moore (11). The aryl isothiocyanates were made with some modification following the process of Van der Kirk (12), or the action of acetic anhydride on the appropriate thiocarbanilide (13). The *p*-alkoxyaniline derivatives needed for the isothiocyanate syntheses were prepared by the method of Bucchi (14).

EXPERIMENTAL

Biological Test Method.—The culture used was the H37Rv strain of *Mycobacterium tuberculosis* var. *hominis* obtained from the American Type Culture Collection.[1] The organism to be used as inoculant was propagated in Dubos broth base.[2] These cultures were grown in 100 ml. of broth in aluminum foil capped Erlenmeyer flasks for 2 weeks before inoculating tubes in the dilution series. Incubation was at 37° for all cultures and dilution tubes.

In the dilution series 4.5 ml. of Dubos broth base, enriched with 10% Dubos Medium Serum,[2] was placed in all tubes except the first tube of the series which received initially 9.0 ml. of the enriched medium. Ten milligrams of the compounds per milliliter of a solvent consisting of equal parts of propylene glycol, Tween 80, ethanol and distilled water was diluted to 10 ml. with nonenriched Dubos broth base. Using a sterile Swinny hypodermic adaptor and a membrane filter, Millipore HA type,[3] 1.0 ml. was aseptically filtered into the first tube of a series. These were mixed by drawing up portions of the medium into a sterile syringe, then 4.5 ml. was withdrawn aseptically from the first tube and placed in the second. This was mixed as before and 4.5 ml. transferred to the next tube. This was continued through all tubes of a specific series; 4.5 ml. was discarded from the last tube in the series. This resulted in increasing dilutions of 2× magnitude

[1] American Type Culture Collection, 2112 M Street N. W., Washington 7, D. C.
[2] Difco Laboratories, Detroit 2, Mich.
[3] Millipore Filter Corp., Bedford, Mass.

from 10 mg. % in the first tube to 0.0195 mg. % in the last tube of a ten tube series.

One-half milliliter of the propagation culture was added to each tube of the diluted agent in Dubos medium in a series. Centrifugation in a Hopkins vaccine tube of the propagation cultures showed the concentration of organisms to average about 0.0007 ml. packed cells per 0.5 ml. of culture.

All tubes in the tests were read at the end of 10 days and again at the end of 2 weeks. There was little difference in the two readings. First, tubes which developed a characteristic pellicle were read as positive for growth and noted. Acid-fast slides were prepared from doubtful positive tubes and also from the most dilute tubes showing macroscopically no growth. These were read "positive" if there were acid-fast bacilli in all fields, and "doubtful" if only a few acid-fast organisms found on the whole smear. Frequently, the microscopic examination resulted in lowering the evaluation of an agent. The compound 4,4'-diaminodiphenylsulfone was used as a standard for the activity of the compounds.

p-Alkoxyaniline Intermediates.—*p*-Phenetidine and *p*-anisidine are commercial products. Following the directions given by Bucchi (14), with the exception of an increased hydrolysis period to 8 hours, the following *p*-alkoxyanilines were prepared: *p*-propoxy (15), *p*-isopropoxy (14), *p*-*n*-butoxy (15), *p*-*n*-amoxy (15). *p*-*sec*-Butoxyaniline was prepared by this method in 80% yield, b.p. 150–151° (23 mm.).

Anal.—Calcd. for $C_{10}H_{15}NO$: N 8.47. Found: N 8.40.

p-*sec*-Amoxyaniline was also prepared by this method in 71% yield, b.p. 161–163° (23 mm.).

Anal.—Calcd. for $C_{11}H_{17}NO$: N 7.86. Found: N 7.79.

Aryl Isothiocyanates.—Phenyl isothiocyanate was a commercial product. The following *p*-alkoxyphenyl isothiocyanates were prepared by the action of sodium chloroacetate on the corresponding dithiocarbamates followed by decomposition of the resulting salt with zinc chloride (12): *p*-methoxyphenyl (12), *p*-ethoxyphenyl (12), *p*-propoxyphenyl (5), *p*-isopropoxyphenyl (5), *p*-butoxyphenyl (5), and *p*-amoxyphenyl (5). Prepared in this same manner was *p*-*sec*-butoxyphenyl isothiocyanate, b.p. 176–178° (28 mm.).

Anal.—Calcd. for $C_{11}H_{13}NOS$: N 6.77. Found: N 6.91.

Also prepared in this fashion was *p*-*sec*-amoxyphenyl isothiocyanate b.p. 157–158° (3mm.).

Anal.—Calcd. for $C_{12}H_{15}NOS$: N 6.36. Found: N 6.27.

2-Pyridyl Thioureas.—A 10-Gm. (0.07 mole) quantity of cyclohexyl isothiocyanate (16) was refluxed with 6.7 Gm. (0.07 mole) of 2-aminopyridine in 15 ml. of thiophene free benzene for 1 hour. The reaction mixture was concentrated through removal of 10 ml. of benzene and allowed to stand overnight. The resulting solid mass was recrystallized from alcohol to yield 10.5 Gm. (63%) of 1-cyclohexyl-3-(2-pyridyl) thiourea, m.p. 147–148°.

Anal.—Calcd. for $C_{12}H_{17}N_3S$: N 17.8. Found: N 17.4.

4-(1-Phenyl-2,3-dimethyl)-5-pyrazolone Thioureas.—*p*-Isopropoxyphenyl isothiocyanate weighing 1.93 Gm. (0.01 mole) and 2.03 Gm. (0.01 mole) of 4-aminoantipyrine were refluxed for ½ hour in 50 ml. of absolute alcohol. The reaction mixture was chilled in ice and filtered to yield after drying in a vacuum desiccator 3.6 Gm. of the thiourea. Concentration of the mother liquor and chilling yielded another 0.3 Gm. for a total of 3.9 Gm. of crude product, m.p. 198–201°. The product recrystallized from methylcellosolve yielded 3.4 Gm. (89%) 1-*p*-isopropoxyphenyl-3-[4-(1-phenyl-2,3-dimethyl)-5-pyrazolone] thiourea, m.p. 202–203° decompn.

Anal.—Calcd. for $C_{21}H_{24}N_4O_2S$: N 14.1. Found: N 14.3.

The pyrazolone thioureas proved to be photosensitive, and upon exposure to light for various periods of time developed a yellow color.

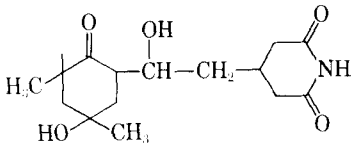
Selection, Evaluation, and Control of the Assay of the Pharmaceutical Product IV



Screening Bulk Drug Stability and Defining the Assay of Choice

By EDWARD R. GARRETT† and ROSS R. HERR

Statistical evaluation of biological assays of bulk streptovitacin A subjected to 70° and room temperature for 60 days permitted the conclusion that the drug was stable in the bulk form. The assay of choice was defined against *Saccharomyces pastorianus* rather than against *Trichomonas vaginalis*. The point is made that operational potency is best defined by assay replication on various days but comparison of lot potencies and production procedures is best made by assay on one given day against the same standards.

WHEN a potential product results from pharmaceutical research, a facile and fast screen of stability in the bulk form of the drug is needed. When biological assays are the major method of potency determination, the stability study must be designed so that confidence in stability estimates must take into account the large inherent error in such assays. Such a design can also contribute supplementary information which can permit a choice of assay and evaluate the effects of variation among days or sampling procedures (1, 2, 3).

A case in point was the antitumor agent streptovitacin A (4–10)

The screening of stability was conducted on samples maintained at both 70° and room temperature. Only if significant differential degradation occurred would a more elegant accelerated stability study at several temperatures for purposes of stability prediction be warranted.

EXPERIMENTAL

Samples of streptovitacin A were weighed and placed in separate vials. One set of vials was subjected to 70° and the other was maintained at room temperature. At intervals, vials were removed and submitted for assay. The two assay procedures used are given in the literature (5), paper chromatographic separation on bioautograph development against *Saccharomyces pastorianus* and *Trichomonas vaginalis*.

RESULTS AND DISCUSSION

The analyses of variance (11) of the assays of streptovitacin A subjected to 70° and room temperature for 60 days are given in Tables I and II, the former for the *S. pastorianus* assay (5) and the latter for the *T. vaginalis* assay (5).

No significant differences between the assays of streptovitacin A maintained at room temperature and 70° for 60 days could be determined. These facts are graphically shown in Fig. 1. No significant trend of assays with days of sampling was apparent for the material maintained at 70°. The differ-

TABLE I.—ANALYSIS OF VARIANCE OF STREPTOVITACIN A MAINTAINED AT TWO DIFFERENT TEMPERATURES[a] AND ASSAYED ON VARIOUS DAYS (ASSAY AGAINST *S. Pastorianus*)

Sources of Variation	Sum of Squares	Degrees of Freedom	Mean Square	Quantities Estimated by Mean Squares
Days[b]	323,242	13	24,864[c]	$2\sigma_D^2 + \sigma_E^2$
Temperatures	11,401	1	11,401[d]	$14\sigma_T^2 + \sigma_E^2$
Error	117,013	13	9,001	σ_E^2
Total[e]	451,657	27	16,728	

[a] Average of room temperature samples: 813; average of 70° samples: 854; overall average, $\bar{x} = 834$. [b] Estimated variance, $\sigma_D^2 = 7{,}930$. [c] F test: days:error = 2.77; 5% F = 2.6 ∴ sign. @ 5% level. [d] F test: temp.:error = 1.27; 5% F = 4.7 ∴ no significance. [e] Estimate of variance among days and error: $\sigma_E^2 + \sigma_D^2 = 16{,}931$

$$\therefore \sigma = 130 \therefore \frac{\sigma}{\bar{x}} = \frac{130}{834} \therefore 15.6\%$$

ences in the mean values of the assays of the 70° and room temperature materials can be attributed solely to assay variation.

Additional information may be obtained from the analyses of variance. For both assay methods, either against *S. pastorianus* or *T. vaginalis*, the assay variation among days is significant. In fact, when an assay is replicated on several days, the variation is twice that for replication on a given day.

The fact that this variation occurs in the same direction for samples run on the same day is apparent from inspection of the plots in the attached Fig. 1. When the 70° assays give results above the mean on given days, so do the room temperature assays; when they give results below the mean, so do the room temperature assays. That this synchronization of daily deviations from the mean for both samples is not a phenomenon attributable to some inherent variation in the day of sampling may be concluded from the analysis of variance for the total data from both assays as given in Table III.

The interaction days × assay is significant on the 1% level whereas variation among days and assays is not significant with respect to this interaction. Yet, as from Tables I and II, variation among days is significant within each assay. Thus it may be concluded that the variation among days is arbitrary with a particular assay; that there is not a common reason for the highs and lows of assay values *vs.* days to be synchronized for the several assays. Assays yield high and low values independently; results with a particular assay show a daily bias peculiar to that assay.

This is graphically shown in Fig. 1 where the assay values against *T. vaginalis* for a given day may be in excess of the mean, whereas those for *S. pastorianus* are just as likely to be less than their mean on that day. Thus no bias is apparent when the data from both assays are averaged.

These facts permit one point to be stressed. Variation among days of assay is a phenomenon common to microbiological methods (12, 13). Fundamental investigations of the causes of diurnal microorganism or biological variation may eliminate the source of increased error among assays replicated on various days. In this particular study, such elimination would have halved the assay variance.

If an assay is to serve as an operational definition of drug potency and since potency may be evaluated on any arbitrary day, replicate assays on several days may most adequately define the drug. How-

TABLE II.—ANALYSIS OF VARIANCE OF STREPTOVITACIN A MAINTAINED AT TWO DIFFERENT TEMPERATURES[a] AND ASSAYED ON VARIOUS DAYS (ASSAY AGAINST *T. Vaginalis*)

Sources of Variation	Sum of Squares	Degrees of Freedom	Mean Square	Quantities Estimated by Mean Squares
Days[b]	1,359,035	13	104,541[c]	$\sigma_E^2 + 2\sigma_D^2$
Temperature	19,189	1	19,189[d]	$\sigma_E^2 + 14\sigma_T^2$
Error	384,431	13	29,572	σ_E^2
Total[e]	1,762,654	22	65,283	

[a] Average of room temperature samples: 880; average of 70° samples: 924; overall average: 906. [b] Estimated variance; $\sigma_D^2 = 34{,}485$. [c] F test; days:error = 3.54; 5% F = 2.6 ∴ sign @ 5% level. [d] F test; temp. error <1 ∴ no significance. [e] Estimate of variance among days and error: $\sigma_E^2 + \sigma_D^2 = 64{,}057$.

$$\therefore \sigma = 253 \therefore \frac{\sigma}{\bar{x}} = \frac{253}{906} \therefore 27.9\%.$$

TABLE III.—ANALYSIS OF VARIANCE OF TWO ASSAYS BY DAYS OF ASSAY[a] WITH 70° AND ROOM TEMPERATURE MATERIAL CONSIDERED AS REPLICATES (ASSAYS AGAINST *S. Pastorianus* AND *T. Vaginalis*)

Sources of Variation	Sum of Squares	Degrees of Freedom	Mean Square	Quantities Estimated by Mean Squares
Days	873,545	13	67,196[b]	$\sigma_E^2 + 4\sigma_D^2 + 2\sigma_{D\times A}^2$
Assays	73,732	1	73,732[b]	$\sigma_E^2 + 28\sigma_D^2 + 2\sigma_{D\times A}^2$
Day × Assay	808,732	13	62,210[c]	$\sigma_E^2 + 2\sigma_{D\times A}^2$
Error	532,034	28	19,001	σ_E^2
Total	2,288,000	55	41,601	

[a] Average among days: 883; average among assays: 906; over-all average: 870. [b] Days and assays are not significant with respect to D × A interaction. [c] F test: D × A:error = 3.22; 1% F = 2.9 ∴ sign. on 1% level; estimated variance $\sigma_{D\times A}^2 = 21{,}600$.

ever, drug lots or development procedures to give higher purity or yield would be most accurately compared by assay on one day with the same standard curves. Of course, the possibility of sample × assay × day interaction must not be ignored.

CONCLUSIONS

A screening procedure was used to evaluate the stability of a drug in the bulk form, and assays of streptovitacin A at 70° and room temperature for 60 days were compared. It is concluded that streptovitacin A is stable in the bulk form and is not subject to any thermal degradation which results in loss of biological potency.

The quantitative papergram assay against *S. pastorianus* for streptovitacin A is the method of choice rather than against *T. vaginalis*. The standard deviation, per cent of the mean, for the estimation of error of a single assay is 16% for the former, and 28% for the latter.

The variation of an assay within a single day is only one-half of the variation of that assay on various days. This phenomenon of daily variation has to do with the bias of the assay and not the day of sampling. Elimination of such daily assay variation could halve the variance.

Selection, Evaluation, and Control of the Assay of the Pharmaceutical Product V

Importance of Assay Validity, a Case in Point

By EDWARD R. GARRETT†

Microbiological assays are used to measure drug potency but unwanted degradation products or impurities may positively interfere. A case in point is the tetracycline salts with normal moisture content in the cylinder-plate assay against *Bacillus subtilis*. Thermal degradation doubles the potency of tetracycline in this microbiological assay. Ultraviolet and infrared spectrophotometry indicate that aromatization and decarboxamidation are implicated. The resultant products have greater diffusivity and sufficient potency in the agar of the cylinder-plate assay method so that an *apparently* greater drug assay results. Dry tetracycline salts are thermally stable. Normal moisture content does not induce instability at usual storage temperatures. The kinetics of acid degradation of tetracycline phosphate and hydrochloride are the same.

The prediction of stability of drugs in pharmaceutical preparations (1) can be made only within the validity and reliability of the assay for drug. Previous papers in this series (2) have essentially considered the reliability or reproducibility of the assay.

The validity of an assay may be defined as its ability to measure that which it is supposed to measure. When biological assays are necessary, it is frequently assumed that degradation products of the drug do not demonstrate potency under the conditions of assay. This is not necessarily so. Biological assays are a complex sequence of physical, biological, and chemical effects. It is possible that the degradation products of a drug may not have the same pharmacological properties as the drug itself and yet give anomalous estimates of potency.

An interesting case in point is tetracycline and the assay in question is a classical microbiological method of antibiotic evaluation, the cylinder-plate assay (3) with *Bacillus subtilis* as the test organism.

EXPERIMENTAL

Biological Assay of Heat-Treated Tetracycline by Cylinder-Plate Assay.—Bulk tetracycline phosphate[1] with 2% moisture content was subjected to

An interesting case in point is tetracycline and the assay in question is a classical microbiological method of antibiotic evaluation, the cylinder-plate assay (3) with *Bacillus subtilis* as the test organism.

EXPERIMENTAL

Biological Assay of Heat-Treated Tetracycline by Cylinder-Plate Assay.—Bulk tetracycline phosphate[1] with 2% moisture content was subjected to

Received September 13, 1961, from the Research Laboratories of The Upjohn Co., Kalamazoo, Mich.
Accepted for publication October 5, 1961.
The author is greatly indebted to Dr. W. T. Sokolski and associates for the microbiological assays and to Mr. J. E. Stafford for technical assistance.
† Present address: College of Pharmacy, University of Florida, Gainesville.

[1] Marketed by The Upjohn Co. as Panmycin Phosphate.

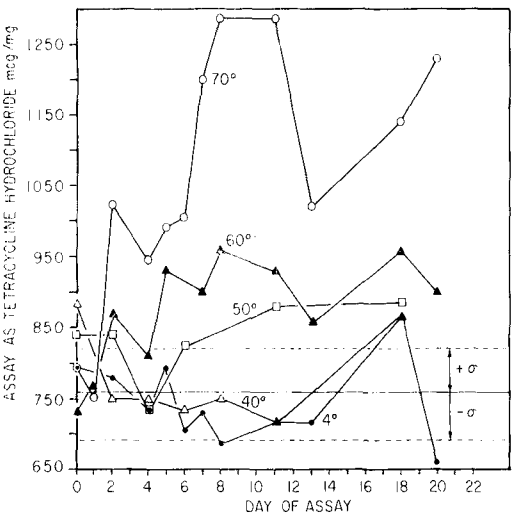

Fig. 1.—Cylinder-plate assay *vs. B. subtilis* of bulk tetracycline phosphate subjected to various temperatures. The solid line represents the mean of the 4° and 40° assays; the dashed lines represent the limits of the mean ± standard deviation.

70°, 60°, 50°, 40°, and 4° and assayed at intervals. The primary assay procedure was by the cylinder-plate method against *Bacillus subtilis* using tetracycline hydrochloride[2] as the standard. The collected assay data for the various temperatures are plotted as tetracycline hydrochloride against days of assay in Fig. 1.

Biological Assay of Heat-Treated Tetracycline Phosphate by Paper Chromatography.—Since the tetracycline phosphate was heat transformed to a material that had increased potency against *B. subtilis* in the cylinder-plate assay, it was deemed advisable to assay the material by paper chromatography against the same organism after the month of thermal treatment. The spot that moved like tetracycline was assayed as tetracycline against the standard. Table I gives the results.

TABLE I.—ASSAY AGAINST *B. Subtilis* OF PAPER CHROMATOGRAM OF TETRACYCLINE PHOSPHATE HEAT TREATED FOR ONE MONTH

Temp. of Treatment	mcg./mg. Assay A	mcg./mg. Assay B
70°	475	721
60°	767	900
50	958	925
40	829	1050
4°	925[a]	1050[a]

[a] This was the same material used as a standard in this assay.

Spectrophotometric Assay of Heat-Treated Tetracycline Phosphate.—The bulk tetracycline phosphate subjected to elevated temperatures was spectrophotometrically analyzed at pH values of 2.32, 4.88, and 9.25. Heat at 70° affected the spectra in that the apparent absorptivity at 218 mμ increased to a maximum of 45%, at 270 mμ to a maximum of 63%, and at 356 mμ decreased to 49.5% at pH 2.32.

[2] Marketed by The Upjohn Co. as Panmycin.

The absorbances at these various wavelengths and pH values became asymptotic with time at 70°. If the symbol for the asymptotic value at 70° is A_∞, then the first-order rate constants may be determined from the slope of plots based on the expression

$$\text{Log}\,(A_\infty - A) = -\text{kt}/2.303 + \text{constant}$$

Such plots for a given temperature were parallel, no matter the wavelength or the pH. Typical plots for 70°, 60°, 50°, and 40° treated material are given in Fig. 2. These were obtained at 218 mμ and at pH 2.32 in 0.005 *M* hydrochloric acid. The slopes of such plots are given in Table II.

TABLE II.—SLOPES OF POSSIBLE FIRST-ORDER HEAT DEGRADATION OF TETRACYCLINE PHOSPHATE

Temp.	Slope, $k/2.303$ in day^{-1}
70°	0.67
60°	0.0062
50°	0.0025[a]
40°	indeterminate

[a] Estimated but could be insignificant with respect to variability of the measurement.

Identification of Gaseous Product of Heat Degradation of Bulk Tetracycline Salts.—The bulk tetracycline phosphate darkened when subjected to temperature. The degree of darkening increased with temperature. The 70° material after a month's time was virtually dark brown. Within the bottles a gas pressure was generated. This gas was isolated and shown by infrared spectroscopy to be carbon dioxide.

Dried and normally hydrated tetracycline hydrochloride and phosphate were subjected to 70° temperature for several weeks. In *both* cases of hydration, decomposition to a gray-black mass was visually noted and CO_2 was determined to be present in both atmospheres. In both cases of the dried tetracycline, no discoloration was observed. It is thus concluded that CO_2 liberation and decomposition occur with moist tetracycline salt.

Solution Degradation of Tetracyclines.—Buffers were prepared of hydrochloric acid-potassium chloride for pH values of 1.2 and 2.2. The former was prepared with 250 ml. 0.2 *M* potassium chloride and

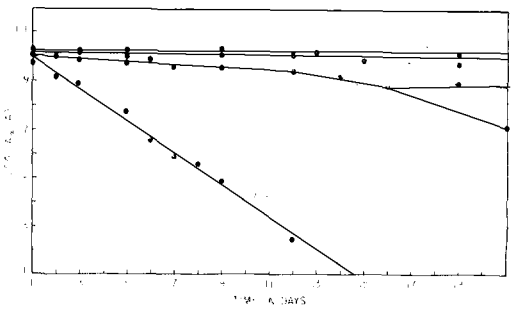

Fig. 2.—Apparent first-order rate plots for the thermal degradation of bulk tetracycline phosphate at various temperatures as based on ultraviolet spectrophotometry in pH 2 acid solution. The A_∞ is taken as the asymptotic absorbance with time of the 70° degraded material.

327.5 ml. 0.2 *M* hydrochloric acid and the latter with 250 ml. 0.2 *M* potassium chloride and 33.5 ml. 0.2 *M* hydrochloric acid (4). Both were brought up to volume in a 1-L. flask.

A 9.797 mg. quantity of tetracycline free base and 13.132 mg. tetracycline phosphate were each dissolved in 10 ml. dimethylformamide. Five milliliters of each solution were brought up to volume with 1.2 and 2.2 pH buffers, respectively. The resultant solutions were maintained at 30.3° and read at intervals on the Beckman model DU spectrophotometer at the maxima of tetracycline, 270 mμ and 356 mμ.

CALCULATIONS AND RESULTS

Anomalous Increase in Potency by Cylinder-Plate Assay of Heat-Degraded Tetracycline Salts.—The screening of bulk drug for instability can be readily effected by assaying heat-treated material at intervals of time. The assays of bulk tetracycline phosphate subjected to various temperatures are plotted as functions of time in Fig. 1.

Since the variation among assay values of the drug subjected to high temperatures was significantly outside the expected assay error, the mean and standard deviation (σ) in this figure is calculated solely from the 4° and 40° data.

The mean and standard deviation of the assay of this material as tetracycline were pooled from the entire month of study and are 760 and ±70 mcg./mg., respectively.

It is readily apparent that the material subjected to 70° and 60° significantly increased in apparent assay. The 70° material developed a potency of 1.7 times the mean value in 1.5 week's time. Although the increase in potency of the 50° material is not as statistically significant, it can be estimated as 1.15 the mean value. The 60° material developed a potency of 1.25 times the mean value.

There can be little doubt that the bulk tetracycline salt was transformed by heat to a new material that demonstrated increased potency *by this particular assay method.* These data do not permit any valid estimate of stability *as tetracycline,* since the assay method responds to degradation products other than tetracycline.

The ultraviolet spectrophotometric assay of the heat-degraded materials could provide a more quantitative estimate of rates of this transformation. Such estimates were given in Table II. Thus, if the ratio of rate constants at 10° intervals is chosen as $k_{70°}/k_{60°} \sim 100$ from Table II, the rate constant at 30° would be 6×10^{-9} day^{-1}. This would result in negligible spectrophotometric change in over a year at 30°. Even if the more disadvantageous ratio $k_{60°}/k_{50°} = 2.5$ were used, there would be negligible spectrophotometric change at 30° within a year.

The results of Table I confirm the spectrophotometric observations. The transformation of bulk tetracycline has a high thermal activation. Although the transformation has a high rate at 70°, it is much less at 60° and negligible at 50° and 40°. The best estimate from these data on the assumption that tetracycline is being assayed by this technique is that it is inherently stable in the bulk form at 30°.

Solution Degradation of Tetracycline Salts.—Plots of absorbance at 270 and 356 mμ, the maxima of tetracycline in acid media, against time in hours for tetracycline phosphate and hydrochloride at pH 2.2 and 1.2 are given in Fig. 3. The coincidence of data for phosphate and hydrochloride proves that both salt types undergo the same degradation at the same rate.

An example of the pseudo first-order plots of the absorbance data is given in Fig. 4 as based on the premise that

$$dx/dt = -k_H{}^+[H^+]x$$

where x is the concentration of tetracycline and $[H^+]$ is the hydrogen ion concentration. This integrates to

$$\log x/x_0 = -k_H{}^+[H^+]t/2.303 = -kt$$

where x_0 is the initial tetracycline concentration.

When absorbance is the measure of concentration, then

$$\log/A_t - A_\infty/ = -kt + \text{constant}$$

where A_t is the absorbance at time t and A_∞ is the asymptotic absorbance at infinite time and

$$k = k_H{}^+[H^+]/2.303$$

The rate of appearance of the chromophore at 270 mμ at pH 1.2 is 0.00211 and 0.00202 for hydrochloride and phosphate, respectively. The rate of disappearance of the chromophore at 356 mμ at pH 1.2 is 0.00200 for both.

The mean value of k in the fifth equation at pH 1.2 is thus 0.00203 and $k_H{}^+$ $[H^+] = 4.675\ 10^{-3}$ $hr.^{-1}$ Thus, $k_H{}^+ = 4.675.10^{-3}/10^{-1.2} = 7.41.10^{-2}$ 1/M/hr.

Thus, in general, the fraction of tetracycline remaining after acid degradation at a given pH and 30° may be calculated from the expression if specific acid catalysis is assumed

$$\log x/x_0 = -7.41.10^{-2}.10^{-pH}t/2.303 = 3.21.10^{-2}\,[H^+]t$$

It follows that a solution of tetracycline salt in 0.01 *M* hydrochloric acid undergoes 10% degrada-

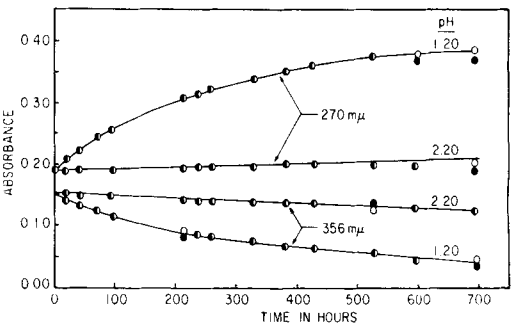

Fig. 3.—Change of absorbance with time for tetracycline hydrochloride, ⊙, and tetracycline phosphate, ●, at several acid pH values at 30.3°. The concentrations of tetracycline were 4.900 mg./L. of hydrochloric acid-potassium chloride buffer or 1.104×10^{-5} *M*. The coincident values are given as half solid circles, ◐.

TABLE III.—ULTRAVIOLET SPECTRAL DATA ON TETRACYCLINES IN ACID SOLUTION

Compound	λ	Absorptivity	λ	Absorptivity	λ	Absorptivity
Tetracycline hydrochloride, standard	218.5	29.23	270	39.52	356	29.85
Tetracycline phosphate, dried	217	26.03	269	33.82	356	25.31
Tetracycline phosphate, non-dried	218	23.49	270	30.74	356	27.34
Heat-degraded tetracycline phosphate, non-dried	218	34.0	270	50.0	356	13.5
Anhydrotetracycline	224	65.73	274	127.82	...	...

tion in 156 hours, 25% in 413 hours, and 50% in 990 hours at 30°. In one day, in 0.01 *M* hydrochloric acid there will be 1.8% decomposition and in 2 days, 3.5% decomposition. At 0°, on the assumption of a heat of activation of 15 Kg. cal./mol., approximately 1% decomposition will occur within a week's time at pH 2.0. The above information should be important in the keeping of standard solutions.

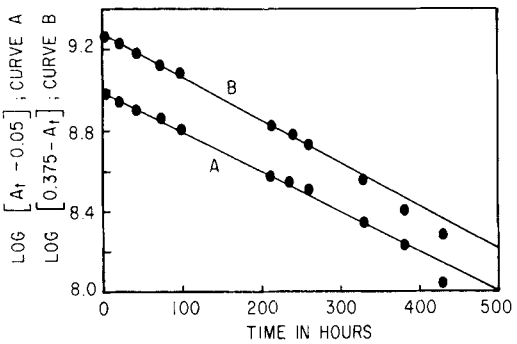

Fig. 4.—First-order rate plots for the acid catalyzed degradation of 1.104×10^{-5} *M* tetracycline hydrochloride in hydrochloric acid-potassium chloride buffer at pH 1.2 at 30°. Curve *A* represents the disappearance of the 356 mμ chromophore; curve *B* represents the appearance of the 270 mμ chromophore. The abscissa is the logarithm of difference of the asymptotic absorbance, A_∞, and the absorbance at any time, A_t.

DISCUSSION

The heat degradation of bulk tetracycline salts occurs when the material contains moisture. However, the normal moisture content of bulk tetracycline salts should not significantly affect the stability at normal temperatures of storage. The dried phosphate and hydrochloride salts of tetracycline are stable at elevated temperatures. Both phosphate and hydrochloride salts of tetracycline degrade at the same rates in acidic solution. This indicates that both salts provide the same tetracycline ion in the acid of the stomach. Thus, no rationale comparable to the greater resistance to acid degradation of penicillin V over G can be proposed for tetracycline phosphate over the hydrochloride.

The validity of the cylinder-plate assay using *B. subtilis* for tetracycline purity is suspect The cylinder-plate assay depends on two parameters: (*a*) rate of diffusion of the antimicrobial agent through the agar to bring it in contact with a greater volume of microorganisms, and (*b*) the minimum inhibitory concentration in the agar media to inhibit microbial growth. It is feasible that a compound derived from the one to be assayed may have less potency but greater diffusibility so that the radius of the clear areas about the dose may be larger for the least potent material. The question as to the specificity of other test organisms is open.

The shift in the ultraviolet spectra of tetracycline after heat degradation in the bulk form or in solution is consistent with what would be expected if it were transformed in part to anhydrotetracycline with aromatization of the C ring. Pertinent spectrophotometric data are given in Table III.

It is apparent that moist tetracycline salts are not completely transformed by heat to a probable anhydrotetracycline. In addition to the appearance of CO_2 on heat degradation that indicates decarboxamidation, it can be estimated on the basis of the increase in absorptivities given in Table III that only 23% of the molecules are aromatized.

On the basis of this observation, anhydrotetracycline and desdimethylaminotetracycline were run in the same cylinder-plate assay as the tetracycline. Anhydrotetracycline and desdimethylaminotetracycline showed twice the activity on weight basis as tetracycline in this assay. Also, a 50-50 mixture of tetracycline and anhydrotetracycline showed twice the activity on a weight basis as tetracycline.

This "case in point" confirms the importance of the axiomatic statement that the specificity of a biological assay of a drug is just as important to evaluate as is its reliability.

Pharmacological Investigation of the Glucoside and Aglucone Isolated from *Caccinia glauca*

By H. R. K. ARORA† and R. B. ARORA‡

A glucoside and its aglucone isolated from *Caccinia glauca* were studied for their pharmacological activity. Both compounds exhibited a diuretic action which appeared to be due to an increase in glomerular filtration. The dose which induced diuresis did not have any other significant effects. Isolated tissue preparations were not affected except by very high concentrations. The compounds were effective by the oral as well as parenteral route and showed a large safety margin.

CACCINIA GLAUCA Savi., commonly known as gaozaban (1, 2), is frequently used in the indigenous system of medicine as a diuretic, in irritation of the bladder, strangury, and in several other conditions. Various uses for this plant have been described by ancient writers (3, 4).[1] Recently, a glucoside, caccinin, and its aglucone, caccinetin, which is the dimethylallyl ester of caffeic acid, have been isolated from it (5). In view of the reputation and extensive use of the drug by practitioners of the indigenous system of medicine, an investigation was undertaken to elucidate the pharmacological properties of the pure compounds.

METHODS AND RESULTS

Extraction and purification was done as reported earlier (5) and the chemical identity of the pure compounds was confirmed.[2] The glucoside was used as 1–5% solution in normal saline and the aglucone, because of its low solubility in water and saline, as a 1–2% solution in 0.5% sodium bicarbonate.

Cardiovascular Actions.—The effects of these compounds on intact circulation were studied on mongrel dogs of both sexes and male albino rats. The dogs weighed 5–8 Kg. and were anesthetized with an i.v. dose of pentobarbital sodium equivalent to 30 mg./Kg. of body weight. The rats weighed 175–250 Gm. and were anesthetized with an i.p. dose of 25% urethane in water equivalent to 0.6–0.8 ml./100 Gm. of body weight. Blood pressure was recorded from the carotoid artery on a smoked drum. Drugs were injected through a cannulated vein. Electrocardiogram, bipolar limb lead II, was recorded in all experiments.

A fall in blood pressure was recorded, both in rats and dogs, during administration of the glucoside and lasted for 1–3 minutes. Following this, the arterial pressure rose in rats but not in dogs (Fig. 1). The duration and extent of the rise depended upon the dose (Table I). An increase in heart rate was noted in rats but not in dogs. Electrocardiogram remained unchanged with doses up to 200 mg./Kg. of body weight on the glucoside and 50 mg./Kg. of body weight of the aglucone.

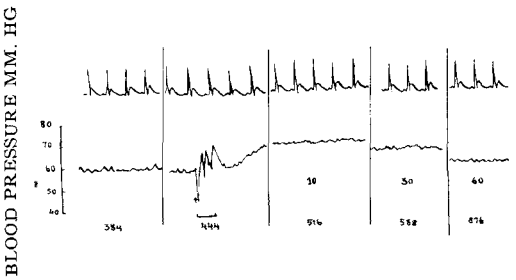

Fig. 1.—From above downwards the records are: electrocardiogram; blood pressure; time in minutes after drug administration; and heart rate per minute showing the effects of the glucoside in the rat. The drug was administered at the time indicated by arrow in a dose of 200 mg./Kg. of body weight intravenously.

The cardiac effects were studied on failing papillary muscle preparation of cat (6), isolated perfused rabbit heart (7), perfused frog ventricle (Straub-Fuehner preparation) (8), and heart-lung preparation of dog (9).

A positive inotropic action was noted on the cat papillary muscle preparation but high concentrations were required to elicit this effect (Table I). Isolated perfused rabbit heart was not significantly affected by doses up to 5 mg. of the glucoside or the aglucone added to the perfusing fluid. Similarly, perfused frog ventricle was unaffected by concentrations of 10^{-4} Gm./ml. of the glucoside or 10^{-3} Gm./ml. of the aglucone, although a concentration of 10^{-3} Gm./ml. of the glucoside reduced heart rate by 45 % ± 9.0 S.E. without producing any other effect.

The heart-lung preparation of dog was unaffected by concentrations of 1.5×10^{-4} Gm./ml. and 6×10^{-4} Gm./ml. of the glucoside. Caffeine, as caffeine citrate, used for comparison, slightly increased venous pressure and decreased competence of the heart when given in a concentration of 1.5×10^{-4} Gm./ml. In a concentration of 6×10^{-4} Gm./ml. it caused an acute fall in blood pressure and a marked rise in venous pressure.

Effect on blood vessels was studied by perfusing rabbit ear vessels (7) with Ringer-Locke solution. Doses of 5 mg. and above of the glucoside or the aglucone reduced the flow through ear vessels by 16 – 20% or more. Lower doses were ineffective.

Received September 29, 1961, from the Department of Pharmacology, Maulana Azad Medical College, New Delhi, India.

Accepted for publication March 6, 1962.

Urinary Actions.—Diuretic activity was studied on conscious and anesthetized rats (10, 11) and anesthetized dogs (12).

In studies on conscious rats, the animals were used in groups of three. All compounds were administered orally. Hourly urine output for the first 5 hours, and the total urine output for the next 19 hours (hereafter referred to as the 24-hr. urine) were noted. The urine outputs of groups receiving test compounds were compared with groups receiving urea or saline only. Chloride and uric acid contents of the total urine excreted during the first 5 hours and the subsequent 19 hours were separately estimated (13, 14).

The glucoside and the aglucone significantly increased the total urine outputs at 5 hours ($0.05 > P > 0.02$) as well as at 24 hours ($0.01 > P > 0.001$) when compared with groups receiving saline only (Table II). The 5- and 24-hr. urine outputs of groups receiving urea were not significantly greater than those receiving the test compounds ($0.5 > P > 0.4$). Chloride excretion was not altered but uric acid excretion was apparently increased. The compounds, however, gave false positive test for uric acid by the method employed.

In anesthetized rats the compounds were injected intravenously and the urine collected every 5 minutes through a polythene catheter placed in the bladder. In this preparation also, urine output was increased by the glucoside as well as the aglucone to the extent of 104% ± 23.8 S.E. and 62% ± 12.8 S.E., respectively. Similarly urine output increased by 85% ± 12.4 S.E. when a dose of 100 mg./Kg. of body weight of the glucoside was injected intravenously in dogs. Chloride excretion in dogs was not affected but endogenous creatinine excretion showed an increase of 92% ± 11.9 S.E. (Table II). Phenol red excretion in dogs was not altered by the glucoside.

Other pharmacological properties.—Intraperitoneal administration of doses up to 400 mg./Kg. of body weight of the glucoside in albino rats failed to

TABLE I.—EFFECT OF GLUCOSIDE AND AGLUCONE ON BLOOD PRESSURE AND HEART RATE OF INTACT ANIMALS AND CAT PAPILLARY MUSCLE[a]

Intact Animals

Animal	No. of Experiments	Drug	Dose, mg./Kg. Body Wt.	Increase, %: Blood Pressure ± S.E.	Increase, %: Heart Rate ± S.E.
Rat	10	Glucoside	50	11.0 ± 2.1	6.0 ± 1.3
Rat	10	Glucoside	100	20.0 ± 2.7	14.0 ± 1.7

1	6	Glucoside	100	85 ± 12.4	92 ± 11.9

elicit any gross sedation or excitation. Hexobarbital sleeping time in mice (15) was not altered by doses up to 200 mg./Kg. of body weight of the glucoside or 50 mg./Kg. of body weight of the aglucone given intraperitoneally.

No anticonvulsant activity against maximal electroshock and maximal metrazol seizures (16) could be elicited in albino rats with i.p. doses up to 400 mg./Kg. body weight of the glucoside or 50 mg./Kg. body weight of the aglucone. Also, no activity could be detected with these doses against pain induced by application of radiant heat to the rat's tail (17).

A concentration of 10^{-4} Gm./ml. of the glucoside or its aglucone did not have any effect on the movements of isolated rabbit intestine or rat uterus (7). Acetylcholine induced contractions of the isolated rabbit intestine, rat uterus, and dog tracheal muscle preparation (18), were also not influenced by this concentration of the two compounds. A concentration of 5% of the glucoside or 0.5% of the aglucone did not exhibit any mydriatic, miotic, or local anesthetic effect on the rabbit eye. Ciliary movements of the frog esophagus (7) and acetylcholine induced contractions of frog rectus abdominis muscle preparation (7) were also not affected by a concentration of 10^{-3} Gm./ml. of the glucoside or its aglucone This concentration failed to show any antibacterial activity against *Staph. aureus*, *E. coli*, *S. typhi*, and *P. vulgaris* by the agar plate method.

Intravenous LD_{50} of the glucoside in mice (19) was found to be 576 mg./Kg. of body weight. Because of its low solubility, only the oral toxicity of the aglucone, as a 10% suspension in 4% acacia, was studied in rats. No mortality could be recorded with doses upto 2 Gm./Kg. of body weight. Chronic administration of 200 mg./Kg. of body weight of the glucoside and 100 mg./Kg. body weight of the aglucone given subcutaneously to mice failed to alter body weight or induce any histological changes in the liver, kidney, heart, spleen, or brain.

DISCUSSION

The most prominent property of the compounds isolated from *Caccinia glauca* is their diuretic activity. This property is exhibited after oral as well as parenteral administration to conscious and anesthetized rats and anesthetized dogs. Activity is manifested in doses which do not have other pharmacological actions. Thus diuretic activity could be elicited with a dose of 50 mg./Kg. of body weight of the compounds while the same dose given intravenously failed to influence blood pressure, heart rate or electrocardiogram. Only very high doses had any significant cardiovascular activity in the intact preparations. Isolated tissues also were affected by very high concentrations only. Since phenol red and chloride excretions were not affected while endogenous creatinine excretion in dogs was increased in proportion to the increase in urine output, it appears that these compounds act by increasing glomerular filtration. This very much resembles the action of xanthines, which have their main value in cases resistant to mercurial diuretics due to a low glomerular filtration (20) and are the only agents available at present which effectively increase glomerular filtration. The xanthines, however, possess undesirable side effects, especially in large doses, on the cardiovascular, gastrointestinal and central nervous systems. On the contrary, the isolated glucoside and the aglucone, even in large doses, do not exhibit any such undesirable actions as shown by this study. They may, therefore, be considered to have some promise for further studies.

Pharmacology and Toxicology of Scandium Chloride

By THOMAS J. HALEY, N. KOMESU, L. MAVIS, J. CAWTHORNE, and H. C. UPHAM

The pharmacological and toxicological properties of scandium chloride have been investigated. The intraperitoneal and oral LD_{50}'s were 755 mg./Kg. and 4 Gm./Kg., respectively. Studies of chronic toxicity showed no body weight changes occurred in any group except the male rats on a 1% dietary level. The hemograms of all animals were within the normal range. Histopathological examination of the tissues revealed no damage related to the ingestion of scandium chloride. Transient ocular irritation was observed and the chemical produced extensive scar formation when applied to abraded skin. Pharmacological studies indicated that the chemical had a depressant action on all systems studied and produced lethality by respiratory paralysis coupled with cardiovascular collapse. The lethal effects could not be counteracted by atropinization or epinephrine administration.

In his review of the chemistry of the rare earths, Moeller (1) pointed out that these elements had certain properties which would eventually lead to their industrial usage. However, our knowledge of the biological effects of one of this series, scandium, is almost nonexistent. Mines (2) reported that scandium chloride decreased systole and stopped the perfused frog heart ventricle in diastole. Washing gradually restored its contractility. In this action, scandium was weaker than both erbium and lanthanum. Ishiwara (3) found that scandium exerted an inhibiting effect on mouse carcinoma. Chargaff and Green (4) showed that scandium exhibited an antithrombic effect but showed no antithromboplastic effect. Grant and Kern (5) found that scandium chloride had little or no effect on the intact rabbit eye but produced a permanent opacification of the corneal stroma when the epithelial layer of the cornea had been removed. In an effort to increase our knowledge of the biological actions of scandium chloride, we have investigated its pharmacological and toxicological effects.

EXPERIMENTAL METHODS

The intraperitoneal LD_{50} was obtained with 258 male CF-1 mice and the oral LD_{50} with 130 male CF-1 mice. Chronic toxic effects of scandium chloride were determined by including 0.01, 0.1, and 1.0% of the compound in the diet and feeding it over a period of 90 days to three groups of CRW rats. Each group contained six males and six females. Observations were made every 2 weeks of the following: total erythrocytes, total leukocytes, differential cell count, platelets, hemoglobin, hematocrit, and body weight. Upon completion of the study, histopathological examination was made of the heart, lung, liver, kidney, spleen, pancreas, adrenal, and small intestine. The method of Draize, *et al.* (6), was used to study ocular and skin irritation in rabbits and intradermal irritation in guinea pigs. Three rabbits were used in the ocular studies. Each rabbit had one eye exposed to 0.1 ml. of a 1:1 aqueous scandium chloride while the other eye served as the control. Rabbit skin irritation studies used six animals according to the design of Draize, *et al.* (6). Three guinea pigs were used in the intradermal studies; the concentrations of scandium chloride were: 1:10 to $1:10^6$. Effects of the chemical on isolated guinea pig ileal strips bathed in Locke-Ringers solution were studied in a thermostatically regulated 25-ml. bath using the Trendelenburg method (7). Studies were also made on the isolated rabbit ileum in the presence of 2.5 mcg. of acetylcholine. Ten cats of both sexes, weighing 2.72–3.90. Kg. were anesthetized with 0.5 ml./Kg. of Dial-urethane intraperitoneally. A six channel Offner Dynagraph with Statham transducers was used to record carotid arterial pressure, respiration, nictitating membrane contraction, ECG Lead II, femoral arterial pressure, and femoral arterial flow. The latter was obtained with a 25-ml. Shipley-Wilson flowmeter (8). Preganglionic stimulation of the cervical sympathetic fibers and the contralateral vagus fibers was accomplished with a Grass model S-4 stimulator at 8V/10 sec. Two hours were allowed to elapse prior to beginning drug administration. Intravenous doses of the drugs used were: scandium chloride 0.5 to 20 mg./Kg.; epinephrine 5 mcg./Kg.; acetylcholine 5 mcg./Kg.; histamine 2 mcg./Kg.; and atropine 2 mg./Kg. All injections were made at a constant volume of 1 ml. Where appropriate, the results were analyzed statistically by the Litchfield-Wilcoxon method (9) or standard errors were calculated.

RESULTS

Acute Toxicity.—The symptoms of acute toxicity were immediate defecation, abdominal stretching, depressed respiration, tremor of the hind legs, and sedation. The first deaths occurred within 24 hours but the peak was not reached until 96 hours.

Received March 19, 1962, from the Laboratory of Nuclear Medicine and Radiation Biology of the Department of Biophysics and Nuclear Medicine, School of Medicine, University of California, Los Angeles.

Accepted for publication May 16, 1962.

These studies were supported by Contract AT(04-1)GEN-12 between the Atomic Energy Commission and the University of California.

Presented to the Scientific Section, A.PH.A., Las Vegas meeting, March 1962.

Throughout the entire 7-day period of observation the animals were unthrifty. The intraperitoneal LD_{50}/7 days for scandium chloride was 755(741.7–768.6) mg./Kg. with a slope value of 1.06(0.99–1.13). The oral LD_{50}/7 days was 4.0(3.96–4.04) Gm./Kg. with a slope value of 1.03(1.0–1.06).

Chronic Toxicity.—Throughout the 12-week period of feeding the various levels of scandium chloride in the diet, the test animals did not appear to differ in general appearance from the controls. The growth curves (Fig. 1) indicate that, at the dietary levels of scandium chloride studied, there was no significant effect on growth except at the 1% level in male rats. However, at the conclusion of the experimental period even these animals were beginning to approach the control animals in growth. The hemogram of all the animals (Table I) indicated that the chemical had no significant effects on the hematological response of the animals. The changes in the various cells and hemoglobin were probably related to the normal growth pattern of the rats because they were within the ranges given for the rat by Gardner (10). Data on differential counts are not included in Table I because there were no significant differences between the control and treated groups and the data were equivalent to the normal distribution given by Gardner (10). At autopsy, the internal organs of all groups appeared normal; there were no outward signs of damage attributable to the ingestion of scandium chloride for 12 weeks. Furthermore, histopathological examination of the heart, lung, liver, kidney, spleen, pancreas, adrenal, and small intestine revealed no changes which could be related to the ingestion of scandium chloride at the dietary levels studied.

Ocular Irritation.—Direct application of 0.1 ml. of 1:1 scandium chloride solution to the eyes of three rabbits produced a slight translucency in-

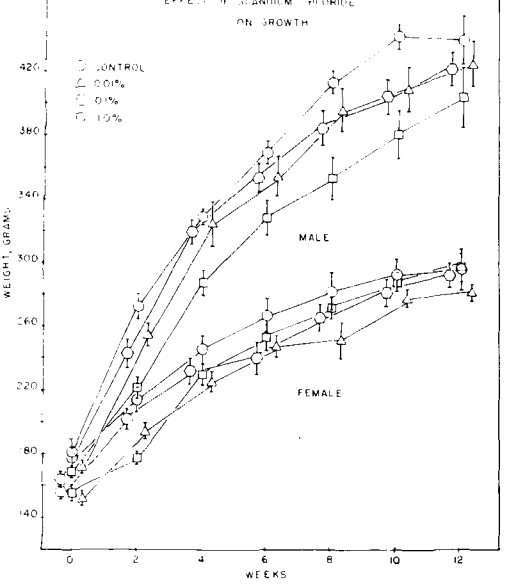

Fig. 1.—Response of male and female CRW rats to feeding various levels of scandium chloride in the diet for 90 days. Bars signify the standard errors. Each group contained six animals for each dosage level.

[a] M ± SE = mean ± standard error—based upon six animals per group per dosage level. Based on determinations done every two weeks.

volving less than half of the cornea with a loss of reaction to light by the iris. This corneal reaction completely cleared up within 48 hours and no residual damage was observed. The 24-hour irritation indices for the cornea and iris were 20 and 5, respectively, indicating a transient medium degree of irritation to these structures. Within 1 hour, the conjunctiva was a diffuse beefy red, chemosis had produced a swelling of the eyelids which kept them more than half closed, and there was a discharge which moistened the lids and a considerable area around the eyes. The irritation index reached the maximum score of 20 and small ulcers appeared on the conjunctiva within 24 hours. Healing progressed satisfactorily. All evidence of damage was absent after 96 hours.

Skin Irritation.—Direct application of 0.5 Gm. of crystalline scandium chloride to intact rabbit skin produced no reaction throughout the entire 14-day observation period. There was a very severe reaction on abraded rabbit skin with a maximum irritation index of 8 at 24 hours. No changes in irritation index occurred up to 14 days. However, healing with scar formation was observed at 45 days. The scars were 25 to 30 mm. in diameter. Intradermal injection of scandium chloride at concentrations of 1:10 and 1:100 produced necrosis within 1 hour and an irritation index (erythema plus edema) of 8 which persisted for 7 days. Healing occurred at 14 days with epilation and scar formation in the injected area. At the concentration of 1:1000, the only difference in response was the absence of the early necrosis. The concentrations of $1:10^4$ to $1:10^6$ gave an irritation index of 2 at 24 hours, and complete healing w.thout scar formation occurred at 72 hours.

Effects on Isolated Ileum.—Scandium chloride, dosage range of 10 to 30 mg., produced an increasing depression of intestinal tonus and contractility terminating in complete paralysis of the rabbit ileum. Repeated washing of the five ileal strips did not restore contractility. This depressant effect counteracted the spasmogenic action of acetylcholine. The antispasmodic ED_{50} of scandium chloride was 15.5(8.0–30.2) mg. with a slope value of 2.15(0.65–7.1). Such depressant action also occurred with the Trendelenburg guinea pig preparation where the ED_{50} figures for blocking both the circular and longitudinal muscular contractions, respectively, were: 11.7(8.8–15.3) mg. and 5.6(2.8–11.2) mg. The muscular contractions of this preparation are related to pressure stimulation of the enteric ganglia, thus it would seem that scandium has ganglionic blocking properties. However, experiments with the superior cervical ganglion preparation of the cat indicated that this was unlikely.

Pharmacological Effect.—Within the dosage range of 0.5 to 2 mg./Kg., scandium chloride produced no observable pharmacological effects in the cat. At a dose of 5 mg./Kg. there was a transient loss of blood pressure varying from 15 to 70 mm. Hg and a permanent loss of 10 to 20 mm. Hg from the predrug level. A similar reaction occurred with femoral arterial pressure and blood flow decreased slightly. At this dose the electrocardiogram showed a decrease in the height of the entire complex followed by a high takeoff of the P-wave and a return to normal rhythm and size. In four of the five animals, complete cardiovascular collapse occurred at 10 mg./Kg. and was followed by respiratory paralysis. A similar effect was observed in the other animal at 20 mg./Kg. Prior to exitus, the respiratory rate was not affected. The terminal electrocardiographic changes included a decrease in the entire complex, P-wave absent, T-wave inverted, transient ventricular fibrillation, increased interval between the QRS and the T-wave, a 2 to 1 heart block, inverted QRS complex, and an increased T-wave. Within the dosage range investigated, scandium chloride did not affect the pharmacological responses to acetylcholine, epinephrine, histamine, or vagal stimulation. Furthermore, it had no effect on transmission in the superior cervical ganglion or on contraction of the nictitating membrane. None of the effects of scandium chloride could be counteracted or modified by atropine and the cardiovascular collapse could not be counteracted by epinephrine.

DISCUSSION

From a toxicological viewpoint scandium chloride is less toxic acutely or chronically than gadolinium or samarium (11) or niobium (12) or hafnium (13). However, its detrimental effects on ocular tissues and skin are only exceeded by niobium and hafnium (12, 13). The depressant effects observed by Mines (2) on the isolated frog heart appear to be quite similar to those we observed on the cat heart *in situ*. In general the overall pharmacological effects of scandium chloride on the various body systems studied were of a depressant nature. The mode of death, respiratory paralysis coupled with cardiovascular collapse, was almost identical with what has been observed for the other chemicals in the rare earth series (11–13). Upon the basis of the present investigation, it would appear that scandium chloride exerts its greatest toxicity locally, and proper application of good industrial hygiene practices; respirators, protective clothing, etc.; would prevent acute or chronic exposure.

Effects of Ionizing Radiation on Two Gelatin Fractions I

Material Preparation, Dosimetry, and Acid-Base Behavior

By LEONARD P. PRUSAK† and BARTLEY J. SCIARRONE

Two fractions, F-I and F-II, were isolated from commercial pigskin gelatin by low-temperature alcohol precipitation. Both fractions, in the form of 1% and 5% solutions and as films, were exposed to variable electron beam irradiation emanating from a 3 Mev Van de Graaff accelerator to give absorbed-dose values of from about 0.1 to about 3 Megarads. Radiation dose was determined by means of Ce(IV)-Ce(III) and polyvinylchloride dosimetry. Acid-base titration curves on the commercial gelatin sample, control fractions F-I and F-II, and irradiated F-I and F-II, as 1% and 5% solutions and as films, all showed differences in —COOH and —NH_2 content.

ASIDE FROM its application to sterilization techniques, the development of ionizing radiation as a research tool has facilitated a more profound understanding of the structure of complex proteins and polymers. Radiation caused by charged and uncharged particles and electromagnetic waves has been widely used by chemists to determine structural vulnerability to high-energy impingement through bond rupture, free radical formation, crosslinking, decarboxylation, and deamination.

Interaction of high-energy radiation with proteins is known to produce a variety of chemical and physical effects, depending on the system. Gelatin was chosen as the test material to study these effects. The wide pharmaceutical importance of gelatin is evidenced by its uninterrupted inclusion in the United States Pharmacopeia since the eighth decennial revision in 1905.

Despite intensive investigation in numerous laboratories, a full explanation of the peculiar behavior of gelatin under varying environment is still unavailable. Interpretative difficulties arise because the material known as "Gelatin" is a heterodisperse system, some fractions having molecular weights as high as 400,000. The distribution of smaller protein molecules depends upon the source and treatment of its precursor, collagen, as well as its subsequent refinement. In general, therefore, more meaningful experimental results are obtainable only after appropriate fractionation, especially when dealing with commercial gelatin.

It is not known to what extent hydrolysis of the protein may occur during separation, such as treatment with alcohol, nor is it known how radiation affects the isoelectric point of the protein. This necessitates the characterization of each fraction by the determination of the milliequivalents of acid and base bound per gram of protein as a function of pH. Hence, these determinations are also useful in comparing the behavior of gelatin fractions following exposure to high-energy radiation at identical levels. This is particularly true if any one or combinations of the following four modes of interaction are operative during irradiation: (*a*) end-group hydrolysis, (*b*) polymerization, (*c*) scission, and (*d*) crosslinking phenomena.

It was intended to establish by this investigation experimental procedures to study the effects of the exposure of gelatin to high-energy radiation. Since we chose to work with commercial pigskin gelatin, a modification of a known fractionation procedure was used to reduce heterogeneity. The modified procedure gave a relatively large molecular weight fraction and a smaller molecular weight fraction both having greater sensitivity and viscosity characteristics (1). There appeared to be no justification to include, in work of this scope, a study of radiation effects on each of several gelatin fractions.

The dosimetry was established using both cericcerous and polyvinylchloride techniques The radiation doses were limited to those producing visually nondiscernible denaturation of the gelatin since acid-base titrations or other physical measurements on solutions containing precipitated protein would not yield readily interpretable results.

Of particular interest was the effect of ionizing radiation on gelatin in the presence and absence of water. For this reason, measurements of the two fractions were attempted on diluted solutions (1%), gels (5%), and solid state films.

EXPERIMENTAL

Material Preparation.—The method of Hultin, *et al.* (1), was modified as follows: Two hundred grams of purified pigskin gelatin (Eastman Kodak Lot No. 5247) were soaked in 4500 ml. distilled water overnight at 25°. The temperature was then increased to 42° whereupon the gelatin immediately dissolved. A sufficient volume of ethanol was then added to bring the volume to 52% v/v, and the mixture was allowed to stand for 24 hours at room temperature. Alcohol was again added to bring the volume to 61%. After 24 hours standing at room temperature, the mixture was halved in volume. The alcohol content of the first half was increased to 72%. After 24 hours, the temperature of the mixture was reduced to −2° and the alcohol content increased to 76%. The mixture was allowed to stand for 72 hours. Ammonium hydroxide was added dropwise to an apparent pH 10, whereupon a precipitate formed which was allowed to settle overnight to permit decantation of the supernate the following morning, leaving Fraction I (F-I).

The second half of the separated volume was allowed to age 4 days at room temperature. The alcohol concentration was then increased to 78%, the temperature reduced to −2°, and ammonium hydroxide added to an apparent pH of 10. A white precipitate formed which was allowed to settle overnight. The supernate was decanted, leaving Fraction II (F-II).

Both fractions (F-I and F-II) were dried under vacuum at room temperature, dialyzed against water and aliquotes lyophilized. Freeze-drying *in vacuo* of F-I produced a dense, hard, white mass which was reduced to granular form. F-II, also white, was characteristically different in texture, less dense, and softer than F-I. Both fractions were stored over Drierite. Yields were 33.2% and 22.4% of F-I and F-II, respectively.

Dosimetry.—Initial experiments on solid-gelatin films and aqueous systems contained in glass were conducted at relatively high (2.5–25 Megarads) ranges on a 6-Mev linear accelerator. All samples suffered degradation, as evidenced by gas evolution and various states of separation from turbidity to heavy precipitation. According to Weiss (2), the radial dimension of glass vessels is critical because of secondary electrons emanating from the vessel wall. As an alternative, polyethylene containers were tried and found to be more satisfactory than glass but precluded irradiating oxygen-free solutions.

Successful irradiation was achieved by exposing the aqueous gelatin systems in 4.5 in. x 6.5 in. heat-sealed polyethylene containers, 3.5 mils average thickness, under the scanned beam of the 3-Mev Van de Graaff accelerator for smaller dosages. Preliminary experimentation on 1% solutions and 5% gels of F-I and F-II indicated upper tolerances of energy at about 2.5–3.0 Megarads for F-I and about 2.0 Megarads for F-II to avoid visible denaturation. When these dose limits for F-I and F-II were exceeded, both the 1% solutions and the 5% gels showed evidence of cloudiness. The 5% gel also became extremely viscous. The degree of apparent denaturation appeared to be proportional to the excessive dose. Therefore, in order to remain below the irradiation dose limits, the Van de Graaff input microamperage was arbitrarily set at 50, 150, 450, and 1000 μ amps. at constant belt speed of 70 in./-min. to give four dose levels with the maximum at about 3 Megarads. (See Table I.)

TABLE I.—COMPARISON OF PVC AND CERIC DOSIMETRY

	Dose (Mrads.) per Individual Run		Average Dose, Mrads.

	2.9	3.020		

Exposure to the electron beam was carried out by placing one sealed polyethylene unit containing 20 ml. of a 1% solution, a second unit containing 20 ml. of a 5% solution and two film strips of a given fraction on 9 in. x 15 in. aluminum trays provided with $^3/_4$ in. wood backing to minimize back scattering. All physical measurements were made on freshly irradiated gelatin solutions and films.

In addition to the gelatin solutions and films to be irradiated, each tray included a polyethylene unit containing 20 ml. of freshly prepared 0.015 *M* ceric ammonium sulfate in 0.8 *N* sulfuric acid (in triple distilled water) for precise dosimetry calculations and one rigid polyvinylchloride (PVC) slide for additional dosage approximation. Weiss (2) found that ceric dosimetry is very reliable when the total absorbed dose is in the order of 6 million rep. Subsequently Harlan, *et al.* (3), established the reliability of ceric dosimetry for high level irradiation measurements up to 10^8 rads. In our hands the ceric system was accurate and reproducible within the dose range applied in the experiments.

Immediately prior to irradiation a 0.005 *M* standard ferrous ammonium sulfate solution was prepared. This was used to standardize the nonirradiated ceric ammonium sulfate and to back-titrate the irradiated volumes, using 1,10-phenanthroline as the end-point indicator. Irradiation runs were completed on the same day and titrations were made immediately following exposure to minimize error due to air-induced oxidation. From the original concentration data and the back-titration, the number of micro-

moles of Ce(IV) reduced (or Ce(III) produced) was calculated. The total absorbed dose, E_t in units of *ev/L.*, was determined from ceric dosimetry through the following (3, 4)

$$E_t = (6.02 \times 10^{17}) \times (\mu \text{ moles Ce(IV) reduced}) \times \left[\frac{1000}{\text{Vol. used}}\right] \times \left[\frac{100}{2.5}\right]$$

and converted to Megarads using the relationship

$$6.37 \times 10^{22} \text{ ev/L.} = 1 \text{ Megarad.}$$

Rigid polyvinylchloride (PVC) dosimetry, as described by Artandi, *et al.* (5), was used concurrently with the ceric indicator. Although the sensitivity of PVC at low levels does not approach that of the ceric-cerous system, its application in the present work as an approximation for absorbed energy proved highly desirable. Table I shows PVC and ceric determinations on a series of five irradiation runs. These data were analyzed and the best fitting equation was calculated to be

$$Y = 0.9259X - 0.0575, 0.11 \leq X \leq 3.02$$

where, Y = PVC reading and X = ceric reading. The above equation is valid only over the stated range of X. The degree of fit, or how well the Y values depended on the X values, was 98.5%, which is considered good.

Acid-Base Behavior.—All titrations were conducted under a nitrogen atmosphere on 10-ml. solutions which were 1% with respect to the gelatin concentration. Several drops of octyl alcohol were added as an antifoaming agent. Titrant volumes of 0.1 *N* sodium hydroxide and 0.1 *N* hydrochloric acid were measured with a model SB2 syringe microburet. The pH values were measured with a Beckman model G pH meter employing a glass and saturated calomel electrode system.

Titrations were performed on the commercial gelatin, irradiated and unirradiated water controls, and fractions F-I and F-II, the latter two as (*a*) controls, (*b*) irradiated 1% solutions, (*c*) irradiated 5% gels, and (*d*) irradiated films. Titration volumes were corrected by subtracting the appropriate water controls. The titration curves were obtained by plotting the observed pH (abscissa) against the milliequivalents of acid or base bound per gram of protein. Gelatin concentrations for this purpose were obtained by dry weight.

In order to provide comparison among the three forms of each fraction, as well as between the two fractions, four-level irradiation was conducted on all forms of both fractions simultaneously. The average dose imparted to each of four separate passes under the electron beam was calculated to be: (*a*) 0.37, (*b*) 0.84, (*c*) 2.00, and (*d*) 3.00 Megarads, respectively.

RESULTS AND DISCUSSION

Unirradiated F-I and F-II titration curves, although nearly identical and characterized by equilibrium pH 7.0, represented a distinct shift from their parent source which showed a pH of 4.8 at equilibrium. (See Fig. 1.) Irradiated F-I and F-II titration curves showed nearly complete superimposability for a given form at various irradiation levels. Thus F-I, irradiated as the 1% solution,

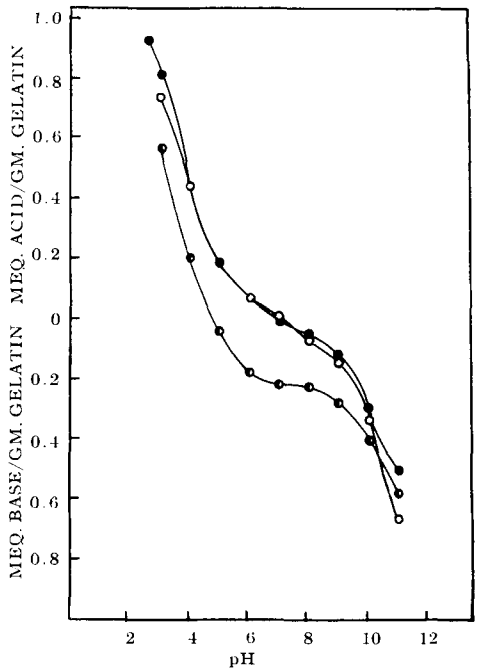

Fig. 1.—Titration curves of controls in the form of unirradiated F-I (○), F-II (●), and commercial gelatin (◐).

showed four nearly identical curves at 0.37; 0.84; 2.00; and 3.00 Mrads. The same pattern prevailed in the remaining five forms and was especially pronounced in the case of irradiated films, with slight departures at the extreme ends of the curves.

Comparison of F-I and F-II at any given radiation level with respect to a particular form, *e.g.*, 1% solution, showed differences in structure. Figure 2 is illustrative. The 1% solutions irradiated at 0.37 Mrad. appeared to be similar at either end of the titration range, but in the region from pH 4.0 to 10.0 more acid than base volumes were required to bind F-I than F-II. Values fell at pH 5.5 and pH 7.0, respectively. At the 0.847 Mrad. level, solutions of both fractions at the same concentration showed similar patterns in the extreme acid and base regions. Deviation in milliequivalents of acid/base bound per gram of protein began at pH 3.0, increased gradually to a maximum at pH 6.0–8.0, then returned slowly to near similarity. Although the equilibrium pH of F-I did not shift (5.5) despite the twofold increase in absorbed dose, a slight increase appeared in F-II (pH 7.2).

By increasing the irradiation dose to 2.0 Mrads., titration curves on 1% solutions of F-I and F-II continued to show the inversely proportional relationship between dose and milliequivalents of acid/base bound in the midportion of the curve. When the irradiation dose was further increased to 3.0 Mrads., curves of F-I and F-II approached superimposability, with only a small difference in milliequivalent values in the midportion.

Plots of F-I and F-II 5% solutions differed from their 1% counterparts along the entire titration curve. A consistently gradual approach toward pH 7.0 in the four cases studied from either extreme was apparent. Figure 3 is illustrative of this series. More milliequivalents of acid were required to bind

1 Gm. of F-I than F-II. This differential was gradually reduced until pH 7.0 where no difference existed and the curves crossed. F-II showed progressively greater milliequivalent requirements and increasing departure from F-I as the extreme alkaline end of the curve was approached.

Films of F-I and F-II, at all four irradiation levels studied, showed remarkably consistent similarity in titration curve behavior. Figure 4 shows a representative curve of a film of F-I irradiated at 0.37 Mrad. in this series. Slight variations (*ca.* 0.02 milliequivalents) among the various plots in isolated sections of the curves were not considered critical, all eight plots being substantially similar within limits of experimental error. Equilibrium values for films of F-I and F-II at all four irradiation doses consistently fell at pH 7.0.

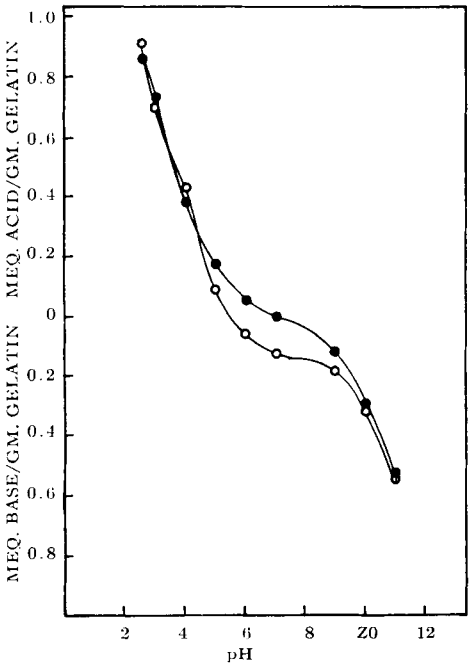

Fig. 2.—Titration curves of F-I (○) and F-II (●) after 1% dispersions of each were subjected to irradiation dose 0.37 of Mrads.

CONCLUSIONS

Treatment of commercial gelatin (pH 4.9) with alcohol under low-temperature conditions and adjustment of pH to a value on the alkaline side appears to disrupt the charge on the parent gelatin molecule, reducing its acid/base binding capacity and shifting the pH to neutrality. In changing from one form to another, there is a loss of amide nitrogen in the form of ammonia, resulting in an increase in the number of free carboxyl groups and base-fixing capacity (6). Further, the shift in position of the titration curve can be attributed to the liberation of carboxyl groups concurrent with release of amine ammonia. The shift is the same regardless of molecular weight

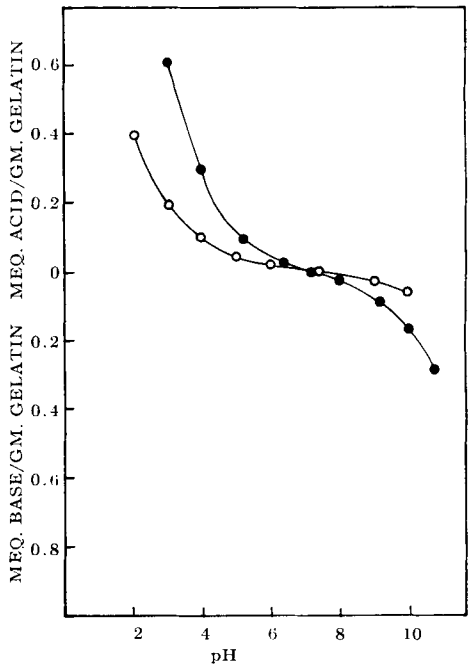

Fig. 3.—Titration curves of F-I (○) and F-II (●) after 5% dispersions of each were subjected to irradiation dose of 20 Mrads.

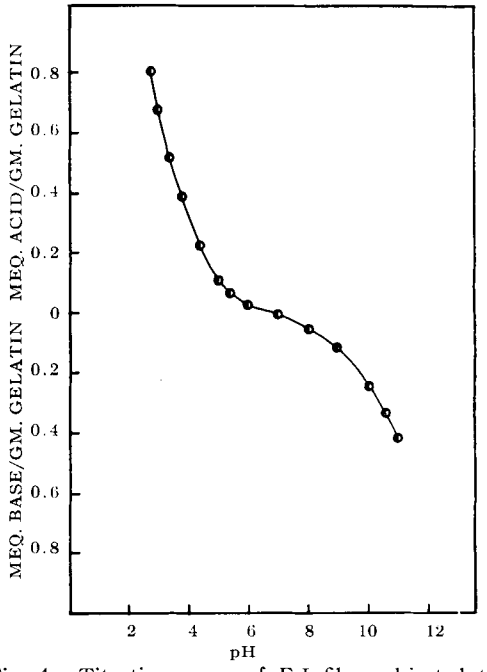

Fig. 4.—Titration curve of F-I film subjected to irradiation dose of 0.37 Mrads.

characteristics of the fractionated components.

Irradiation at similar levels of the two gelatin fractions as 1% solutions does not materially affect either their acid-binding or base-binding capacity at the distal ends of the titration curves.

In the region of neutrality, and 2 pH units on either side of it, a substantial variance occurs at the lowest irradiation level which gradually lessens as the dose is increased. To this portion of the curve are attributable the imidazole groups of the protein. It is evident that the low molecular weight fraction (F-II) requires acid/-base milliequivalents of constant value in this region whereas the high molecular weight fraction initially (0.37 Megarads) binds 0.12 milliequivalents of base; this requirement gradually diminishes as the dose of ionizing radiation is increased.

In 1:20 solute:solvent ratio during the ionization process, a given gelatin fraction shows entirely different charge structure from that when irradiation occurs at 1:100 ratio. The decrease in volume requirements of acid and base indicates a reduced availability of titratable amino and carboxyl groups.

In subsequent reports we shall present the results of further studies showing experimental evidence supporting our belief that the two fractions not only differed from each other but behaved differently under changing irradiation stress.

Kinetics of Steroid Effects on Ca^{47} Dynamics in Dogs with the Analog Computer I

By EDWARD R. GARRETT†, RICHARD L. JOHNSTON, and ELLIOTT J. COLLINS

Intravenous administration of the short-lived isotope Ca^{47} in dogs was followed by the measurement of Ca^{47} in blood, feces, and urine during a control phase, a steroid regimen (2 mg./Kg./day), and a final recovery, post-steroid phase. Methods and procedures were developed to analyze the data by a combination of digital and analog computer techniques. In all dogs and in all phases the specific rate constants of a polyexponential fit for the distribution of Ca^{47} in all hypothetical compartments under all the experimental conditions studied were similar. The cumulative fecal and urinary Ca^{47} eliminations were fitted to a first order curve as a function of time by the analog computer. The most striking effect of steroid therapy in the young dog used as his own control is the increase in first order Ca^{47} elimination within the first 200 hours to $1\frac{1}{2}$ to 2 times the control values. After cessation of steroid therapy, the per cent of the total intravenous dose eliminated decreased and approached the amount of the control period within these 200 hours. The residual Ca^{47} is tied up in the bone and is slowly released at an apparently linear rate over longer periods of time. The rate of release between 200 and 700 hours is twice as great with steroid regimen as without for both control and recovery phases.

RADIOCALCIUM and other bone-seeking isotopes have been used in kinetic analyses of changes in blood and excretion of injected radioisotope (1–4). The radioisotope, Ca^{47}, has recently become available and presents certain advantages over previous radiocalcium studies in that it is a gamma emitter of short half-life of 4.56 days and an animal can be used as his own control in short-term sequential studies of the effect of a therapeutic agent or experimental condition on the kinetics of radiocalcium distribution, metabolism, and excretion.

The advantages of this isotope have permitted us to initiate an investigation of the osteoporotic effects of adrenal steroid regimen and its potential reversibility. Preliminary studies have demonstrated that this phenomenon is common to all the adrenal steroids in varying degree (5, 6) but one was chosen for the detailed study presented in this paper.

This paper presents a detailed quantitative analysis of our first studies on the effects of adrenal steroids on the distribution and kinetics of intravenously administered Ca^{47}. The digital- and analog-computer techniques described herein greatly facilitated the quantification of the huge masses of data it was necessary to obtain in such studies.

Special emphasis was also placed on the initial disappearance curves of radiocalcium from the blood, studies of which have not received too much attention previously (7).

METHODS

Treatment of Animals.—Three beagle dogs and one mongrel were used in these experiments. The animals were conditioned to the metabolism cages and laboratory routine prior to experimentation. Pertinent data for dogs 0 through 3, given as initial age in months, body weight in Kg. and sex are for dog 0: 7, 9.30, M; dog 1: 7, 7.50, M; dog 2: 9, 6.25, F; and dog 3: mongrel of indeterminate age, 9.20, F. The methods and procedures of intravenous administration of Ca^{47} and of the determination of radioactivity in blood serum, urine, and feces have been detailed elsewhere (5).

The studies were conducted in five sequential phases. Ten days after the initial administration and study of the distribution of 50 μc. of Ca^{47} (control, study *A*), 2 mg./Kg./day of 6α-methylprednisolone were given orally. Two weeks later, Ca^{47} was again administered and the distribution studied (steroid, study *B*). Five weeks after initiating steroid therapy, Ca^{47} was again administered and the distribution studied (steroid, study *C*). Steroid therapy was reduced at the rate of 1 mg./day for 52 days and was halted 112 days after its inception. The radioisotope Ca^{47} was administered and the distribution studied at 40 days (recovery, study *D*) and at 117 days (recovery, study *E*) after cessation of steroid therapy.

The dogs were sampled for blood after intravenous administration of Ca^{47} at 2, 4, 6, 8, 10, and 15 minutes; then at 15-minute intervals to 120 minutes; at 30-minute intervals to 4 hours; at hourly intervals to 9 hours; at 12, 24, 30, 36, and 48 hours; and at subsequent 24-hour intervals for 10 days.

The urine was collected at 4, 8, 12, 24, 30, 36, and 48 hours and at subsequent daily intervals until the study was terminated. Catheterization was used throughout the first 48 hours. The feces were collected at the end of 12 hours and at subsequent daily intervals.

In the studies biopsies were performed on a long bone and costal bone 48 hours after radioisotope administration, each time from a different limb. Antibiotics, tetracycline phosphate and novobiocin, were administered for 8 days after surgery. The site of the biopsy was replicated as closely as possible. However, the data were so variable from dog to dog and without any consistent pattern among the sequence of studies *A* through *E* that they are not worth reporting. Similar experiences have been encountered from biopsies of bone after radioisotope administration by Rich (8).

Treatment of Data.—The actual counts of Ca^{47} in blood, feces, and urine were converted into the % of the initial count of the dose of Ca^{47} given to each dog. This necessitated the counting of a standard aliquot of Ca^{47} in solution simultaneously with the samples of the studies to correct the values for the natural radioactive decay of Ca^{47}. The errors in counting were computed by statistical methods considering the time of counting and the magnitude of the count for the tissue, the standard, and the background (9).

The blood serum data reported consisted of the time of blood withdrawal, the total radiation count, c for v ml. of serum counted for t minutes. Alternately, a background count c_B, was taken for t_B minutes. A fraction of the Ca^{47} solution used for injection was conserved as a standard and was counted alternately with all samples, a count of c_S for t_S minutes. The initial total Ca^{47} dose, D in c.p.m. after correction for background, was also counted alternately with the standard, c_{S_o} minutes, at the time of intravenous administration of the dose. The Burroughs *E*-102 digital computer was programed to calculate and read out the Ca^{47} content of blood serum at time t, $Ca_B{}^{47}$, per ml. of serum as the % of the initial total dose as

$$Ca_B{}^{47} \text{ (per ml. serum, \% of total dose)} = 100\, q(c/tv - c_B/t_B)/D \quad \text{(Eq. 1)}$$

where

$$q = (c_{S_o}/t_o - c_{B_o}/t_o)/(c_S/t_S - c_B/t_B) = S_o/S \quad \text{(Eq. 2)}$$

The error E due to counting per ml. serum as the % of the initial total dose can be estimated from

$$E = Ca_B{}^{47}\sigma_{qc}/qc \quad \text{(Eq. 3)}$$

where the counting error of D is ignored since D is a constant for all serum samples. The fractional error in the count after correction for the normal radioactive decay of Ca^{47} can be estimated (10) as

$$\sigma_{qc}/qc = \sqrt{\sigma_c{}^2/c^2 + \sigma_q{}^2/q^2} \quad \text{(Eq. 4)}$$

where

$$\sigma_c = K\sqrt{c/t^2 + c_B/t_B{}^2} \quad \text{(Eq. 5)}$$

and

$$\sigma_q = q\sqrt{\sigma_{S_o}{}^2/S_o{}^2 + \sigma_S{}^2/S^2} \quad \text{(Eq. 6)}$$

$$\sigma_S = K\sqrt{c_S/t_S{}^2 + c_B/t_B{}^2} \quad \text{(Eq. 7)}$$

$$\sigma_{S_o} = K\sqrt{c_{S_o}/t_{S_o}{}^2 + c_B/t_B{}^2} \quad \text{(Eq. 8)}$$

where the K values are given in the literature (9).

When 9.158×10^6 c.p.m. of Ca^{47} were intravenously administered with a standard count at the time of injection of $S_o = 3891$ for $t_{S_o} = 1$ minute with a background count of $c_B = 1070$ for $t_B = 30$ minutes, typical data for a blood serum sample taken 2 minutes later are: $c = 6625$, $t = 1$ minute, $v = 1$ ml., $c_B/t_B = 36$ c.p.m., $c_S = 3868$ for $t_S = 1$ minute and thus $q = 1.006263$, and $Ca_B{}^{47} = 0.0724\%$ of initial radioactive dose per ml. of serum. With a K of 1.96 for 95% limits (9) $\sigma_S = 122.4647$, $\sigma_{S_o} = 122.28968$, $\sigma_c = 159.9653$, then $\sigma_q = 0.045305$, $\sigma_{qc} = 340.42131$, $\sigma_{qc}/qc = 0.051064$, and the error E due to counting variability is $0.0724 \pm 0.0037\%$.

The urine and feces data reported were similar to that of the blood except that the volume of urine collected V was included with the v ml. of urine counted c for t minutes; and the weight of feces collected W was included with w g of feces counted c for t minutes. The methods of calculation for Ca^{47} excreted by feces and urine were similar to those outlined for the blood serum except that the fecal and urine excretion of Ca^{47} was calculated in terms of the % of the total dose

$$P = 100q(c/t - c_B/t)W/wD \quad \text{(Eq. 9)}$$

where W/w of the feces becomes V/v in the case of urine.

The cumulative % excretion of injected dose at any time is summed, $\sum_{i=1}^{n} P_i$, and the error E in the accumulated ΣP_i is estimated from

$$E(\Sigma P_i) = \sqrt{\sum_{i=1}^{n} \sigma_i^2} \qquad \text{(Eq. 10)}$$

where a σ_i for a particular i^{th} urine or fecal sample is equivalent to the previously described σ_{qc}.

For a typical urine sample taken 4 hours after intravenous injection of Ca^{47}, $c = 5467$ for $v = 4.0$ ml. counted for $t = 5$ minutes with a background count of $c_B = 1385$ for 30 minutes and a standard count of $c_S = 10773$ for $t_S = 1$ minute. The total volume of urine, $V = 5.5$ ml. The correction factor calculated out to $q = 1.06704$ so that the % of the initial dose of Ca^{47} excreted in this urine sample was $P = 0.02685\%$. Since this was the first urine sample, $\Sigma P_i = P_1$. The error computations were $\sigma_S = 203.4489$, $\sigma_{S_0} = 210.1275$, $\sigma_q = 0.028165$, $\sigma_c = 29.08595$, $\sigma_{qc} = 43.6772$, so that the fractional error of the count was $\sigma_{qc}/qc = 0.03744$. The error in % of the original dose excreted in the urine was $0.0268 \pm 0.0010\%$.

For a typical fecal sample taken 24 hours after intravenous injection of Ca^{47}, $c = 879$ for $w = 2.8437$ g counted for $t = 1.0$ minute with a background count of $c_B/t_B = 33$ c.p.m. The total weight of the feces was $W = 730$ g. The correction factor calculated out to $q = 1.318133$ so that the % of the initial dose of Ca^{47} excreted in this fecal sample was $P = 4.8356$. The error computations were $\sigma_S = 208.2955$, $\sigma_{S_0} = 238.7188$, $\sigma_q = 0.03240$, $\sigma_c = 59.1907$, $\sigma_{qc} = 83.0112$ so that the fractional error of the corrected count was $\sigma_{qc}/qc = 0.07165$. The error E in % of the original dose excreted in this fecal sample was 4.84 ± 0.351.

Analog Computer Programing and Operation for Serum Data.—The Ca_B^{47} content of a ml. of the blood serum expressed as the % of the total radioactive dose is a function of time and can be described by an additive series of exponentials (1, 7, 11–13)

$$Ca_B^{47} = \sum_{i=1}^{n} A_i e^{-k_i t} \qquad \text{(Eq. 11)}$$

The final exponential of the series, $e^{-k_n t}$, can be obtained by a direct analog computer fitting, *i.e.*, by determining the best potentiometer setting, k_n, and best initial voltage A_n to fit the terminal data of a plot of Ca_B^{47} against time by the discharge of a capacitor (14, 15).

An equivalent procedure which gives the same information as to k_n and A_n is to plot the logarithm of Ca_B^{47} against time and determine the k_n from the slope ($= k_n/2.303$) and the A_n from the intercept (log A_n at $t = 0$) of the semilogarithmic plot for the terminal data of the blood serum Ca^{47} as a function of time. Typical plots are given in Fig. 1 for the data obtained in excess of 1,000 minutes after Ca^{47} administration.

The values plotted as log Ca_B^{47} between 1,500 and 7,000 minutes (Fig. 1) approximate linearity and provide a good estimate of a first order decrease of radioisotope for the elimination of Ca^{47} from the blood characterized by an exponential. The data beyond 7,000 minutes were frequently higher than could be expected on the premise that this was the true terminal exponential. However, these aberrant values would have little effect on the summation of exponential expressions

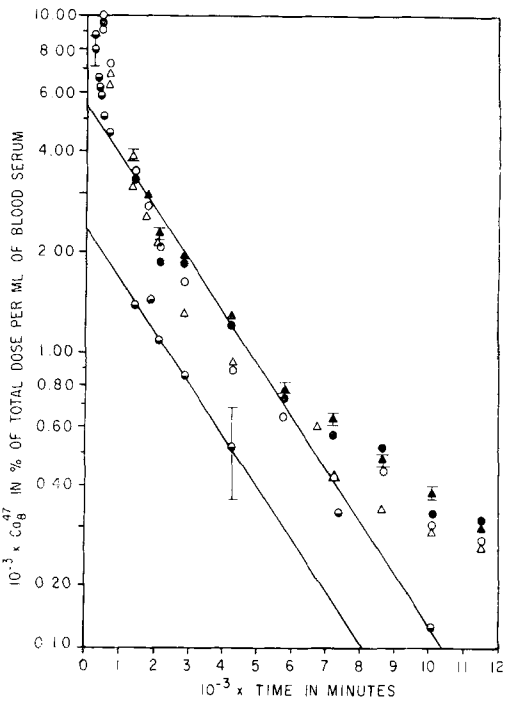

Fig. 1.—Typical semi-logarithmic plots of Ca_B^{47} in blood, % of total dose per ml. of serum, against time for that portion of total curve assigned to the final exponential. The data are for dog 0, studies A, ◐; B, ⊙; C, ●; D, △; and E, ▲. The horizontal lines above and below some of the data indicate the 95% confidence limits due to counting error.

$$\sum_{i=1}^{n-1} A_i e^{-k_i t} = Ca_B^{47} - A_n e^{-k_n t} \qquad \text{(Eq. 12)}$$

where Ca_B^{47} was defined in Eq. 11.

Both the analog computer and graphical techniques described gave similar values of k_n and A_n.

The analog computer program for determining the sum of exponentials is given in Fig. 2. The data calculated from Eq. 12 were fitted by the read out on the Mosely model 14 recorder summed from the necessary exponential functions so as to fully describe the overall decrease of Ca^{47} with time. The rapid decrease of Ca^{47} content of blood serum in the first 15 minutes was independent of the slower decreases over the remaining first thousand minutes. This is fitted on the analog computer with the best A_1 and k_1 value. Subsequently, an A_2 and k_2 value was attempted to account for the remaining data. It was found that two more exponentials were necessary to fully characterize the data so that the data have been plotted as $Ca_B^{47} - A_4 e^{-k_4 t}$ and is equal to $A_1 e^{-k_1 t} + A_2 e^{-k_2 t} + A_3 e^{-k_3 t}$. The $A_2 + A_3$ values and k_2 and k_3 values of the potentiometers were chosen to completely fit the data.

Thus the expression

$$Ca_B^{47} = A_1 e^{-k_1 t} + A_2 e^{-k_2 t} + A_3 e^{-k_3 t} + A_4 e^{-k_4 t} \qquad \text{(Eq. 13)}$$

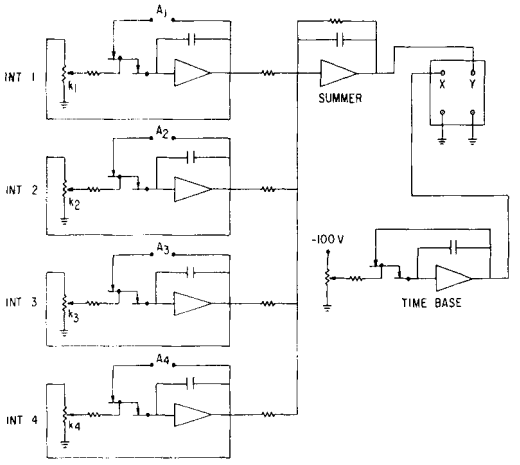

Fig. 2.—Analog computer program for fitting the sum of exponentials to plots of Ca_B^{47} in blood, % of total dose per ml. of serum, against time.

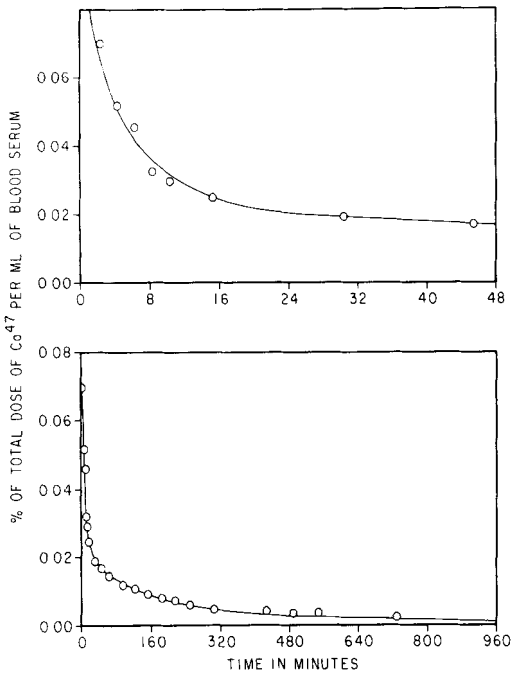

Fig. 3.—Examples of goodness of fit of analog computation of summed polyexponentials to the early phases of the plots of Ca_B^{47} in blood, % of total dose of Ca^{47} per ml. of blood serum against time, dog O, study *E*.

and the determined A_i and k_i values accounted for all the Ca_B^{47} data as a function of time with the possible exception of amounts in the order of thousandths of the original dose in the blood in excess of 7,000 minutes after administration of the dose. The drawn lines in Figs. 3 and 4 are typical examples of the goodness of fit obtained from the program of Fig. 2 and plotted out on the recorder. The A_i and k_i data so obtained for all studies on all 4 dogs are given in Table I.

[a] A_i are in % of initial total dose of Ca^{47}/ml. of serum and k_i are in sec.$^{-1}$. [b] Study *A* was the control study. Studies *B* and *C* were the steroid administration studies. Studies *D* and *E* were the recovery studies, *i.e.*, after cessation of steroid administration. [c] The injected doses of Ca^{47} were, in c.p.m., 5.92×10^6 for *A*, 9.16×10^6 for *B*, 15.2×10^6 for *C*, 5.72×10^6 for *D*, and 8.62×10^6 for *E*. The only exception was *A*, Dog 3, *viz.*, 2.96×10^6 c.p.m. [d] Dog deceased after this run.

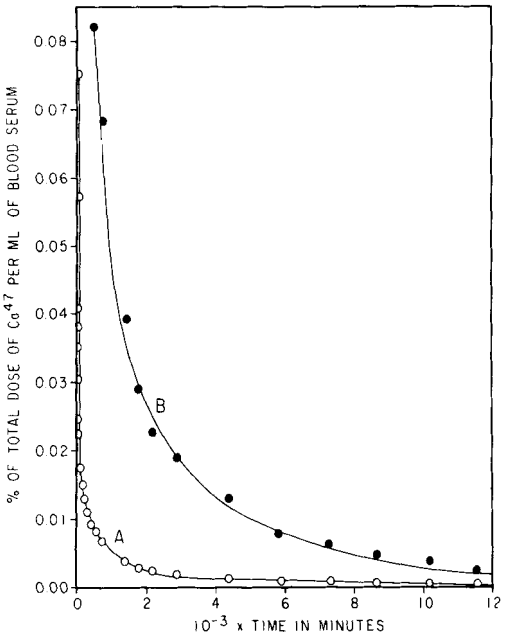

Fig. 4.—Examples of goodness of fit of analog computation of summed polyexponentials to the later phases of the plots of Ca_B^{47} in blood, % of total dose of Ca^{47} per ml. of blood serum against time, dog O, study *E*. Curve B is a ten-fold magnification, and the ordinate values should be divided by 10.

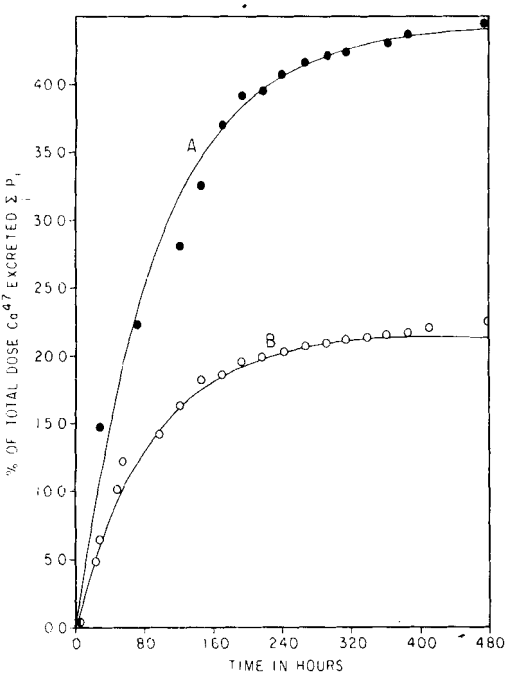

Fig. 5.—Examples of goodness of fit of analog computation of pseudo first-order fecal excretion with time, $\Sigma P_i = P_\infty (1 - e^{-kt})$, of cumulative Ca^{47}. Curve A is for dog 2, study *E*; Curve B is for dog O, study *E*.

Feces and Urine Data.—The Ca^{47} appearing in the urine and feces is cumulatively plotted as ΣP_i against time as in the typical curves of Figs. 5 and 6 for feces and is reasonably consistent with the expression

$$\Sigma P_i = P_\infty(1 - e^{-kt}) \qquad \text{(Eq. 14)}$$

where P_∞ is the total % of the total dose of Ca^{47} appearing in the feces (or urine) over the entire period on the postulate of first-order elimination as defined in Eq. 14.

The Ca^{47} data from feces (or urine) were fitted to this expression on the assumption that none had been eliminated at zero time. It was observed that the first-order fit was not strictly true, that an increase in the ΣP_i, percentage of total Ca^{47} dose excreted in urine and feces, occurs for a longer period of time than that interval defined by the blood studies, that fecal and urinary elimination is not strictly first-order in that a slight positive deviation from the first-order asymptote occurs with time, Fig. 6. Also, a short lag period before the initial fecal elimination of Ca^{47} is to be expected due to gastrointestinal holdup and was indicated in several of the studies. The urinary elimination mirrors the fecal elimination and a set of typical cumulative curves for all studies on one dog is given in Fig. 7. The drawn lines are typical examples of the goodness of analog computer fitting to the first-order expression of Eq. 14.

RESULTS

Blood serum.—The A_i and k_i values for the sum of exponentials in Eq. 13 that describe the Ca_B^{47} content of blood serum as a function of time are given in Table I for the various dogs and studies.

Typical analog computer fittings of the data from which these values were derived are given in Figs. 3 and 4. In general, the fit was very good by a four-factor exponential except perhaps for the very tail end of the curve in excess of 7,000 minutes where the data maintained a level above zero. The counting error is included in the size of the data circles.

Inspection of Table I shows that there is no great difference in the k_i values for any of the four exponentials of Eq. 13 whether the dog is under control (study *A*), under steroid regimen (studies *B* and *C*), or in recovery from steroid regimen (studies *D* and *E*). All the stated k_i values for any given factor are within the error of the fit regardless of the experimental condition of the animal.

The major difference within dogs and among the studies under the various experimental conditions was in the magnitude of the A_i values or the total amount of Ca^{47} transferred from the blood as characterized by the four exponentials.

This is most readily and graphically demonstrated in the example plotted in Fig. 8 where the log Ca_B^{47} *vs.* time for all studies in a given dog are parallel (*i.e.*, the k_i are similar) but the curves are displaced along the ordinate (*i.e.*, the amounts of Ca_B^{47} appearing in the blood vary with the experimental condition of the animal.).

This can be observed with the $\Sigma_i A_i$ values given in Table I and indicates that animals under steroid therapy (studies *B* and *C*) have higher Ca^{47} contents

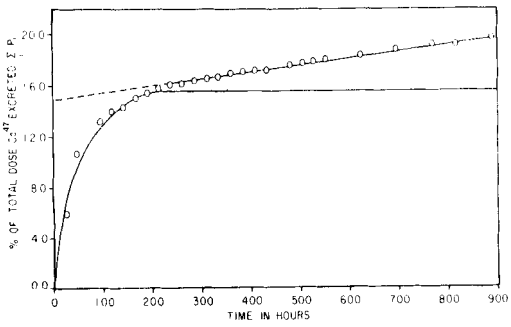

Fig. 6.—Example of zero order deviation $\Sigma P_i = mt + b$, from the analog computer fitted pseudo first-order asymptote P_∞, of the cumulative fecal excretion with time, dog O, study *D*.

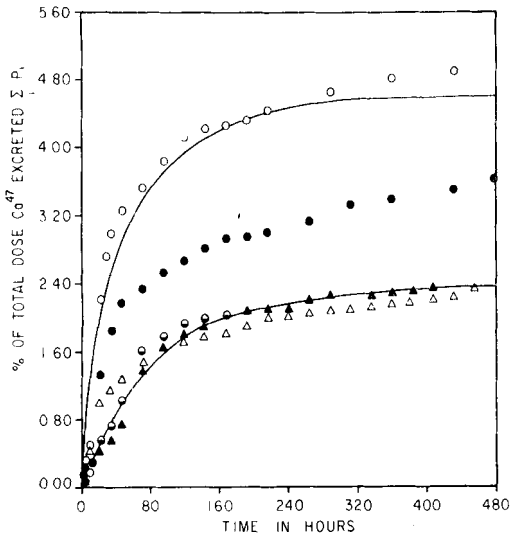

Fig. 7.—Typical examples of cumulative urinary and fecal excretion of Ca^{47} with time for a dog under different experimental conditions with typical analog computer fits. The urinary Ca^{47} excretion of dog 2; study *A*, ◐; *B*, ⊙; *C*, ●; *D*, ◬; and *E*, ▲.

in the blood than control animals (study *A*) or on recovery from steroid (studies *D* and *E*). The only study that provides an exception from this latter case is study *E* of dog 3.

With all dogs the A_1 and A_2 values of the control (study *A*) were less than that value for the steroid regimen (studies *B* and *C*).

Feces and urine.—The P_∞ and k values in accordance with the first order cumulative excretion of Ca^{47} as in Eq. 14 are given in Table II as fitted to the plots of total Ca^{47} excreted in feces (or urine) *vs.* time by the analog computer with the curve forced through the origin. Typical plots of such fits are given in Figs. 5 and 6 for feces and in Fig. 7 for urine. Since the data are cumulative, large deviations may be expected from a smooth curve with the initial fecal Ca^{47} contents. The good fit is well demonstrated for the duration of time covered by the blood studies. The counting error is included in the circles representing the data.

Over longer periods of study the fecal and urinary elimination of Ca^{47} deviates from first order, and this deviation over the theoretical asymptote, P_∞, can be approximated by a straight line of slight slope (Fig. 6)

$$\Sigma P_i = mt + b \qquad \text{(Eq. 15)}$$

where the slope m in % of total dose excreted per hour and intercept b are also given in Table II.

Inspection of the fecal and urinary elimination curves for all studies and dogs clearly showed that the amount of Ca^{47} appearing in both urine and feces for dogs on steroid regimen is greater than for these dogs during their control period as is demonstrated in the typical plots of Fig. 7. In addition, during the period of recovery from the steroid regimen, significantly less Ca^{47} appeared in the feces and urine.

The rate constants k among runs for a particular dog and among dogs show no significant correlation with the treatments and no highly significant variation outside of the experimental error of their estimates. Thus the k_u for urinary elimination is *ca.* 5×10^{-6} sec.$^{-1}$ ($t_{1/2}$ = 39 hours), and the k_f for fecal elimination is *ca.* 3×10^{-6} sec.$^{-1}$($t_{1/2}$ = 64 hours). The possible gastrointestinal lag in these latter cases may give erroneously low values for k_f.

The deviations defined in Eq. 15 of Ca^{47} data ΣP_i in the urine and feces from the first-order accumulative asymptote P_∞ defined in Eq. 14 are significant with respect to the counting errors. Unfortunately, fecal and urinary data were not accumulated beyond 170 hours for the control run and no deviation from first-order elimination of Ca^{47} could be calculated. Inspection of the data, however, indicates that in the first recovery study *D* on feces, the slopes m are less than for the steroid studies *B* and *C*. For both steroid recovery studies *D* and *E*, on urine, the slopes m are less than for the steroid studies *B* and *C*.

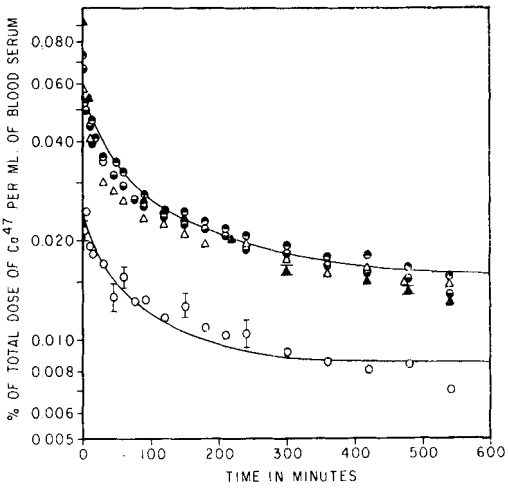

Fig. 8.—Typical examples of Ca_B^{47} blood content with time for the early phases of a dog under different experimental conditions with typical analog computer fits, dog 3, study *A*, ⊙; *B*, ◓; *C*, ◒; *D*, ◬; and *E*, ▲. The horizontal lines above and below some of the data indicate the 95% confidence limits due to counting error.

DISCUSSION

Blood serum.—The disappearance of labeled Ca^{47} from the blood of the dog after intravenous administration can be represented by a four-factor linear homogeneous equation of exponentials as in Eq. 13 in agreement with the observations of Thomas, *et al.* (2), for the rabbit and Bronner, *et al.* (4), for man.

This mechanistically implies that the initial 100% of the Ca^{47} administered distributes itself into four compartments as

$$\sum_1^4 A_i = A_1 + A_2 + A_3 + A_4 \quad \text{(Eq. 16)}$$

and that a certain fraction, *i.e.*, $A_1/\Sigma_i A_i$, $A_2/\Sigma_i A_i$, etc., leaves the blood into these compartments with respective rate constants k_1, k_2, k_3, and k_4. This also implies that the losses of Ca^{47} into each of these compartments are independent processes. This is not a physiologically true model since the transfer of Ca^{47} from blood into the tissue, although it may simulate a first-order process, actually may be a series of equilibria, or one transfer in a sequence of transfers, and the k_i and A_i may be interdependent.

However, the summation of exponentials of Eq. 13 may serve as a first approximation of a physiological model (2). The major contribution to the first exponential may be the relatively fast diffusion or transfer of Ca^{47} into extravascular spaces, some soft tissues, and the gastrointestinal tract. The major contribution to the second and third exponentials may be the slower diffusion or transfer into other depots. One such may be a metabolic pool, *e.g.*, chelation and/or complexation with bone surface. A simultaneous contribution may be the apparently irreversible incorporation of radioisotope into bone, *i.e.*, Ca^{47} covered by subsequent calcium deposition and unavailable for ready redistribution among blood and tissues during the interval studied. The major contribution to the fourth exponential may be the fecal and urinary elimination of radioisotope where the first-order accumulative rates are of similar magnitude as the fourth exponential. The positive deviations from first-order eliminations and the fourth exponential characterizing the blood curves may be due to resorption of radioisotope from bone. It must be emphasized that these cited assignments are oversimplified possibilities.

From the A_i data of Table I, the apparent volume of a particular compartment in terms of equivalent ml. of serum may be estimated by $1/A_i$ where $1/\Sigma A_i$ is an estimate of the total ml. of serum in the dog. The effect of steroid regimen is to increase the Ca^{47} content of the blood, a phenomenon which is reversed on cessation of such therapy. This may indicate that steroid therapy affects the instantaneous diffusion of Ca^{47} from the blood to some easily accessible other compartment characterized by A_1 and k_1 and/or the blood volume is significantly decreased by steroid therapy. There are too many variables extant in this study to permit a definite assignment of cause. This phenomenon will be further evaluated in future studies.

Urine and feces.—If it is postulated that the Ca^{47} is either in the feces, urine, or some "deep" compartment that may be "bone" at 200–400 hours after administration, then the difference of the measured amounts excreted from the total dose could give the % of the original dose in the "bone." Steroid regimen decreased the incorporation of calcium into the "bone" and with cessation of steroid regimen provided a "rebound" effect, an increased incorporation of blood calcium into "bone." On these premises, the gross effect of adrenal steroid administration is to induce a reversible osteoporosis. The procedures described herein can provide a quantitative measure.

The deviations of the cumulative Ca^{47} excreted in the urine and feces from first-order asymptotes were significant with respect to counting errors. It is naive to assume that the slow diffusion of Ca^{47} through the "bone" from the sites of "accretion"

to the sites of "resorption," the subsequent reentry into the blood and the final elimination into the urine and feces is a simple constant rate that is only apparent after the first-order accumulation of the greater portion of Ca^{47} excreted in feces and urine. However, it may be practical to use the slope of this straight line as a possible measure of "resorption" of calcium from "bone." The quantification of these slopes well indicates a decrease in the rates of "resorption" from bone on cessation of steroid therapy, a possible physiological "rebound" from steroid therapy. The data were insufficient to contrast steroid regimen with the control period.

The male beagles showed greater incorporation of calcium into the "deep" compartment than the slightly older female. The older mongrel showed the least such incorporation but the greatest "rebound."

SUMMARY

Methods and procedures have been developed to utilize the analog computation of a summation of four polyexponentials to describe the Ca^{47} content of blood as a function of time after intravenous administration. Quantitative measures of determining calcium incorporation into a "deep" compartment that may be synonymous with "bone" have been described. The exponential constants for the distribution and elimination of Ca^{47} for all dogs and under all experimental conditions studied, *i.e.*, control, steroid, and recovery periods, were similar.

The short half-life of Ca^{47} of 4.56 days permitted a sequence of studies of experimental effects on calcium dynamics as followed by the study of the distribution and excretion of Ca^{47} with each dog used as his own control.

The most pronounced effect of steroid regimen in dogs is the increased amount of Ca^{47} accumulated in the feces over the control period. A similar effect is observed with the Ca^{47} accumulated in the urine although the percentage of the total administered dose excreted in the urine (2–6%) is very much less than that excreted in the feces (20–60%).

A possible, but less well defined effect of steroid regimen, is the decrease in apparent blood volume from the control period as based on radioisotopic measurement of Ca^{47}-labeled blood. It is also well indicated that the rate of Ca^{47} return from the "deep" compartment is accelerated by steroid therapy. In the classical nomenclature, it may be that bone "accretion" is inhibited and bone "resorption" accelerated by steroid therapy to induce the reversible osteoporosis of Cushing's syndrome.

A "rebound" effect is also noted in that on cessation of steroid therapy, the dog utilizes more Ca^{47} and the rate of return from the "deep" compartment is lessened.

The possible utilization of more effective osteoporotic agents as measured by these techniques should be of great interest in the removal of bone-seeking radioisotopes produced from radiation or fall-out contamination. Also, these methods are applicable to the recognition and quantification of nonosteoporotic anti-inflammatory agents, and therapeutic agents that may prevent or treat bone diseases.

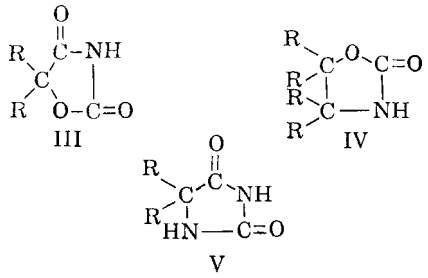
Synthesis of Sydnones as Potential Therapeutic Agents

By LEMONT B. KIER and DEVINDRA DHAWAN

A number of new 3-alkyl sydnones have been prepared as potential therapeutic agents. A preliminary pharmacological evaluation indicated that these compounds were central nervous system stimulants. The partition coefficients between chloroform and water were determined and a correlation was found between this and the millimole dosage per kilogram in the sydnones with nonfunctional side chains. Ultraviolet and infrared data are reported for the sydnones.

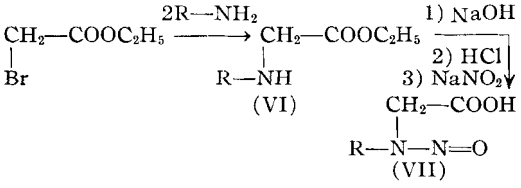
THE FIRST mesoionic compounds known as sydnones (I) were synthesized in 1935 by Earl and Mackney at the University of Sydney (1). They observed that when N-nitroso-N-phenyl glycine is heated with acetic anhydride, water is lost and a compound having a 1,2,3-oxadiazole ring structure is formed:



The bicyclic structure (II), originally postulated, was unacceptable to subsequent investigators (2–4) who showed that the sydnones are resonance hybrids of numerous canonical forms, including the three above. Dipole moment (5, 6), X-ray analysis (7), and molecular-orbital treatment (8) have subsequently substantiated this structural assignment. The term "mesoionic" has been coined for this type of system and has been defined (9) as a five- or six-membered heterocyclic compound, which cannot be represented satisfactorily by any one canonical structure. It possesses a sextet of π electrons in association with all of the ring atoms. Further, the ring bears a fractional positive charge balanced by a corresponding negative charge on a covalently attached exocyclic atom or group. Structures like I are used by convention for mesoionic compounds.

A review of the literature revealed no pharma-

I II



III IV V

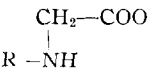
cological study of these compounds as possible chemotherapeutic agents.[1] A comparison of the sydnone (I) structure with that of the 2,4-oxazolidinediones (III), 2-oxazolidinone (IV), and hydantoins (V) revealed some similarity. These last three are known anticonvulsants though alkylation of the nitrogen atom will frequently reverse the action, producing a convulsant (10, 11).

With these thoughts in mind, a systematic study of some sydnones and other mesoionic compounds was initiated in this laboratory. For this initial study a number of new 3-substituted sydnones were prepared representing the simplest type of substitution on the ring.

Among several routes leading to the nitrosoamino acid (VII), the following one was chosen

A recent study on the synthesis of α-alkylamino esters (12) of the type VI showed that a higher yield could be obtained by using an α-bromo-ester and two equivalents of the amine. The second equivalent of the amine proved to be an acid scavenger superior to trialkyl amines or inorganic bases. All of the α-alkylamino esters in our study were high-boiling liquids which could be easily purified by vacuum distillation. See

Received March 16, 1962, from the Department of Pharmaceutical Chemistry, University of Florida, College of Pharmacy, Gainesville.



Accepted for publication April 23, 1962.

[1] Since completion of this manuscript, another report covering antitumor activity of several sydnones has been published (23).

Table I. Hydrolysis of VI was done in refluxing base. Isolation and purification of the resulting α-alkylamino acids proved to be very tedious and costly. Since the α-alkylamino esters could be easily purified and characterized, isolation of their hydrolysis products was considered unnecessary. This product was then nitrosated *in situ* after rendering the solution strongly acid. All of the nitrosoamino acids (VII) were solids and were purified with no difficulty. See Table II.

A number of reagents have been employed for the ring closure of VII to the sydnone including acetic anhydride and trifluoroacetic anhydride (4, 13). The mechanism involves the formation of a mixed anhydride with the nitroso acid (VII). Because of the grater lability of the C_4 hydrogen, due to the absence of an alkyl group on the same carbon, it was felt that acetic anhydride would be a satisfactory ring-closing reagent. The exclusion of water in this step was essential for maximum yield, hence freshly distilled acetic anhydride was employed throughout. The initial heating followed by a prolonged period of standing in the dark was found to give the best yield of sydnone (I). The solids were generally crystallized from water while the liquids were vacuum distilled. Several explosions resulted from distilling the allyl sydnone until it was distilled under nitrogen. See Table III for analyses.

The ultraviolet absorption maxima fell in the range reported for a few of these compounds (14–16). An infrared maximum at 5.75–5.85 μ was found for each sydnone, which can be ascribed to the pseudo-keto group (17–19). In addition, each sydnone had a strong absorption band at 9.5 μ which is in the region of the C—O stretching frequencies (20).

A preliminary pharmacological evaluation (21) indicated that all but the phenethyl sydnone were central nervous system stimulants with a particularly stimulating effect on respiration. As comparative parameters the LD_{50} and CD_{50} (convulsive dose) i.p. in mice were chosen. See Table IV.

In an attempt to relate structural effect with pharmacological action, the partition coefficients between chloroform and water were determined. Because of the simple nature of the modifying groups it was felt that the ring itself imparted the pharmacological action while the side chain determined the rate of absorption and transport to the receptor site.

If the pharmacological action was chiefly central, as preliminary data indicated, then the sydnones with a greater affinity for lipid solvents would be expected to penetrate the lipid barrier into the CNS with greater facility. This conjecture was proven to be correct as far as the sydnones with nonfunctional aliphatic side chains. Those with a higher partition coefficient between chloroform and water were more active in eliciting convulsions on a millimole per kilogram basis. Those with functional groups in the side chain such as the allyl, phenethyl, and furfuryl sydnones did not follow this pattern. Both of these aspects of mono and disubstituted sydnones are under current study in this laboratory.

EXPERIMENTAL [2]

Alkylamino Esters (VI).—A solution of two moles of the amine in 500 ml. of anhydrous ether was cooled to 0° in a two-necked flask equipped for stirring. To this was added dropwise, one mole of ethyl bromoacetate in 150 ml. of anhydrous ether. The temperature was maintained at 0°. The mixture was stirred for 3 hours then allowed to stand overnight. The precipitate was filtered off and the filtrate vacuum distilled. In all cases the products were liquids. See Table I for yield, b.p., and analyses. Infrared analyses corroborated the assigned structures.

Hydrolysis of Esters.—The alkylamino esters (VI) were hydrolyzed by refluxing them with 1.5 equivalents of aqueous sodium hydroxide. The refluxing was stopped when the reaction mixture formed a single phase. The solution was then cooled and made acid to pH 2 with hydrochloric acid.

Nitrosoamino Acids (VII).—The strongly acidified solution of the alkylamino acid was cooled to 0° in an ice-salt bath and then treated dropwise with a solution containing 1.1 equivalents of sodium nitrite. This reaction mixture was stirred for two hours at 0° after the addition. The crude nitrosoamino acid was filtered and recrystallized from ether, acetone, or mixtures of the two. All of the nitrosoamino acids gave positive Liebermann tests (22). See Table II for yields, m.p., and analyses.

3-Alkyl Sydnones (I).—The nitrosoamino acids (VII) were added to a five molar excess of freshly distilled acetic anhydride and warmed on a steam bath for 3 hours. The reaction mixture was allowed to stand for three days at room temperature in the dark. The acetic anhydride was removed under vacuum using toluene to remove the last traces. The sydnone was then either distilled under vacuum or crystallized from ether. Distillation of the 3-allyl sydnone had to be done under nitrogen in order to prevent the ignition or explosion of the product. See Table III for m.p. or b.p., yield, and analyses. The infrared and ultraviolet spectra were obtained for each compound. See Table IV.

Partition Coefficients.—The partition coefficients of the sydnones (I) were obtained between water-saturated chloroform and chloroform-saturated water. Several concentrations of each compound in water-saturated chloroform at 23° were shaken for 1 hour with varying quantities of chloroform-saturated water. The concentration in the chloroform before and after shaking with the water was determined from the ultraviolet absorption at the maximum. An average of at least four determinations for each sydnone was used. See Table IV.

[2] All melting points were done on the Kofler apparatus and are corrected. Analyses were performed by Weiler and Strauss Microanalytical Labs., Oxford, England and Galbraith Laboratories, Knoxville, Tenn.

Protective Coatings XIII. Amphoteric Polyvinylpyridine Derivatives

By TADAO IDA, SHUZO KISHI, SHOJI TAKAHASHI, and ISAMU UTSUMI

Polyampholites of vinylpyridine or its alkyl derivatives with acrylic or methacrylic acid and the copolymers of these compounds with other vinyl derivatives were synthesized and studied as protective coating agents for tablets. Results showed that the synthesized copolymers had adequate viscoelasticity, protective qualities, and disintegration characteristics to serve as protective coating agents.

POLYAMPHOLYTES of vinylpyridine or its derivatives with acrylic or methacrylic acid and copolymers of those with other vinyl compounds were experimentally synthesized. The purpose of synthesis was to obtain such protective-coating agents as to exhibit protective activity on drugs and solubility in both gastric and intestinal juice. Solubility, water vapor permeability through the film, and viscoelasticity were tested on each of copolymers.

The practical coatings on tablets were also carried out and disintegration time of the coated tablets, absorption of moisture and aging deterioration of the active ingredients were subsequently investigated. Most of the compounds have shown outstanding properties as protective-coating agents.

In the preceding reports, observations were made on the applicability of polyvinylpyridine derivatives and other compounds to protective-coating agents (1). All preparations coated with these compounds were easily dissolved in acid of gastric juice to release medicament. However, it is believed that there are marked differences in gastric acid secretion among individuals, particularly those patients with hypoacidity or anacidity. In this sense, it is feared that preparations coated with one of these compounds may be not disintegrated by gastric juice. In order to overcome this disadvantageous property of these compounds, preparations should be coated with such protective-coating agents as to be insoluble near the neutral pH but disintegrate favorably both in gastric juice of lower acidity and in intestinal juice.

Attempts to elucidate the properties of the polyampholytes obtained by the reaction of vinylpyridine or its alkyl derivatives with methacrylic or acrylic acid were made to examine their eligibilities for protective-coating agents.

Copolymerization of 2-vinylpyridine and methacrylic acid and physico chemical properties of the products have been reported by Alfrey (2) and Katchalsky (3), respectively. There have been other reports on the copolymerization of the main body of acrylonitrile with vinylpyridine, methacrylic acid or other vinyl compounds for textile-improving (4–6). On the other hand, no reported study has dealt with these products as coating agents for medicaments.

As starting monomers 4-vinylpyridine (4VP), 2-vinylpyridine (2VP), 2-methyl-5-vinylpyridine (MVP), and 2-vinyl-5-ethylpyridine (VEP) were used for basic components, whereas methacrylic acid (MAA) and acrylic acid (AA) were used for acidic components. Styrene (St), methylacrylate (MA), and acrylonitrile (AN) were used as other monomers.

Copolymers were synthesized from any two or three components using either a catalyst of benzoylperoxide (BPO) or α,α'-azo-bis-isobutyr-

onitrile (AIBN) and their applicability to the protective-coating agents were studied.

EXPERIMENTAL

Materials.—Each monomer was rectified just before using. BPO and AIBN of pure grade in commerce were used without purification.

Synthesis of Copolymers.—A mixture of two or three monomers was dissolved in methanol and then polymerized at 50–60° and 60–70° in the presence of BPO and AIBN as catalyst, respectively, for 5 hr. To purify, each polymer thus obtained was dissolved in an adequate solvent, *e.g.*, methanol or acetone, and subsequently separated by pouring the solution into a large quantity of water. After repeating this reprecipitation, the polymer was dissolved in diluted hydrochloric acid and finally precipitated by adjusting the pH to isoelectric point with caustic alkali.

The copolymers with acrylic acid were synthesized by the presynthesis of the copolymers with MA followed by hydrolysis with an equimolecular amount of potassium hydroxide in acetone-methanol mixture for 5 hr. with heating.

Tables I, II, III, IV, and V show the yields of the copolymerizations and the analytical data of the copolymers.

Composition of Copolymers.—Vinylpyridine content in each copolymer was determined from nitrogen content (micro-Dumas method) and ultraviolet absorption (7, 8). Carboxyl content was determined by titration of copolymers with 0.1 *N* sodium methoxide solution in absolute pyridine using thymol blue as indicator (9).

Isoelectric Zone.—A 100-mg. quantity of each copolymer was dissolved in 0.1% hydrochloric acid to make 100 ml. of the solution. A 50-ml. part of this solution was titrated with 0.1 *N* sodium hydroxide by using glass electrode pH meter (2). Isoelectric zone determined the pH value at which the solution began to get turbid and the pH value at which it became clear again.

Dynamic Viscoelasticity of Films.—Dynamic viscoelasticity of films was determined by "vibrating reed" method in a room at 20° and 60% R.H. The method of preparing the film of copolymers has been reported in a previous paper (10).

Water Vapor Permeability of Films.—The quantity of water permeated through the films per 24 hr. was examined by "cup method" specified in ASTM E-96-53T in a room at 25° and 92% R.H. (10).

Disintegration Test.—By the dipping method, the protective coating was applied on the starch-lactose tablets which were compressed in accordance with the method of a previous paper (10). Disintegration times of the coated tablets in distilled water, artificial gastric juice, artificial intestinal juice, and buffer solution from pH 2 to 9 were separately determined by the method specified in U.S.P. XVI. Acetic acid-sodium acetate system was used as the buffer solutions of pH 4 and 5, while Clark-Lubs system was employed as the buffer solutions with a pH other than pH 4 and 5.

The thickness of the coating film was calculated from the difference between the weight of coated and uncoated tablets. The composition of copolymers, solvents used in the coating process, and thickness of the films are shown in Table VI.

Aging Test.—Formulas of tablets used in the experiment for aging test were: (*a*) Carnitine chloride tablet containing 200 mg. of carnitine chloride was 9.6 mm. in diameter, 2.8 mm. of thickness and 260 mg. of total weight. (*b*) Acetylsalicylic acid tablet containing 115 mg. of acetylsalicylic acid had 8.0 mm. in diameter, 2.5 mm. of thickness and 150 mg. of total weight.

The dipping method was used to apply the protective coating to both tablets. Four copolymers selected from each series of VEP, MVP, 2VP, and 4VP were used as protective coating agents.

Coated carnitine chloride tablets were stored in a room at 25° and 90% R.H.; absorption of moisture was observed by measuring the change of tablet weight. Coated acetylsalicylic acid tablets were stored in a room at 37° and 85% R.H.; the amount of salicylic acid produced as a result of decomposition of acetylsalicylic acid was determined by means of its ultraviolet absorption (11).

Toxicity Test.—Each copolymer, suspended in water plus a small amount of sodium carboxymethylcellulose, was given to dd-strain male mice weighing 20 ± 1 Gm. by stomach tube. The mortality of mice 72 hr. after administration was observed to evaluate the toxicity of copolymers. The dose administered to the mice was the maximum which could be given.

RESULTS AND DISCUSSION

Solubility.—As shown in Table VII, two-component copolymers of vinylpyridine or its derivatives with MAA or AA were insoluble in water, soluble in

[a] I = insoluble, S = soluble, SS = slightly soluble, and G = gelatinized or swollen.

weak acid and alkali, but very sparingly soluble in organic solvents, with a few exceptions, so that most of the compounds seemed to be unsuitable for protective coating agents.

On the other hand, three-component copolymers with St, AN or MA, as shown in Tables VIII, IX and X, were easily dissolved in organic solvents to form transparent films, were soluble in weak acid and alkali, but insoluble in near neutral. As seen in Table VIII, the copolymers composed of St in 30 mol. % content showed the highest solubility when the content ratio of VEP to MAA was 4:3 or 1:1. Therefore, various ratios of components for the synthesis of copolymers were later set up by maintaining the ratio of VEP to MAA; either 4:3 or 1:1.

Table XI represents the composition for synthesizing copolymers providing the most favorable solubility.

The copolymer films were strengthened with an increase of MA, St, or AN. Since copolymers containing up to 70 mol. % MA content were soluble, as indicated in Table XI, the films containing MA were considered the strongest.

As appended in Tables VIII, IX and X, each copolymer showed various ranges of the isoelectric zone according to the variation of composition. Therefore, a suitable copolymer could be selected freely depending on the property of medicament to be coated.

Water Vapor Permeability and Viscoelasticity of Films.—As indicated in Table XII, water vapor permeability of the film formed by these protective-coating agents was close to 10^{-4}–10^{-5} Gm. cm./cm.^{2}/24 hr. which were obtained by the protective-coating agents reported in a previous paper (10).

Less water vapor permeability of the films produced by three-component copolymers was noted as

compared with those produced by two-component copolymers in a same series of vinylpyridine derivatives. Furthermore, the copolymers with MA, St, or AN showed a decrease of water vapor permeability of the films with increasing the content of these components. Especially, the copolymers composed of MVP-MAA-MA and MVP-MAA-St showed the lowest water vapor permeability. It is believed that the lower water vapor permeability of films is desirable for a protective-coating agent.

Dynamic elasticity and dynamic viscosity of the films of copolymers, as indicated in Table XII, were approximately 10^{10} dynes/cm.^{2} and 10^6 poises, which are generally suitable for a protective-coating agent.

Disintegration of Protective Coated Tablets.—Disintegration tests of the tablets coated with a protective-coating agent were carried out in artificial gastric juice, intestinal juice, and also in the buffer solution to evaluate disintegration time and water resistance. The results of the disintegration tests are shown in Table XIII. All of the coated tablets showed a resistance to disintegration in distilled water for more than 3 hr. but disintegrated within 15 min. in artificial gastric juice and within 30 min. in artificial intestinal juice. The results of

disintegration tests in the buffer solutions showed generally same tendency within the pH range of the isoelectric zone determined previously.

Based on the foregoing, these copolymers seemed to be suitable protective-coating agents having an isoelectric zone around neutral and enough water resisting property suited for the purpose of this study. The tablets coated with these copolymers might be expected to disintegrate in a hypoacidic stomach or in the intestine even if it passed through the stomach without disintegration and subsequently exert therapeutic effect. This was noted in oral administration tests using vitamin B_2 tablets coated with these copolymers. These data will be disclosed in the near future.

Protective Effect on Active Ingredients.—Experiments to assess a protective effect of the copolymers against absorption of moisture were carried out by coating the carnitine chloride tablets, which are remarkably hygroscopic. Fig. 1 sets forth the results.

Hygroscopicity of the coated tablets was greatly reduced as compared with the uncoated control tablets. Both the appearance and hardness of the coated tablets remained unchanged while the uncoated tablets were softened, followed by change of form.

As described in Fig. 2, the results of aging test on the acetylsalicylic acid tablets coated with the copolymers revealed that the tablets were apparently stabilized when compared with stability of the uncoated tablets. The coated tablets disclosed a favorable result with reasonable disintegration time.

Toxicity.—The toxicity of polymers of vinylpyridine or vinylpyridine alkyl derivatives and copolymers of these monomers with VAc, AN, MA, or St has been reported in a previous paper (10). As summarized in Table XIV of this paper, no acute toxic

action upon mice was observed after the oral administration of four kinds of the typical copolymers with MAA and MA.

SUMMARY AND CONCLUSIONS

1. The polyampholites of vinylpyridine or its alkyl derivatives with acrylic or methacrylic acid and the copolymers of these compounds with other vinyl derivatives were synthesized to obtain new protective-coating agents.

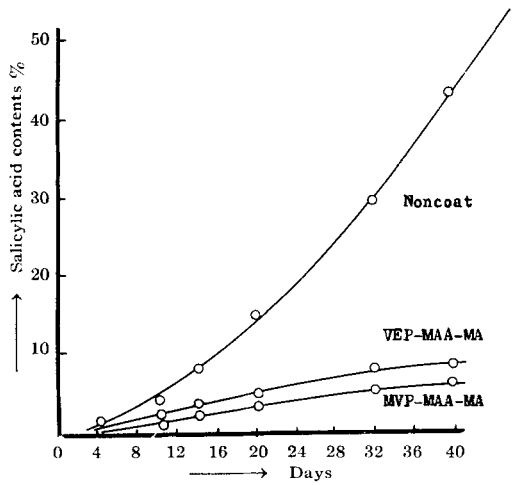

Fig. 2.—Aging of acetylsalicylic acid in acetylsalicylic acid tablets at 37°, 85% R.H.

TABLE XIV.—ACUTE TOXICITY TEST IN MICE[a]

No. of Animals	Protective-Coating Agent	Dose, mg./Kg.
5	VEP-MAA-MA	2000
5	MVP-MAA-MA	2000
5	2VP-MAA-MA	2000
5	4VP-MAA-MA	2000

[a] No deaths 72 hr. after administration.

2. These copolymers were dissolved in organic solvents to form transparent films which were soluble in both acidic and alkaline solutions but insoluble in an approximately neutral solution. Water vapor permeability through the copolymer films was found to be very low.

3. It was found that the copolymers synthesized had adequate viscoelasticity to serve as protective-coating agents.

4. Sufficient protection against absorption of moisture and aging deterioration of the active ingredients was provided by the copolymer coatings.

5. The tablet coatings were insoluble only in an approximately neutral solution, but seemed to be disintegrated in stomach with hypoacidity and in the intestine to produce the desired therapeutic effect.

Tablets of Pyrilamine Resin Adsorbate with Aspirin and Vitamin C

By SHELDON SIEGEL, ROY H. REINER, JAMES A. ZELINSKIE, and EDWARD J. HANUS

Marked changes in physical appearance manifested by dry formulations containing aspirin, an antihistamine, and vitamin C during an accelerated temperature stability study are discussed. The stabilization afforded by a resin adsorbate of a commonly used antihistamine, pyrilamine, is noted. Discrepancies in the results obtained from stability studies of these preparations have been traced to the efficiency of the closure utilized in the packaging of the product, as well as the methods employed in the pretreatment, sampling, and evaluation of test samples. The implications of these observations from a developmental standpoint are discussed.

THE AVAILABILITY of ion exchange resins suitable for oral administration has presented the formulator with a means of tailoring products in a way not heretofore possible. These materials are currently available in a wide range of types and mesh specifications and present a new means of complexation of an active ingredient which can lead to a significant enhancement in both the stability of the medicament and in the manipulation of its release pattern. It is with a variation of the former case, the reduction of an undesirable incompatibility of salts of pyrilamine in common formulations, that this paper concerns itself.

Tablet and capsule formulations for the symptomatic treatment of the common cold constitute a significant segment of the ethical and proprietary drug market. These products usually contain aspirin, an antihistamine, and vitamin C. The development of such products is complicated by interactions between the ingredients, resulting in marked changes in the physical appearance of the preparation after short storage intervals. Certain antihistamines have been shown to be incompatible in dry dosage forms containing aspirin and/or vitamin C (1, 2). This interaction is manifested by softening and darkening of tablets, surface crystal growth, and an acetous odor. Methods such as compression coating, multilayering, and pan coating, which overcome the existing problems by physical separation of the reactants, have been utilized to produce products having an acceptable shelf life. We have investigated resin adsorbates of pyrilamine for possible reduction in the degree of incompatibility in formulations of this type.

Received March 26, 1962, from Merck & Co., Inc., Chemical Division, Product Development Laboratories, Rahway, N. J.
Accepted for publication May 4, 1962.
Presented to the Scientific Section, A.PH.A., Las Vegas meeting, March 1962.
Grateful appreciation is given to Miss B. Feller and Mr. J. Kanora for the chemical assays, and to Dr. G. Litt and Mr. J. Blodinger for their helpful suggestions.

EXPERIMENTAL

Analytical Methods

Pyrilamine Resin Adsorbate.—Accurately weigh a sample of finely ground tablets equivalent to 25 mg. of pyrilamine maleate. Disperse in 25 ml. of 2 *N* hydrochloric acid and shake vigorously for 30 minutes at room temperature. Extract with three 15-ml. portions of chloroform, discarding the chloroform layers. Add 5 ml. of 50% potassium hydroxide to the acid layer, shake well, and let stand at room temperature for 15 minutes. Extract with three 15-ml. portions of chloroform. Extract the combined chloroform extracts twice with 25 ml. of 1 *N* hydrochloric acid and measure the absorbance at 315 mμ in a suitable spectrophotometer. Use 1 *N* hydrochloric acid as the reference solution.

$$\frac{A \text{ of sample at } 315 \text{ m}\mu \times 10}{0.205 \times \text{No. of tablets}} = \text{mg. per tablet as pyrilamine maleate}$$

Ascorbic acid.—Ascorbic acid was assayed by the official U.S.P. XVI method.

Acetylsalicylic and Salicylic Acids.—A rapid spectrophotometric assay of acetylsalicylic and salicylic acids was utilized in this investigation (3). It is to be noted that the utilization of this assay procedure in preparations containing pyrilamine is somewhat inaccurate because of the interference exhibited by the absorbance of pyrilamine at the 308 mμ peak. To simplify the numerous assays involved, this interference was considered negligible; however, the values obtained should not be considered absolute.

$$\frac{A \text{ of sample at } 315 \text{ m}\mu \times 10}{0.205 \times \text{No. of tablets}} = \text{mg. per tablet as pyrilamine maleate}$$

Ascorbic acid.—Ascorbic acid was assayed by the official U.S.P. XVI method.

Acetylsalicylic and Salicylic Acids.—A rapid spectrophotometric assay of acetylsalicylic and salicylic acids was utilized in this investigation (3). It is to be noted that the utilization of this assay procedure in preparations containing pyrilamine is somewhat inaccurate because of the interference exhibited by the absorbance of pyrilamine at the 308 mμ peak. To simplify the numerous assays involved, this interference was considered negligible; however, the values obtained should not be considered absolute.

Sample Preparation and Treatment

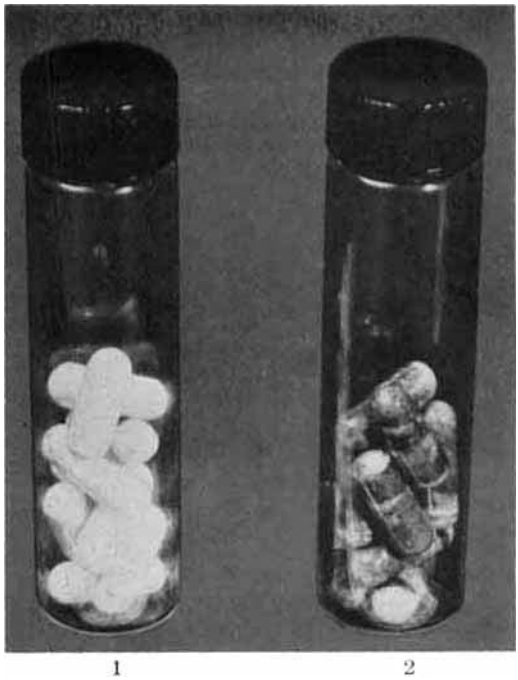
Pyrilamine base was adsorbed on a weakly acidic carboxylic acid ion exchange resin (XE-64)[1] in varying concentrations. The pyrilamine resin adsorbate formed (PRA) is a free flowing, off-white, essentially odorless powder. Economic and formulation considerations resulted in the utilization of a resin product containing the equivalent of from 61.2 to 64.0% pyrilamine maleate.

Hard gelatin capsules of PRA, aspirin, and vitamin C; PRA, aspirin, and sodium ascorbate; and controls containing pyrilamine maleate in place of the resin adsorbate were prepared and placed in storage at several temperature stations. The ratio of the ingredients in the formulations placed on this study is summarized in Table I.

TABLE I.—RATIO OF INGREDIENTS IN FORMULATIONS IN STUDY

	Formulation			
	1	2	3	4
Pyrilamine resin adsorbate, mg.	20.4[a]	...	20.4[a]	...
Pyrilamine maleate, mg.	...	12.5	...	12.5
Aspirin, mg.	300	300	300	300
Ascorbic acid, mg.	...	...	50	50
Sodium ascorbate, mg.	56.24[b]	56.24[b]	...	...

[a] Equivalent to 12.5 mg. pyrilamine maleate. [b] Equivalent to 50 mg. ascorbic acid.



Compressed tablets containing aspirin powder, 300 mg., sodium ascorbate, 28 mg. (equivalent to 25 mg. ascorbic acid); PRA, 20.4 mg. (equivalent to 12.5 mg. pyrilamine maleate); and a control containing the maleate in place of the resin adsorbate were prepared by dry slugging methods. Corn starch, 10%; dried talcum, 5%; and Cab-O-Sil,[2] 0.5% were utilized as tableting aids. These were also placed in storage at elevated temperatures and observed periodically for gross physical changes.

As several apparent inconsistencies were disclosed in the interpretation of the observations of both the capsule and tablet formulations, a somewhat more detailed study was undertaken. The relationship of such factors as preheating of the tablets prior to packaging, the type of closure used on the container, and the frequency of inspection of the samples were investigated.

DISCUSSION

In all preparations studied under accelerated conditions, those containing the resin adsorbate of the antihistamine showed the least physical change. Figure 1 shows the difference in appearance between the capsule formulation containing PRA, aspirin, and sodium ascorbate, and that with pyrilamine maleate, aspirin, and sodium ascorbate after storage for 1 month at 45°. The enhancement of physical appearance by using the resin form is immediately apparent. It was also observed that preparations containing sodium ascorbate were far superior in this same respect to those containing ascorbic acid.

In the initial investigation, several inconsistent results were noted concerning the stability of the tablets which were not readily explainable. A significant lack of uniformity was observed between

1 2

samples stored in bottles with polyethylene snap caps and those stored with Bakelite screw caps. Tablets in containers with the polyethylene closures were superior in physical appearance to those in containers sealed by screw caps. An investigation of the relationship of closure to stability was then undertaken and Fig. 2 illustrates the difference in physical stability experienced with the same formulation under different packaging conditions after storage for 2 months at 40°. Note the evidence of decomposition in the vial sealed with a nonporous cap (A), the improvement when a permeable polyethylene closure is used (C), and the absence of physical change when the containers are left open (E and F).

Although it is well known that polyethylene will allow the passage of air and other volatile material, the significance of this in common stability studies of this type has not, to our knowledge, been given sufficient recognition. Based on our accelerated studies with formulations of this type, it would then appear that the more permeable the container closure, the greater the physical stability of the contents. The following explanation is offered for this phenomenon. Under the temperature conditions imposed, this permeability would allow the escape of moisture from the formulations, thereby effectively removing the component responsible for the hydrolytic degradation of aspirin. In addition, the open container (E) and, to a lesser degree, the container with a permeable closure (polyethylene snap cap), permit the escape of the acidic gaseous degradation products resulting from aspirin hydrolysis. This would suggest that the autocatalytic degradation of aspirin is promoted by the presence of these acidic degradation products. It should also be men-

[1] Rohm and Haas Co., Philadelphia, Pa.
[2] Godfrey L. Cabot, Inc., Boston, Mass.

tioned that an acidic environment within the container would promote the desorption of the pyrilamine from the resin in the form of an acid salt, which was previously shown to be less desirable in preparations of this type.

Several other very practical considerations which may be explained on the above basis were observed during this investigation. Filled containers appeared to exhibit greater instability than partially filled ones (see Fig. 2). This indicates that this difference is due to the entrapment of significantly more volatile decomposition products, hence increasing the rate of degradation. Further corroboration of this postulate is taken from the observation that samples which had been opened frequently to check stability appeared more stable than counterparts which had remained unopened.

It was reasoned that if the foregoing explanation for the marked stability differences was valid, preheating the tablets prior to packaging should result in a significant enhancement of stability. Figure 3 illustrates the result of heating tablets for 20 and 40 hours at 50° before packaging and subsequent storage at 45° for 1 month. The unheated sample (G) underwent considerable physical degradation, evidenced by darkening of the tablets and appearance of a large number of crystals, shown by infrared spectroscopy to be salicylic acid. The heated samples (H and I) show no change in physical appearance. It thus appears that this preheating procedure resulted in the expulsion of both moisture and aspirin degradation products and, in this way, exerted a stabilizing influence on the formulation in addition to that achieved by the use of the resin adsorbate of pyrilamine. The chemical stability of this formulation is summarized in Table II. It is clear from the analytical data that the gross physical appearance of the preparation served as a valid indicator for the actual decomposition of the formulation.

It is felt that the observations reported here have strong implications from the developmental standpoint. The type of container closure and degree of fill are obviously of prime importance in evaluation of these products by accelerated temperature studies. It is interesting that formulations of this type appear to reverse the well documented belief that, to a large extent, stability is dependent upon the ability of the container to isolate the ingredients from the environment. It can be seen that a stability study that does not take into consideration factors of this type is quite likely to lead to fallacious extrapolations.

SUMMARY

Formulations containing pyrilamine resin adsorbate, aspirin, and vitamin C were found to be less subject to physical change in accelerated stability studies than control formulations containing the maleate salt of pyrilamine. An apparent lack of uniformity in the stability of such formulations has been related to the selection of container closures, container fill,

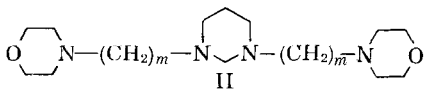
Hexahydropyrimidines I. Preparation of 2-Substituted-1,3-bis(*p*-dimethylaminobenzyl)-hexahydropyrimidines



By JOHN H. BILLMAN and LINNEAUS C. DORMAN†

A number of 2-substituted-1,3-bis(*p*-dimethylaminobenzyl)hexahydropyrimidines have been prepared by allowing various aldehydes to react with 1,3-bis(*p*-dimethylamino)propane. The latter diamine was prepared by the catalytic reduction of the di-Schiff base 1,3-bis(*p*-dimethylaminobenzylideneamino)propane. It was felt that *these compounds might possess antifungal, antibiotic, and antiviral activity.*

ALTHOUGH the synthesis of hexahydropyrimidines from 1,3-diamines and carbonyl compounds has been described for some time by a number of workers (1–7), a review of the literature reveals that relatively few hexahydropyrimidines have been prepared and examined for medicinal activity. Two particularly interesting publications by Van Hook and Craig report that 1,3-bis(dialkylaminoalkyl)- (I) (8) and 1,3-bis(heterocyclicaminoalkyl)hexahydropyrimidines (II)(9) possess antifungal, antibacterial and

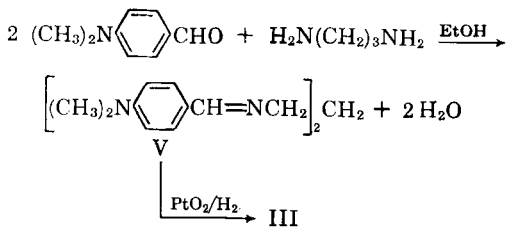
[a] Procedure (*B*). [b] Procedure (*A*).

substituted hexahydropyrimidines, (I) and (II).

To this end, a series of 2-substituted-1,3-bis(*p*-dimethylaminobenzyl)hexahydropyrimidines (IV) (Table I) were prepared by allowing the desired aldehydes to react with 1,3-bis(*p*-dimethylaminobenzylamino)propane according to the following equation. The reason for selecting the hexahydropyrimidines we did is that the N,N-dimethylaminobenzyl grouping resembles in a way



III

IV

the side-chains in the 1,3-bis(dialkylaminoalkyl)-hexahydropyrimidines (I) and 1,3-bis(heterocyclicaminoalkyl)hexahydropyrimidines (II). All three series of compounds have a tertiary-amino group at the end of the side-chains. In addition, the benzyl group should contribute to the solubility of the compounds to about the same extent as compounds of I and II with an average of five methylene groups in the side-chains.

Methanol was a convenient solvent for the ring closure reaction for producing the hexahydropyrimidines in yields of 33–78%. All of the compounds were solids and it was found that they could be hydrolyzed with dilute acid to regenerate the original reactants. In general the condensation reactions proceeded smoothly and rapidly at room temperature or on heating at moderate temperatures. However, difficulties were experienced with vanillin and furfural as these aldehydes failed to yield solid derivatives with 1,3-bis(*p*-dimethylaminobenzylamino)propane. Instead, dark viscous oils separated from their reaction mixtures and no pure products could be isolated.

The 1,3-bis(*p*-dimethylaminobenzylamino)propane (III) was prepared in two steps from trimethylenediamine and *p*-dimethylaminobenzaldehyde. In the initial step, the diamine was condensed with two moles of the aldehyde to produce the di-Schiff base, 1,3-bis(*p*-dimethylaminobenzylideneamino)propane (V). Reduction of the di-Schiff base with hydrogen over platinum oxide yielded the desired reagent.

V

III

The results to date indicate that none of the 2-substituted-1,3-bis(*p*-dimethylaminobenzyl)-hexahydropyrimidine derivatives possess antifungal or antibacterial activity. Other derivatives are now being prepared for testing.

EXPERIMENTAL[1]

Aldehydes.—Either reagent grades of aldehydes were used or they were purified by recrystallization from appropriate solvents. 3-Thiophenealdehyde was prepared by hydrolysis of its hexamethylenetetraammonium chloride salt (10) and used without further purification.

1,3 - Bis(*p*-dimethylaminobenzylideneamino)-

[1] Melting points were taken in open capillaries and are corrected. Microanalyses were performed by Miss J. Dickey of the Chemistry Department of Indiana University and/or by Midwest Microlab, Inc., Indianapolis, Ind.

propane (V).—To a refluxing solution of 64.3 Gm. (0.430 mole) of *p*-dimethylaminobenzaldehyde in 225 ml. of absolute ethanol was added a solution of 13.1 Gm. (0.177 mole) of trimethylenediamine in 30 ml. of absolute ethanol during a 30-min. period. The reaction mixture was refluxed an additional 30 minutes and the crystals which formed on cooling were collected and washed with ethanol; yield, 57.1 Gm. (96%), m.p. 144–145°. Recrystallization from absolute ethanol provided 45 Gm. (74%) of white crystals, m.p. 144.5° to 145°, $\lambda_{max.}^{KBr} = 6.05\mu$ (=C=N—).

Anal.—Calcd. for $C_{21}H_{28}N_4$: N, 16.65. Found: N, 16.59.

1,3 - Bis(*p*-dimethylaminobenzylamino)propane (III).—A mixture of 23.0 Gm. (0.069 mole) of 1,3 - bis(*p*-dimethylaminobenzylideneamino)propane, 1 Gm. of platinum oxide and 150 ml. of absolute ethanol was reduced at room temperature in a low pressure Parr hydrogenator with an initial hydrogen pressure of 47 p.s.i. Approximately 35 minutes were required to complete the reduction. The catalyst was removed by filtration and the filtrate was treated with 100 ml. of absolute ethanol, then slowly, while stirring vigorously, with 34 ml. of concentrated hydrochloric acid. The precipitated hydrochloride salt was removed by filtration, washed with absolute ethanol, dried partially under suction and completely in a vacuum desiccator over sodium hydroxide. The yield of crude 1,3-bis(*p*-dimethylaminobenzylamino)propane tetrahydrochloride monohydrate was 33.6 Gm. (98%). An analytical sample was obtained by two recrystallizations of the crude material from a mixture of 10% hydrochloric acid and absolute ethanol, 1:10, (the hot amine salt dilute hydrochloric acid solution was filtered into the absolute ethanol); decompn. point, 240–242° (brass Maquenne block).

Anal.—Calcd. for $C_{21}H_{38}Cl_4N_4O$: N, 11.11; Cl, 28.12. Found: N, 11.03; Cl, 28.10.

The free tetramine was recovered from its aqueous salt solution by precipitation with 10% sodium hydroxide. It was collected on a filter, washed with water, partially dried (rubber dam), then quickly transferred to a vacuum desiccator where drying was completed over sodium hydroxide. The tetramine occasionally softened in the desiccator, but solidified again on repeated drying *in vacuo*. The tetramine liquifies in air, but remains in solid form when kept in a desiccator over solid alkali. An analytical sample of 1,3-bis(*p*-dimethylaminobenzylamino)propane was prepared from its purified hydrochloride salt with aqueous alkali and dried *in vacuo* over sodium hydroxide and Ascarite, m.p. 38–40° (sealed capillary).

Anal.—Calcd. for $C_{21}H_{34}N_4$: C, 74.07; H, 9.47; N, 16.46. Found: C, 73.72; H, 9.57; N, 16.45.

2 - Substituted - 1,3 - bis(*p*-dimethylaminobenzyl)hexahydropyrimidines (IV).—The 2-(2-propyl)- derivative was prepared by the following procedure (*A*). To a stirred solution of 5.0 Gm. (0.015 mole) of 1,3-bis(*p*-dimethylaminobenzylamino)propane in 15 ml. of methanol was added dropwise 1.1 Gm. (0.015 mole) of isobutyraldehyde during a 5-min. interval. The reaction mixture was refrigerated and the crystalline precipitate which formed was collected and washed with methanol, 5.4 Gm. (92%), m.p. 107–108°. Recrystallization from ethanol provided 4.1 Gm., m.p. 107.3° to 108.3°, for an overall yield of 70%.

Anal.—Calcd. for $C_{25}H_{38}N_4$: N, 14.19. Found: N, 14.48.

The 2-(3,4-dimethoxyphenyl)- derivative was prepared by the following procedure (*B*). To a solution of 9.3 Gm. (0.019 mole) of 1,3-bis(*p*-dimethylaminobenzylamino)propane tetrachloride monohydrate in 190 ml. of water was added dropwise, with stirring, 44 ml. of 10% sodium hydroxide. The precipitated tetramine (III) was collected on a filter, washed well with water, freed of most of the adhering water, then dissolved in 13 ml. of hot methanol. To this hot solution was added a hot solution of 3.1 Gm. (0.019 mole) of veratraldehyde in 6 ml. of methanol. The resulting solution was swirled, cooled to room temperature, then refrigerated. The precipitated derivative was collected and washed with methanol. The dried crude product, 6.3 Gm., was recrystallized from absolute ethanol providing 5.0 Gm. (54%) of white prisms, m.p. 118–119°.

Anal.—Calcd. for $C_{30}H_{40}N_4O_2$: N, 11.47. Found: N, 11.67.

SUMMARY

1. A series of ten 2-substituted-1,3-bis (*p*-dimethylaminobenzyl)hexahydropyrimidines has been prepared.

2. In general, these compounds failed to show any biological properties of significant interest.

Interaction of Ouabain and Malonate upon the Contractile Response of Myocardium

By DUANE G. WENZEL and IVENS A. SIEGEL

The interaction of two positive inotropic agents, ouabain and malonate, was studied upon the electrically-stimulated rat ventricle strip. Dose-response relationships of each were determined independently and in combination. The response to ouabain was linear within the concentration range tested, while malonate induced depression of the contractile force in higher concentrations. The combined administration resulted in potentiation and it was concluded that ouabain and malonate induce their positive inotropic actions through different mechanisms.

NUMEROUS attempts have been made to determine the mechanism by which the cardiac glycosides increase the efficiency of the failing heart. Such studies have formed the basis for several reviews or summaries (1–3). It has been observed that ouabain, a typical cardiac glycoside, increases the contractile force of the hypodynamic heart when glucose is employed as a substrate, yet does not affect the response in the presence of pyruvate (4). On the basis of this evidence it has been postulated that the cardiac glycosides may remove a rate-limiting step in the glycolytic pathway. Malonate, as metabolic inhibitor with positive inotropic properties, has been observed to have a similar locus of action (5). While the specific site of action within the glycolytic pathway is not known for either ouabain or malonate, it is possible to determine whether they act in the same manner by observing the nature of their interaction upon the myocardial contractile force. Such a study forms the basis of this communication.

EXPERIMENTAL

The method employed to determine the nature of the interaction between ouabain and malonate upon myocardial contractility was the electrically-driven rat ventricle strip. The details of the equipment have been described previously (6). The method, in brief, employed a strip from the right ventricle of young male rats (135–170 Gm.). Such strips were placed in a phosphate-buffered oxygenated medium containing 0.9% sodium chloride, 0.042% potassium chloride, 0.036% calcium chloride, and 1 m*M* sodium phosphate buffer at pH 7.4. The tissue was supramaximally stimulated with 20 v. at a frequency of 4 per sec. Bath volume was 100 ml. and the temperature was maintained at 27°. Drugs were added in 1 ml. of bath solution following withdrawal of an equivalent volume.

Heart strips were allowed to rest in the bath without stimulation for a period of 1.5 to 2 hours, dependent upon the time required for a satisfactory response to stimulation. Following the initiation of stimulation, during what is termed the equilibration period, the amplitude of contraction gradually increased, reaching a maximum termed the 100% level. This was then followed by a steady decline over a period of several hours. Contractile amplitude was measured at 5-min. intervals and drugs were added when it had declined to 75% of the maximal response. In this manner, tests were conducted with the heart strips being in the same relative hypodynamic state.

The method for the determination of the type of interaction between ouabain and malonate is based upon that of Loewe (7). A right isosceles triangle is formed in which the length of each leg represents the concentration of one of the pair of drugs producing the same per cent increase in contractile amplitude. If the concentration of one of the pair is reduced in a stepwise manner from the arbitrary response concentration to nothing, and if this response decrement is compensated for by necessary amounts of the other agent, the plot of the points obtained from these concentration pairs will indicate the type of interaction. If the points lie along the hypotenuse of the triangle, the drugs are additive; if they lie outside the triangle, they are antagonists; and if they lie within the triangle, the drugs are potentiative.

RESULTS

Ouabain was tested for its positive inotropic effect with seven concentrations arrayed in a geometric progression from 9 to 50 $\times 10^{-4}$ m*M*. Four strips were employed for each concentration. As shown in Fig. 1, the response was linear within this concentration range. The increase in contractile amplitude induced by ouabain reached its maximum in 5.8 $\pm$ 0.62 min. for the 28 strips used. After reaching the peak contractile force, the developed tension declined at a faster rate than that noted with untreated strips.

Twelve concentrations of disodium malonate were similarly investigated. The results are also presented in Fig. 1. Only two strips were employed with each of the larger doses of malonate, as indicated by the dotted line. The response of the strips to malonate was distinctly different from that to ouabain. In the lower concentrations (0.26–0.70 m*M*) there occurred a slight immediate decrement (1 to 4%) followed by a slow increase to slightly more than the initial 75% level after 30 to 40 min. With intermediate concentrations (1 to 5 m*M*), the initial decrement was larger (5 to 10%) and was followed by even greater increases in amplitude. The greatest positive inotropic action was developed with a concentration of 5 m*M*. At the highest con-

centration tested (10 m*M*), a 25% decrement occurred within 1 minute and was followed by a gradual increase which never reached the original (75%) level. All per cent changes were based upon the maximum or 100% amplitude developed after the equilibration period. Those values shown in Fig. 1 are the maximum effects developed after addition of the drug without regard for the time required. With ouabain, the response was maximal in about 6 min. whereas with malonate, this maximum effect required from 30 to 40 min. In order to have the positive inotropic actions of ouabain and malonate coincide when tested for their interaction, malonate was first added to the bath and 30 minutes later, when the response was near maximal, ouabain was added.

The decision as to the per cent increase to be used was based, in part, upon the fact that malonate, in concentrations larger than 5 m*M*, exerted an inhibitory effect. If, for example, the maximum increment induced by 5 m*M* malonate (16%) were selected as the desired positive inotropic action, then any antagonism between the drugs would necessitate using inhibitory concentrations of malonate. An arbitrary 10% positive inotropic action was selected as the desired response. The concentration of each drug required to elicit this 10% positive inotropic action was determined from Fig. 1. For ouabain this was 27.5 × 10^{-4} m*M* and for malonate, 3.0 m*M*.

Five concentrations of ouabain, up to the concentration producing the 10% response (27.5 × 10^{-4} m*M*), were individually tested with sufficient malonate in order to yield the 10% increase in contractile amplitude. The five concentration combinations of ouabain and malonate with the mean values for each are presented in Table I. The curve, or isobol, formed by plotting these equieffective pairs is shown in Fig. 2. From the shape of the isobol it is apparent that the interaction is potentiative.

DISCUSSION

Ouabain was found to produce a positive inotropic action on the rat ventricle strip in concentrations as low as 9 × 10^{-4} m*M* (1:1,500,000). This was considerably below the lowest effective concentration reported by Masuoka and Saunders on the same preparation (8). As these investigators had employed a 50% decrement prior to the addition of the ouabain, in contrast to the 25% reduction in this study, the greater effectiveness could have been related to a lesser depletion of endogenous substrate. Results obtained with disodium malonate were similar to those of Covin and Berman except that they did not observe the decrease in amplitude with concentrations above 5 m*M* (5). There is no obvious explanation for such a difference in the results with high malonate concentrations.

Theoretically, there are at least several possible mechanisms by which drugs can improve the contractility of the myocardium. Energy production, transfer, or utilization may be involved. The contractile protein may be directly affected. Alterations in the electrolyte composition of the myocardium is thought by many to be the underlying mechanism. It is also possible that the efficiency with which the electrical excitation of the cell membrane is coupled with muscle response could be involved. One of the many difficulties related to studying the mode of action of positive inotropic agents is that potential mechanisms are so interdependent that an initiating event is difficult to isolate and identify. In studies employing various

TABLE I.—CONCENTRATION PAIRS OF OUABAIN AND MALONATE PRODUCING THE SAME POSITIVE INOTROPIC ACTION[a]

	Concentration, m*M*				
Ouabain × 10^{-2}	0.21	0.16	0.13	0.09	0.03
Malonate	0.26	0.37	0.50	1.0	2.0
Mean positive inotropic action, % ± S.E.	9.99 ± 0.92	10.55 ± 1.07	10.65 ± 0.54	9.62 ± 1.14	10.58 ± 0.87

[a] Per cent positive inotropic actions are the mean values from four determinations.

substrates with a cardiac glycoside or malonate it has been demonstrated that both may act through the removal of a rate-limiting step in the conversion of glycogen or glucose to pyruvate and thus, at least in part, affect energy production or utilization (4, 5). Such an hypothesis does not account for the inhibition observed with high concentrations of malonate, but neither does it preclude the possibility of other concentration-related mechanisms. Malonate may owe a portion of its positive inotropic effect to removal of a rate-limiting step in the glycolytic pathway and possibly to its ability to function as a metabolite (9). Its inhibition of succinic dehydrogenase (10) could account for the initial decrement and that decrement observed with high concentrations. While the results of the ouabain-malonate interaction suggest neither the sites of action nor the mechanisms, they do indicate the individual actions to be different from one another. If these agents shared the same site or mechanism of action, the interaction would be either additive or antagonistic. The potentiative response indicates complementary activity.

Stability of Vitamins A, B_1, and C in Selected Vehicle Matrices

By KEE-NENG WAI, H. GEORGE DEKAY, and GILBERT S. BANKER

The relative stability of vitamins A, B_1, and C in eight commonly used solid vehicle matrices was determined. Vitamin preparations, each containing one vitamin and one solid matrix, were first subjected to accelerated aging tests and were evaluated for their loss in vitamin contents. The results indicated that a diluent moisture content in excess of one per cent played an important role in determining the stability of these preparations. Mannitol and lactose were found to be superior solid diluents on the basis of the stability studies conducted. The influence of formulation (use of coated or U.S.P.-grade vitamins), method of combination, and manufacturing procedures were studied for their effect on vitamin stability in an uncoated tablet dosage form.

IN RECENT years many new, uncoated multivitamin tablets have appeared on the market. The majority of these products have been chewable, pediatric vitamin tablets, although conventional vitamin tablet formulations in uncoated, compression-coated, and film-coated form are also making their appearance. The advantages of uncoated vitamin tablets over vitamin liquids, capsules, and coated tablets are numerous, obvious, and of considerable economic significance. The development of commercially feasible uncoated vitamin tablet formulations is being made possible by at least three advances: (*a*) the application of new excipient materials to solid vitamin products; (*b*) the commercial availability of new, more stable chemical forms of vitamins, and coated, wax imbedded, and other modifications of vitamin materials, and (*c*) studies which accurately describe the stability, reaction kinetics, and incompatibilities of the various vitamins.

The reports of McLaughlan, Clark, Campbell, and McLeod (1–3) have revealed that vitamins A, B_1, B_{12}, and pantothenic acid in many commercial multivitamin products are quite unstable. Ascorbic acid is known to be incompatible with riboflavin, vitamin B_{12}, and folic acid (4). Thiamine reacts with riboflavin (5) and folic acid (6). Extensive investigations of the interactions among thiamine, niacinamide, and vitamin B_{12} have also been carried out in the past few years (7–14).

Accelerated aging tests of vitamin products have been conducted by Garrett (15) and Yamamoto (16). These workers related the stability of various vitamins with storage time and temperature and found that the degradation of ascorbic acid, thiamine, vitamin B_{12}, and pantothenyl alcohol was a first-order reaction and the degradation rate of vitamin A was independent of concentration. They also showed that at 45° the degradation of vitamin A in 8 weeks and ascorbic acid in 6 weeks was approximately equivalent to their degradation at room temperature for 1 year. Taub and Katz (17) have indicated that thiamine decomposition in tablets and capsules, after storage at 45°

substrates with a cardiac glycoside or malonate it has been demonstrated that both may act through the removal of a rate-limiting step in the conversion of glycogen or glucose to pyruvate and thus, at least in part, affect energy production or utilization (4, 5). Such an hypothesis does not account for the inhibition observed with high concentrations of malonate, but neither does it preclude the possibility of other concentration-related mechanisms. Malonate may owe a portion of its positive inotropic effect to removal of a rate-limiting step in the glycolytic pathway and possibly to its ability to function as a metabolite (9). Its inhibition of succinic dehydrogenase (10) could account for the initial decrement and that decrement observed with high concentrations. While the results of the ouabain-malonate interaction suggest neither the sites of action nor the mechanisms, they do indicate the individual actions to be different from one another. If these agents shared the same site or mechanism of action, the interaction would be either additive or antagonistic. The potentiative response indicates complementary activity.

Presented to the Scientific Section, A.PH.A. Las Vegas meeting, March 1962.

The reports of McLaughlan, Clark, Campbell, and McLeod (1–3) have revealed that vitamins A, B_1, B_{12}, and pantothenic acid in many commercial multivitamin products are quite unstable. Ascorbic acid is known to be incompatible with riboflavin, vitamin B_{12}, and folic acid (4). Thiamine reacts with riboflavin (5) and folic acid (6). Extensive investigations of the interactions among thiamine, niacinamide, and vitamin B_{12} have also been carried out in the past few years (7–14).

Accelerated aging tests of vitamin products have been conducted by Garrett (15) and Yamamoto (16). These workers related the stability of various vitamins with storage time and temperature and found that the degradation of ascorbic acid, thiamine, vitamin B_{12}, and pantothenyl alcohol was a first-order reaction and the degradation rate of vitamin A was independent of concentration. They also showed that at 45° the degradation of vitamin A in 8 weeks and ascorbic acid in 6 weeks was approximately equivalent to their degradation at room temperature for 1 year. Taub and Katz (17) have indicated that thiamine decomposition in tablets and capsules, after storage at 45°

for 3 weeks, was comparable to a year of shelf life.

While a good deal has been learned about vitamin stability in recent years, no comprehensive report of the stability of the less stable vitamins in common, solid vehicles is in the literature. Such information could be of value in the development of uncoated tablets, whether designed to be chewed or swallowed, compression-coated tablets in which a portion of the vitamin formulation is in the coat or all the vitamin formulation is in the coat and the core is comprised of minerals, or film-coated tablets in which the film adds pharmaceutical elegance but affords incomplete protection to oxygen or water vapor transmission.

It was the objective of this research to study the stability of three selected, relatively unstable, vitamins in different solid vehicle matrices and to study various formulations and manufacturing procedures which might relate to the stability of solid multivitamin products.

EXPERIMENTAL

Materials.—The vitamins A and D[1] used in this study were in the form of a granulation containing gelatin, sugar, and starch with a labeled content of 500,000 U.S.P. units (150 mg.) of vitamin A acetate and 50,000 U.S.P. units of vitamin D_2 per gram of granulation. The other vitamins used were U.S.P.-grade chemicals or coated vitamins in the form of thiamine mononitrate Mercote,[2] niacinamide Mercote, riboflavin Mercote, and ascorbic acid coated with 5% ethylcellulose type N.[3]

The diluents used included mannitol, lactose, sucrose, aluminum hydroxide dried gel, kaolin, starch, calcium sulfate, and hydrous dextrose. All of these were U.S.P.- or N.F.-grade chemicals with the exception of the calcium sulfate which was in the form of $CaSO_4 \cdot 2H_2O$.[4] The lubricant in all of the preparations was magnesium stearate, U.S.P.

Equipment.—The equipment used to prepare the solid vitamin products included a kitchen-aid model Hobart mixer[5] for the mixing of powders and granulations; stainless steel wire screens for the reduction of particle size and mixing of powders (30 mesh) and for granulating and resizing (20 mesh); the Stokes oscillating granulator,[6] fitted with a 12-mesh screen, for dry granulating; and a Stokes B2 rotary tablet machine[6] equipped with $^3/_8$-inch standard concave punches and dies and $^5/_8$-inch flat-face punches and dies, for tableting and slugging, respectively.

The instruments used for the assays of the vitamins included a Beckman model DU spectrophotometer[7] for the measurement of absorbance of vitamin A solution and a Fisher nefluorophotometer[8] for the measurement of the fluorescence of thiochrome.

A constant-temperature electric oven, adjusted to 45° (±2°) was used to store the tablets for the accelerated aging tests. The other equipment used included the Monsanto hardness tester[9] and the Cenco moisture balance.[10]

Methods of Assay for Vitamins A, B_1, and C.—The official methods for the assay of these three vitamins as described in the monograph of decavitamin tablets U.S.P. were used throughout the course of this study. However, some modifications were made. In the assay of vitamin A, the saponification of vitamin A acetate was carried out in 7 ml. of glycerin, 25 ml. of alcohol, and 3 ml. of 50% potassium hydroxide solution. The glycerin was used because it had a greater softening effect than alcohol on the brand of commercial vitamin A granules used. All calculations for vitamin A content were based on the absorbance at 325 mμ instead of the three points prescribed by the U.S.P. In the assay of vitamin B_1, the concentration of the "Standard Preparation" was about 1.0 mcg. per ml. instead of 0.2 mcg. per ml. as suggested in the U.S.P. This change was made in order to permit the measurement of fluorescence at the optimum sensitivity range of the equipment employed in this work. The alcoholic extracts of the vitamin A and aqueous extracts of vitamin B_1 were transferred into 100-ml. volumetric flasks and brought to volume with dilute alcohol or water before filtration. Exactly 50 ml. of the filtrates was collected for the assays.

Study of the Stability of Vitamins A, B_1, and C in Solid Matrices.—Thirty-six samples, each containing one vitamin, one diluent, and 0.5% magnesium stearate, were separately prepared with the three vitamins and 12 commonly used solid matrices. The solid matrices included mannitol, sucrose, lactose, calcium sulfate, aluminum hydroxide dried gel, starch, kaolin, dextrose, and combinations of 80% mannitol with 20% each of starch, aluminum hydroxide dried gel, sucrose and dextrose. Each gram of sample contained 4 mg. of vitamin A in the form of dry vitamin A acetate with D, or 5 mg. of thiamine hydrochloride, U.S.P., or 300 mg. of ascorbic acid U.S.P. These combinations were compressed on a rotary-tablet machine into one-gram disks, $^5/_8$ inch in diameter. These disks were employed to individually study the stability of the vitamins in the various matrices in a compacted, simulated tablet condition. They were kept in six-ounce, brown, dry-square bottles and stored at 45° and at room temperature. The vitamins in these preparations were assayed as follows: (*a*) prior to storage, (*b*) after 1 month's storage at 45°, (*c*) after 3 months' storage at room temperature, and (*d*) after 3 months' storage at 45°.

Study of the Stability of Multivitamin Chewable Tablets.—Following the study of vitamin stability in various solid matrices, one of the tablet diluents was selected for subsequent research dealing with the stability of multivitamin chewable tablets. Utilizing mannitol as the selected diluent, six batches of tablets were prepared. These tablets differed

To make 1000 tablets			

from one another in the forms of vitamins used, the methods of vitamin combination, and the method of manufacture. All of these formulas contained equal labeled quantities and overages of the vitamins. To prepare the tablets, the vitamins which were known to be mutually incompatible were granulated separately with a part of the mannitol and lubricated with magnesium stearate. One of the typical working formulas is given in Table I and the composition and methods of manufacture of the six batches of tablets are summarized in Table II.

These multivitamin chewable tablets were assayed immediately after manufacture and after storage for 1 month at 45°. Three commercial chewable tablets were studied simultaneously for the purpose of comparison. The hardness of these tablets and any changes in physical appearance with aging were also observed.

RESULTS AND DISCUSSION

The moisture contents of the solid vehicles used in this work are shown in Table III.

TABLE III.—MOISTURE CONTENT OF SOLID VEHICLES STUDIED

Vehicle	Moisture, %[a]
Mannitol	0.2
Sucrose	0.2
Lactose	1.0
Aluminum hydroxide	15.0
Starch	8.0
Calcium sulfate	2.7
Kaolin	1.0
Dextrose	8.0
Mannitol and sucrose	0.2
Mannitol and aluminum hydroxide	2.9
Mannitol and starch	1.8
Mannitol and dextrose	1.6

[a] Moisture contents were determined using the Cenco moisture balance at a pan temperature of 90°.

Tables IV, V, and VI show that vitamin A was most stable in manitol and lactose; thiamine was stable in mannitol, sucrose, lactose, and kaolin; and ascorbic acid appeared to have good stability in all of the diluents with the exception of aluminum hydroxide. Most of the ascorbic acid preparations, however, changed color during the storage period. The color change was not universally indicative of a loss of vitamin potency. Mannitol, sucrose, and lactose were the only three diluents in which no color change was observed with ascorbic acid under the conditions of storage.

Table IV also shows that the degradation of vitamin A at 45° for 1 month was usually slightly greater than its degradation after storage at room temperature for 3 months. Accordingly, it is expected that the degradation of vitamin A at 45° for 3 months might be approximately equal to its degradation at room temperature for a year.

Thiamine appears to be much more thermolabile than vitamin A. The accelerated aging test of the vitamin B_1 preparations after 1 month clearly indicated the role of the diluent on the stability of the vitamin.

The degradation of vitamins A, B_1, and C is accelerated by the presence of moisture in the solid vehicles. In mannitol, sucrose, lactose, and kaolin, which contained not more than 1% moisture, these vitamins were quite stable. In starch, aluminum hydroxide, and dextrose which contained 8, 15, and

TABLE II.—DESIGNATION OF TABLET COMPOSITION AND METHOD OF MANUFACTURING

Tablet Number	Form of Vitamins	Granulation Method	Granulation Agent	Vitamin-Granulation Combinations 1[b]	2	3
1	USP Powder	Dry	...	A, D, & B_1	C	Other B Vit.
2	Coated[a]	Dry	...	A, D, & B_1	C	Other B Vit.
3	Coated	Dry	...	A & D	B_1 & C	Other B Vit.
4	Coated	Wet	Alcohol	A & D	B_1 & C	Other B Vit.
5	Coated	Wet	Dil. Alc.	A & D	B_1 & C	Other B Vit.
6	Coated	Wet	Water	A & D	B_1 & C	Other B Vit.

[a] The coated vitamins included the Mercotes and the ethylcellulose coated ascorbic acid. The other B vitamins in the formula were uncoated U.S.P. grade. Since the coated vitamins contained less active ingredient than an equal weight of U.S.P.-grade vitamin, a correspondingly larger amount of coated vitamin was taken and the weight of the diluent in these formulations was reduced so that each tablet at the same theoretical weight would contain the same potency of each vitamin.
[b] The vitamins A and D in formulas 3 to 6 were not granulated with the diluent. The vitamin granules were added directly to granulations 2 and 3.

8% moisture, respectively, the vitamins were generally very unstable.

It is believed that kaolin adsorbed a part of the thiamine and caused the apparent low activity of thiamine in this combination. Also, in the assays of vitamin A in lactose and glucose, excessive caramelization of the sugars was observed. The light absorbance of the isopropanol extracts of these preparations measured at wavelengths of 310 mμ, 325 mμ, and 334 mμ indicated the presence of interference materials. However, no correction was made for this interference since all data were calculated by the same method according to the light absorbance of the sample at 325 mμ.

Table VII shows that maximum stability was achieved in Tablet No. 2 by using the dry granulation method and by granulating vitamins A and B_1 separately from the other vitamins. Tablets No. 3, 4, 5, and 6 each showed approximately the same degree of stability, but tablets No. 5 and 6, granulated with dilute alcohol and water, respectively, changed color quite rapidly. The tablets prepared by double compression had no apparent change in color after storage at 45° for a month and were generally softer than those prepared by the wet-granulation method. These results indicated that the use of water as the granulating agent or granulating agents containing water caused a more rapid change in the color of the solid multivitamin products than when no water was added. The findings

[a] See Table II. [b] A commercial multivitamin chewable tablet. [c] "Stable" means no apparent change in color during the period of accelerated aging test.

of Table VII also showed that the manner in which the vitamins were combined was as important as the granulating method used (wet or dry) or the granulating agent used.

CONCLUSIONS

Of the eight commonly used diluents evaluated, mannitol appeared to be the best diluent with regard to the stability of the vitamin products studied with lactose being a close second. A diluent moisture content in excess of 1% played an important part in catalyzing the degradation of vitamins B_1 and C. Some chemical change in the tablets containing ascorbic acid is manifested by an intense discoloration of the products, although the actual assay values may not be significantly reduced. Hence, the choice of a nonhygroscopic solid vehicle is essential in formulating a stable, uncoated, multivitamin tablet.

The stability of uncoated multivitamin tablets was found to be improved by the following techniques:

1. Use of coated ascorbic acid, thiamine, riboflavin, and niacinamide. This process enhances the stability of the vitamins.

2. Preparation of the granulations of the incompatible vitamins separately with a portion of the inert matrices. The best stability results were obtained when the vitamins A, D, and B_1 were granulated with one-fourth of the matrix, the vitamin C with one-half of the matrix, and the remaining B vitamins with one-fourth of the matrix. These three granulations were blended together in the proper proportion before compression.

3. Avoiding use of water as a granulating agent. Vitamin tablets granulated with water or dilute alcohol discolored rather rapidly, however the assays of these tablets indicated no significant difference in stability from those granulated with alcohol or prepared by the dry-slugging method.

Experimental Method for Studying Growth Rates of Particles in Aqueous Media

By W. I. HIGUCHI and P. K. LAU

A simple procedure for following growth of suspension particles has been developed. It is suitable for studying mechanisms of growth, for evaluation of potential growth retarding agents, and possibly for accelerated stability studies in dispersed systems. It involves the determination of the particle concentration and size distribution as a function of time with the Coulter counter. The sensitivity of the method is better than 0.1 μ for particles in the micron size range. Prior removal of the particles from the suspension is unnecessary. The technique has been applied to growth rate studies in the methylprednisolone system.

THERE ARE A NUMBER of situations in which an understanding of the factors determining the rate of crystal growth is helpful to the pharmacist. In connection with stability, the coarsening of suspensions by growth of the larger particles at the expense of the smaller ones is a good example. The problem of caking, the cementing together of particles in a sediment, is also well known. More recently, attention (1) has been given to the possible utilization of more energetic crystal forms of drugs in pharmaceutical preparations. The problem of preventing the conversion of these crystals may be frequently one of inhibiting the growth of more stable and less active forms. Thus, a systematic investigation of the growth rates of crystals may greatly extend our knowledge in these areas.

To study situations mentioned above, the experimental method should be one in which the following requirements are met: The method should be highly sensitive, capable of detecting growth in the order of one micron. The method should be reproducible or, alternatively, statistically significant. This requirement is most conveniently met if the growth of a large number of crystals could be followed at the same time. Finally, the method should be convenient and rapid if reasonable progress is to be expected.

The present report describes a method which meets these requirements. It is highly sensitive, reproducible, and simple. In its present form it might be used, for example, to perform accelerated stability studies and to screen and study potential growth inhibiting agents.

EXPERIMENTAL

General Consideration.—It was decided to select a method which involves following the changes in the distribution of suspension particle sizes with time. A solution suitably supersaturated with a drug could be seeded with crystals of the drug and the size distribution of the crystals determined from time to time with the Coulter counter.[1] If, during the experiment, sedimentation or aggregation of the crystals remains negligible, the changes in the particle sizes may be attributed entirely to growth by molecular transport and deposition.

The steroid, methylprednisolone, was chosen for this study because the polymorphism of this compound has been investigated (2). In the present studies growth from solution of the most stable form of methylprednisolone was followed.

Procedure.—Methylprednisolone[2] was recrystallized from a 50% ethanol-water solution and dried. The crystals were then finely ground by means of a mortar and pestle. An amount of the powder equal to about four times that necessary for saturation was placed in 500 to 1000 ml. of redistilled water in a round-bottom flask. The suspension was stirred vigorously for at least 2 hours at some temperature higher than the 25° employed for the growth studies. In most of the experiments this saturation temperature was around 50° where the solubilities are about twice that at room temperature. After saturation, the suspension was filtered through a 0.45 μ pore-size Millipore[3] filter and the filtrate was placed in a 1 L. glass-stoppered round-bottom flask, ready for seeding.

The seed crystals were prepared and added to the supersaturated solution in the following manner: About 10 ml. of the above prepared solution was placed in a 25-ml. glass-stoppered graduated cylinder. To this was added about 25 mg. of the finely ground drug powder. To promote dispersion, surfactant was added, and the seed suspension was subjected to about 5 minutes of ultrasonic irradiation in a cleaning unit.[4] Then it was allowed to stand undisturbed for about 30 minutes to 2 hours to insure removal of large crystals by sedimentation. After this period, a few tenths of a ml. was pipetted from the uppermost regions of this suspension and added to the supersaturated solution.

The flask containing the seeded solution was then placed in a water bath thermostated at 25.0 ± 0.05°. A Teflon-coated magnetic stirrer activated from below the bath provided gentle agitation of the suspension. Periodically, 50 ml. of the growing

suspension was pipetted out and mixed with an equal volume of 0.9% sodium chloride solution which had been previously saturated at 25° with methylprednisolone and filtered through the 0.45 μ Millipore filter. This mixing with an electrolyte was necessary for the Coulter counter operation. It also reduced the supersaturation, thus retarding growth during the actual counting.

In all of the present experiments, the 50- and the 100-μ aperture tubes were employed. With these, the 1- to 20-μ diameter (equivalent volume sphere) range of particle sizes could be conveniently studied. The 100-μ aperture tube was calibrated with a suspension of partially aggregated 1.83 μ polystyrene latex particles which had been sized with the 50-μ aperture tube. The latter was calibrated earlier (3, 4) with nonaggregated 1.17 μ and 1.83 μ polystyrene latex particles.

There were some important variations in the above procedure. In most experiments a surfactant was added to the growth solution either during the high temperature saturation period or after filtering of the suspension. In some experiments the suspension equilibrated at high temperatures was not filtered through the Millipore filter but instead through a medium-grade sintered glass filter. In these runs, the solutions were not seeded since it was expected that much of the fine crystals would pass through the filter. However, this procedure was unsatisfactory in that the crystallite population varied greatly from run to run. In another modification of the procedure, about 0.1% of Tween 80 was added to the 0.9% sodium chloride solut on which was used to mix with the aliquot of the growing suspension for counting. The presence of this surfactant apparently helped to further reduce growth during the counting.

Along with the Coulter counter determinations, the solution concentrations of the drug were determined as a function of time. Samples were removed from the growth flask by means of a syringe fitted with a Swinny adapter[5] for a Millipore filter. The solutions were then spectrophotometrically assayed after appropriate dilution in 95% ethanol.

DISCUSSION OF THEORY AND EXPERIMENTS

Change of Particle Size with Time (Theory).—Before we proceed with the presentation of data, let us briefly consider the mathematical relationships which apply to the various models for particle growth. These will be helpful in interpreting the experimental results.

For the growth rate, G_i, of a given particle of radius (equivalent volume sphere), a_i, n the distribution we may write

$$G_i = 4\pi\rho a_i^2 \frac{da_i}{dt} \qquad \text{(Eq. 1)}$$

where t is time and ρ is the density of the solid drug. This may be combined with various rate expressions presented below to give a relationship between a_i and t.

If the growth rate is proportional to the particle radius, then

$$G_i = K_1 a_i \qquad \text{(Eq. 2)}$$

where K_1 is a constant if everything else but a_i is constant. This rate law applies to the important case of the diffusion-controlled growth of fine isometric particles ($\lesssim 10$ μ) under zero to moderate agitation (5). For this special case, K_1 may be expressed as

$$K_1 = 4\pi D\Delta C \qquad \text{(Eq. 3)}$$

where D is the diffusion coefficient of the drug molecule and ΔC is the supersaturation defined as $\Delta C = C - C_o$ where C is the solution concentration of the drug and C_o is the solubility. If Eq. 2 and 1 are combined, we obtain

$$\frac{da_i}{dt} = \frac{K_1}{4\pi\rho a_i} \qquad \text{(Eq. 4)}$$

Thus, according to this equation, the rate of change of the particle radius (or diameter) with time is proportional to the reciprocal of the radius.

Consider now the case in which the growth rate is proportional to the square of the particle radius, *viz.*

$$G_i = K_2 a_i^2 \qquad \text{(Eq. 5)}$$

where again K_2 is a constant if everything but a_i is constant. Equation 5 may apply to the growth of isometric particles in which the rate of growth is controlled by the particle surface area and the probability of growth is the same for all surfaces of the particle. If Eq. 5 is combined with Eq. 1 we obtain

$$\frac{da_i}{dt} = \frac{K_2}{4\pi\rho} \qquad \text{(Eq. 6)}$$

This relationship predicts that the rate of change of a_i with time is constant. As will be seen later, most of the data appear to fit Eq. 6 the best.

The last case we shall present is that in which the growth rate is proportional to the cube of the radius of the equivalent volume sphere. We may write

$$G_i = K_3 a_1^3 \qquad \text{(Eq. 7)}$$

where again K_3 is a constant if a_i is the only variable. To the authors' knowledge, no simple physical counterpart exists for this case. The following case, however, might approximate the cube law. If the particles in the initial distribution are composed of aggregates of relatively uniformly sized primary particles, and if the growth rate is surface-area controlled, then at constant t Eq. 7 might apply since the true surface area would be proportional to the mass in this instance. If Eq. 7 is combined with Eq. 1, we obtain

$$\frac{da_i}{dt} = \frac{K_3 a_i}{4\pi\rho} \qquad \text{(Eq. 8)}$$

Thus, for this case the rate of change in a_i is proportional to a_i.

Experimental Results.—The results of experiments under a number of different conditions are presented in Figs. 1–5. These are illustrative of the method. In each, both the Coulter counter data and the solution concentrations of the drug are given as a function of time. The counter data are plotted as the cumulative count *vs.* particle size. Note that the derivatives of these plots would be the usual particle-size distribution curves.

[5] Marketed by Millipore Filter Corporation, Bedford, Mass.

In all of these results the time decrease in drug concentration of the solutions agreed with the amount of growth calculated from the counter data. The calculations here involve the use of the following equation for the conservation of matter

$$\int_{a=o}^{\infty} {}^4/_3\pi\rho\, a^3 n(a)\, da = \text{constant} - M$$

where M is the solution concentration of the drug and n (a) is the distribution function and equal to minus twice the slope of the curves in the plots. The integral may be easily evaluated at various times by means of conventional numerical methods (6) and compared with the right side of this equation. The data given in Fig. 1 may be used to best illustrate this, since in this instance, appreciable solution depletion occurred. This mass balance is a confirmation of the validity of the method.

In cases where all of the initial seed particles had grown beyond the lower size limit of the counter, plateaus or near-plateaus appeared in the plots of counts *vs.* size (see Figs. 1 and 5). This again demonstrated that growth is the main contribution to the time change in the particle size distribution. If, say, aggregation were to be important in the early stages of the experiment, the development of a plateau would be highly unlikely. Instead, the slope of the plots would be expected to steadily increase with decreasing particle diameter.

In those runs in which plateaus appeared, the levels of the plateaus remained constant for an appreciable length of time. For example, in the 0.025% Tergitol 4 case (Fig. 1) the level of the plateau remained constant to a few per cent for about 2 hours during which rapid growth took place. However, after this period, the plateau level began to fall slowly, then more rapidly. This suggested that when the number of relatively large particles reached some level, aggregation or wall losses became important. This drop-off of the plateau level occurred in all experiments whenever the number of large particles became great.

Negligible aggregation and wall losses in the absence of large particles was also demonstrated by an experiment identical to that shown in Fig. 1, except that the supersaturation was about 0.03

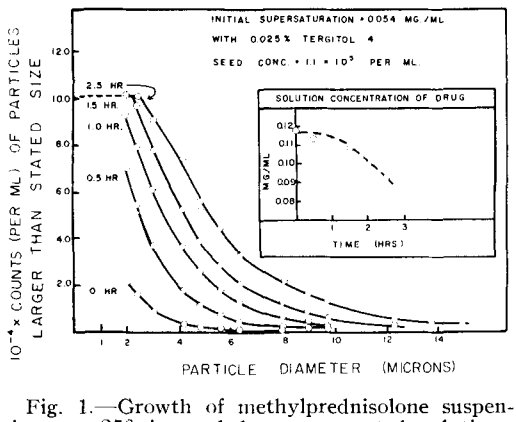

Fig. 1.—Growth of methylprednisolone suspensions at 25° in seeded supersaturated solutions. Main plots are number integral size distribution as function of time. Insets give data on relief of supersaturation over same time ranges.

mg./ml. The growth rate was found to be negligible in this case and both the particle concentration and the distribution of sizes remained unchanged for the duration of the experiment (about 5 hr.). Thus, aggregation or wall losses was absent when large particles were absent.

Let us now direct our attention to the actual rates of growth and the rather interesting effects of small amounts of surfactants. When no surfactant was employed (see Fig. 5) the rate of growth was most rapid. In fact, from the data given in Fig. 5, the rate was found to be within a factor of approximately three of the diffusion controlled rate predicted by Eqs. 3 and 4 and with $D = 5 \times 10^{-6}$ cm.^{2} sec.$^{-1}$ for methylprednisolone. The addition of one drop of Tween 80 (see Fig. 2) reduced the rate of growth by about 500-fold. At somewhat higher Tween 80 concentrations (see Fig. 3) there appeared to be an initial period of growth; this was followed by a great reduction in the rate. In the presence of 0.05% Triton X-100, similar effects were observed (Fig. 4). Tergitol 4, an anionic surfactant, did not reduce the rate (Fig. 1) as markedly as the nonionics. Comparable amounts of sodium lauryl sul-

fate elicited effects similar to Tergitol 4. Solubility studies carried out showed that none of these surfactants increased the solubility of methylprednisolone by more than 0.01 mg./ml. at the concentrations used in these studies. Thus, these effects are not due to reduction in the driving force for growth but probably due to the creation of some kind of an interfacial barrier.

In most instances, particularly for those cases in which the growth rates were relatively small, the rate law given by Eq. 6 appeared to be approximately obeyed. In terms of the plots of the cumulative counts *vs.* particle size, conformation of the data to Eq. 6 would mean that the curves would be displaced to the right at a constant rate with respect to time. The results shown in Figs. 2 and 3 appear to do just that. This suggests strongly that in these cases the growth rates are proportional to the surface area of the particles.

In the experiments with Tergitol 4, it was observed that, while a given ordinate value moved constantly with time to the right, the upper portions of the curves moved more slowly than the lower. For reasons mentioned earlier, this was probably not due to aggregation of the particles. This type of behavior appears to be analogous to the theoretical case leading to Eq. 8. At any given time t the smaller particles appear to be growing more slowly than the larger ones. Further studies are necessary to establish the situation unambiguously for this type of growth behavior.

Control of Urine pH and Its Effect on Sulfaethidole Excretion in Humans

By H. B. KOSTENBAUDER, JOEL B. PORTNOFF†, and JOSEPH V. SWINTOSKY

A technique is described whereby urine can be excreted by human subjects, at a pH near 5.0 or 8.0, with a variation of not more than 0.1 or 0.2 pH unit over periods of at least 15 hours. The significance of controlled urinary pH in humans with respect to the excretion kinetics of a weak acid, sulfaethidole, has been determined. The harmonic mean $t_{1/2}$ for SETD at a controlled urinary pH of 5.0 is 11.4 hours; the $t_{1/2}$ for this drug at a controlled urinary pH of 8.0 is 4.2 hours.

THIS STUDY was undertaken to establish a technique whereby urine would be voided at a constant pH over a protracted time. Using this technique, the elimination of sulfaethidole (SETD) from human subjects was studied to determine the influence of controlled urinary pH on its excretion kinetics. That the elimination processes of some drugs are influenced by administration of agents which affect the acidity or alkalinity of the urine is well known. For example, Smith, Gleason, Stoll, and Ogorzalek (1) and others (2–6) have demonstrated that renal

clearance of salicylates is increased when sodium bicarbonate or other alkalinizing agents are employed to increase pH of the urine. Similar results have been shown by Waddell and Butler (7) and by Mollaret, Rapin, Pocidalo, and Monsallier (8, 9) for phenobarbital, by Waddell and Butler (10) for 5,5-dimethyl-2,4-oxazolidinedione, by Gutman, *et al.* (11), for phenylbutazone analogs, and by Peterson, Finland, and Ballou (12) for sulfadiazine. It is generally accepted in clinical practice that the excretion process of chemotherapeutic sulfonamides can be hastened by administration of sodium bicarbonate. Also, it is well known that the elimination of many basic drugs is hastened by agents which acidify the urine (13–18).

The influence of urinary pH on the elimination of a drug such as SETD can be attributed to the pH dependence of renal tubular transfer of the drug. A large portion of SETD in the human body is contained in extracellular fluids, of which the blood is a large component. Blood passing through the nephron of the kidney is filtered of many of its components. The capillary networks of the glomeruli act as filter beds for the plasma, whereby most of the nonprotein substances filter passively through the glomeruli into the renal tubules. Many of the normal components of the glomerular filtrate are, in part, reabsorbed into the circulation from the tubules; absorption is effected by both active and passive processes, depending upon the substance in question. In addition, tubules may actively and passively secrete substances from the blood into the tubular fluid.

Drugs may be filtered through the glomeruli, secreted into the tubules, and reabsorbed from the tubules in ways similar to those which apply to normal blood components; however, knowledge of the active or passive nature of drug secretion and reabsorption at the renal tubule level is limited. For many drugs it is thought that passive diffusion may be more important than active transport in their excretion and reabsorption at the renal tubule level.

A difference in pH between plasma and tubular fluid can result in a considerable difference in the fraction of undissociated weakly acidic or weakly basic drug in these two fluids. In the absence of a specific transport mechanism it is usually the undissociated form of the drug which most readily diffuses between the two fluid compartments. The concentration gradient of the nonionized drug across the cellular barrier separating plasma from tubular fluid is, therefore, considered to be of primary importance in passive transport. Though it is difficult to determine the pH of fluid at sites in the tubule intermediate of the glomeruli and the bladder, the pH of the beginning and terminal processes can be readily determined by measuring plasma and urine pH. Plasma pH in humans is generally very constant, near 7.4, whereas urine pH may vary through a range of about 4.5 to 8.5 under different natural or experimental conditions.

Milne, Scribner, and Crawford (19) have shown that the pH of the tubular fluid and the pKa and partition coefficient of the drug would be expected to influence the renal tubular transfer of many weak acids and bases, just as such factors influence the absorption and secretion of drugs in the gastrointestinal tract (20–24). It was thought that by devising a technique for maintaining urine pH constant at several pH values, a convenient method would become available for assessing quantitatively, in kinetic terms, the effect of pH on the excretion of drugs. Since SETD is a weak acid which is eliminated virtually completely *via* the urinary route, and methodology for the kinetic elimination studies has been established (25–28), this appeared to be a suitable drug for such study.

EXPERIMENTAL

Human Studies.—Twelve healthy young adult white male human volunteers were employed in the excretion trials of this study. For most trials, food and fluid intake were not controlled.

Ammonium chloride and sodium bicarbonate were used, in the manner previously reported (29), to maintain the desired acidic or alkaline condition of the urine throughout the studies. Normally, a 3- to 4-Gm. dose of one of these agents was given in tablet form for 2 or 3 hours, until measurement of urine pH indicated that pH values of 5 or 8 had been attained. Smaller doses of these agents were administered, usually each hour, to maintain the pH at the desired value. The pH of the urine was monitored, usually every hour, to determine whether succeeding doses should be increased or decreased to maintain a constant pH.

After the desired urine pH was attained, a single 2-Gm. dose of powdered SETD suspended in water was administered orally. Samples of urine were collected, usually at hourly intervals, for at least 10 hours. Volumes of urine voided, pH, and free SETD excreted were measured in a total of 16 trials at a urinary pH near 8, and in 17 trials at a urinary pH near 5. All subjects were used in at least one trial at each of the two urinary pH values. One subject was studied to determine the effect of induced diuresis on the excretion profile. Another variation involved an excretion profile study with one subject where, in a single trial, the urine was maintained first at an acid pH and then at an alkaline pH.

Analytical Methods.—Urine pH measurements were made with a Beckman model G pH meter.

Each urine sample, when collected, was rapidly brought to room temperature and the pH was determined immediately.

Urine samples were assayed for free SETD using a modification of the Frisk macro method (30). Spectrophotometric measurements of the final colored solutions, involving use of the Bratton-Marshall reagent (31), were made with a Beckman model B spectrophotometer, at a wavelength of 550 mμ.

RESULTS

Control of Urine pH.—Typical dosage regimens and the resulting urine pH are presented in Table I. Subjects were somewhat variable with regard to the quantities of ammonium chloride or sodium bicarbonate required to attain and maintain a constant pH; however, after gaining experience with this technique, and by monitoring the urine pH at about hourly intervals, it was a relatively easy matter to maintain urine pH within ±0.2 units over periods of at least 15 hours. The occasional incidence of nausea from the large doses of sodium bicarbonate and ammonium chloride was the principal difficulty encountered in employing this technique.

While good control of urine pH can be attained near pH 5 or pH 8, it was more difficult to maintain constant pH at intermediate values. It was concluded that this could not be accomplished conveniently to the degree of constancy desired for the excretion studies; therefore, studies on the SETD excretion profile were limited to values near pH 5 and pH 8.

Excretion Studies.—Typical data for the SETD excretion profile studies under conditions of constant pH are presented in Tables II and III. Since it has been shown previously (26, 27, 32) that oral doses of SETD are virtually completely absorbed, almost totally excreted in the urine, and that virtually all of the drug in the urine is measurable by use of the Bratton-Marshall reagent, interpretation of the excretion data was not difficult. As shown previously for this drug, rate of elimination can be expressed as

$$dW/dt = -k_b W \qquad \text{(Eq. 1)}$$

where W is the amount of drug remaining in the body at any time, t, or W = (dose − amount excreted), and k_b is the specific velocity constant for disappearance of drug from the body. Since

$$\log W = -(k_b/2.303)t + \text{constant} \qquad \text{(Eq. 2)}$$

k_b can be determined from the slope of the straight line resulting from a plot of log W *vs.* time (27). The biologic half-life, $t_{1/2}$, is determined for each trial from $t_{1/2} = 0.693/k_b$.

Plots of logarithm mg. of unexcreted drug *vs.* time, for single subjects, gave straight line plots after 1 or 2 hours following administration. Table IV illustrates the biologic half-life values obtained from inspection of the exponential plots of the urinary excretion data and the average urine pH as observed for each trial. Average acid urine pH values for subjects in 17 trials ranged from pH 4.5 to pH 5.3. When two trials are eliminated from the summary data, 15 trials fall within the pH range 4.8 to 5.2. The harmonic mean for $t^1/_2$ values observed in the 15 trials at pH 5 ± 0.2 is 11.4 hours with fiducial limits (26) of 9.9 to 13.5 hours. This corresponds to an arithmetic average k_b of 0.061 ± 0.004 hr.$^{-1}$, where ± designates standard error.

Average alkaline urine pH values for subjects in 13

trials ranged from pH 7.4 to pH 8.1. When the three trials at the lowest pH are excluded, 10 trials are observed to fall within the average pH range of 7.9 to 8.1. The harmonic mean for $t_{1/2}$ values in the 10 trials at pH 8 ± 0.1 is 4.2 hours, with fiducial limits of 3.7 to 4.8. Average k_b is 0.165 ± 0.009 $hr.^{-1}$

Figure 1 is a presentation of the composite urinary excretion data from which Table IV values for $t_{1/2}$ were determined. It is a rather dramatic illustration of the adherence of the urinary excretion process, of many trials, to first-order kinetics in the time range studied. In addition, it gives a clear visual illustration of the dependence of the process upon the magnitude of the equilibrium urine pH. Figure 2 also illustrates this very well where an abrupt change in the slope of the excretion curve occurs when urine, being collected during a single trial, was suddenly changed from a pH of 5 to a pH of 8.

Though previous data had supported the opinion that, in the presence of adequate urine flow, elimination kinetics of SETD is relatively independent of urine volume (27), in the early phase of this study experimental verification of this point seemed desirable. During the course of an excretion study, a single subject who had consumed approximately 100 ml. of water each hour was suddenly changed to a regimen where he consumed almost 1000 ml. per hour for several hours. Data presented in Fig. 3 indicate that SETD excretion was essentially unchanged even by tenfold or greater increases in urine volume, so long as precautions were taken to maintain constant urine pH.

DISCUSSION

The fact that urine pH influences net elimination of SETD to the degree indicated in Table IV indicates that renal tubular transport of the drug plays an important role in the elimination process. Approximately 95% of the SETD in plasma is

bound (33) and, therefore, only a small fraction of the total SETD is cleared in any single pass of fluids through the glomeruli. While the concentration of diffusible drug in the glomerular filtrate must be low, a condition favoring diffusion of SETD back into general circulation might be created through water reabsorption in the proximal tubule, thus increasing the concentration of drug in tubular fluid over that of unbound drug in the plasma. Furthermore, a decrease in pH of tubular fluid would favor reabsorption of drug by increasing the concentration of the more readily diffusible undissociated form of the drug.

The pKa of SETD, determined by potentiometric titration, is about 5.5, and the fraction of SETD which is undissociated is given by

$$(H^+)/[(H^+) + Ka]$$

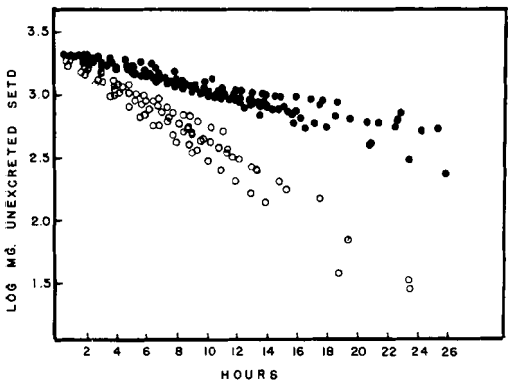

Fig. 1.—Exponential plot of the composite urinary excretion data for sulfaethidole following single 2-Gm. oral doses to 12 subjects in 30 trials. Darkened circles indicate data at constant urine pH near 5 and open circles indicate data where urine pH was maintained near 8 as described in the text.

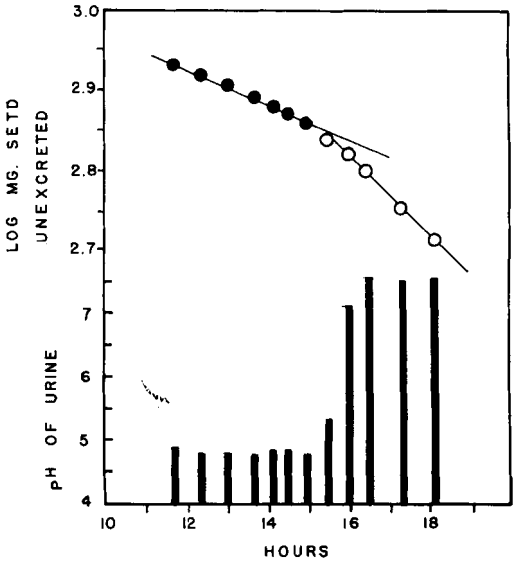

Fig. 2.—Exponential plot of SETD urinary excretion data for a single human subject after a 2-Gm. oral dose. The figure illustrates the abrupt change in slope of the exponential process when urine pH is changed from about pH 5 to pH 8.

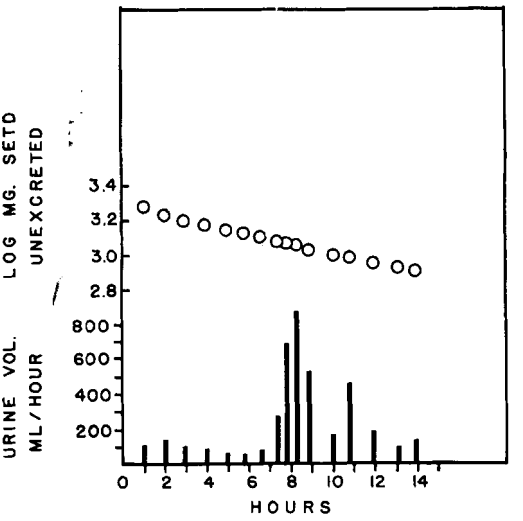

Fig. 3.—Exponential plot of SETD urinary excretion data for a single human subject after a 2-Gm. oral dose when urine pH was maintained near 5, but where the rate at which urine is voided was changed appreciably. The figure illustrates that the elimination rate is relatively independent of urine volume voided.

The fraction of SETD undissociated in plasma and urine under conditions of this study is as follows: plasma, pH 7.4, 1.2% free SETD is nonionized; urine, pH 8.0, 0.3% SETD is nonionized; urine, pH 5.0, 76% SETD is nonionized.

Although the pH of tubular fluid at sites for reabsorption of SETD is unknown, it seems fairly certain that under conditions of this study the fluid

would be alkaline when urine pH was maintained at pH 8 and acid when urine was maintained at pH 5. The longer biologic half-life for SETD under conditions of acid urine suggests that reabsorption of the drug from tubular fluids is favored by higher concentrations of undissociated drug. This concept is similar to those concerning gastrointestinal absorption which have seen considerable discussion in recent literature by Schanker, Brodie, Hogben, *et al.* (20–24). Milne, Scribner, Crawford (19), Gutman, *et al.* (11), and others have developed such thinking regarding factors influencing net drug elimination *via* the urinary route.

Though the pKa of SETD and other acidic and basic drugs apparently plays an important role in the mechanism of drug elimination, and though controlled urinary pH can exert a profound effect on the rate of net drug elimination, the intrinsic lipid solubility of the undissociated drug, concomitant administration of other drugs, and other factors must also be important in influencing the net elimination rate. It would seem important to obtain a clearer understanding of the mechanism of drug excretion by the kidney, and of the interrelationships of the physical-chemical properties of drugs and the mechanisms which come into play in body elimination of drugs. Such knowledge, coupled with additional knowledge of other body mechanisms for eliminating drugs and drug activity, has a bearing on the intelligent design of drugs and their dosage forms for controlling their duration of action.

The results of this study supplement and support, in a number of respects, previously reported findings concerning SETD excretion kinetics (25–28, 30, 32). In previous studies without benefit of controlled urinary pH, and using both blood concentrations and urinary excretion data, the $t_{1/2}$ for SETD in human subjects was shown to be about 8.4 hours (27). This value is about midway between the values of 4.2 and 11.4 hours, at controlled urine pH of 8 and 5, respectively, determined in this study. These results also give further reinforcement to the opinion that the $t_{1/2}$ values of drugs determined experimentally in human subjects are not to be construed as fixed values. Rather, they are subject to variation by a number of factors about which much additional data are necessary for a better understanding of elimination mechanisms and kinetics.

SUMMARY

1. A technique has been developed to permit control of the pH of urine being excreted by human subjects to ±0.1 pH unit, in the vicinity of pH 5 or pH 8, over periods of at least 15 hours.

2. Constant urinary pH in the vicinity of pH 5.0 can be attained by administering several grams of ammonium chloride each hour until the desired pH has been attained, and then increasing or decreasing the maintenance dose as indicated by hourly monitoring of urine pH. Constant urinary pH in the vicinity of pH 8.0 can be attained by employing sodium bicarbonate in a similar fashion.

3. Modification of urine pH in human subjects has a profound effect on the rate of elimination of sulfaethidole from the body.

4. The harmonic mean $t_{1/2}$ for SETD is 11.4 hours when urine pH is maintained at pH 5.0; the harmonic mean $t^{1}/_{2}$ is only 4.2 hours when urine pH is maintained at pH 8.0.

Effects of Certain Compounds on Experimental Muscular Dystrophy

By NATHAN WATZMAN†, WILLIAM J. KINNARD, MARIO D. ACETO, and JOSEPH P. BUCKLEY

Several compounds which represent classifications of drugs known to have effects on muscular efficiency were administered to dystrophic animals in which atrophy was achieved utilizing a vitamin E-deficient diet. A myopathic mutation of the house mouse (dystrophia muscularis) was also utilized in certain portions of the study. Motor coordination, weight, muscle strength, and urinary creatine and creatinine were measured. The effects of some of the compounds on the isolated diaphragm muscle of normal and dystrophic mice were also studied. Norethandrolone, methimazole, and digoxin increased the ability of vitamin E-deficient rats to perform forced motor activity. The same compounds increased the offspring survival rate of vitamin E-deficient female rats. Potassium chloride (10 mg./Kg./day) temporarily increased the mean rotarod performance time and arrested loss of weight of dystrophic mice. Although there was no statistical difference between the life span of the control and drug-treated groups of strain-129 mice, the group receiving digoxin, 0.05 mg./Kg. subcutaneously, twice a week survived the longest.

MUSCULAR DYSTROPHY is a chronic disease manifested by a gradual weakening of the voluntary muscles. As the condition progresses, there occurs loss of function, mild contractions, and finally contractures in which the muscle is entirely inert and no longer capable of response to stimuli.

The etiology of muscular dystrophy has eluded investigators for many years, but it appears to be due to some defect in metabolism. The following metabolic alterations and abnormalities invariably appear in dystrophic muscle tissue: decreased concentration of creatine and increased concentration of creatinine in striated muscle (1); creatinuria (2); decreased concentration of extracellular potassium and magnesium (3); diminished glycogenolysis (4); increased collagen nitrogen (5); and decreased concentrations of the enzymes aldolase and phosphorylase (5).

In the light of these consistent findings, it seemed plausible to administer certain therapeutic agents which might metabolically or pharmacologically reverse the specific patterns elicited by the dystrophic conditions.

Methimazole (1-methyl-2-mercaptoimidazole),[1] one of the most active of the antithyroid agents (6), was selected as one of the test compounds. Increasing evidence exists that muscle weakness, tremors, and reduced muscle efficiency occur in hyperthyroidism. Du Toit (7) reported that the oxidative efficiency of phosphorylation is reduced in the presence of thyroxin, suggesting that muscle efficiency might be reduced in hyperthyroidism. Thomson and his associates (8) reported that hyperthyroidism was accompanied by tremors, atrophy, myasthenia, and muscle lesions. In their studies, denervation atrophy was accelerated by thyroxin and retarded by thiouracil, an antithyroid agent. In addition, Boldrini (9) using liver slices of hyperthyroid rats, showed that the creatine content of liver and muscle of hyperthyroid animals was less than that of normal animals. Creatine synthesis was also depressed and this was reversed by methylthiouracil, an antithyroid agent.

The wasting of muscle in muscular dystrophy suggested the use of norethandrolone (17 alpha-ethyl - 17 - hydroxy - 19 - nor - 4 - androsten - 3-one),[2] an androgenic hormone, which enhances protein anabolism by reversing negative nitrogen balance. Saunders and Drill (10), using the levator ani muscle of the rat reported that norethandrolone had marked myotrophic activity. The most familiar example of the anabolic effects of the androgens is the rapid growth and muscular development of the adolescent male. Methandrostenolone,[3] another androgenic steroid with anabolic properties, was also selected as a test compound.

Digoxin[4] is widely used in the treatment of congestive heart failure. It acts directly on the myocardium to increase muscle tone and contractile force, thereby increasing the mechanical efficiency of the failing heart (11). This compound is deposited in skeletal muscle as well as the myocardium and might possibly produce an effect in skeletal muscle similar to that produced in the failing heart.

The finding of increased collagen nitrogen (12)

in the dystrophic muscle suggests an increase in fibrous tissue resulting from an inflammatory condition. This fact, coupled with evidence of diminished glycogenolysis (4) led to the consideration of an anti-inflammatory corticosteroid as one of the experimental compounds. Methylprednisolone acetate,[5] the 6-methyl derivative of prednisolone (delta-1-hydrocortisone), was selected because it has been reported to be more potent than prednisolone and less prone to produce early side effects (13).

Evidence of electrolytic disturbances in atrophic muscle such as decreased concentrations of extracellular potassium and magnesium ions (14) and increased sodium and calcium ions (14) led to the selection of the electrolytic compound, potassium chloride, as another test substance. Dystrophic muscles have been reported to have a slightly lower potassium content than normal muscle (15). Overholt and his associates (16) have reported the prevention of periodic paralysis associated with hyperthyroidism by the use of a high potassium diet.

Finally, three other pharmacologically active agents were utilized on modified *in vitro* diaphragm preparations. Ephedrine was employed because of evidence that this substance reversed the effects of fatigue, a condition not unlike that of muscular dystrophy. Burns (17) demonstrated in dogs that ephedrine causes a marked and prolonged rise in tension of skeletal muscle fatigued by repeated stimulation of the sciatic nerve. The second compound selected for *in vitro* study was ouabain (g-strophanthin), a cardiac glycoside having a very quick onset of action. Cattell (18) has shown that this compound produces an increase in force of striated muscle contraction. Caffeine is known to increase the amplitude of muscle contractions (19). Contractions of isolated nerve-muscle preparations are enhanced and muscle made less susceptible to fatigue if low concentrations of xanthines are present in the bath solution (20); therefore, theophylline (21) was selected as the third compound.

Several experimental methods for the development of dystrophic symptoms in laboratory animals are available to investigators in this field. Muscular weakness and wasting similar to human muscular dystrophy have been accomplished by vitamin E-deficient (22) or choline-deficient (23) diets in many species of animals. Also, through the efforts of the staff at Jackson Memorial Laboratories, Bar Harbor, Maine, a myopathic mutation appeared among a colony of inbred strain-129 mice (dystrophia muscularis) in 1951. The clinical manifestations of the disease in this species are first recognizable at $3^1/_2$ weeks when ataxia and paresis of the hind limbs are observed.

The objectives of this study were: (*a*) to determine if the test compounds delay or arrest, to any degree, the onset of experimental muscular dystrophy and (*b*) to determine if the test compounds affect the contraction of normal and fatigued muscle.

EXPERIMENTAL

Development of Experimental Muscular Dystrophy.—Muscular weakness and ataxia were observed in albino Wistar rats after 5 months feeding on the vitamin E-deficient diet utilized successfully by Olcott (22).

Dose Regimen.—Thirty albino Wistar rats, weighing approximately 100 Gm., were divided into five groups of six animals each (two males and four females). Group 1 received a normal rat diet (Purina Rat Chow); group 2 received a vitamin E-deficient diet; group 3 received the vitamin E-deficient diet and norethandrolone, 2 mg./Kg. orally; group 4 received the vitamin E-deficient diet and digoxin, 0.2 mg./Kg. initially and then 0.1 mg./Kg. daily by oral route; group 5 received the vitamin E-deficient diet and methimazole, 4 mg./Kg. orally. Drugs were administered daily, 6 days a week.

One hundred and sixty-four pairs of dystrophic mice (dystrophia muscularis, Jackson Memorial Laboratories, Bar Harbor, Maine) and their littermate controls were divided into 14 groups of not less than nine pairs each. Twenty pairs comprised the control group. Group 1 (controls) received no drugs; group 2 received norethandrolone, 2 mg./Kg. orally; group 3 received norethandrolone, 10 mg./Kg. orally; group 4 received methimazole, 4 mg./Kg. orally; group 5 received methimazole, 20 mg./Kg. orally; group 6 received digoxin, 0.2 mg./Kg. for 1 week and then 0.05 mg./Kg. daily by the subcutaneous route; group 7 received digoxin, 0.2 mg./Kg. initially for one dose and then 0.1 mg./Kg. daily by the subcutaneous route; group 8 received digoxin, 0.2 mg./Kg. daily by the subcutaneous route; group 9 received potassium chloride, 10 mg./Kg. orally; group 10 received potassium chloride, 50 mg./Kg. orally; group 11 received potassium chloride, 100 mg./Kg. orally; group 12 received methylprednisolone acetate, 10 mg./Kg. intramuscularly; group 13 received methylprednisolone acetate, 100 mg./Kg. intramuscularly; and group 14 received methandostrenolone, 10 mg./Kg. orally. Drugs were administered daily, 7 days per week except methylprednisolone acetate which was given twice weekly. The animals were weighed every fourth day and careful records maintained on their life spans.

Measurement of Motor Coordination.—Rats were placed on an electrically driven rotarod (24), $1^1/_4$ inches in diameter, which was set to turn at 18 r.p.m. The animals were forced to walk the turning rod without side excursions until they fell off. The rats were trained for a period of 1 week and then the relative forced motor activity and muscle coordination were determined by the length of time

[5] Marketed as Depo-Medrol by The Upjohn Co.

the animals could maintain their position on the rod, allowing a maximum of 2 minutes per animal. Coordination in strain-129 mice (dystrophia muscularis) was measured in the same manner as the rats, using a rod of smaller diameter (1 inch), set to rotate 11 r.p.m.

Measurement of Muscle Strength.—This factor was measured in rat offspring and dystrophic mice by placing them on a vertical screen (90 degrees) and recording the length of time they could remain on it. The maximum experimental time was established at 60 seconds and the average of each group recorded in seconds.

Measurement of Urinary Creatine-Creatinine Ratio.—Twenty-four hour urine samples were obtained from rats placed in individual metabolism cages every 2 weeks. A urine analysis of creatine and creatinine was determined according to a modification of Folin's method (25).

Survival of Offspring of Pretreated Vitamin E-Deficient Female Rats.—Female rats of all groups were mated with normal males 90 days following the initiation of the vitamin E-deficient diet. On the first day of mating, a single oral dose of 0.5 Gm. of wheat germ oil (not less than 2 i.u. vitamin E per Gm.) was administered to each female to assure proper reproductive ability. Size of litters and survival rates as well as motor coordination and muscle force of the offspring were recorded.

In Vitro Studies.—The effect of the test compounds on the amplitude of contractions of the diaphragm muscle of normal and dystrophic mice (dystrophia muscularis) was studied utilizing a modified method of Bülbring (26). The test compounds were added to the muscle bath to produce the following concentrations: potassium chloride (1:1500); ephedrine sulfate (1:1000); ouabain (1:35,000,000); theophylline ethylenediamine (1:50,000). A similar study was done, utilizing the fatigued diaphragm of normal and dystrophic mice. A submaximal threshold was established for each preparation and then the muscle was fatigued by stimulating every 10 seconds until a 50% decrease in amplitude of contraction was achieved. The test compounds were then administered directly into the bath and effects on the amplitude of contractions and recovery recorded.

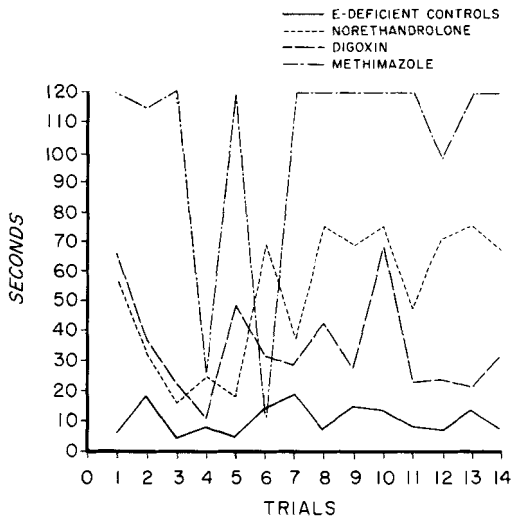

Fig. 1.—Effects of norethandrolone, digoxin, and methimazole on he rotarod performance times of vitamin E-deficient male rats. Doses: norethandrolone, 2 mg./Kg., daily; digoxin, 0.1 mg./Kg., daily; and methimazole, 4 mg./Kg., daily.

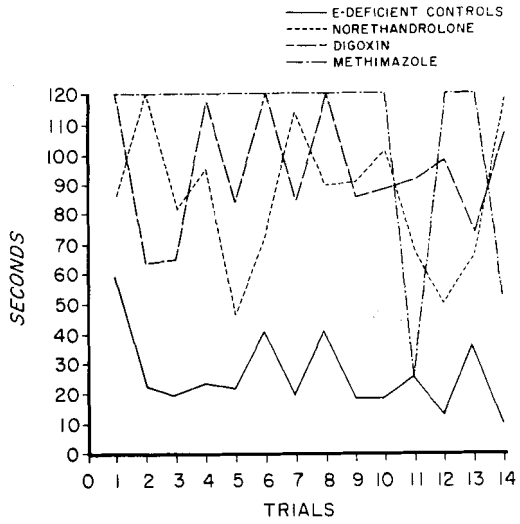

Fig. 2.—Effects of norethandrolone, digoxin, and methimazole on the rotarod performance times of vitamin E-deficient female rats. Doses: norethandrolone, 2 mg./Kg., daily; digoxin, 0.1 mg./Kg., daily; and methimazole, 4 mg./Kg., daily.

RESULTS AND DISCUSSION

The initial pilot study of this investigation in experimental muscular dystrophy utilized albino rats of both sexes. After 5 months on a vitamin E-deficient diet it was quite apparent that there was a significant difference in the abilities of the treated groups to perform on the rotarod apparatus (Figs. 1 and 2). Methimazole-treated rats demonstrated the greatest ability to perform forced motor activity. The data further indicated that the methimazole, digoxin, and norethandrolone-treated rats demonstrated greater ability to perform forced motor activity than the untreated vitamin E-deficient rats. This was true of both sexes (Figs. 1 and 2), and it appears that the compounds in some way alleviated the paralysis-producing phenomenon of a vitamin E-deficient diet.

The consistently lower weights of the methimazole-treated animals from the fifth week on (Fig. 3) are unexplainable in view of the fact that since methimazole is an antithyroid compound, it would be expected that animals treated with this compound might be heavier than the nontreated rats.

The data on the urinary creatine-creatinine ratios were inconclusive. There appeared to be no correlation between loss of motor ability and creatine-creatinine values. The vitamin E-deficient control ratios were moderately higher than the other groups but were generally within the normal 0.1–1.0 range.

The moderate success of the experimental compounds in the pilot study on vitamin E-deficient rats gave impetus to the investigation of the offspring of vitamin E-deficient females. As observed by Olcott (12), offspring of vitamin E-

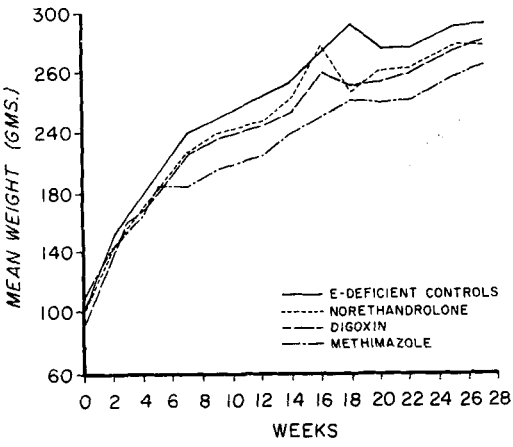

Fig. 3.—Effects of norethandrolone, digoxin, and methimazole on the weights of vitamin E-deficient female rats. Doses: norethandrolone, 2 mg./Kg., daily; digoxin, 0.1 mg./Kg., daily; and methimazole, 4 mg./Kg., daily.

deficient female rats developed a temporary muscular weakness on about the twentieth day of life. The phenomenon of muscular involvement in vitamin E-deficient animals is not understood. It would appear that the characteristic symptoms are genetically transferred to offspring. However, the temporary nature of these abnormalities at a specific age is not consistent with the fixed, permanent nature of genetics. This investigation corroborated Olcott's results and, in addition, elaborated two significant findings. A total of 74 offspring were produced by all groups (Table I). The normal control group

Offspring litter	9.0	5.0	5.0	4.0	3.0
Survival, %	70.3	0.0	26.6	25.0	50.0

[a] Group 1, normal control; group 2, E-deficient control; group 3, norethandrolone; group 4, digoxin; and group 5, methimazole.

had a mean of nine offspring per litter whereas the other groups ranged between three and five animals per litter. Nineteen offspring from normal control females survived, three from methimazole-treated females, four from norethandrolone-treated females, and three from digoxin-treated females. Per cent survival was fairly good for all groups with the exception of the vitamin E-deficient control group of which all offspring died within 18 days. The normal control group had a significantly higher per cent survival, 70.3%. The evidence thus indicated that all of the test compounds administered to the females increased the ability of the offspring of vitamin E-deficient rats to survive. However, in the light of the role of vitamin E as an antioxidant, the mechanisms by which the test compounds were able to increase offspring survival rate could not be resolved.

The second notable finding was that the offspring of norethandrolone-treated females were able to perform forced motor activity consistently better than the offspring of normal females (Fig. 4) and they experienced only slight difficulty in remaining on the vertical screen. In general, there appeared to be no correlation between motor coordination (as measured on the rotarod) and muscle strength (as measured by the vertical screen). This was evidenced by the poor performance of the digoxin offspring on the rotarod (Fig. 4), and their excellent agility on the vertical screen. Although norethandrolone produced highly beneficial effects in the vitamin E-deficient dystrophic rats, the effects of this compound in human muscular dystrophy has been discouraging. Dowben and Perlstein (27) have reported that the administration of 0.5 mg./Kg. of norethandrolone daily failed to produce an improvement in muscle function and strength.

The effects of the experimental compounds on the life span, motor coordination, and muscle strength of the strain-129 dystrophic mouse were observed. Rotarod performance graphs, life-span charts, cage score and weight graphs were carefully scrutinized to determine if any of the test compounds were successful in simultaneously (*a*) prolonging the life-span, (*b*) increasing motor performance times, (*c*) increasing the vertical cage scores, (*d*) increasing weight or at least arresting loss of weight. The data indicate that potassium chloride in the dose 10 mg./Kg. (group 9) was able to produce these responses temporarily (Figs. 5 and 6). From the 16th–64th day of therapy, mean rotarod performance times consistently ranged from 10.0–39.6 seconds. Thereafter the scores steadily decreased to zero. In comparison, the control dystrophics (group 1) never achieved a mean score higher than 5.4 seconds. Secondly, the mean weights of the potassium chloride-treated (10 mg./Kg.) animals ranged consistently between 13–17 Gm. with no apparent pattern of steady weight loss through the 120th day of drug administration. The mean cage

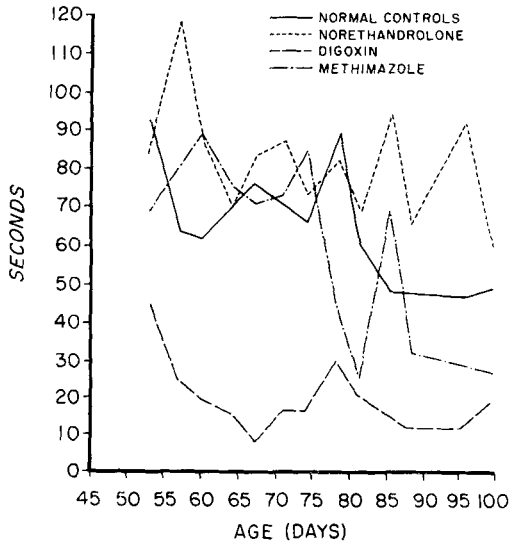

Fig. 4.—Effects of norethandrolone, digoxin, and methimazole on the rotarod performance times of the offspring of vitamin E-deficient female rats.

scores ranged steadily from 25.0–53.0 seconds through the 104th day of therapy whereas the control scores ranged from 7.0–28.0 seconds. Furthermore, the mean life-span of the potassium chloride-treated group was prolonged 16 days over that of the controls (Table II). However, statistical analysis showed this to be an insignificant response. The temporary beneficial results of potassium chloride in this study were understandable in the light of potassium evoked muscular improvements noted in the literature and previously discussed in the statement of the problem. Although norethandrolone has been reported to increase the survival time of strain-129 dystrophic mice (28), daily administration of this compound failed to increase the life-span of this strain of mice in this present study.

Although there was no statistical difference between the life spans of the untreated and drug-treated groups of strain-129 dystrophic mice, the group receiving digoxin 0.05 mg./Kg. subcutaneously twice a week (group 6) survived the longest. There appeared to be no correlation between mean rotarod performance times, mean cage scores, and life spans.

The results of the *in vitro* studies indicated that ouabain (1:35,000,000) and potassium chloride (1:1500) increased the amplitude of the contractions of the diaphragm muscle obtained from normal mice, 20.4 and 11.5%, respectively. None of the test compounds was able to evoke a change in the amplitude of diaphragm contractions of the dystrophic mouse. However, when the diaphragm muscle was partially fatigued, potassium chloride (1:1500) and ephedrine sulfate (1:1000) produced significant mean per cent recoveries, 33.5 and 20.3, respectively. Potassium chloride also produced a mean per cent recovery of 20.0 in the fatigued diaphragm of the normal mouse. The

[a] 0.2 mg./Kg. initially (subcutaneously). [b] Administered twice weekly.

moderate success of potassium chloride in both *in vitro* and *in vivo* experiments on this special strain of mouse indicates that further investigation into the role of potassium as well as other ions should be carried out.

CONCLUSIONS

1. Methimazole-, digoxin-, and norethandrolone-treated rats of both sexes fed on a vitamin E-deficient diet demonstrated greater ability to perform forced motor activity than the untreated control groups.

2. Norethandrolone, digoxin, and methimazole increased the offspring survival rate of vitamin E-deficient female rats.

3. There appeared to be no correlation between motor coordination and muscle strength in the offspring of vitamin E-deficient female rats.

4. Oral dose of potassium chloride, 10 mg./Kg., appears to temporarily improve motor coordination in the strain-129 dystrophic mouse (dystrophia muscularis).

5. There appears to be no correlation between weights, motor coordination, and muscle strength in the strain-129 dystrophic mouse (dystrophia muscularis).

6. There was no statistical difference between the life spans of the control group and the drug-treated groups of strain-129 dystrophic mice (dystrophia muscularis).

7. Potassium chloride (1:1500) and ephedrine sulfate (1:1000) increased the amplitude of contractions in the partially fatigued diaphragm muscle of the strain-129 dystrophic mouse (dystrophia muscularis).

8. None of the test compounds appears to significantly delay or arrest the onset of experimental muscular dystrophy.

Gas Chromatography of Alkaloids, Alkaloidal Salts, and Derivatives

E. BROCHMANN-HANSSEN and A. BAERHEIM SVENDSEN

A number of alkaloids and alkaloidal derivatives have been gas chromatographed on columns of silicone rubber SE-30. The method has also been applied to alkaloidal extracts of crude drugs. Phenolic alkaloids are readily gas chromatographed as the trimethylsilyl ethers. Alkaloidal salts have been gas chromatographed directly. The salt dissociates in the flash heater and the alkaloid is eluted as the base. Under certain conditions, many alkaloids decompose when subjected to gas chromatography. These decompositions often appear to be catalyzed by the glass wool used on top of the column packing.

In 1958 Quin used gas-liquid chromatography to study the alkaloidal composition of tobacco smoke (1–3). Two years later, Lloyd, *et al.*, demonstrated that a large number of high molecular weight alkaloids could be successfully gas chromatographed (4). This furnished a new and useful tool for research in an area in which pharmaceutical chemists have been interested since the days of Sertürner, more than 150 years ago.

This paper reports the gas chromatography of several alkaloids and alkaloidal derivatives, many of which have not been analyzed previously by this method. The gas chromatographic technique has also been applied to ex-

moderate success of potassium chloride in both *in vitro* and *in vivo* experiments on this special strain of mouse indicates that further investigation into the role of potassium as well as other ions should be carried out.

CONCLUSIONS

1. Methimazole-, digoxin-, and norethandrolone-treated rats of both sexes fed on a vitamin E-deficient diet demonstrated greater ability to perform forced motor activity than the untreated control groups.

2. Norethandrolone, digoxin, and methimazole increased the offspring survival rate of vitamin E-deficient female rats.

3. There appeared to be no correlation between motor coordination and muscle strength in the offspring of vitamin E-deficient female rats.

4. Oral dose of potassium chloride, 10 mg./Kg., appears to temporarily improve motor coordination in the strain-129 dystrophic mouse (dystrophia muscularis).

5. There appears to be no correlation between weights, motor coordination, and muscle strength in the strain-129 dystrophic mouse (dystrophia muscularis).

6. There was no statistical difference between the life spans of the control group and the drug-treated groups of strain-129 dystrophic mice (dystrophia muscularis).

7. Potassium chloride (1:1500) and ephedrine sulfate (1:1000) increased the amplitude of contractions in the partially fatigued diaphragm muscle of the strain-129 dystrophic mouse (dystrophia muscularis).

8. None of the test compounds appears to significantly delay or arrest the onset of experimental muscular dystrophy.

tracts of alkaloidal crude drugs and to direct gas chromatography of alkaloidal salts without prior isolation of the base.

EXPERIMENTAL

A Barber-Colman model 15 gas chromatograph equipped with an argon β-ionization detector was used for the experimental work. The columns were glass U-tubes 4 to 8 feet in length and having an inner diameter of 3 mm. The solid support was Gas-Chrom P, 100–140 mesh, washed with concentrated hydrochloric acid and methanolic potassium hydroxide and treated with hexamethyldisilazane (5). The siliconized material was immediately coated with 0.1% polyethylene glycol 9000 and, after drying, with about 1% silicone rubber SE-30. Both stationary phases were applied by means of solutions in toluene as described by Horning, *et al.* (6). The treatment with polyethylene glycol was found to reduce the adsorptive effects of the support material to an appreciable extent (5). The alkaloids were introduced with a Hamilton microliter syringe as 1.0 μl. of a 0.5 to 1.0% solution in tetrahydrofuran, acetone, or chloroform. Addition of methanol was sometimes used to dissolve alkaloidal salts.

Most extracts of crude drugs were prepared by conventional methods and purified by immiscible solvent extraction. Opium, however, was extracted by treatment with a cationic exchange resin (7).

RESULTS AND DISCUSSION

The retention times of alkaloidal bases, salts, and derivatives are listed in Table I.

Alkaloidal Salts.—The alkaloids could be gas chromatographed directly as salts without prior liberation of the base. This was especially true if the acid component was an organic acid or a hydrogen halide. However, even sulfates, phosphates, and nitrates could be gas chromatographed directly. The salts dissociated in the flash heater, which was maintained at about 325°, and the alkaloids were eluted as the free bases. Therefore, no difference

Column, 6 ft. long, 3 mm. I.D.; packing, 1.15% silicone rubber SE-30 on Gas-Chrom P, 100–140 mesh. [a] Inlet pressure, 20 lbs. p.s.i., flow rate, 25 ml./min. [b] 22 lbs., 25 ml./min. [c] 24 lbs., 25 ml./min. [d] Major peak; decomposition resulted in additional minor peaks.

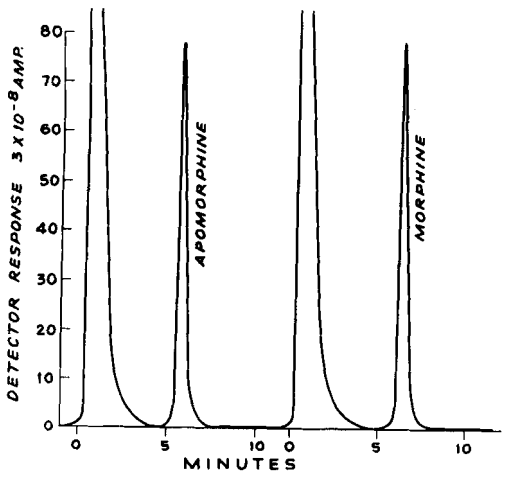

Fig. 1.—Gas chromatograms of apomorphine and morphine as the trimethylsilyl ethers. Column, 4 feet long and 3 mm. I.D.; packing, 1.2% silicone rubber SE-30 on Gas-Chrom P, 100–140 mesh; temp., 200°; inlet pressure, 20 lbs. p.s.i.

in retention time could be observed whether the alkaloid was applied as the salt or the base, Table I. Atropine sulfate produced two peaks, one of which appeared to be apoatropine resulting from dehydration in the flash heater. Although no difficulties were encountered during this work, the liberated mineral acids may in the long run have an adverse effect on the column and/or the detector.

Phenolic Alkaloids.—Phenolic alkaloids are often difficult to gas chromatograph because of adsorptive effects. Morphine generally gave only about one-half the peak height which one would expect on the basis of the amount applied. Apomorphine with two phenolic hydroxyl groups also produced a badly tailing peak. Such peaks are unsuitable for quantitative work. This difficulty was overcome by converting the phenols to the trimethylsilyl ethers (8). To a solution of 50 mg. of alkaloid in 3 ml. of tetrahydrofuran was added 2 ml. of hexamethyldisilazane. The mixture was allowed to stand in a well-closed container for about 24 hours and then gas chromatographed directly without isolation of the reaction product. Gas chromatograms of the trimethylsilyl ethers of morphine and apomorphine are illustrated in Fig. 1.

Extracts of Crude Drugs.—Figures 2 to 5 represent gas chromatograms of alkaloids extracted from several crude drugs. Where the alkaloidal mixture spans a wide range of vapor pressures, temperature programing is often useful to speed up the elution and obtain the high boiling components as relatively sharp peaks, Fig. 5. The gas chromatographic method may be used for identification of crude drugs, alkaloidal extracts and tinctures, and to differentiate between varieties of crude drugs having somewhat different alkaloidal composition. It also lends itself to a study of the various factors which may be expected to influence alkaloid production in plants.

Decompositions.—Some alkaloids could not be gas chromatographed without decomposition. Physostigmine, for example, gave two to four peaks, depending on the temperature of the flash heater. All attempts to produce a single-peak gas chromatogram of physostigmine were in vain. Hydrastinine and cotarnine also gave complex chromatograms containing several peaks. Atropine and scopolamine, which normally produced sharp, single-peak chromatograms, would under certain

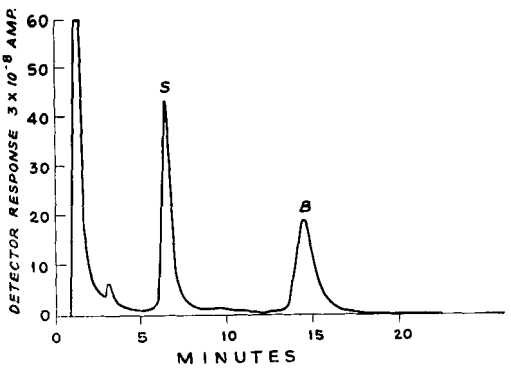

Fig. 4.—Gas chromatogram of an extract of nux vomica on silicone rubber SE-30, 1.15%. S, strychnine; B, brucine. Column, 8 feet long and 3 mm. I.D.; temp. 245°.

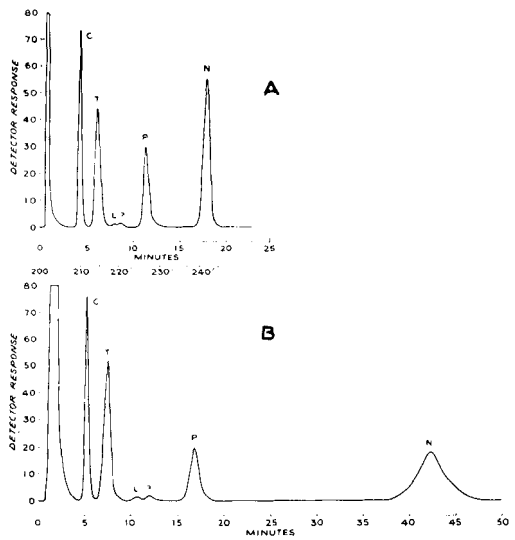

Fig. 5.—Gas chromatograms of the non-phenolic alkaloids of opium on silicone rubber SE-30, 1.15%. A, temperature programing; B, isothermal at 213°. C, codeine; T, thebaine; L, laudanosine; P, papaverine; N, noscapine. Column, 8 feet long and 3 mm. I.D.

operating conditions give two or even three peaks each. One of these appeared to represent the dehydrated alkaloid because the retention value of one of the peaks from atropine was identical with that given by apoatropine prepared according to Hesse (9). The degree of dehydration was found to be associated with the amount of glass wool placed on top of the column packing, and with the temperature of the flash heater. When a fairly large amount of glass wool was used, the degree of decomposition decreased as the flash heater temperature was reduced, but could never be entirely eliminated. When the amount of glass wool was reduced to a very small amount or removed completely, no decomposition took place even at flash heater temperatures of 350°. Similar dehydration of certain steroids has been described as a function of the flash heater temperature by Horning, *et al.* (10).

Hydrolysis and transesterification reactions were also sometimes noticed. Diacetylmorphine was eluted as a sharp peak when chromatographed alone. In mixtures with codeine, morphine or other alcoholic or phenolic substances, reactions taking place in the flash heater gave rise to several new esters not present in the original solution. Both 3, O-monoacetylmorphine (11) and 6, O-monoacetylmorphine[1] gave single peak chromatograms in the absence of glass wool. An apparent catalytic effect of glass wool resulted in peaks corresponding to morphine, monoacetyl- and diacetylmorphine.

Antiradiation Compounds III

N-2-Mercaptoethylpiperazines

By WILLIAM O. FOYE and DOUGLAS H. KAY

For the purpose of obtaining 2-mercaptoethylamine derivatives having an additional basic function located two carbons distant from the nitrogen, several N-2-mercaptoethylpiperazines have been synthesized. Procedures were employed that involved conversion of the 2-hydroxyethylpiperazines to the corresponding bromo compounds with subsequent thiolation, as well as those employing ethylene sulfide. Both 1-(2′-mercaptoethyl)piperazine and 1,4-bis(2′-mercaptoethyl)piperazine were found to give some protection to mice exposed to 575 roentgens of X-irradiation.

MERCAPTANS have been recognized as effective protective agents against the lethal effects of ionizing radiation, but all of the significantly successful compounds of this variety have so far had a basic function located two or three carbons distant from the sulfhydryl group. The most outstanding examples of the mercaptoamines are 2-mercaptoethylamine (1) and 2-mercaptoethylguanidine (2). Some question remains regarding the basicity of 2-acylthioethylamines, however, which were found to have appreciable antiradiation effects in mice (3), since the acyl groups shift to the nitrogen in neutral or alkaline media (3, 4). Otherwise, a fairly strongly basic group has been required in mercaptans for antiradiation properties, so it appeared desirable to prepare mercaptoamines having an additional basic group located two carbons from the parent amine.

Antiradiation Compounds III

N-2-Mercaptoethylpiperazines

By WILLIAM O. FOYE and DOUGLAS H. KAY

For the purpose of obtaining 2-mercaptoethylamine derivatives having an additional basic function located two carbons distant from the nitrogen, several N-2-mercaptoethylpiperazines have been synthesized. Procedures were employed that involved conversion of the 2-hydroxyethylpiperazines to the corresponding bromo compounds with subsequent thiolation, as well as those employing ethylene sulfide. Both 1-(2′-mercaptoethyl)piperazine and 1,4-bis(2′-mercaptoethyl)piperazine were found to give some protection to mice exposed to 575 roentgens of X-irradiation.

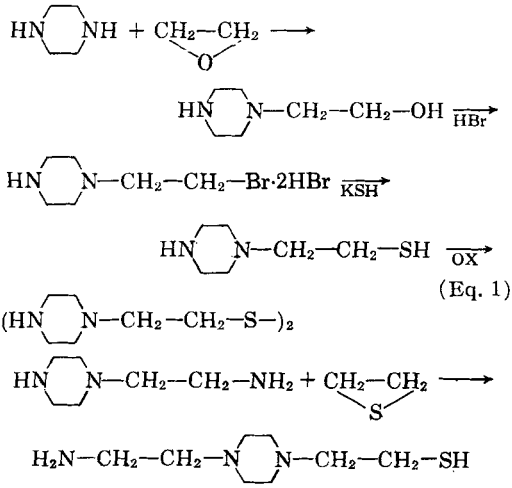
MERCAPTANS have been recognized as effective protective agents against the lethal effects of ionizing radiation, but all of the significantly successful compounds of this variety have so far had a basic function located two or three carbons distant from the sulfhydryl group. The most outstanding examples of the mercaptoamines are 2-mercaptoethylamine (1) and 2-mercaptoethylguanidine (2). Some question remains regarding the basicity of 2-acylthioethylamines, however, which were found to have appreciable antiradiation effects in mice (3), since the acyl groups shift to the nitrogen in neutral or alkaline media (3, 4). Otherwise, a fairly strongly basic group has been required in mercaptans for antiradiation properties, so it appeared desirable to prepare mercaptoamines having an additional basic group located two carbons from the parent amine.

Received March 27, 1962, from the Department of Chemistry, Massachusetts College of Pharmacy, Boston.
Accepted for publication May 31, 1962.
This project was carried out under a contract (DA-49-193-MD-2029) with the Office of the Surgeon General, U. S. Army Medical Research and Development Command.
The authors express their gratitude for this support as well as for the testing data supplied by Dr. D. P. Jacobus.
Presented to the Scientific Section, A.Ph.A., Las Vegas meeting, March 1962.

Previous experience with a series of dithiocarbamates having additional basic groups showed the two carbon distance to be of importance (5). 2-Diethylaminoethyldithiocarbamic acid had radiation-protective ability, while 3-dimethylaminopropyldithiocarbamic acid had none.

For the purpose of providing an additional basic function to the mercaptoamine type of molecule, N-2-mercaptoethylpiperazines have been prepared. In this connection, however, it should be mentioned that N,N-diethylaminoethyl mercaptan is less effective as a radiation-protective agent than 2-mercaptoethylamine (2, 6).

DISCUSSION



1-(2′-Mercaptoethyl)piperazine was prepared in a conventional manner from the corresponding alcohol. This compound was obtained from the reaction of anhydrous piperazine and ethylene oxide according to McElvain and Bannister (7). This procedure also gave small quantities of the 1,4-bis-alcohol. The latter compound was prepared in quantity, however, by the procedure of Pollard, *et al.* (8). The 1-(2′-hydroxyethyl)piperazine obtained was converted to the corresponding bromo compound by means of 48% hydrobromic acid, a much longer period of refluxing being required than that recommended by McElvain (7), however. Treatment of the 1-(2′-bromoethyl)piperazine dihydrobromide under pressure with a solution of potassium hydroxide saturated with hydrogen sulfide readily yielded the desired mercaptan. This compound was purified under nitrogen and isolated as the dihydrobromide. This reaction sequence is shown in Eq. 1.

The 1,4-bis(2′-hydroxyethyl)piperazine was converted to the bis-mercaptan by the same reaction scheme. The corresponding dibromo compound had been previously reported by McElvain (7), but he listed a bromide analysis that varied from theoretical by several per cent and a melting range of 240–360°. Our product was found analytically acceptable after extraction with hot alcohol. The dibromo compound was converted to the desired bis-mercaptan by treatment under pressure with potassium hydroxide saturated with hydrogen sulfide. It was again necessary to convert the product to the dihydrobromide before isolation was successful.[1]

Ethylene sulfide was employed in an attempt to prepare mercaptoethylpiperazines more conveniently and in better yield. Reaction with anhydrous piperazine in 95% ethanol, however, led only to ethylene sulfide polymer. Reaction in chloroform gave an impure oil that reacted with carbon disulfide to give a solid melting at 55–60°. A satisfactory carbon-hydrogen analysis for the suspected 1-(2′-mercaptoethyl)piperazine-4-carbodithioic acid was not obtained.

Treatment of 1-ethylpiperazine with ethylene sulfide yielded a characterizable product, however. Analysis indicated that the monomercaptoethyl derivative was formed. A lower melting product, from which practically identical analytical values were obtained, was also isolated; this was assumed to be the corresponding disulfide. The low yields obtained may be explained by formation of ethylene sulfide polymer as generally found by Reynolds, *et al.* (10), from reactions with ethylene sulfide.

Reaction of 1-(2′-aminoethyl)piperazine with ethylene sulfide in chloroform also produced a mercaptoethyl derivative for which the analytical results were satisfactory. Infrared absorption showed the presence of a primary amine at 1620 cm.$^{-1}$ so the mercaptoethylation apparently took place on the piperazine nitrogen to give 1-(2′-aminoethyl) - 4 - (2′ - mercaptoethyl)piperazine (see Eq. 2). This was isolated as the trihydrochloride.

(Eq. 1)

(Eq. 2)

Some question remained regarding the structure of the 1-(2′-mercaptoethyl)piperazine. Since this reduced iodine rather slowly, it was suspected that the compound might possibly be the disulfide. However, oxidation of the dihydrochloride of this compound with hydrogen peroxide gave a product of different melting point and with approximately the same analytical values. The latter compound did not reduce iodine and accordingly should be the disulfide.

Biological Activities.—Tests for the ability of three of these compounds to protect mice against X-irradiation have been carried out at the Walter Reed Army Institute of Research under the direction of Dr. D. P. Jacobus. 1,4-Bis(2′-mercaptoethyl) piperazine afforded significant protection to mice when administered 30 minutes prior to exposure to 575 Roentgens. An increase of 65% in 30-day survival over that of the control animals was observed. 1-(2′-Mercaptoethyl)piperazine, however, provided only a 30% increase in 30-day survival. This much lower protective ability may be related to the relative slowness of the compound to reduce iodine and undergo mixed disulfide formation with glutathione (11) in accordance with the mixed disulfide hypothesis of radioprotective action (12). 1 - (2′ - Aminoethyl) - 4 - (2′ - mercaptoethyl)-piperazine, however, provided no protection at the same drug level. None of these compounds provided any protection for mice given a dosage of 800 *r*. A summary of the testing data is given in Table I.

[1] The free base, 1,4-bis-(2′-mercaptoethyl)piperazine, was recently reported by Reynolds, *et al.* (9), from the reaction between piperazine and ethyl 2-mercaptoethylcarbonate.

TABLE I.—ANTIRADIATION PROPERTIES OF N-(2-MERCAPTOETHYL)PIPERAZINES

Compound[a]	Drug Level, mg./Kg.	Adm. Time	Dose, r	30-Day Survival, % Treated	30-Day Survival, % Controls
1-(2′-Mercaptoethyl)piperazine	50	15 min. prior	575	60	30
1,4-Bis-(2′-mercaptoethyl)piperazine	60	30 min. prior	575	95	30

[a] Aqueous solutions of the dihydrobromides were brought to a pH of 7.2 before injection in mice.

EXPERIMENTAL

1-(2′-Hydroxyethyl)piperazine.—Using the procedure of McElvain and Bannister (7), we obtained a 52% yield of product, b.p. 110°(2 mm.). An 8% yield of 1,4-bis(2′-hydroxyethyl)piperazine was also recovered; m.p. 135–136°, which agrees with the reported value (7).

1,4-Bis-(2′-hydroxyethyl)piperazine.—The procedure of Pollard, *et al.* (8), was used, giving an 89% yield of product which melted at 135–136°.

1-(2′-Bromoethyl)piperazine Dihydrobromide.—Twenty grams (0.154 mole) of 1-(2′-hydroxyethyl)-piperazine was cooled in an ice bath and 75 ml. of 48% hydrobromic acid was added slowly, with shaking. The resulting solution was distilled slowly for 30 minutes and the reaction mixture was then refluxed for 8 days.

After a 24-hour reflux period, the presence of 1-(2′-hydroxyethyl)piperazine dihydrobromide was detected by removing a portion of the solution and rubbing it in acetone. A white crystalline solid was obtained which melted at 208–210°. A Volhard bromide determination gave the following result.

Anal.—Calcd. for $C_6H_{16}Br_2N_2O$: Br, 54.79. Found: Br, 54.36.

After 8 days of refluxing, the reaction mixture was evaporated to dryness *in vacuo*. The residue was triturated in acetone to yield approximately 38 Gm. (70%) of product which decomposed at 242–243°, the reported value (13), after recrystallization from 95% ethanol.

1-(2′-Mercaptoethyl)piperazine Dihydrobromide.—A solution containing 2.8 Gm. of 85% potassium hydroxide, 1.5 ml. of distilled water, and 20 ml. of absolute ethanol was saturated with hydrogen sulfide. It was added to 5.0 Gm. (0.014 mole) of 1-(2′-bromoethyl)piperazine dihydrobromide in a 250-ml. pressure bottle which was capped immediately and heated in a water bath for 3 hours with occasional shaking.

After being cooled, the flask contents were evaporated to dryness *in vacuo*. The residue was extracted with 100 ml. of hot absolute ethanol, filtered to remove potassium bromide, and the filtrate was concentrated to about 70 ml. About 35 ml. of ethyl acetate was added to the cooled solution and dry hydrogen bromide was introduced. The solution was stirred and the walls of the flask scratched, and a white, crystalline solid was obtained. After extraction with 95% ethanol, 2.5 Gm. of 1-(2′-hydroxyethyl)piperazine dihydrobromide, m.p. 208–210°, remained. Chilling the ethanolic extract gave 1.3 Gm. (31.6%) of 1-(2′-mercaptoethyl)-piperazine dihydrobromide which decomposed at 220°, with previous softening at 175°.

Anal.—Calcd. for $C_6H_{16}Br_2N_2S$: C, 23.35; H, 5.23. Found: C, 23.50; H, 5.20.

1,4-Bis-(2′-bromoethyl)piperazine Dihydrobromide.—Twenty-five grams (0.144 mole) of 1,4-bis(2′-hydroxyethyl)piperazine was cooled in an ice bath and 100 ml. of 48% hydrobromic acid was added slowly, with shaking. The resulting solution was distilled slowly for 1 hour and was then refluxed for 3 days.

After 24 hours, the reaction mixture was concentrated at 70° (20–30 mm.) and refluxing was resumed. The presence of 1,4-bis(2′-hydroxyethyl)-piperazine dihydrobromide was demonstrated at this time by removing a portion of the solution and rubbing it in acetone. A white, crystalline solid was obtained which melted at 170–185°. A Volhard bromide determination gave the following result.

Anal.—Calcd. for $C_8H_{20}Br_2N_2O_2$: Br, 47.61. Found: Br, 47.20.

After 3 days, the reaction mixture was evaporated *in vacuo* to a syrup. This was triturated in acetone to yield a gummy material; more was obtained by adding ethyl acetate to the acetone extract. The gummy product was extracted with 400 ml. of hot 95% ethanol, and 41 Gm. (62%) of white, crystalline product was obtained which was insoluble in the hot alcohol. The solid decomposed at 230°, which agrees with the reported value (7) for 1,4-bis(2′-bromoethyl)piperazine dihydrobromide.

Anal.—Calcd. for $C_8H_{18}Br_4N_2$: C, 20.81; H, 3.92. Found: C, 21.07; H, 4.05.

1,4-Bis-(2′-mercaptoethyl)piperazine Dihydrobromide.—A solution containing 2.3 Gm. of 85% potassium hydroxide, 1.5 ml. of distilled water, and 15 ml. of absolute ethanol was saturated with hydrogen sulfide. It was added to 4.0 Gm. (0.008 mole) of 1,4-bis-(2′-bromoethyl)piperazine dihydrobromide in a 250-ml. pressure bottle which was capped immediately and heated in a water bath for 3 hours with occasional shaking.

After being cooled, the flask contents were evaporated almost to dryness *in vacuo*. The residue was extracted with 175 ml. of hot absolute ethanol, filtered, and the filtrate was concentrated to about 125 ml. About 30 ml. of ethyl acetate was added and anhydrous hydrogen bromide was introduced into the chilled solution. The solution was chilled and the vessel scratched, and a white, crystalline solid was obtained. The solid was washed with cold ethyl acetate and extracted five times with 200-ml. portions of hot 95% ethanol About 5.0 Gm. (52%) of 1,4-bis-(2′-mercaptoethyl)piperazine dihydrobromide was obtained which was insoluble in the hot alcohol. The compound decomposed at 260°.

Anal.—Calcd. for $C_8H_{20}Br_2N_2S_2$: C, 26.09; H, 5.47. Found: C, 26.24; H, 5.37.

1-Ethyl-4-(2′-mercaptoethyl)piperazine Dihydrochloride.—Ten grams (0.087 mole) of 1-ethylpiperazine (14) was cooled in an ice bath and treated with 5.26 Gm. (0.087 mole) of ethylene sulfide (15) slowly, with shaking, during 20 minutes. The ice bath was removed, and the mixture was allowed to stand overnight at room temperature under nitrogen. It was then refluxed gently for 2 hours and again allowed to stand overnight under

nitrogen. The mixture was evaporated at 60° (20–30 mm.) under nitrogen, and a semisolid was obtained after cooling. This was taken up in 30 ml. of absolute ethanol and cooled, and the solution was saturated with anhydrous hydrogen chloride. A white solid precipitated and after extraction with absolute ethanol, 0.5 Gm. remained which melted at 240–250°, with decomposition beginning at about 210°. The compound contained 11.52% sulfur. From the chilled extract was obtained 0.65 Gm. of solid which melted at 205–207°. This contained 11.55% sulfur. Neither product formed an addition compound with carbon disulfide, and both reduced iodine T.S.

Anal.—Calcd. for $C_8H_{20}Cl_2N_2S$: C, 38.86; H, 8.09; S, 12.95. Found: C, 38.57; H, 8.34; S, 11.52.

1-(2′-Aminoethyl)-4-(2′-mercaptoethyl)-piperazine Trihydrochloride.—A solution of 4.6 Gm. (0.036 mole) of 1-(2′-aminoethyl)piperazine in 30 ml. of chloroform was cooled in an ice bath and treated with ethylene sulfide (4.3 Gm., 0.072 mole) slowly, with shaking, during 30 minutes. The mixture was allowed to stand for 3 days at room temperature under nitrogen, and was then distilled under nitrogen at 40° (20–30 mm.). The residual oil was extracted with two 50-ml. portions of ether, and 125 ml. of absolute ethanol was added to the ether-insoluble material. The alcohol solution was chilled and saturated with anhydrous hydrogen chloride; a solid was obtained which was extracted with 100 ml. of hot acetone in two portions and quickly transferred to a desiccator. About 2.5 Gm. (24%) of ivory-colored product was obtained which melted at 165–170°.

Anal.—Calcd. for $C_8H_{22}Cl_3N_3S$: C, 32.15; H, 7.42; S, 10.71. Found: C, 32.52; H, 7.72; S, 10.94.

1-(2′-Mercaptoethyl)piperazine Dihydrochloride.—The same reaction sequence was used as in the preparation of the corresponding dihydrobromide. A very small yield of hygroscopic product was obtained which melted in the range of 145–150°.

Anal.—Calcd. for $C_6H_{16}Cl_2N_2S_2 \cdot H_2O$: C, 30.37; H, 7.65; N, 11.81. Found: C, 30.15; H, 7.51; N, 10.49.

1-Piperazinoethyl Disulfide Tetrahydrochloride.—The previous product, 1.0 Gm., was dissolved in 5 ml. of 50% aqueous ethanol containing 5 ml. of 3% hydrogen peroxide solution. The solution was heated on a water bath for 30 minutes and allowed to stand overnight. The solution was evaporated *in vacuo* to a gum, treated with absolute ethanol, and again concentrated *in vacuo*. This process was repeated. The semicrystalline material was removed from the flask and triturated in absolute ethanol; an extremely hygroscopic product was isolated which did not decolorize iodine T.S. without remaining in solution for some time. The product, 0.7 Gm., melted at 95–100°.

Anal.—Calcd. for $C_{12}H_{30}Cl_4N_4S_2 \cdot 2H_2O$: C, 30.51; H, 7.25; N, 11.86. Found: C, 29.90; H, 7.19; N, 10.20.

1-(2′-Aminoethyl)-4-(2′-mercaptoethyl)-piperazine Trihydrochloride.—A solution of 4.6 Gm. (0.036 mole) of 1-(2′-aminoethyl)piperazine in 30 ml. of chloroform was cooled in an ice bath and treated with ethylene sulfide (4.3 Gm., 0.072 mole) slowly, with shaking, during 30 minutes. The mixture was allowed to stand for 3 days at room temperature under nitrogen, and was then distilled under nitrogen at 40° (20–30 mm.). The residual oil was extracted with two 50-ml. portions of ether, and 125 ml. of absolute ethanol was added to the ether-insoluble material. The alcohol solution was chilled and saturated with anhydrous hydrogen chloride; a solid was obtained which was extracted with 100 ml. of hot acetone in two portions and quickly transferred to a desiccator. About 2.5 Gm. (24%) of ivory-colored product was obtained which melted at 165–170°.

Anal.—Calcd. for $C_8H_{22}Cl_3N_3S$: C, 32.15; H, 7.42; S, 10.71. Found: C, 32.52; H, 7.72; S, 10.94.

1-(2′-Mercaptoethyl)piperazine Dihydrochloride.—The same reaction sequence was used as in the preparation of the corresponding dihydrobromide. A very small yield of hygroscopic product was obtained which melted in the range of 145–150°.

Anal.—Calcd. for $C_6H_{16}Cl_2N_2S_2 \cdot H_2O$: C, 30.37; H, 7.65; N, 11.81. Found: C, 30.15; H, 7.51; N, 10.49.

1-Piperazinoethyl Disulfide Tetrahydrochloride.—The previous product, 1.0 Gm., was dissolved in 5 ml. of 50% aqueous ethanol containing 5 ml. of 3% hydrogen peroxide solution. The solution was heated on a water bath for 30 minutes and allowed to stand overnight. The solution was evaporated *in vacuo* to a gum, treated with absolute ethanol, and again concentrated *in vacuo*. This process was repeated. The semicrystalline material was removed from the flask and triturated in absolute ethanol; an extremely hygroscopic product was isolated which did not decolorize iodine T.S. without remaining in solution for some time. The product, 0.7 Gm., melted at 95–100°.

Anal.—Calcd. for $C_{12}H_{30}Cl_4N_4S_2 \cdot 2H_2O$: C, 30.51; H, 7.25; N, 11.86. Found: C, 29.90; H, 7.19; N, 10.20.

Soluble Steroids I

Sugar Derivatives

By WINTHROP E. LANGE and MERLE E. AMUNDSON†

Glucamine, glucosamine, and N-methylglucamine derivatives of cholesterol, testosterone, 9-α-fluorohydrocortisone, triamcinolone acetonide, and hexestrol have been synthesized in an attempt to provide compounds with increased aqueous solubility. The acylable hydroxy group of the steroid was converted to the chloroformate and then condensed with the appropriate amino sugar. In general, the derivatives which have been prepared possess 8 to 13 times the aqueous solubility of the parent compounds. The N-methylglucamine and glucosamine derivatives of triamcinolone acetonide, when applied topically, failed to show appreciable pharmacological activity.

THERE HAVE been two general methods for the preparation of water-soluble steroidal compounds. One method is by means of physical factors, that is, solubilizing agents which have been used to increase the solubility of the steroid. The second method for the preparation of water-soluble steroidal compounds has been by modification of structure. Of the many modifications that have been reported, the preparation of poly-hydroxy derivatives have been mentioned in only a few cases. Water-soluble compounds, useful as sedatives showing no hormonal activity, have been prepared by the formation of glycosides of 21-hydroxysteroids and of hemiglutarates and hemiphthalates (1, 2). A patent granted to the Upjohn Co. (3) describes physiologically active water-soluble glycoside derivatives of corticoid hormones. One of the compounds prepared was the N-methylglucamine salt of hydrocortisone-21-hemi-β-methylglutarate.

Nakagawa and Mori (4) prepared methoxy poly-(oxyethylene)-propionic acid and obtained water-soluble esters with various steroids.

Plungian (5) reported the preparation of a stable, nontoxic complex of rutin and N-methylglucamine (3:1), which retained the therapeutic properties of rutin. This complex was soluble in water to the extent of 20% and had a pH suitable for oral or parenteral preparations.

These various findings suggested then that a sugar moiety attached to a steroid nucleus might give compounds with increased water solubility. The poly-hydroxy chain would be so attached to the steroid nucleus that it would be readily hydrolyzed in the body, a condition which would allow the free steroid to exert its full pharmacological effect. It is also possible that such derivatives should have some effect upon the absorption and distribution of the drug in the body. Thus, the present investigation is intended to make available for testing various steroids containing sugar moieties, such as glucamine, N-methylglucamine, and glucosamine.

DISCUSSION

Several methods have been reported for the preparation of amine derivatives of steroids. Pierce and co-workers (6) prepared a series of steroidal amines by direct replacement of halogen or tosylate groups with an amine group.

Heyl and Herr (7) prepared a series of C_3-(N-pyrrolidyl)-enamines (α,β-unsaturated amines) from steroidal C_3-ketones by azeotropic distillation with pyrrolidine. The enamines were readily hydrolyzable to regenerate the carbonyl function. Using this method, a model synthesis for application to steroids was attempted with cyclohexanone. Cyclohexanone was refluxed with N-methylglucamine in benzene with constant water separation. The compound prepared, N-methyl-N-(1-cyclohexenyl)-glucamine, was completely water soluble. However, when Δ^4-cholestenone-3 was chosen as a representative steroid, the enamine was not obtained. Several modifications were also attempted without success. The reactants were refluxed in solvents other than benzene, dehydrating agents were added, the steroid was changed to testosterone, and the sugar was changed to 2,3,4,5,6-pentaacetyl-N-methyl glucamine. The application of the Leukart reductive amination process (8) to Δ^4-cholestenone-3 and the direct reaction of cholesteryl chloride with a sugar amine also were unsuccessful.

The report of Verdino and Schadendorff (9) that amines could be condensed with cholesterol chloroformate to give carbamates, and the finding of Miescher and Scholz (10) that carbonates of 17-estradiol had increased physiological action, suggested a second method for the attachment of amino sugars to steroids.

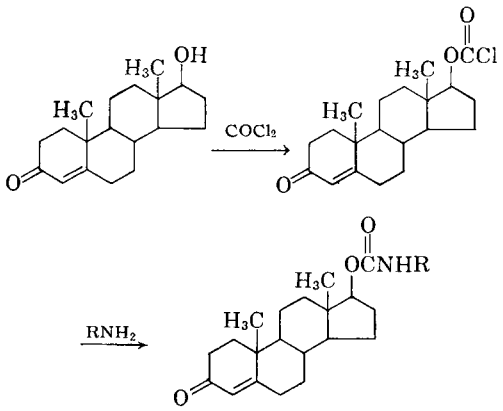
Cholesterol was converted to 5-cholesten-3β-yl-chloroformate by the method of Wieland, Honold

Received March 27, 1962, from the Samuel M. Best Research Laboratories of the Massachusetts College of Pharmacy, Boston.

Accepted for publication May 17, 1962.

Abstracted in part from the dissertion presented by Merle E. Amundson to the Graduate Council, the Massachusetts College of Pharmacy, in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

The authors are deeply indebted to Dr. L. V. Blubaugh for his generous donation of several of the steroids and arranging for the pharmacological screening of the sugar derivatives.



Presented to the Scientific Section, A.PH.A. Las Vegas meeting, March 1962.

† Fellow of the American Foundation for Pharmaceutical Education, 1960–1961; present address: Eli Lilly and Co., Indianapolis, Ind.

and Pascual-Vila (11) in quantitative yields. The chloroformate was then refluxed with N-methylglucamine in a dioxane-water mixture. The reaction was completed in 1 hour and the product, 3β-(5-cholesten-N-methyl-N-1-(1-desoxyglucosyl) carbamate was isolated. Carbon-hydrogen analysis on recrystallized samples of this compound repeatedly resulted in low results, and it was only after the compound had been dried 2 hours at 105–110° that a satisfactory analysis was obtained. A water analysis showed the presence of 1 mole of water per mole of compound in the sample dried at 56° *in vacuo*.

5-Cholesten-3β-yl-chloroformate was also coupled with glucosamine, but only gave a gummy product with glucamine.

The product obtained after the treatment of 9α-fluorohydrocortisone with phosgene contained only one chloroformyl group. Thus, it was desirable to determine the position of condensation since hydroxyl groups are present at positions 11, 17, and 21. Steric considerations make it practically impossible for reaction to occur with the 11β-hydroxyl group. The two strong methyl:hydroxyl repulsions and one hydroxyl:hydrogen interaction place the molecule under considerable strain. Since these factors would not be relieved by chloroformyl formation, the 11β-hydroxyl group is practically unacylable. In addition, an equatorial hydroxyl group is acylated more readily than an axial group at the same position and, in this case, the hydroxyl groups at the 11 and 17 positions are axial. Final evidence that the 21 position is involved was obtained when phosgene was introduced into a tetrahydrofuran solution of 9α-fluorohydrocortisone-21-acetate and no chloroformate was obtained. Only the parent substance, the acetate, was isolated.

R = Sugar Moiety

Triamcinolone acetonide also gave only a monochloroformate. However, with this compound as well as with the 9α-fluorohydrocortisone all three sugar derivatives were obtained. The general reaction for the preparation of the sugar derivatives is summarized by the following equation and the analytical data are given in Table I.

An attempt was also made to prepare the sugar derivatives of diethylstilbestrol as it is a representative of that class of steroids and steroid-like materials which contain a phenolic hydroxyl group. The method of Crosby and Niemann (12) for the preparation of chloroformates of phenol with diethylstilbestrol gave, on one attempt, a product with the properties of a chloroformate. However, a carbon-hydrogen analysis did not agree with the calculated values for the chloroformate. Successive trials, and even modifications in the procedure as suggested by Dirschel (13) were of no avail in the preparation of the chloroformate of diethylstilbestrol.

When hexestrol, however was dissolved in aqueous sodium hydroxide and a cooled solution of phosgene in benzene was added, a good yield of 3,4-bis-(*p*-chloroformylphenyl)-*n*-hexane was obtained. Sugar derivatives of hexestrol chloroformate were then prepared in the usual manner. The hydroscopic nature of the chloroformate and sugar derivatives of hexestrol presented difficulty in obtaining analytically pure samples.

Absorption Data.—The ultraviolet spectra of the

[c] NMG is N-methylglucamine, GLS is glucosamine, GLC is glucamine, and CF is chloroformate. [d] With decomposition. [e] These compounds possess a molecule of water which is not driven off at 105–110°. [f] Softened only. [g] With previous softening.

sugar derivatives which have been described parallel those of the parent compounds, and no new maxima are exhibited.

Several significant changes appear, however, in the infrared spectra of the derivatives in the range from 2.5 to 6.5 μ. The 2.8 or 2.9 band, which is attributed to the hydroxyl group, is not found in the spectrum of the chloroformates but is present in the sugar derivatives of cholesterol, testosterone, and hexestrol.

The carbonyl band of the chloroformyl radical exhibits a maximum between 5.60 and 5.62 μ for all of the steroids. The carbonyl band for the substituted carbamates exhibits a maximum between 5.84 and 5.90 μ. The glucosamine and glucamine derivatives also show a new band between 6.44 and 6.58 μ which is attributed to the amide II band of secondary amides or secondary carbamates. Thus, this band furnishes evidence that the sugar derivatives are carbamates and not carbonates. The characteristic maxima of all compounds are found in Table II.

Although a pure chloroformate of diethylstilbestrol was not obtained, spectral evidence was obtained for the formation of such a compound.

Solubility Studies.—Since the primary objective of this project was an attempt to prepare a series of steroidal derivatives which would have an increased solubility in water over the parent steroids, a solubility study was undertaken. Approximately 25 mg. of product was accurately weighed and placed in a 50-ml. Erlenmeyer flask which contained exactly 25 ml. of distilled water. The flask was stoppered and placed on a mechanical shaker for 24 hours at 25°. At the end of this time the contents of the flask were filtered by means of a tared sintered-glass funnel. The insoluble material which collected on the funnel was dried to constant weight in a desiccator over anhydrous calcium chloride. The funnel and the contents were then accurately weighed and the amount of product which dissolved was determined by difference. The results of this study are summarized in Table III.

It will be noted that the increase in solubility of the various sugar derivatives of the steroids follows a pattern when steroids substituted at the same position are compared. However, when a 3-hydroxy steroid is compared with a 21-hydroxy steroid, the solubilizing effect of a particular sugar moiety does not follow a pattern as would be expected. No explanation for these results is available at this time.

Preliminary Hydrolysis Study.—It was desirable to obtain information regarding the rate of hydrolysis of the sugar derivatives in order to predict their stability characteristics.

Using the N-methylglucamine derivative of cholesterol it was noted that no measureable hydrolysis occurred after 7 hours in either U.S.P. XVI simulated gastric or intestinal fluid at 37°. However, after 4 hours in solutions of 1 *N* sodium hydroxide and 1 *N* hydrochloric acid, 13% of the sugar derivative in the alkaline solution had hydrolyzed, while no hydrolysis was noted in the acid solution.

Hydrolysis was detected in the aqueous solutions by extracting them with ether and isolating the cholesterol which was released.

Preliminary Pharmacological Results.—At the present time, two of the compounds (N-methylglucamine and glucosamine derivatives of triamcinolone) have been tested at the Squibb Institute for Medical Research. The steroids were assayed in adrenalectomized male rats. In liver glycogen studies the N-methylglucamine derivative was approximately 10 times as active as cortisone acetate, while the glucosamine derivative was only 2.5 times as active. In antigranuloma (pellet) and thymolytic tests, the sugar derivatives were about 0.1 as active as the parent compound. It appears from these tests that the sugar moiety stabilizes the carbamate linkage to hydrolysis with the resultant loss in activity.

EXPERIMENTAL

All melting points were taken on a Fisher-Johns melting point apparatus and are uncorrected.

***N*-Methyl-*N*-1-(1-cyclohexenyl)glucamine.**—Cyclohexanone (National Aniline), 10.0 Gm. (0.1 mole), was dissolved in 50 ml. of dried benzene. N-Methylglucamine (Aldrich Chemical Co.), 19.52 Gm. (0.1 mole), was added to the benzene solution and the resulting mixture was refluxed for 5 hours with constant water separation by means of a Bidwell-Sterling moisture trap. The insoluble material was then filtered, dried, and recrystallized from a benzene-methanol mixture. A quantitative yield of white needles which melted at 93–95° was obtained.

Anal.—Calcd. for $C_{13}H_{25}NO_5$: C, 56.7; H, 9.1. Found: C, 56.4; H, 7.9.

2,3,4,5,6-Pentaacetyl-*N*-methylglucamine Hydrochloride.—N-Methylglucamine hydrochloride, 15 Gm. (0.064 mole), was placed in 75 ml. of acetic anhydride, and five drops of concentrated sulfuric acid was slowly added to the mixture. The mixture was heated 2 hours on a steam bath, cooled, and refrigerated overnight. The product was precipitated from solution by the addition of several volumes of ether and was collected on a filter. The white amorphous product was washed several times with ether and stored under anhydrous conditions in a refrigerator. The product weighed 22.8 Gm. (80%) and melted at 90–92° with previous softening.

Anal.—Calcd. for $C_{17}H_{27}NO_{10}\cdot HCl$: C, 46.20; H, 6.39. Found: C, 45.29; H, 6.17.

5-Cholesten-3β-yl-chloroformate.—This compound was prepared according to the method of Wieland, Honold, and Pascual-Vila (11). A yield of 79% was obtained which melted at 121–122°. This melting point agrees with the reported value.

3β-(5-Cholestenyl)-N-methyl-N-1-(1-desoxyglucosyl)carbamate.—To 9 Gm. (0.02 mole) of 5-cholesten-3β-yl-chloroformate dissolved in 100 ml. of dioxane was added 8.0 Gm. (0.04 mole) of N-methylglucamine and sufficient water to obtain a clear solution. The mixture was refluxed for 1 hour and was then cooled and refrigerated. The product was collected on a filter and recrystallized from ethanol. A yield of 11.0 Gm. of white needles was obtained which melted at 131–133°.

Anal.—Calcd. for $C_{35}H_{61}NO_7\cdot H_2O$: H_2O, 2.88. Found: H_2O, 2.70.

3β-(5-Cholestenyl)-N-2-(2-desoxyglucosyl)-carbamate.—5-Cholesten-3β-yl-chloroformate, 4.5 Gm. (0.01 mole), was dissolved in 60 ml. of dioxane with slight warming. D(+) Glucosamine hydro-

[a] All determinations were made on a Perkin-Elmer model 137 Infracord spectrophotometer. Samples were mounted as Nujol mulls. [b] CF is chloroformate, NMG is N-methylglucamine, GLS is glucosamine, and GLC is glucamine.

chloride (Nutritional Biochemicals Corp.), 4.31 Gm. (0.02 mole), was placed in 20 ml. of distilled water and 0.80 Gm. (0.02 mole) of sodium hydroxide was added. The neutralized aqueous solution of the sugar was then added to the dioxane solution, and the mixture was heated for 10 minutes on a hot plate. The mixture was then shaken for 1 hour and the precipitate which formed was collected on a filter, washed with acetone, and dried *in vacuo* at 56°. A yield of 3.75 Gm. was obtained, which melted at 155–158°.

Anal.—Calcd. for $C_{34}H_{57}NO_7 \cdot H_2O$: H_2O, 2.95. Found: H_2O, 3.26.

4-Androsten-3-one-17β-yl-chloroformate.—To a solution of 5.0 Gm. (0.0175 mole) of testosterone (Matheson, Coleman, and Bell) dissolved in 100 ml. of benzene was added an excess of phosgene. The mixture was allowed to stand 1 hour, after which the solution was aerated for 2 hours. The benzene was evaporated *in vacuo* and the residue recrystallized from Skelly B. A yield of 5.8 Gm. of yellow needles, which melted at 110–111°, was obtained. The melting point has previously been reported as 139–140° (14).

Anal.—Calcd. for $C_{20}H_{27}ClO_3$: C, 68.46; H, 7.75. Found: C, 68.72; H, 7.76.

17β-(4-Androsten-3-one)-N-methyl-N-1-(1-desoxyglucosyl)carbamates.—In a manner similar to that described for the preparation of the N-methylglucamine derivative of cholesterol, using an acetone-water mixture as the solvent and a 3-hr. reflux time, there was obtained a white product. The product melted at 183–185° after recrystallization from aqueous methanol.

17β-(4-Androsten-3-one)-N-2-(2-desoxyglucosyl)carbamate.—This was prepared by the procedure given for the condensation of glucosamine with cholesterol using an acetone-water solvent

[a] The solubilities of the compounds in water at 25° were determined by a gravimetric procedure following agitation for 24 hours. [b] Solubility of the derivative/solubility of the parent steroid. [c] NMG is N-methylglucamine, GLS is glucosamine, and GLC is glucamine. [d] Exact solubilities were not determined for hexestrol and its sugar derivatives due to the limited amount of material which was obtained in synthesis.

system. The product melted at 185–190°, with decomposition.

9α - Fluoro - 11β,17α - dihydroxy - 4 - pregnen-3,20 - dione - 21 - chloroformate.—The 9α - fluorohydrocortisone (E. R. Squibb and Co.) was treated with phosgene in tetrahydrofuran, as previously described, to give a waxy, light brown compound which melted at 159–162°.

21 - (9α - Fluoro - 11β,17α - dihydroxy - 4-pregnen - 3,20 - dione) - N - methyl - N - 1 - (1-desoxyglucosyl)carbamate.—This was prepared by the procedure given previously for N-methylglucamine derivatives. The light brown product softened at 120°.

21 - (9α - Fluoro - 11β,17α - dihydroxy - 4-pregnen - 3,20 - dione) - N - 2 - (2 - desoxyglucosyl)-carbamate.—This was prepared by the procedure given previously for glucosamine derivatives. The product melted at 176–178°.

21 - (9α - Fluoro - 11β,17α - dihydroxy - 4-pregnen - 3,20 - dione) - N - 1 - (1 - desoxyglucosyl)-carbamate.—The glucamine was prepared according to the method of Holly, *et al.* (15). The derivative was prepared by the procedure given previously for N-methylglucamine. The product after recrystallization from aqueous methanol, melted at 128–130°.

9α - Fluoro - 11β - hydroxy - 16α,17α - isopropylidenedioxy - 1,4 - pregnadien - 3,20 - dione - 21-chloroformate.—The triamcinolone acetonide (E. R. Squibb and Co.) was treated with phosgene in dioxane. The yellow waxy product, after recrystallization from aqueous acetone, melted at 165–167°.

21 - (9α - Fluoro - 11β - hydroxy - 16α,17α - isopropylidenedioxy - 1,4 - pregnadien - 3,20 - dione)-N - methyl - N - 1 - (1 - desoxyglucosyl)carbamate.—This was prepared by the procedure given previously for N-methylglucamine derivatives. Purification of the product was accomplished by treating a warm acetone solution of the compound with charcoal. The yellow product, after drying for 2 hours at 110°, melted at 152° with previous softening.

21 - (9α - Fluoro - 11β - hydroxy - 16α,17α - isopropylidenedioxy - 1,4 - pregnadien - 3,20 - dione)-N - 2 - (2 - desoxyglucosyl)carbamate.—This was prepared by the procedure given previously for glucosamine derivatives. Purification was accomplished in the same manner as described above. The product melted at 250–255°, with decomposition.

21 - (9α - Fluoro - 11β - hydroxy - 16α,17α - isopropylidenedioxy - 1,4 - pregnadien - 3,20 - dione)-N - 1 - (1 - desoxyglucosyl)carbamate.—This was prepared according to the procedure given previously for N-methylglucamine derivatives. The product recrystallized from aqueous methanol melted at 150°, with decomposition.

3,4 - Bis - (*p* - chloroformylphenyl) - *n* - hexane.—Hexestrol, 0.54 Gm. (0.002 mole), (Nutritional Biochemicals Corp.) dissolved in 100 ml. of 2.5% aqueous sodium hydroxide was added, dropwise, to a cooled solution of 1.0 Gm. of phosgene in 75 ml. of benzene. The mixture was stirred for 3 hours at room temperature. The benzene layer was separated and was washed with two volumes of 2.5% aqueous sodium hydroxide and one volume of water. The benzene solution was dried and evaporated to give 0.52 Gm. of white crystals which melted at 115–117°.

3,4 - Bis - {*p* - [N - methyl - N - 1 - (1 - desoxyglucosyl)carbamoylphenyl]} - *n* - hexane.—This was prepared by the procedure given previously for N-methylglucamine derivatives. The syrupy residue which was obtained was dried *in vacuo* at 56°. The hygroscopic product melted at 80–82°.

3,4 - Bis - {*p* - [N - 2 - (2 - desoxyglucosyl)-carbamoylphenyl]} - *n* - hexane.—This was prepared by the procedure given previously for glucosamine derivatives. Purification was effected in an acetone solution by treatment with charcoal. The product melted at 188–190°.

Treatment of Primary and Secondary Infections of the Skin with Cetyltrimethylammonium Bromide

By H. H. RODIN

Cetyltrimethylammonium bromide incorporated in an aromatic mix base is effective in the treatment of primary and secondary pyogenic cutaneous infections. The failure of this preparation to produce allergic reactions suggests a low sensitizing index.

IN THIS investigation cetyltrimethylammonium bromide (CETAB) incorporated in a water soluble base containing an aromatic mix[1] was found to be effective antimicrobial agent in the treatment of primary skin infections. It has also been found to be effective in the elimination of complicating secondary infections of various skin conditions thus permitting proper treatment of the primary condition.

METHODS AND TECHNIQUES

This study was conducted in the out-patient dermatological clinic of a large mid-western county hospital and is based on observations made on 100 patients treated for superficial pyodermic infections of the skin with a cream containing CETAB and an aromatic mix.

In this series there were 21 white male subjects; 38 male colored subjects; 9 white female subjects and 32 colored female subjects. The youngest patient treated was a 2-year old colored female child and the oldest a 79-year old white female patient.

Treatment consisted of having the subjects apply the medication to the involved areas at least twice daily. In the more severe cases it was applied as often as three or four times daily. Although a few cases were treated shortly after the onset of the disease, less than 1 week, the majority of cases were subacute or chronic and had been present for 2 weeks to 6 months or longer. As a result, many of the cases presented disseminated lesions.

There were 75 subjects who presented six different types of primary skin infections and 25 subjects who presented secondary infections complicating 10 different types of common dermatological disorders. The diagnosis, order of frequency, and results are listed in Table I. The period of treatment in the majority of cases was 7 days, although several cases were treated for 2 weeks, and in a few cases, therapy was continued for 1 month. All clinical evaluations were made at the end of 1 week, regardless of the duration of treatment, in order to maintain the evaluation of the therapeutic index as constant as possible.

Cultures were taken from the lesions of 14 patients selected at random by the dry swab technique. These were transported within a short time (1–2 hr.) to the bacteriological laboratory where they were transferred to blood-agar plates and incubated for 48 to 72 hours. The organisms were then identified and reported by the director of the laboratory.

Of 75 patients treated for primary skin infections, 53 (70.6%) obtained satisfactory results (estimated improvement 50% or better), 15 (20%) obtained fair results (estimated improvement 25% to 50%) while 7 failed to obtain any benefit from therapy.

In those patients treated for dermatological conditions complicated by secondary infection 15 patients (60%) obtained satisfactory results while 10 patients obtained only partial benefit from this form of therapy.

Culture.—An analysis of the cultures revealed that hemolytic *Staphylococcus aureus coagulase positive* was obtained as the only infecting microorganism in six cases and that both it and hemolytic *Staphylococcus albus* were present in five cases. The culture in one case of folliculitis of the scalp revealed a neisseria organism along with an unidentified yeast, while in two cases no growth was reported initially. One of these two cases failed to show growth on repeated culture.

Of the six patients from whom only hemolytic *Staphylococcus aureus coagulase positive* was recovered, four obtained good results and two obtained fair results from the treatment with CETAB cream.

In those cases in which both hemolytic *Staphylococcus aureus coagulase positive* and hemolytic *Staphylococcus albus* were recovered, three patients obtained good results, one patient fair results while one patient failed to obtain any benefit from therapy. The one case in which the neisseria organism and yeast were recovered obtained an excellent result from treatment. In the two cases with negative findings, one obtained excellent results from therapy and the other only fair results.

Reactions.—No clinical evidence of allergic or primary irritant reactions were noted in any of the cases treated for primary skin infections or secondary infections complicating pre-existing dermatological conditions where active treatment was indicated. In several cases, patients complained of a slight transient burning sensation when the medication was first applied. This burning sensation usually disappeared in a matter of seconds and in no instance interfered with the continuation of treatment or affected clinical results. These results suggest that CETAB cream when used properly and in indicated conditions[2] has a low sensitizing and irritant index.

Received December 20, 1961, from 822 Oakridge Dr., South Bend 17, Ind.
Accepted for publication March 16, 1962.

[1] Furnished as Bactine cream, Miles Laboratories, Inc., Elkhart, Ind.

[2] Like all antimicrobial agents, CETAB cream will produce irritation when applied to those cases which are complicated by superimposed acute dermatitis venanata, regardless of cause, and when such active treatment is contraindicated.

TABLE I.—RESULTS OF THERAPY

Diagnosis	No. Cases	Excellent	Good	Fair	No Change
Primary Skin Infections					
Pyoderma	25	4	12	5	4
Infectious eczematoid dermatitis	20	3	11	4	2
Impetigo	13	8	4	1	...
Folliculitis	9	5	2	2	...
Ecthyema	4	1	1	2	...
Sycosis barbae	4	...	2	1	1
Total	75	21	32	15	7
Secondary Infected Dermatoses					
Herpes simplex	6	4	2	...	...
Contact dermatitis	4	1	2	1	...

Lichen simplex chronicus	1	...	...	1	...
Pediculosis corporis	1	...	...	1	...
Pustular dermatitis-palm	1	...	...	1	...
Total	25	6	9	10	...

DISCUSSION

A comparison of the results of treatment in those subjects treated for primary skin infections involving the uppermost skin structure such as the epidermis and the upper portion of the dermis for example, impetigo, pyoderma, infectious eczematoid dermatitis and folliculitis, to those involving the deeper portion of the dermis, for example, ecthyema or sycosis barbae, revealed the following interesting results. In the former group 49 patients out of a total of 67 patients, or 73.1%, obtained satisfactory results whereas in the latter group only four patients out of a total of eight, or 50%, obtained satisfactory results. This observation suggests that CETAB cream will be most effective in the treatment of those cutaneous infections involving the more superficial structure of the skin.

In the majority of cases treated for secondary infection of preexisting dermatoses, treatment with CETAB cream for 1 week produced sufficient improvement of this complication to allow proper dermatological therapy for the underlying skin condition This was of particular importance where adequate control of the micro-organism was necessary prior to institution of topical steroid therapy.

SUMMARY

The quaternary ammonium compound cetyltrimethylammonium bromide incorporated in a water soluble aromatic mix base as a cream is an effective antimicrobial agent in the treatment of primary and secondary types of skin infections.

Treatment of patients with primary skin infection produced satisfactory results in 71% of the cases treated. Treatment of patients with secondary type skin infection produced satisfactory results in 60% of the cases treated and permitted indicated therapy of underlying dermatoses, in the majority of cases within one week.

CETAB cream is effective against cutaneous pyogenic infections produced either by hemolytic *Staphylococcus aureus coagulase positive* organisms or in combination with hemolytic *Staphylococcus albus*.

The failure of this preparation to produce allergic or irritant reactions, when used in indicated conditions, indicates a low sensitizing and irritant index.

Isolation of Polyporic Acid from *Lopharia papyracea*

By V. JIRAWONGSE, E. RAMSTAD, and J. WOLINSKY

IN RECENT years a mushroom known as Hed Dchig (hed, mushroom; dchig, tummy wood) or Hed Tin Tŭkgae (Tin, foot; tŭkgae, gecko) has come into use in folk medicine in northeastern Thailand as an anthelmintic and is claimed to be effective, especially in the treatment of tapeworm infestations. The mushroom grows on *Careya arborea* Roxb. (*Mytaceae*) and is used as a food. It may be found in local drugstores in Udorn City.

Hed Dchig has been identified as *Lopharia papyracea* (Jungh.) Reid, belonging to the family of *Hydnaceae*.

Received January 29, 1962, from the Departments of Pharmacy and Chemistry, Purdue University, Lafayette, Ind.

Accepted for publication March 7, 1962.

Having available a small supply of the dried mushroom[1] we subjected it to chemical investigation and found it to contain 11.4% of polyporic acid, a compound we found to cause contraction of isolated rabbit ileum suspended in oxygenated Tyrode solution.

EXPERIMENTAL

Isolation.—The leathery tan mushroom was dried over calcium oxide (9.5% moisture), powdered, defatted with petroleum ether by extraction in a

[1] We wish to express our gratitude to Mr. Vichian Bhamarasiri, Bangkok, for providing a sample of the drug, to Mr. Derek A. Reid, Royal Botanical Gardens, Kew, London, for identification of the mushroom, and to Dr. R. L. Frank for making available a sample of polyporic acid.

Received January 29, 1962, from the Departments of Pharmacy and Chemistry, Purdue University, Lafayette, Ind.

Accepted for publication March 7, 1962.

Having available a small supply of the dried mushroom[1] we subjected it to chemical investigation and found it to contain 11.4% of polyporic acid, a compound we found to cause contraction of isolated rabbit ileum suspended in oxygenated Tyrode solution.

EXPERIMENTAL

Isolation.—The leathery tan mushroom was dried over calcium oxide (9.5% moisture), powdered, defatted with petroleum ether by extraction in a

[1] We wish to express our gratitude to Mr. Vichian Bhamarasiri, Bangkok, for providing a sample of the drug, to Mr. Derek A. Reid, Royal Botanical Gardens, Kew, London, for identification of the mushroom, and to Dr. R. L. Frank for making available a sample of polyporic acid.

Soxhlet apparatus, and then extracted exhaustively with chloroform. During the extraction, quantities of permanganate-colored, glittering crystals separated from the brownish-violet solution. Further amounts were obtained by concentration of the solution. Total yield of crystals was 11.4% of the dry weight of the mushroom. The crystals were very sparingly soluble in cold ether, chloroform, xylene, and pyridine, but soluble in alkali. They were iridescent in polarized light and possessed a slight mushroom odor.

Identification.—A sample which crystallized from pyridine as orange needles, turning brown on drying, was sublimed *in vacuo* and then recrystallized from chloroform to give shiny purple plates, m.p. 310.5–312°[2] (sealed capillary), $\lambda_{max.}^{EtOH}$ 205, 256, 262, infl. 330 and 465 mμ (ε, 48,000, 43,000, 43,000, 11,600, and 400, respectively), $\lambda_{max.}^{EtOH-NaOH}$ 530 mμ, (ε 200). Literature: m.p. 303–305° (1), $\lambda_{max.}^{dioxane}$ 261, 332 (4.45 and 3.86) (2), $\lambda_{max.}^{pyridine-H_2O}$ 530 mμ (3). The infrared spectrum of this compound was identical with that of an authentic sample of polyporic acid.

Anal.—Calcd. for $C_{18}H_{12}O_4$: C, 73.95; H, 4.14. Found: C, 74.02; H, 4.37.

The diacetate derivative of polyporic acid was prepared using acetic anhydride and pyridine and showed m.p. 212–214° after recrystallization from methylene chloride-ether, $\lambda_{max.}^{EtOH}$ 236, 240 mμ (ε 1,100, 2,350). Literature: m.p. 215° (4); $\lambda_{max.}^{dioxane}$ 240 and 336 mμ (4.33 and 3.78).

The dimethyl ether of polyporic acid was prepared by adding an excess of diazomethane in ether to a suspension of the acid in methylene chloride. The solvents were removed immediately and the residue recrystallized from benzene-petroleum ether to give an orange solid, m.p. 192–194° [reported (5) m.p. 192°].

[2] All melting points are uncorrected.

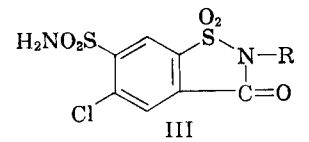
Saccharin Derivatives VI. Synthesis and Diuretic Activity of 2-Methyl-6-sulfamoylsaccharin

By GLENN H. HAMOR



THE APPEARANCE in the literature in 1957 of a report describing the diuretic activity of 6-chloro-7-sulfamoyl-1,2,4-benzothiadiazine-1,1-dioxide (I) (1) led to the preparation of a series of structurally related saccharins. This paper relates the synthesis and result of pharmacological testing of 2-methyl-6-sulfamoylsaccharin (II). Novello, in a recent paper (2), describes the preparation of certain 5-chloro-6-sulfamoylsaccharins (III).

I

II

III

The 2-methyl-6-sulfamoylsaccharin was synthesized by chlorosulfonation of toluene, followed by treatment with 28% ammonia, which gave toluene-2,4-disulfonamide. Oxidation of this compound, succeeded by a Williamson reaction of the resulting 6-sulfamoylsaccharin with methyl iodide, gave the desired 2-methyl-6-sulfamoylsaccharin.

Pharmacological screening in rats has indicated that 2-methyl-6-sulfamoylsaccharin possesses marked diuretic activity (Table I). Testing in the dog for effect on renal clearance of electrolytes and water shows primarily an increase in urine volume accompanied by a slight increase in the excretion of sodium and an increased excretion of potassium.[1]

TABLE I.—DIURETIC EFFECT IN RATS[a]

The 2-methyl-6-sulfamoylsaccharin was synthesized by chlorosulfonation of toluene, followed by treatment with 28% ammonia, which gave toluene-2,4-disulfonamide. Oxidation of this compound, succeeded by a Williamson reaction of the resulting 6-sulfamoylsaccharin with methyl iodide, gave the desired 2-methyl-6-sulfamoylsaccharin.

Pharmacological screening in rats has indicated that 2-methyl-6-sulfamoylsaccharin possesses marked diuretic activity (Table I). Testing in the dog for effect on renal clearance of electrolytes and water shows primarily an increase in urine volume accompanied by a slight increase in the excretion of sodium and an increased excretion of potassium.[1]

TABLE I.—DIURETIC EFFECT IN RATS[a]

Dose, mg./Kg. p.o.	Excreted, %	Effect Excreted, %[b]
Control	60[c]	...
5	84	24
15	111	51
30	154	94
60	171	111

[a] Eight rats per group; each group hydrated with 25 ml./Kg. of 0.9% sodium chloride p.o.; length of test was 5 hours. [b] Test minus control. [c] Experience has fixed the control per cent excretion value at 60% for rats. An effect of 22% or greater (82% or more excreted) shows a significant diuretic response.

EXPERIMENTAL[2]

6-Sulfamoylsaccharin.—This compound was prepared by alkaline potassium permanganate oxidation of toluene-2,4-disulfonamide by the method used by Noyes (3) to synthesize 6-nitrosaccharin. The toluene-2,4-disulfonamide was synthesized according to Wynne and Bruce, m.p. 173–174.5° [reported

Quinazolines I. ω-Tertiaryamino-α-(4-quinazolyl)-α-phenylalkanenitriles

By RAYMOND N. CASTLE and MASAYUKI ONDA†

Six new ω-tertiaryamino-α-(4-quinazolyl)-α-phenylalkanenitriles have been prepared for pharmacological screening and have been tested for anti-inflammatory activity. Attempts to hydrolyze and decarboxylate these nitriles into the corresponding ω-tertiaryamino-α-(4-quinazolyl)-α-phenylalkanes in acid solution gave none of the desired products. Instead, the only compound isolated was 4-hydroxyquinazoline.

THE PURPOSE of the present work was the synthesis of several ω-tertiaryamino-α-(4-quinazolyl)-α-phenylalkanenitriles for pharmacological screening.

These nitriles were prepared by the methods of Cutler, Surrey, and Cloke (1) with some modification shown in the diagram below. The α-phenyl-ω-tertiaryaminoalkanenitriles used in this work that have not been previously reported in the literature are described in another publication by the present authors (2).

Attempts to convert III to the ω-tertiaryamino-α-(4-quinazolyl)-α-phenylalkanes by heating with 60 per cent sulfuric acid solution resulted only in the isolation of 4-hydroxyquinazoline in each instance attempted. This is in accord with the report of Elderfield and co-workers (3) involving treatment of similar quinazolines with mineral acids.

All six compounds of type III were tested[1] for anti-inflammatory activity in rats. The decrease in intrapleural fluid volume was measured. Compounds 1, 3, 5, and 6 were classed as being active at dose levels of 20 mg./Kg.

EXPERIMENTAL[2]

4-Chloroquinazoline.—The method of Gabriel and Stelzner (4) was modified as follows: a mixture of 3.0 Gm. of 4-hydroxyquinazoline, 6.0 Gm. of phosphorus pentachloride, and 12 ml. of phosphorus oxychloride was heated at 120–130° for 50 minutes. The resulting clear solution was evaporated to dryness *in vacuo* at 80°. Chloroform was added to dissolve most of the solid and the mixture poured on a mixture of crushed ice and concentrated ammonia. The product dissolved in the chloroform layer and this solution was washed with dilute sodium carbonate solution, then with water and dried over anhydrous magnesium sulfate. After evaporation *in vacuo* there was obtained 3.2 Gm. (95%) of a white solid, m.p. 95–97° (literature m.p. 96°) (4).

Preparation of α-(4-Quinazolyl)-α-phenyl-γ-dimethylaminobutyronitrile.—To a solution of 5.4 Gm. of α-phenyl-γ-dimethylaminobutyronitrile in 54 ml. of dry toluene was added 1.3 Gm. of sodium amide and the mixture was refluxed with stirring for 1.5 hours. After cooling, 4.3 Gm. of 4-chloroquinazoline was added and the mixture refluxed and stirred for 3 hours. The mixture was diluted with ether, washed with water and the ether layer

Hofmann (3) reported the preparation of benzothiazole from 2-aminobenzenethiol and formamide. His synthesis required a high temperature and yielded only a small amount of benzothiazole. This note reports convenient syntheses for the derivatives of benzothiazole, benzoxazole, and benzimidazole from the appropriate 2-substituted aniline and a secondary or tertiary amide. A new synthesis for benzimidazole from the acid catalyzed reaction of triethyl orthoformate and *o*-phenylenediamine is also reported.

DISCUSSION

Benzoxazole, benzothiazole, and benzimidazole are formed in good yields when the appropriate substituted aniline is reacted with the phosphorus oxychloride adduct of dimethylformamide. When N-methyl or N,N-dimethylacetamide are reacted with phosphorus oxychloride and 2-aminobenzenethiol, 2-methylbenzothiazole is produced. If acetamide or formamide are allowed to react under the same conditions, no product is formed.

From these experimental results, it is noted that the amide nitrogen must be at least monosubstituted.

To discover the fate of the amide nitrogen in this reaction, it was decided to devise an experiment where the amide nitrogen would remain in the final heterocyclic product. The cyclic amide, N-methylpyrrolidone, was reacted with phosphorus oxychloride and 2-aminobenzenethiol. The product was as expected: 2-(methylaminopropyl)benzothiazole.

EXPERIMENTAL

To a solution of phosphorus oxychloride (0.25 mole) in anhydrous ether (40 ml.) was added dropwise a solution of the appropriate amide (0.25 mole) in anhydrous ether (50 ml.). The addition was carried out at 15°. The amide-phosphorus oxychloride adduct separated as an oily layer or low melting solid and the mixture was allowed to come to room temperature. The adduct was washed with three portions (50 ml.) of anhydrous ether (6).

To the amide-phosphorus oxychloride adduct was added the appropriate *ortho*-substituted aniline (0.125 mole) in anhydrous ether (50 ml.). When the substituted aniline was not sufficiently soluble in ether, the order of addition was reversed. The addition was accomplished with rapid stirring and cooling. After the addition was completed, the ether was evaporated and water (100 ml.) added with cooling. The aqueous solution was extracted with ether and the ethereal solution dried over anhydrous sodium sulfate. The ether was evaporated and the residue distilled; except benzimidazole, which was recrystallized from water. The physical constants of the compounds prepared by this method are listed in Table I.

Benzimidazole *via* the Orthoformate Reaction.—in a 100-ml. round-bottomed flask were placed phenylenediamine (18.4 Gm., 0.17 mole), triethyl orthoformate (37 Gm., 0.25 mole), and 2 drops of concentrated sulfuric acid. The flask was set up for distillation and the ethanol was distilled over a 1-hr. period. After 38 ml. of ethanol was collected, the residue was allowed to cool and solidify. The melting point of the crude material was 162–168°. The solid was recrystallized from water at a melting point of 172–173°; lit. (5) m.p. 175; yield, 17.2 Gm. (88%). This material was identical to that prepared by the phosphorus oxychloride reaction.

Effect of Gibberellic Acid on *Chenopodium ambrosioides* var. *anthelminticum*

By L. D. KAPOOR and B. K. KAUL

The application of gibberellic acid, also known as GA_3, to *Chenopodium ambrosioides* L. var. *anthelminticum* (L.) A. Gray, induced increases of approximately 25 and 33% in the volatile oil content and yield of fruits. Vegetative growth was also increased. The per cent of ascaridole ($C_{10}H_{16}O_2$) in the treated and control plants was not altered appreciably.

During the course of investigations on the effect of gibberellic acid (GA) with various important aromatic plants, the authors studied the effect of this substance on the growth and production of volatile oil in the chenopodium plant. The per cent of ascaridole in chenopodium oil was also determined. This paper describes the results of our preliminary study with this plant.

EXPERIMENTAL

Young chenopodium seedlings, about 20–30 cm. tall and bearing 15 to 20 leaves, were transplanted during the second week of May 1961 into well-manured beds of six square meters. The first treatment with GA at an average rate of 10 ml. per plant was given on May 28 at the preflowering stage. The same treatment was repeated 1 week later. GA was sprayed in concentrations of 25, 50, 100, and 200 p.p.m. Chenopodium seedlings which were planted in individual clay pots (10 × 12 inches) were simultaneously given GA-spray treatments at fortnightly intervals for 8 weeks in order to determine growth differences.

Observations on Growth.—The plants responded favorably to the various concentrations of GA. Increased internodal elongation was noted in the main shoots of the treated plants. Two weeks after the treatment, the axillary and side shoots appeared in all the treated plants, but in the untreated ones they were found after 4 weeks. After 8 weeks the maximum height (70 cm.) was observed in the plants given a dose of 100 p.p.m. of GA, as compared with 0, 25, 50, and 200 p.p.m. The corresponding figures for these groups were 26, 42, 48, and 68 cm., respectively. Maximum growth responses were observed in plants treated with 100 p.p.m. of GA until the sixth week, but thereafter the differences in length resulting from treatments with the higher concentrations of GA became less pronounced. The leaves were narrower and chlorotic in the treated plants. By the end of June, almost half of the flowers had opened. However, fruit formation was not complete until the end of August. The increased number of nodes and increased elongation of internodes in the treated plants resulted in a large number of axillary shoots bearing more fruit. It was also observed that if the seedlings were sprayed with high concentrations of GA in winter (December to January) the treatment did not initiate a characteristic growth response. However, when the length of day and the temperature were increased, a favorable growth response from GA is controlled by specific temperature and photoperiodic conditions. The optimum period of growth for chenopodium is from April to the end of August.

Fruit and Oil Yield.—The plants were harvested in the first week of September and dried in the shade for a period of 2 weeks. The fruits were then gathered from the dry plant material. The most favorable response on fruit development was induced by treatment with 50 p.p.m. of GA. An increase of about 33% in the dry weights of this group was noted (Table I). The increased amount of fruit was due mainly to the development of a greater number of fruits. This was caused by the formation of additional flowering shoots by the GA treatment. The per cent of volatile oil, determined by steam distillation of the fruits, was found to be up to 25% greater in the treated plants (Fig. 1).

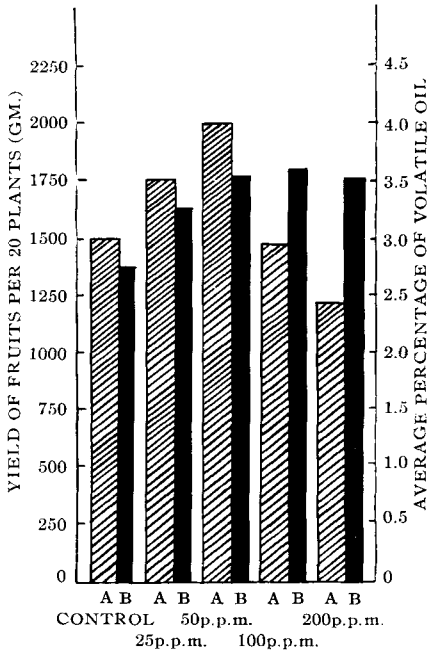

Fig. 1.—Histogram showing the per cent of volatile oil and yield of chenopodium fruits; A = fruit yield, B = % volatile oil.

The oil fractions from the variously treated groups were analyzed for ascaridole ($C_{10}H_{16}O_2$) according to the *Pharmacopoeia of India* (2). The per cent of ascaridole in the oil of treated plants was about the same as in the controls (Table I). It is interesting to note that the ascaridole content for all plants is above the 65% recommended in the *British Pharmacopoeia*.

Received January 15, 1962, from the Regional Research Laboratory, Jammu and Kashmir, India.

Accepted for publication March 5, 1962.

The authors thankfully acknowledge the keen interest of Dr. I. C. Chopra in the work and I. C. I., Ltd., London, for supply of samples of gibberellic acid.

TABLE I.—VOLATILE OIL, ASCARIDOLE, AND FRUIT YIELD IN CHENOPODIUM FOLLOWING TREATMENT WITH GIBBERELLIC ACID

Determination	Treatment with GA, p.p.m. 0	25	50	100	200
Volatile oil in fruits (v/w),[a] %	2.80	3.25	3.45	3.50	3.20
Ascaridole content of oil, %[b]	79.6	79.4	79.0	78.5	78.0
Dry fruit yield, Kg.[c]	1.50	1.75	2.00	1.45	1.25

[a] Mean from 10 determinations. [b] Average from three determinations. [c] Average yield from 20 plants occupying an area of 6 sq. meters.

DISCUSSION

From the foregoing observations it appears that, like *Anethum sp.* (4), the volatile oil of the chenopodium fruits also registers an increase with the application of GA. The fruit yield was also increased, which may be due to longer and more numerous flowering shoots. The increase in percentage of oil in the fruits suggests the possibility that GA may enhance the biosynthesis of essential oils in certain specific organs by either increasing the size and number of the cells which store the essential oil or prolonging the process of synthesis of oil. The ascaridole content in the oil fractions was not, however, altered appreciably by GA treatment but the increase in oil percentage in the chenopodium and anethum is in contrast with the observations on *Mentha spicata* (5) and *M. arvensis* (6) where the percentage of oil was decreased following GA treatment. The difference in behavior by the two categories of aromatic plants is of interest and needs further study.

The observations of Stevens, *et al.* (3), and Kaul and Kapoor (4) suggest that the increase may be due to prolonged biosynthesis of volatile oil and also the increased cell dimensions in the fruits containing the oil.

SUMMARY

1. The plants of *Chenopodium ambrosioides* Linne var. *anthelminticum* responded favorably to the treatment of GA.

2. It induced 25 and 33% increase in the volatile oil and the yield of the fruits, respectively.

3. GA did not appreciably alter the ascaridole content of the oil fractions from the various treatments.

4. The increased yield of fruits was due to increased number of axillary shoots which consequently bore more fruits.

5. The increased oil content in the treated plants may be due to increased cell size of fruits or prolonged biosynthesis of the essential oil.

A Modified Method for Preparing Litmus Solution

Sir:

The procedure prescribed by N.F. XI for the preparation of litmus T.S. (1) is tedious and results in a product which is subject to deterioration due to microbial growth. These difficulties may be removed by (*a*) preparing the solution by means of a continuous extractor and (*b*) dehydrating the product by means of freeze-drying. The resulting powder is not subject to microbial growth and may be used to prepare the test solution as needed. The following extraction procedure was used: Place 25 Gm. of powdered litmus in a paper extraction thimble and insert the thimble into a Soxhlet extractor. Add sufficient alcohol to allow for free siphoning into the receiving flask, immerse the flask up to its neck in a steam bath, adjusting the flow of steam to maintain the extracting alcohol at a gentle boil, and continue the extraction for 3 hours. Raise the Soxhlet apparatus so the steam heats enough of the receiving flask to boil only the alcohol in the flask and permit the extraction to continue with the condensor-cooled alcohol for 30 minutes. Draw off all the alcohol in the system and discard. Reassemble the apparatus as it was originally, add sufficient water, arrange for heating with a Bunsen burner, and wash the litmus powder with reflux-cooled water for 3 hours. Discard the water. Remove the extraction thimble with the litmus powder from the extractor, place it in the emptied receiving flask,

A Modified Method for Preparing Litmus Solution

Sir:

The procedure prescribed by N.F. XI for the preparation of litmus T.S. (1) is tedious and results in a product which is subject to deterioration due to microbial growth. These difficulties may be removed by (*a*) preparing the solution by means of a continuous extractor and (*b*) dehydrating the product by means of freeze-drying. The resulting powder is not subject to microbial growth and may be used to prepare the test solution as needed. The following extraction procedure was used: Place 25 Gm. of powdered litmus in a paper extraction thimble and insert the thimble into a Soxhlet extractor. Add sufficient alcohol to allow for free siphoning into the receiving flask, immerse the flask up to its neck in a steam bath, adjusting the flow of steam to maintain the extracting alcohol at a gentle boil, and continue the extraction for 3 hours. Raise the Soxhlet apparatus so the steam heats enough of the receiving flask to boil only the alcohol in the flask and permit the extraction to continue with the condensor-cooled alcohol for 30 minutes. Draw off all the alcohol in the system and discard. Reassemble the apparatus as it was originally, add sufficient water, arrange for heating with a Bunsen burner, and wash the litmus powder with reflux-cooled water for 3 hours. Discard the water. Remove the extraction thimble with the litmus powder from the extractor, place it in the emptied receiving flask,

and add 100 ml. of water. Attach a reflux water-cooled condensor to the flask and reflux for 1 hour over a Bunsen burner. Cool the solution and filter. Measure the volume of filtrate collected, and if necessary, add water to make 100 ml. This constitutes the litmus solution.

While the above procedure appears lengthy, it requires for the most part only cursory supervision during the various stages of extraction. The entire extraction, both with alcohol and with water, takes place in the same apparatus using only 75 ml. of alcohol.

The resulting solution can be used as such; but if the volume is more than is required for immediate use, it may be freeze-dried and kept until needed. It is feasible to freeze-dry 100 ml. of the solution in the VirTis freeze-dryer. No doubt other types of dryers are also suitable for this purpose.

The yield of dried residue from 100 ml. of extract is 500 ±2 mg. so that reconstitution can be effected by dissolving the powder in water in the proportion of 5 mg. per ml. Dried material so obtained has not been noted to undergo any change on storage for 12 months.

The Absolute Configuration of (-)-N-[2-(Methylbenzylamino)-propyl]-propionanilide

Sir:

The importance of configurational factors on the activity of various synthetic analgesics has been illustrated by several investigators (1–6). These studies have shown that nearly all the activity resides in only one of the enantiomorphs. Beckett (7–10) has determined that the more active enantiomorphs of methadone-type and thiambutene-type analgesics possess the D-configuration. Though there are only a few classes of analgesics of known absolute configuration, a hypothesis has been proposed which attempts to explain this antipodal specificity on the basis of three point contact with a specific receptor in which only one antipode can fit properly (7). The above findings and speculations have prompted us to determine the absolute configuration of (-)-N-[2-(methylbenzylamino)propyl]-propionanilide (I) (11), a member of a new class of potent analgesics (12). We have related the absolute configuration of I to D-alanine by the following sequence

The above findings and speculations have prompted us to determine the absolute configuration of (-)-N-[2-(methylbenzylamino)propyl]-propionanilide (I) (11), a member of a new class of potent analgesics (12). We have related the absolute configuration of I to D-alanine by the following sequence

D-Carbobenzoxyalanine (II) (13) was converted to the corresponding anilide (III), m.p. 162–164°, $[\alpha]_D^{30°}$ +28.4° (c 5% in HOAc), by the action of dicyclohexylcarbodiimide.

Anal.—Calcd. for $C_{17}H_{19}N_2O_3$: C, 67.96; H, 6.38; N, 9.32. Found: C, 68.19; H, 6.13; N, 9.66.

Reduction of III with lithium aluminum hydride in tetrahydrofuran afforded the hygroscopic diamine (IV), m.p. 35–36.5°, b.p. 67–71° (0.1 mm.), $[\alpha]_D^{30°}$ −29.2° (c 5% in ethanol). This compound was analyzed as the dipicrate, m.p. 143–144.5°.

Anal.—Calcd. for $C_{22}H_{22}N_8O_{14}$: C, 42.43; H, 3.56; N, 18.00. Found: C, 42.49; H, 3.60; N, 18.23.

The DL-alkylene diamine (V), m.p. 42–44°, was prepared according to the procedure of Wright, Brabander, and Hardy (11, 12). This compound was previously reported as an oil. Optical resolution of V was accomplished *via* its *d*-bitartrate salt. Five recrystallizations from ethanol afforded a bitartrate, m.p. 101–103°, of high purity. Treatment of the bitartrate with aqueous sodium hydroxide regenerated the resolved diamine (V), m.p. 59–61°, $[\alpha]_D^{27°}$ + 31.2° (c 5% in ethanol). The compound formed a monopicrate, m.p. 168–169°.

Anal.—Calcd. for $C_{23}H_{25}N_5O_7$: C, 57.11; H, 5.21; N, 14.48. Found: C, 56.84; H, 5.33; N, 14.38.

Catalytic hydrogenolysis of the resolved (+)-diamine (V) with palladium-on-carbon catalyst at 40 p.s.i. produced diamine IV, $[\alpha]_D^{27°}$ −29.5°, m.p. 34–35°. The infrared spectrum, gas chromatographic retention time, and dipicrate all were identical with those of diamine IV derived from D-alanine.

Treatment of the D-(+)-diamine (V) with propionic anhydride afforded the D-(−)-enantiomer of I, $[\alpha]_D^{27°}$ −45.7° (c 5% in ethanol), b.p. 152–157° (0.3 mm.). This compound exhibited an infrared spectrum and retention time which is identical with racemic I (11). Wright, Brabander, and Hardy (14) have independently prepared the (+)- and (−)-enantiomers of I. Our physical constants are in agreement with their data.

The analgesic potency ratio between the D- and L-forms will be the subject of a future communication.

Studies on the Mechanism of Biotin Action

Sir:

Biotin has been implicated as an essential factor in a wide variety of carboxylation reactions in biosynthetic pathways, but the exact mechanism by which biotin functions remains unknown. For example, in the biosynthesis of purines, it has been suggested (1) that biotin is required in the carboxylation of 5-aminoimidazole ribotide to 5-aminoimidazole 4-carboxylic acid ribotide, which after several further reactions is converted into inosinic acid. Also, in the preliminary steps of fatty acid synthesis, it has been shown that a biotin-containing enzyme is involved in carboxylation of acetyl CoA to malonyl CoA (2). Studies of fatty acid synthesis in certain cell-free extracts have demonstrated that carbon dioxide is activated by a biotin-containing enzyme and that the activated $CO_2 \sim$ biotin-enzyme complex acts as the carboxylating reagent (3). It is unlikely that the carboxyl group of biotin is transferred in this carboxylation reaction since it is known that biotin is covalently bound to protein, probably through an amide linkage to the ϵ-amino group of lysine (4). We have felt that the most logical manner in which carbon dioxide could be activated by biotin is *via* one of the nitrogens of the imidazolidine ring. Recently, evidence has ac-

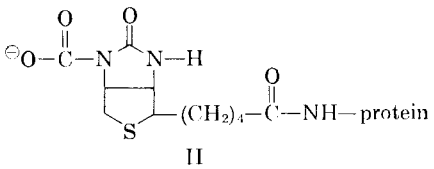
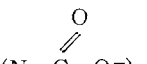
Studies on the Mechanism of Biotin Action

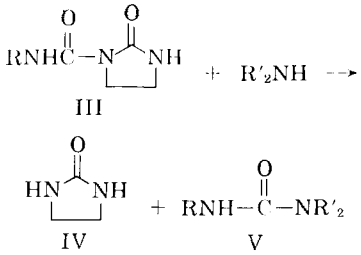


Sir:

Biotin has been implicated as an essential factor in a wide variety of carboxylation reactions in biosynthetic pathways, but the exact mechanism by which biotin functions remains unknown. For example, in the biosynthesis of purines, it has been suggested (1) that biotin is required in the carboxylation of 5-aminoimidazole ribotide to 5-aminoimidazole 4-carboxylic acid ribotide, which after several further reactions is converted into inosinic acid. Also, in the preliminary steps of fatty acid synthesis, it has been shown that a biotin-containing enzyme is involved in carboxylation of acetyl CoA to malonyl CoA (2). Studies of fatty acid synthesis in certain cell-free extracts have demonstrated that carbon dioxide is activated by a biotin-containing enzyme and that the activated $CO_2 \sim$ biotin-enzyme complex acts as the carboxylating reagent (3). It is unlikely that the carboxyl group of biotin is transferred in this carboxylation reaction since it is known that biotin is covalently bound to protein, probably through an amide linkage to the ϵ-amino group of lysine (4). We have felt that the most logical manner in which carbon dioxide could be activated by biotin is *via* one of the nitrogens of the imidazolidine ring. Recently, evidence has ac-



cumulated (3) concerning a biotin-containing enzyme which can utilize free D-biotin as its substrate to give an unstable product which could not be directly characterized but, after treatment with diazomethane, gave the methyl ester of N-carbomethoxybiotin (I) (5). This observation has led to the suggestion (5) that the chemical structure of the $CO_2 \sim$ biotin-enzyme complex may be represented by II.



I

II

Compounds with structure  related to II are known to be very unstable and undergo decarboxylation with extreme ease. Therefore, it is probable that the actual structure of the $CO_2 \sim$ biotin-enzyme complex is not one in which the carboxylate anion is present as such but rather one in which the carboxylate anion of biotin has been partially stabilized by reaction with the associated protein. Thus, we visualize these carboxylation reactions as involving the following steps: (*a*) formation of a $CO_2 \sim$ biotin-enzyme complex, (*b*) temporary stabilization of the complex by reaction of the carboxylate anion with a functional group of the associated protein, such as an amino or hydroxyl group, and (*c*) transfer of the carboxyl group to an attacking nucleophilic agent, which would produce the corresponding carboxylic acid and regenerate the biotin-containing enzyme.

In order to gain more information about the mechanism of this reaction, we have undertaken a study of the transfer of a carbonyl group to an attacking nucleophilic reagent using model compounds related to the proposed $CO_2 \sim$ biotin-enzyme complex; *i.e.*, we have studied step (*c*) of the biochemical carboxylation reaction. Because of the instability of compounds with the general structure II, it was necessary to use model compounds which would not undergo spontaneous decarboxylation. The simplest model systems for such a study are the N-substituted derivatives of 2-imidazolidone (III).

III IV V

The model compounds which we chose for our initial study were those in which *R* in III was *p*-methoxyphenyl, phenyl, or *p*-nitrophenyl, and the nucleophilic reagents were morpholine or piperidine.

In a typical experiment, 2-imidazolidone was allowed to react with *p*-methoxyphenyl isocyanate to give a good yield of N-*p*-methoxyphenylcarbamyl-2-imidazolidone (m.p. 175–176°).

Anal.—Calcd. for $C_{11}H_{13}N_3O_3$: C, 56.11; H, 5.52; N, 17.86. Found: C, 56.46; H, 5.28; N, 17.86.

When N-*p* methoxyphenylcarbamyl-2-imidazolidone was allowed to react with morpholine at reflux temperature, the model compound was cleaved to give 2-imidazolidone (IV) and the corresponding urea (V) (m.p. 124–125° in agreement with the literature value (6)).

These reactions represent examples of the transfer of a carbonyl group from model compounds, which are related to the proposed $CO_2 \sim$ biotin-enzyme complex, to a nucleophilic reagent. Although the rate of these reactions is relatively low, experiments with other model compounds and other nucleophilic reagents are in progress in which we hope to observe more facile transfer of the carbonyl group. Nevertheless, the transfer of carbonyl groups in model compounds offers support to the proposed mechanism of action of biotin involving the complex represented by II.

PARMATMA S. BHARGAVA

Department of Medicinal Chemistry
School of Pharmacy
The University of Buffalo
Buffalo, New York

Received August 3, 1962.
Accepted for publication September 17, 1962.
This investigation was supported by Research Grant RG-9775 from the National Cancer Institute, National Institutes of Health, Public Health Service.
Abstracted in part from research by Parmatma S. Bhargava in partial fulfillment of the M. S. degree requirements.

Book Notices

Tumor Viruses of Murine Origin. Edited by G. E. W. WOLSTENHOLME and MAEVE O'CONNOR. Little Brown and Company, 34 Beacon St., Boston 6, Mass., 1962. xiii + 441 pp. 13.5 × 20 cm. Price $10.75.

Another volume in the Ciba Foundation Symposium series which contains the discussion and recent experience of 27 investigators on murine viruses in the mechanism of carcinogenesis. Seventy-two illustrations assist in evaluating and better understanding the presentations and discussions. Extensive author and subject indices permit ready access to both the presentations and discussion comments of each of the participants. This volume also contains the proceedings of two group discussions: a summarization of the symposium and prospects for further research, and the relevance of the proceedings to cancer causation in man.

Enzymes and Drug Action. Edited by A. V. S. DE REUCK and J. L. MONGAR. Little Brown and Company, 34 Beacon St., Boston 6, Mass., 1962. xv + 556 pp. 13.5 × 20 cm. Price $12.50.

The eigth volume of the Ciba Foundation Symposium series organized by the Coordinating Committee for Symposia on Drug Action reports the proceedings of two simultaneous meetings involving 71 participants on evolving concepts in biochemistry which are most likely to be of importance for future advances in pharmacology. Session headings of one of the meetings include enzymes as primary points of drug action, active transport, multiple mechanisms, receptors, altered drug metabolism, and drug metabolism: subcellular aspects. The other meeting concerned itself with drug-enzyme interaction at the molecular level and topic headings include enzymes, receptors, and interaction at the subcellular and cellular levels.

Kurzes Lehrbuch der Pharmaczeutischen Chemie, Auch Zum Bebrauch Fur Mediziner. 6th ed. By K. BODENDORF. Springer-Verlag, Berlin-Wilmersdorf, Heidelberger Platz 3, West Berlin, 1962. viii + 504 pp. 17 × 24.5 cm. Price DM 37.50.

As indicated in its title, this is a textbook (in German) on pharmaceutical chemistry intended for pharmacists and physicians. It contains material on both organic and inorganic chemistry and is thoroughly indexed.

Methoden der Organischen Chemie (Houben-Weyl). 5th vol. of the new series. Band V/3, Halogenverbindungen. Edited by EUGEN MULLER. Georg Thieme Verlag, 7000 Stuttgart 1, Germany, Postfach 732, Herdweg 63, 1962. Agents in U. S. and Canada, Intercontinental Book Corp., 381 Fourth Ave., New York 16, N. Y. xlix + 1217 pp. 17 × 25.5 cm. Price DM 262.

This is another volume (in German) in a long recognized standard reference series. Volume 5 deals with fluorine and chlorine in a comprehensive manner. This treatise abounds with references to the literature throughout the text and includes subject and author indexes.

Handbuch der Kolorimetrie, Kolorimetrie in der Pharmazie. Band I. Vol. 1. By BOHUMIL KAKÁČ and ZDENĚK J. VEJDĚLEK. Veb Gustav Fischer Verlag, Jenna/DDR, Villengang 2, Postfach 176, Germany, 1962. xv + 1139 pp. 16.5 × 24 cm. Price DM 79.20.

This is the first volume (in German) of a three volume encyclopedia on colorimetry. It contains laboratory procedures and methods in great detail, for alkaloids, glycosides and aglycones, other plant constituents, vitamins, and antibiotics. Under individual listings, a discussion of the procedure as well as criticisms of the methods with literature references is included.

Analyse des Stéroïdes Hormonaux. Méthodes de dosage. Tome II. Vol. 2. By M. F. JAYLE. Masson et Cie, Editeurs, 120 boulevard Saint-Germain, Paris VIe, France, 1962. 498 pp. 16.5 × 24.5 cm. Price 80 NF.

This second volume of a three volume series (in French) on the analysis of steroids covers four major groups of steroids which are the 17-cetosteroids, corticosteroids, pregnandiol, and phenolsteroids. Methods of analyses and discussions of the methods are included in each chapter.

Liofilizzazione. Note Teorico-pratiche. By LUIGI CALCAGNO. Istituto Editoriale Cisalpino, Milano-Varese, Italy, 1962. 444 pp. 16 × 23.5 cm. Price Lire 9000.

A survey of the theory and practice of lyophilization methods and procedures is presented (in Italian) in this book. A rather extensive bibliography, covering nearly 70 pages, keyed to eight general categories is appended and arranged alphabetically by author. Many of the references are in English.

Le Compresse Farmaceutiche. Preparazione, Copertura, Formulario. By ENZO ROTTEGLIA. Società Editoriale Farmaceutica, Via California 21, Milano, Italy, 1962. 432 pp. 16.5 × 24.5 cm. Price L. 7500.

This volume (in Italian) treats, in some detail, the preparation and coating of pharmaceutical tablets. One section of the book consisting of over 100 pages contains tablet formulas with references to the various source compendia. Adequate author and subject indexes are appended.

Introduction to Immunochemical Specificity. By WILLIAM C. BOYD. John Wiley & Sons, Interscience Division, 440 Park Ave. South, New York 16, N. Y., 1962. vii + 158 pp. 15 × 23 cm. Price $8.

Some of the important modern advances in the field of immunochemical specificity are discussed in the text of this book, which is based primarily on a series of lectures given by the author in 1959. The subjects included are: Antibodies I and II, Antigens Blood groups, Plant agglutinins I and II, Blood group antigens, Salmonella antigens, Union of antibody with antigen (thermodynamics), and Energy of antibody-antigen reactions.

Tumor Viruses of Murine Origin. Edited by G. E. W. WOLSTENHOLME and MAEVE O'CONNOR. Little Brown and Company, 34 Beacon St., Boston 6, Mass., 1962. xiii + 441 pp. 13.5 × 20 cm. Price $10.75.

Another volume in the Ciba Foundation Symposium series which contains the discussion and recent experience of 27 investigators on murine viruses in the mechanism of carcinogenesis. Seventy-two illustrations assist in evaluating and better understanding the presentations and discussions. Extensive author and subject indices permit ready access to both the presentations and discussion comments of each of the participants. This volume also contains the proceedings of two group discussions: a summarization of the symposium and prospects for further research, and the relevance of the proceedings to cancer causation in man.

Enzymes and Drug Action. Edited by A. V. S. DE REUCK and J. L. MONGAR. Little Brown and Company, 34 Beacon St., Boston 6, Mass., 1962. xv + 556 pp. 13.5 × 20 cm. Price $12.50.

The eigth volume of the Ciba Foundation Symposium series organized by the Coordinating Committee for Symposia on Drug Action reports the proceedings of two simultaneous meetings involving 71 participants on evolving concepts in biochemistry which are most likely to be of importance for future advances in pharmacology. Session headings of one of the meetings include enzymes as primary points of drug action, active transport, multiple mechanisms, receptors, altered drug metabolism, and drug metabolism: subcellular aspects. The other meeting concerned itself with drug-enzyme interaction at the molecular level and topic headings include enzymes, receptors, and interaction at the subcellular and cellular levels.

Kurzes Lehrbuch der Pharmaczeutischen Chemie, Auch Zum Bebrauch Fur Mediziner. 6th ed. By K. BODENDORF. Springer-Verlag, Berlin-Wilmersdorf, Heidelberger Platz 3, West Berlin, 1962. viii + 504 pp. 17 × 24.5 cm. Price DM 37.50.

As indicated in its title, this is a textbook (in German) on pharmaceutical chemistry intended for pharmacists and physicians. It contains material on both organic and inorganic chemistry and is thoroughly indexed.

Methoden der Organischen Chemie (Houben-Weyl). 5th vol. of the new series. Band V/3, Halogenverbindungen. Edited by EUGEN MULLER. Georg Thieme Verlag, 7000 Stuttgart 1, Germany, Postfach 732, Herdweg 63, 1962. Agents in U. S. and Canada, Intercontinental Book Corp., 381 Fourth Ave., New York 16, N. Y. xlix + 1217 pp. 17 × 25.5 cm. Price DM 262.

This is another volume (in German) in a long recognized standard reference series. Volume 5 deals with fluorine and chlorine in a comprehensive manner. This treatise abounds with references to the literature throughout the text and includes subject and author indexes.

Handbuch der Kolorimetrie, Kolorimetrie in der Pharmazie. Band I. Vol. 1. By BOHUMIL KAKÁČ and ZDENĚK J. VEJDĚLEK. Veb Gustav Fischer Verlag, Jenna/DDR, Villengang 2, Postfach 176, Germany, 1962. xv + 1139 pp. 16.5 × 24 cm. Price DM 79.20.

This is the first volume (in German) of a three volume encyclopedia on colorimetry. It contains laboratory procedures and methods in great detail, for alkaloids, glycosides and aglycones, other plant constituents, vitamins, and antibiotics. Under individual listings, a discussion of the procedure as well as criticisms of the methods with literature references is included.

Analyse des Stéroïdes Hormonaux. Méthodes de dosage. Tome II. Vol. 2. By M. F. JAYLE. Masson et Cie, Editeurs, 120 boulevard Saint-Germain, Paris VIe, France, 1962. 498 pp. 16.5 × 24.5 cm. Price 80 NF.

This second volume of a three volume series (in French) on the analysis of steroids covers four major groups of steroids which are the 17-cetosteroids, corticosteroids, pregnandiol, and phenolsteroids. Methods of analyses and discussions of the methods are included in each chapter.

Liofilizzazione. Note Teorico-pratiche. By LUIGI CALCAGNO. Istituto Editoriale Cisalpino, Milano-Varese, Italy, 1962. 444 pp. 16 × 23.5 cm. Price Lire 9000.

A survey of the theory and practice of lyophilization methods and procedures is presented (in Italian) in this book. A rather extensive bibliography, covering nearly 70 pages, keyed to eight general categories is appended and arranged alphabetically by author. Many of the references are in English.

Le Compresse Farmaceutiche. Preparazione, Copertura, Formulario. By ENZO ROTTEGLIA. Società Editoriale Farmaceutica, Via California 21, Milano, Italy, 1962. 432 pp. 16.5 × 24.5 cm. Price L. 7500.

This volume (in Italian) treats, in some detail, the preparation and coating of pharmaceutical tablets. One section of the book consisting of over 100 pages contains tablet formulas with references to the various source compendia. Adequate author and subject indexes are appended.

Introduction to Immunochemical Specificity. By WILLIAM C. BOYD. John Wiley & Sons, Interscience Division, 440 Park Ave. South, New York 16, N. Y., 1962. vii + 158 pp. 15 × 23 cm. Price $8.

Some of the important modern advances in the field of immunochemical specificity are discussed in the text of this book, which is based primarily on a series of lectures given by the author in 1959. The subjects included are: Antibodies I and II, Antigens Blood groups, Plant agglutinins I and II, Blood group antigens, Salmonella antigens, Union of antibody with antigen (thermodynamics), and Energy of antibody-antigen reactions.

Review Article

Pharmaceutics of Penicillin

By M. A. SCHWARTZ and F. H. BUCKWALTER

PROBABLY no group of drugs has received more attention and been more intensively studied than the penicillins (I).

(I)

Their basic structure includes a double ring thiazolidine β-lactam moiety which has been named 6-aminopenicillanic acid (6-APA). The differences in the physical, chemical, and biological properties of the various penicillins are due to their side chains (R in I).

The β-lactam ring is quite labile in all the penicillins known at present. Differences in stability of the several penicillins are determined by the side chains, the structural characteristics of which confer varying degrees of protection against degradation.

Before the isolation of 6-APA from fermentation broths by a group at the Beecham Laboratories in England in 1958 (1), complete penicillins could be made commercially only by fermentation, and variations in the side chain were made by the addition of appropriate precursors to the fermentation broth. This severely limited the number and types of penicillins which could be produced. Since 1958, however, penicillins have achieved a revived importance in chemotherapy because now, theoretically any side chain may be linked by chemical means with the 6-APA nucleus to form a new penicillin. In addition, other workers (2–4*a*) have found enzymes which will selectively hydrolyze penicillin at the amide linkage to produce 6-APA.

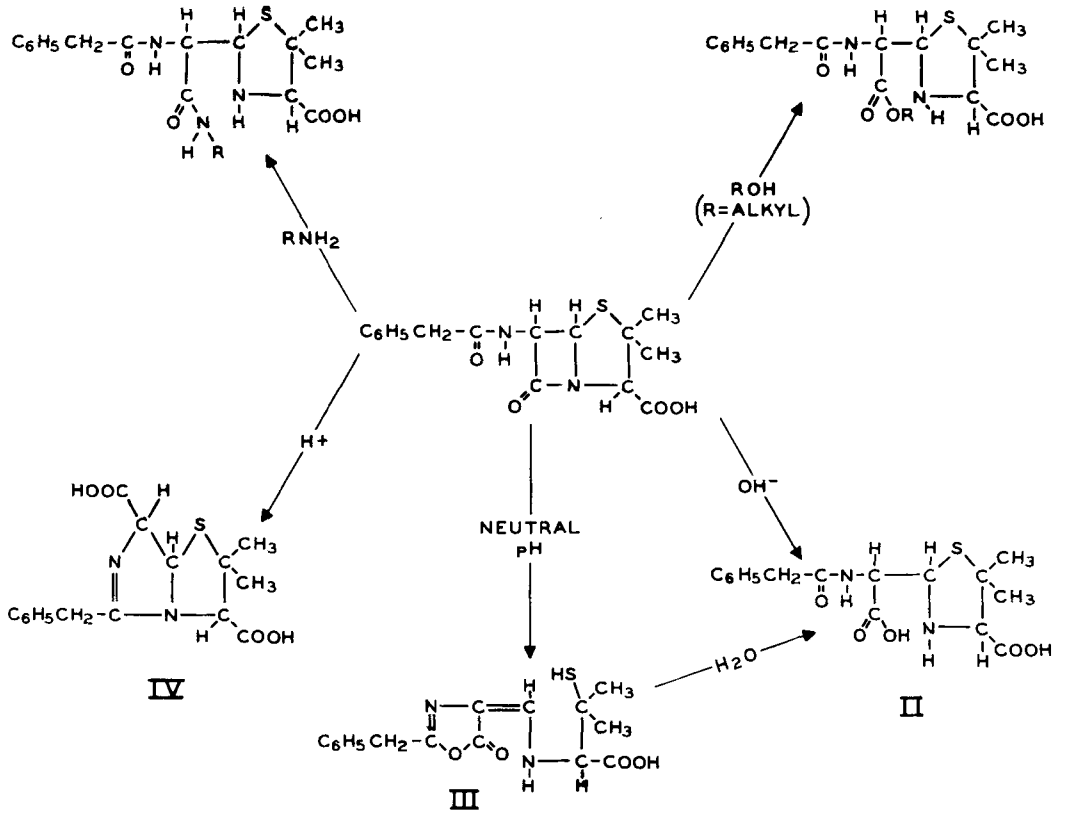
Because of this revived interest in penicillins, their stability and incompatibilities with other medicinals have become of major importance to pharmacists in every area of the profession. It is the purpose of this paper to review and correlate all the available data on penicillin stability. Penicillin G (I, R = $C_6H_5CH_2$—), on which most of the work has been done, will be discussed first, and then the newer penicillins compared with it.

PENICILLIN G

Routes of Degradation.—Figure 1 depicts the major routes of degradation of penicillin G of importance in pharmaceuticals. In neutral or alkaline medium it is hydrolyzed at the β-lactam to penicilloic acid (II) (5). The reaction at constant temperature and pH is first order with respect to penicillin and is directly proportional to hydroxyl ion concentration (6). Benzylpenicillin is much more reactive toward alkali than simpler β-lactams, and this has been attributed to facilitation of hydrolysis by the sulfur bonded to the β-lactam ring and/or fusion of the β-lactam ring with a five-membered ring (7). The mechanism of this reaction in neutral solution is not completely understood, but several workers (8, 9) have obtained evidence from ultraviolet absorption data that it proceeds through penicillenic acid (III). This compound has been isolated and shown to have a maximum

Received from the Research Division, Bristol Laboratories, Syracuse, N. Y.

Presented, in part, to the Pharmaceutical Technology Section, A.PH.A., Las Vegas meeting, March 1962.



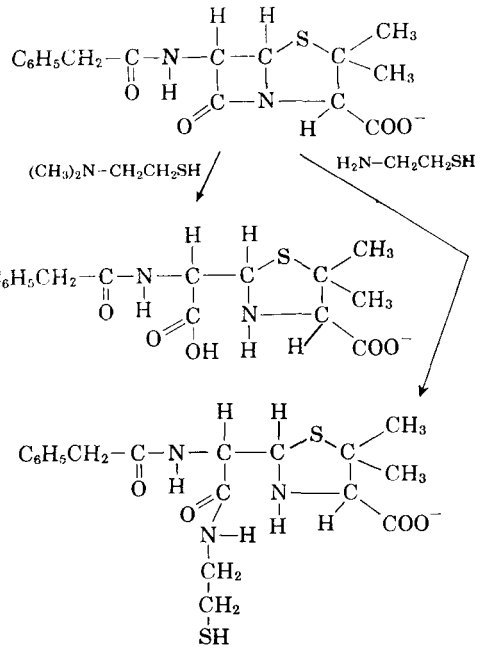


Fig. 1.—Major degradative reactions of penicillin.

in its ultraviolet absorption spectrum at 322 mμ (10). During hydrolysis of penicillin at pH 7.5 the absorption at 322 mμ increases, indicating the presence of this compound. It is rapidly converted to penicilloic acid with half-life, at pH 7.5 and 37°, of 6.5 minutes (10). The overall half-life of penicillin G under these conditions is about 60 hours. In strongly alkaline solution, penicillin G is probably hydrolyzed directly to penicilloic acid. In strong acid solution, penicillin is rearranged to penillic acid (IV) (5). At constant temperature and pH, this reaction is also first order (11) and depends on hydrogen ion concentration (12–14). This dependence is not linear due to the ionization of penicillin which has a pKa about 2.8 and, therefore, exists in two forms, free acid and ion, in the pH range from about 1.5 to 4.5. Each of these species is inactivated at a different rate, and this produces the curvature in the pH profile of Fig. 2. Similar pH dependence, although at different rates, has recently been demonstrated for phenethicillin (15) (I, R = C_6H_5OCH(CH$_3$)—) and this is also shown. Penicillins F, K, and X, all of which were made by fermentation, are also inactivated at different rates (16), but are not important therapeutically.

From the pH profile it may be observed that the pH of minimum degradation is about 6.5. This naturally is quite important in formulation of pharmaceuticals.

Penicillin reacts fairly rapidly with certain alcohols and amines to form the esters and amides, respectively, of penicilloic acid (5).

The reaction of penicillin with cysteine and some related mercaptoamines has been investigated from a mechanistic standpoint (17). With primary mercaptoamines, the products were found to be N-penicilloylamides, whereas with tertiary mercaptoamines the product was free penicilloic acid. From the pH dependence of the reaction it was concluded that the active species was a mercaptide ion and the rate-limiting step was formation of a semimercaptol intermediate. In the case of the primary mercaptoamines, this intermediate rearranged to the amide. With the tertiary mercaptoamine, amide formation was impossible and the product was penicilloic acid.

Some other reactions of penicillin of pharmaceutical interest will be discussed below in the section on imcompatibilities.

One other route of degradation which is more important therapeutically, but which deserves mention here, is the hydrolysis of penicillin by penicillinase. This enzyme is formed by certain microorganisms, notably certain strains of staphylococci, and rapidly catalyzes the hydrolysis of penicillin to penicilloic acid. The reaction is known to follow the usual Michaelis–Menten kinetics (18, 19). Certain compounds have been shown to inhibit penicillinase *in vitro* (20–24) but none of these has been used therapeutically.

STABILITY OF PENICILLIN IN DOSAGE FORMS

Solid Dosage Forms.—The most critical factor governing stability of penicillin in the solid state is moisture content. In one study of crystalline sodium penicillin G (25) it was shown that when the moisture content in vials was above 4%, significant loss of potency (40–80%) occurred after 6 months at 25°. This effect was much less pronounced at refrigerator temperature. Thus, the hygroscopic capacity of the powder and the type of closure on the vial are extremely important (26).

In the early days of penicillin amorphous forms of the salt were often used. It was generally found that the crystalline forms were much more stable than the amorphous, although this could not be correlated with moisture content (27). It was also found that the calcium salt was less hygroscopic than the sodium salt (28). Nevertheless, calcium penicillin has not seen wide usage.

A study of many commercial lots of crystalline sodium and potassium penicillin in vials showed that there were only slight losses (1.5–2%) after 3 years storage at room temperature (29). Thermolability of sodium penicillin has been followed by several workers (30, 31) and it was found that the antibiotic could be heated at 100° for 4 days with no more than 10% loss in activity. At temperatures over 140° however, loss was quite rapid.

Relatively insoluble amine salts of penicillin, such as the procaine and dibenzylethylenediamine salts, are also stable as dry powders for periods of 3 years or more at room temperature (32), as are combinations of procaine and potassium

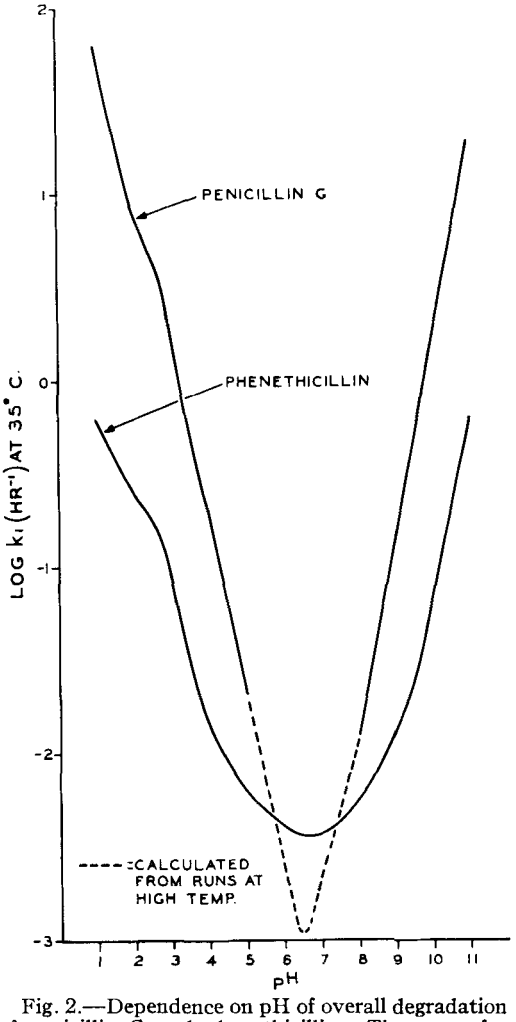

Fig. 2.—Dependence on pH of overall degradation of penicillin G and phenethicillin. The curve for penicillin G was taken from ref. 16.

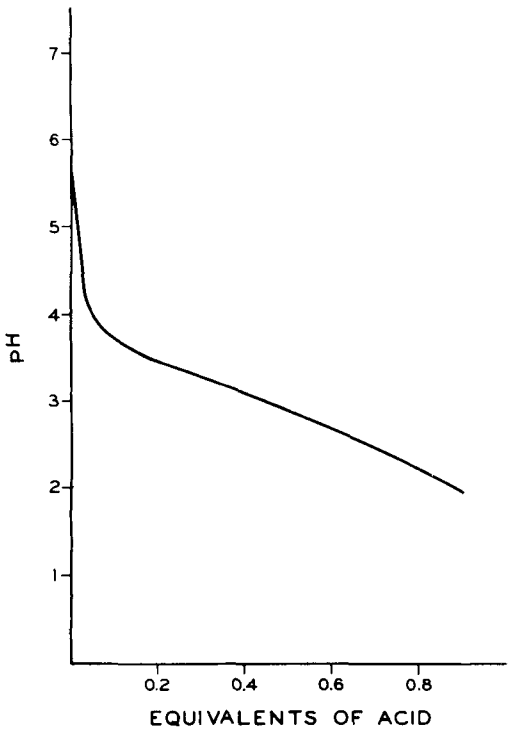
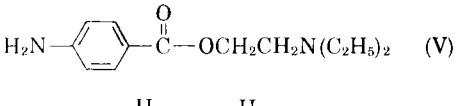
penicillins (33). Buffered penicillin powder, marketed for oral use after reconstitution with water, and combined with flavors, dyes, and sweeteners, was found to exhibit virtually no loss in potency after storage at room temperature for 4 years (34).

The stability of penicillin tablets is also dependent on moisture content. An early report (35) showed that tablets packaged with silica gel were much more stable than those packaged without the moisture absorber. Later it was shown that buffered penicillin tablets (36) and soluble tablets in hermetically sealed aluminum foil (37) were stable for at least 3 years, as were troches of potassium and procaine penicillin (38, 39). It has also been stated that sugar coating improves the stability of penicillin in tablets (40).

Liquid Dosage Forms.—As noted in referring to the kinetic studies of the degradation of penicillin in aqueous solution, the antibiotic is destroyed fairly rapidly and this reaction is catalyzed by both acid and base. It has been noted also that the reaction in neutral solution produces acid (penicilloic). From a glance at the titration curve of penicillin in Fig. 3 it can be seen that a small amount of acid will lower pH very rapidly. Thus, in a solution of penicillin in plain water, one may expect the rate of hydrolysis to increase as the initial reaction lowers pH to a point where the acid-catalyzed reaction becomes appreciable. It was recognized quite early that it was necessary to buffer solutions of penicillin near neutral pH in order to obtain optimum stability (41, 42). A controversy arose as to whether phosphate or citrate was the better buffer system. Hahn (43) claimed that citrate stabilized penicillin to a greater extent than would be indicated by its buffering action alone. He compared stability in citrate and phosphate buffer of the same pH and found that the solution in citrate buffer was more stable. Pulvertaft and Yudkin (44) claimed that phosphate also stabilized penicillin beyond its buffer effect yet, at the same time, showed that there existed an optimum concentration of phosphate for a particular concentration of penicillin. If phosphate were exerting some stabilizing effect, one would expect higher concentrations to stabilize even more so. The fact that higher concentrations caused less stability suggests that phosphate buffer had some catalytic effect on hydrolysis of penicillin. Pratt (45) found that phosphate buffers of a particular concentration stabilized penicillin better than lower concentrations, but found no difference in half-life when concentrations above his "optimum" were used. This indicates that the lower concentrations were simply of too low a buffer capacity for the concentration of penicillin used. Thomas (46) claimed that phosphate, citrate, and acetate buffers all stabilized penicillin. On the other hand, Macek, *et al.* (47), presented evidence which showed that the stabilizing effect of phosphates and citrates depends on their buffering action and not on any specific ion effect. Other workers (48, 49) have shown that increasing concentrations of penicillin require increasing concentrations of phosphates to maintain optimum stability. It thus appears that the action of buffers in stabilizing penicillin is strictly related to their ability to maintain pH. It should be noted here that the penicillin available at the time most of these studies were being done was of doubtful purity and the impurities may have been such as to cause some error. For example, buffer materials from the fermentation medium were often carried over to the final penicillin powder.





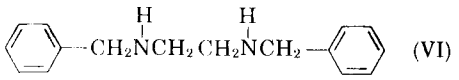


Fig. 3.—Titration curve of penicillin (potassium salt titrated with acid).

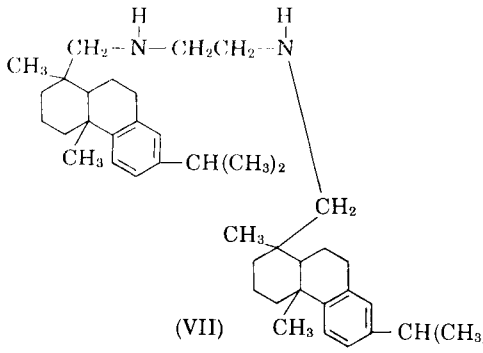
From what has already been said it is obvious that a solution of penicillin cannot, with present techniques, be made stable for more than about 2 weeks even at refrigerator temperatures. Partly for this reason, many sparingly soluble amine salts of penicillin were prepared. In these,



the protonated amine replaces the potassium or sodium of the soluble salt. Of these only a few have been marketed, *e.g.*, procaine (V), N,N′-dibenzylethylenediamine (VI), and N,N′-bis-(dehydroabietyl) ethylenediamine (VII). It was

(V)

(VI)

(VII)

found that suspensions of these salts in aqueous vehicles could be made stable for a year or more, allowing marketing of a "ready-made" penicillin product.

The stability of these salts in aqueous suspension is based mainly on their solubility and the rate of degradation of material in solution. A theoretical treatment of the solubility of these salts has been presented by Brunner (50, 51). He has derived equations by which one may calculate solubility as a function of pH, and pH of minimum solubility. These are based on mass-action law, a knowledge of the ionization constants of the amine and penicillin, and the solubility of the salt in pure water. The rate of loss of penicillin from a suspension in which the two phases are kept at equilibrium at constant temperature and pH will be pseudo zero order where the rate constant (k_0) will be the product of the first-order rate constant (k_1) for the material in solution, and the saturation concentration of penicillin under these conditions

$$\frac{-d(\text{Pen})}{dt} = k_0; \quad k_0 = k_1(\text{Pen})_{\text{sat.}}$$

Since the salt in solution is dissociated, or at least partly dissociated, some suppression of solubility may be achieved by the common ion effect. This has been demonstrated by Swintosky, *et al.* (52), with procaine penicillin by addition of procaine hydrochloride. These workers further reduced the solubility of the penicillin salt by the addition of salts and sorbitol to the vehicle. The rates of degradation of saturated solutions of procaine penicillin in this vehicle at several temperatures, as well as solubility as a function of temperature, were also measured (53). From these data predictions of long range stability of the product were made. These agreed fairly well with experimental values despite many assumptions made in the calculations.

While amine salts offered a means of stabilizing liquid penicillin preparations, generally their low solubility led to reduced penicillin serum levels after oral administration, as compared with those observed after oral administration of a soluble penicillin salt. It was demonstrated (54) that a stable oral liquid preparation of potassium penicillin could be made by suspending the salt in an edible, modified coconut oil. This preparation provided penicillin serum levels similar to those achieved with previously available preparations of the potassium salt.

Slawinska (55) showed that ultrasonic waves had a deleterious effect on stability of penicillin in aqueous solution, but not in paraffin suspension.

Stability in Ointments.—As is the case with powders and tablets, the stability of penicillin in ointment bases depends mostly on water content (56–58). In anhydrous bases the penicillin is relatively stable (59), whereas in emulsion bases the opposite is true. In Carbowax bases penicillin is also quite unstable (60, 61). Peroxides also appear to have a deleterious effect on penicillin stability. It was found that penicillin ointments made with peroxide-bleached bases lose about 30% potency in 7 months (62). If the peroxide value of petrolatum is kept below 0.06%, stability will be much greater (63). Procaine penicillin ointment made with a base consisting of peanut oil, beeswax, and petrolatum was stable for 4 years at room temperature (64).

INCOMPATIBILITIES OF PENICILLIN

Table I summarizes the reported incompatibilities of penicillin together with the appropriate literature references. As previously noted, penicillin is incompatible with acid and alkali and, in one sense, even with water. Any material which, when mixed with penicillin in solution, will change the pH away from the neutral region will be incompatible.

Generally alcohols, glycols, polyglycols, glycerin, and some sugars appear to react with

TABLE I.—INCOMPATIBILITIES OF PENICILLIN G

Type Compound	Reference
Oxidized cellulose	65
Chlorocresol	66
Glycerin and glycols	66–71
Heavy metals	72–76
Amines	77–80
Resorcinol	81
Zinc oxide	81, 82
Vitamin B_1	81
Procaine	81
Ephedrine	81, 83, 84
Iodine and iodides	81
Alcohols	71, 81, 85
Oxidizing agents	76, 79

Sugars	93, 94
Acids	82, 95
Aminoacridine hydrochloride	71
Thimerosal	71
Certain flavors	96

penicillin, probably by esterification of the potential acid group of the β-lactam, thereby forming biologically inactive penicilloates. Thiols act in a similar manner, although thiosulfate and metabisulfite have no deleterious effect (97). It has been reported, however, that penicillin is rapidly inactivated by sulfite and bisulfite (98). There was no sulfite found in the product and 82% of the original sulfite was recovered, indicating that some catalytic pathway is involved. Certain types of rubber tubing inactivate penicillin due to the presence of mercaptans from the vulcanization process (86, 87). Traces of heavy metals catalyze the hydrolysis and alcoholysis of penicillin. While the mechanism of this catalysis is not understood, it appears to involve the sulfur of the thiazolidine ring. Oxidizing agents also react with penicillin but the mechanism also is not known. The loss in activity might be caused by opening of the thiazolidine ring and oxidation of the sulfur to a sulfonic acid (penicillaminic acid) (76).

Amines may be incompatible with penicillin in two ways: precipitation of a salt if the latter is insoluble and/or reaction to form a penicilloamide.

STABILIZATION OF PENICILLIN

From the picture presented thus far, certain generalizations may be made concerning means of stabilization of penicillin in pharmaceutical preparations.

With solid dosage forms and ointments, the presence of water should be avoided to the maximum extent possible. This includes processing of materials during manufacture. It has been shown that dehydrating agents improve the stability of ointments containing up to 0.1% water (99).

The most important single factor in liquid formulations is pH control. Products made for solution will have maximum stability when pH is kept at about 6.5 by a buffer of sufficient capacity to maintain that pH throughout the useful life of the product.

With suspensions of amine salts, both solubility and rate of degradation are functions of pH, as shown in Fig. 4. The pH of optimum stability will be that at which the product of solubility and rate is a minimum. In addition, anything which reduces the solubility of the salt will aid stability, *e.g.*, addition of a soluble salt of the amine, salting out, etc. As a corollary, any substance which tends to solubilize the salt should be avoided in formulation. Since penicillin is known to react with certain amines, those chosen for preparation of insoluble salts should be unreactive toward the drug.

Claims have been made that several compounds "stabilize" penicillin in solution. Hobbs, for example, claimed that hexamine improved the stability of sodium penicillin G in solution (100). To the authors' knowledge this has not been refuted. When hexamine was added to a suspension of procaine penicillin, however, stability was decreased. This was due to some solubilization of the salt by the hexamine (101).

A German patent (102) claims the stabilization of penicillin solutions with soluble salts of 8-chlorotheophylline. The inventors claim a complex is formed in which the β-lactam is protected from hydrolysis. The preparation of this complex is given in a recent publication

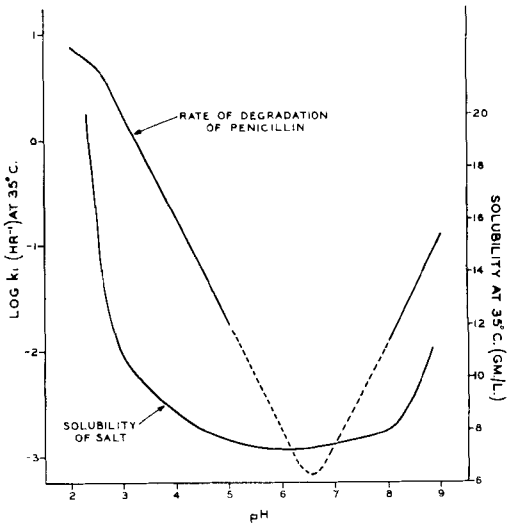

Fig. 4.—Solubility of procaine penicillin G and rate of degradation of penicillin G as functions of pH.

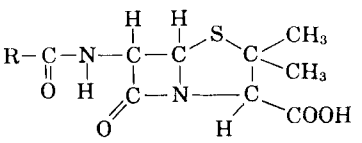
(103). Since the 8-chlorotheophylline is acidic, it is possible that this may be another case of a buffer effect causing stabilization. 8-Chlorotheophylline was ineffective as a stabilizer for phenethicillin in buffered solutions at pH 6.5 (104).

Aminopyrine (105) and sodium hexametaphosphate (76) also appeared to stabilize penicillin in solution, but again the comparisons were made with unbuffered solutions.

Paolini, *et al.* (106), have presented evidence to show that sodium sulfamethoxypyridazine "exerts a protective action against degradation of penicillin G sodium in aqueous solution at pH greater than 7." Their experiments however, were conducted in such a manner that pH dropped during each run, and this could have a significant effect on rate of hydrolysis. This is especially true above pH 7.5 where the rate becomes very highly pH dependent. Further work will be required to establish definitely whatever utility sulfonamides may have as stabilizers of penicillin.



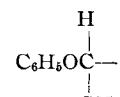
NEWER PENICILLINS

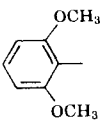
This section will compare the stability of the newer penicillins with penicillin G. For purposes of convenience penicillin V is included in this group although it should not be categorized with the synthetic penicillins. The chemical structures and nomenclature of these compounds are shown in Table II.

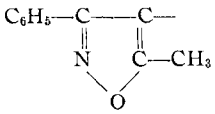
Acid Stability.—From a therapeutic standpoint, stability of penicillins to acid is quite important since it may be a limiting factor in oral effectiveness of the drugs. Table III gives the approximate half-life, at pH 1.3 and 35°, of several penicillins for which data are available. The most stable of these is ampicillin which has been recently marketed in Great Britain, the half-life being about 200 times that of penicillin G. This has been attributed to the electron attraction of the positively charged amino group which might be expected to hinder the electron displacements initiating rearrangement to the penillic acid (111). The authors also found a qualitative correlation between pKa of the side chain acids and acid stability of the penicillins. This should be useful in predicting acid stability of new penicillins, at least within a given structural group.

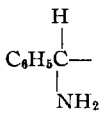
Stability in Pharmaceuticals.—As was the case with penicillin G, none of the newer penicillins is sufficiently stable in aqueous solution to

TABLE II.—NEWER PENICILLINS









R	Nonproprietary Name	Chemical Name	Trade Name
$C_6H_5OCH_2$—	Penicillin V	Phenoxymethyl-penicillin	V-Cillin, Lilly Pen-Vee, Wyeth
	Phenethicillin	α-Phenoxyethyl-penicillin (107)	Syncillin, Bristol Darcil, Wyeth Chemipen, Squibb Alpen, Schering Maxipen, Pfizer Rocillin, Rowell Semopen, Massengill Dramcillin-S, White
	Methicillin	2,6-Dimethoxy-phenylpenicillin (108)	Staphcillin, Bristol Dimocillin, Squibb
	Oxacillin	3-Phenyl-5-methyl-4-isoxazolylpenicillin (109)	Prostaphlin, Bristol Resistopen, Squibb
	Ampicillin	α-Aminobenzyl-penicillin (110)	Penbritin, Beecham Laboratories (Great Britian)

TABLE III.—ACID STABILITY OF PENICILLINS

Penicillin	Half-life, min.[a]	Reference
"G"	3.5	111
"V"	160	111
Phenethicillin	68[b]	15
Methicillin	2.3	112
α-Methoxybenzyl	77	111
α-Chlorobenzyl	300	111
Ampicillin	660	111
Oxacillin	160	112

[a] pH 1.3, 35°, in 50% alcohol. [b] In aqueous solution (no alcohol present).

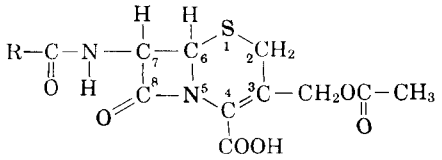
be marketed as such. The rate of degradation of phenethicillin in aqueous solution as a function of pH and temperature was investigated and found to follow the same general pattern as penicillin G, although the rates were slower (15). The pH of maximum stability was 6.5 and secondary phosphate ion was found to catalyze the loss of activity. Based on these data, a powder for reconstitution by the pharmacist at the time of dispensing was formulated. This lost only about 1% of its penicillin potency when reconstituted and stored for 2 weeks at refrigerator temperature (113). Phenethicillin in solution was studied in combination with 77 common liquid prescription preparations, most of which had no effect on stability for 3 days at 4° (113). Those which had the greatest effect were the products which changed the pH outside the range for maximum stability.

Methicillin is relatively unstable in aqueous solution. It has been reported that solutions kept at room temperature should be used within 12 hours of preparation and those stored at 4° within 24 hours (114). Work done in our own laboratories indicates that methicillin buffered with sodium citrate has much greater stability in solution.

Oxacillin is stable for about 24 hours at room temperature in aqueous solution buffered with sodium citrate (115).

Ampicillin, at neutral pH and room temperature, maintained 80% of its activity for 1 week (116). Whereas one would suspect that the other newer penicillins would show a dependence of rate of loss of activity on pH similar to that of penicillin G, one might also speculate that ampicillin might be different because of its zwitterionic character at almost neutral pH. From the reports available to date it appears to be the most stable penicillin available, in both acid and neutral solution.

Stability to Penicillinase.—It has been shown that the Michaelis constants for the catalysis of hydrolysis of these penicillins by staphylococcal penicillinase is in the order expected from previous experience with these drugs in treatment of infections caused by staphylococci resistant to penicillin G (117). That is, the greatest affinity for the enzyme is shown by penicillin G and the least by methicillin and oxacillin, the others being intermediate. Ampicillin is rapidly inactivated by penicillinase (112) but kinetic data are not available.



FUTURE PENICILLINS

Now that the means of making almost any penicillin is available, one may speculate on what the future may bring in this field. This might be done in terms of the properties desired in the ideal penicillin: (*a*) it should be active against a broad spectrum of microorganisms, including possibly fungi and viruses; (*b*) it should be sufficiently acid-stable so that it will not be destroyed in the stomach; (*c*) it should be rapidly and completely absorbed from all sites in the gastrointestinal tract, and slowly excreted; (*d*) it should not be strongly bound by serum protein; (*e*) it should be stable in aqueous solution; (*f*) it should be resistant to attack by penicillinase and/or other enzymes; (*g*) it should be nonallergenic; (*h*) it should be nontoxic.

Each of the newer penicillins has only two or three of these properties and, indeed, it may turn out to be impossible to make a single penicillin with all of them. Nevertheless, these criteria point the way for future research.

With regard to stability, it may be possible to make penicillins which will be stable in solution. In order to design such molecules further insight into the mechanisms of inactivation and the effects of structural changes upon these should be gained.

One group of compounds similar to the penicillins, but appearing to have much greater stability, are the cephalosporins. These are naturally occurring compounds which are derivatives of 7-aminocephalosporanic acid (VIII).

(VIII)

One of these, cephalosporin C

(R = H_3N^+—CH(—OOC)—$CH_2CH_2CH_2$—)

was found by Abraham and Newton (118) to inhibit competitively the hydrolysis of penicillin G by

penicillinase. These authors also isolated 7-aminocephalosporanic acid in very small quantities and acylated it with phenylacetyl chloride to obtain the derivative corresponding to penicillin G (119). This compound was several hundred times more active than cephalosporin C and yet resistant to hydrolysis by penicillinase. Apparently difficulties have been encountered which have prevented commercial production of these compounds thus far.

One other area which requires further exploration is the mechanism of action of penicillinase and the structural features of its active sites. This knowledge may enable us to design inhibitors of the enzyme.

SUMMARY

A survey of knowledge to date on stability of penicillins has been presented, including acid stability, stability in pharmaceutical preparations, and stability to the enzyme penicillinase. Incompatibilities and possible "stabilizers" were also discussed.

The side chain structure of the various penicillins endows each with different stability characteristics, although none available at present is sufficiently stable to allow marketing in solution.

Despite the great improvements in penicillins which have been made in the past 3 years, there is still much room for further work. With current ability to make structural modifications relatively easily, it is expected that even better penicillins will be seen in the future.

Availability of Ionic Iron from Iron Chelates

By WINTHROP E. LANGE, ALFRED G. BARNET†, and WILLIAM O. FOYE

Several commercial hematinic preparations have been tested for their ability to liberate ionic iron at different conditions of pH and in the presence of simulated gastric and intestinal fluids. A chromatographic method was employed in which both Fe(II) and Fe(III) ions were measured by means of absorbance determinations. It was concluded that chelated, or complexed, iron is carried through the gastrointestinal tract with less loss and lower toxicity than is ionic iron.

Some confusion exists regarding the requisites for the state of iron necessary for therapeutic use as a hematinic. Brading, *et al.* (1), for instance, have reported that more Fe(III) than Fe(II) was absorbed by rats fed inorganic Fe^{59}, and that the distribution in the tissues did not depend on either dose or valency of iron. Hartwig, *et al.* (2), also found that $Fe^{59}Cl_3$ was incorporated into new erythrocytes to a significantly greater degree than was Fe^{59}(II) citrate. Elsewhere it has been stated that only ferrous iron can be absorbed and that the ferric form must first be reduced before it can enter the gastrointestinal mucosa (3).

The advantages of chelated *vs.* inorganic iron for therapeutic use also appear to be in question. Franklin, *et al.* (4), claimed that chelation of iron minimized its toxicity and did not impair its hemopoietic response in humans. A difference in effectiveness of iron chelate preparations has been noted (5), however, which is evidently due to relative ease of liberation of ionic iron from iron chelates. Injectable ferric ammonium citrate, for instance, gave low hemoglobin levels and erythrocyte counts in weanling pigs in comparison with injectable iron-dextran, oral iron in

paste form, and ferrous sulfate. Only the ferrous sulfate maintained normal blood values.

It is well known that ferric chelates show much more stability than ferrous in regard to liberation of ionic iron, since Fe(III) falls well above Fe(II) in the Mellor-Maley and Irving-Williams series. Also, in regard to oxidation-reduction potentials, it is known that when a ligand is anionic, the higher valence state of the metal is favored (6). Furthermore, ferric iron in many of its chelates is more difficult to reduce than inorganic ferric ion (6, 7).

The foregoing facts lead obviously to questions regarding the availability of iron in hematinic preparations where chelating agents are employed, the possibility, or necessity, of reduction of Fe(III) to Fe(II), and the competition of the administered ligand with cellular ligands where iron chelates of sufficient liposolubility to penetrate cells are present. In order to look into some of these problems, several commercial hematinic chelates have been subjected to various conditions under which ionic iron might be liberated. A comparison has been made with inorganic Fe(II) and Fe(III), and chelates containing both Fe(II) and Fe(III) were included.

The possibility also exists of iron exchange between the administered chelate and the heme pigments, without liberation of ionic iron, since the porphyrins have such an extreme affinity for iron (as yet no measurement of iron-porphyrin stability constants has been possible). In this connection, however, Rubin (8) has shown that chelating agents of the EDTA type were unable to remove iron from siderophilin, and siderophilin was likewise unable to remove iron from the tighter chelates.

EXPERIMENTAL

Separation of Fe(II) and Fe(III) Ions.—The method of Stevens (9) was used with some modification. A chromatogram holder consisting of four glass tubes fitted with corks into which horizontal glass rods were inserted and held in place by rubber bands was constructed to avoid contamination from metal racks or clips. The developing solution was a mixture of 40 parts of *n*-butanol, 25 parts of ethanol, 25 parts of glacial acetic acid, and 35 parts of distilled water. The solvent was allowed to equilibrate in the tank overnight before use. Whatman No. 1 chromatography paper was cut into strips 15 in. by 2 in., washed with 2 *N* hydrochloric acid for 30 minutes, and rinsed with distilled water until a pH of 6.5 to 7 was reached. The strips were allowed to dry in air.

Solutions of $FeSO_4 \cdot 7H_2O$ and $Fe_2(NH_4)_2(SO_4)_2 \cdot 24H_2O$ were prepared to contain a concentration of approximately 1 mcg./μl. The pH of the ferrous sulfate solution was buffered to 4, and the ferric ammonium sulfate solution to 2.5, using saturated sodium acetate solution and sulfuric acid. This was done to minimize reduction and hydroxide formation. The solutions were spotted on the paper in 1 to 5 μl. amounts by means of a micropipet under a stream of warm air. The ferrous solution was spotted first and allowed to dry; the ferric solution was superimposed on the ferrous spot and allowed to dry. The strips were placed in contact with the developing solution and allowed to develop for 3.5 to 4 hours. The strips were removed, allowed to dry in air, and then exposed to water vapor containing a small amount of 8-hydroxyquinoline (oxine) from the side-arm of a distilling flask. The presence of Fe(II) and Fe(III) ions was indicated by green-black spots. The R_f value for Fe(III) was found to be 0.57, and that for Fe(II) was 0.24. The temperature was kept at 23–25°.

Preparation of a Standard Curve.—Exact quantities of 1 to 5 μl. of the standard solutions (containing 0.5 to 1.5 mcg. per μl.) were spotted on strips of Whatman No. 1 chromatography paper and placed in contact with the developing solution for 4 hours. The strips were removed and dried in air, and the spots were made visible by exposure to water vapor containing oxine. The strips were allowed to dry, and the maximum and minimum absorbances were determined using a Welsh Densichron densitometer, model 3853D, with a 3-mm. aperture. The minimum absorbance was that reading obtained from the paper itself. The average absorbance was determined by adding the maximum and minimum absorbances, dividing by two, and subtracting the paper blank. The areas of the spots were determined by tracing on graph paper and counting the squares, or by use of a planimeter.

Six to ten chromatograms were prepared for each known concentration, unsatisfactory results being discarded. An average of the results of the runs for each concentration was taken and the area multiplied by the average absorbance was plotted *vs.* the concentration.

Quantitative Determinations of Iron.—Each product or compound was analyzed under five different conditions: (*a*) untreated, (*b*) after treatment with stimulated gastric fluid U.S.P. XVI, (*c*) after treatment with simulated intestinal fluid U.S.P. XVI, (*d*) after treatment with 5 ml. of concentrated hydrochloric acid, and (*e*) after treatment with a solution of pH 7.5.

(*a*) *Untreated.*—An equivalent of the compound or product was diluted to 100 ml. with distilled water so that each microliter contained approximately 1 mcg. of iron. The paper strips were spotted in 1 to 5 μl. amounts and developed as described above. The average absorbances and areas of the spots were determined as described, and the concentration of iron read from the standard curve.

(*b*) *Treatment with Simulated Gastric Fluid.*—An equivalent of the compound or product was diluted to 100 ml. with simulated gastric fluid so that each microliter contained approximately 1 mcg. of iron. The solution was placed in a constant temperature bath for 1.5–2 hours at 37° with occasional agitation. The paper strips were spotted with 1 to 5 μl. amounts, and concentrations were determined.

(*c*) *Treatment with Simulated Intestinal Fluid.*—This procedure was carried out in the same manner as in (*b*).

(*d*) *Treatment with Concentrated Hydrochloric Acid.*—An amount of the compound or product was diluted with 5 ml. of hydrochloric acid and enough distilled water to make 100 ml. so that each microliter contained approximately 1 mcg. of iron. The solution was allowed to stand for 4 hours with occasional shaking, and paper strips were spotted with 1 to 5 µl. amounts. The remainder of the procedure was as described above.

(*e*) *Treatment with a Solution of pH 7.5.*—An amount of the product or compound was diluted to 100 ml. with an aqueous solution of pH 7.5, obtained with phosphate buffer, such that each microliter contained approximately 1 mcg. of iron. The solution was placed in a constant temperature bath at 37° for 1.5–2 hours with occasional agitation. The strips were spotted with 1 to 5 µl. amounts, and the concentrations of iron determined in the customary manner.

RESULTS AND DISCUSSION

In order to make comparisons of the amount of ionic iron liberated from commercial hematinic preparations under different conditions of acidity, a convenient assay procedure was required in which other components of the preparations, such as syrups, vitamins, coloring agents, calcium salts, phosphates, and the organic ligands, do not interfere. A chromatographic separation of Fe(II) and Fe(III) ions was carried out essentially as described by Stevens (9) except that ascending rather than descending development was employed. Quantitative estimation of the ionic iron liberated from the various commercial preparations and the inorganic iron salts selected as control compounds was based on techniques previously described by Block, Durrum, and Zweig (10). The method consisted primarily of measurement of area and absorbance of chromatographic spots of liberated ionic iron in the presence of oxine. A standard curve was drawn, plotting average absorbance times area *vs.* concentration and found to follow the Lambert-Beer law. A considerable number of volumes and concentrations were employed before optimum experimental conditions were determined.

Some difficulty was encountered in determining the areas of the spots, largely because of the contaminating ingredients present in the commercial preparations. Not only area, but also regularity and R_f value were affected, but employment of a sufficient number of determinations generally gave satisfactory average values. It was possible to determine ionic iron in amounts less than 0.5 mcg. per µl. by this procedure.

The relative amounts of ionic iron liberated under varying conditions of acidity: (*a*) without prior treatment, or after treatment with (*b*) simulated gastric fluid, (*c*) simulated intestinal fluid, (*d*) concentrated hydrochloric acid, and (*e*) aqueous solution of pH 7.5 were determined (see Table I). Treatment with concentrated hydrochloric acid was designed to liberate all of the iron present, and treatment with simulated gastric and intestinal fluids was carried out to determine effect of pH, pepsin, and pancreatin on the state of oxidation and release of ionic iron. Solutions of pH 7.5 were designed to show any effects due to pancreatin other than a pH effect. Treatment with simulated intestinal fluid and solution of pH 7.5 generally caused extreme tailing of the chromatographic spots, so these results are not included in Table I. The R_f value of the iron also was not reached in the former case, evidently due to combination of iron with pancreatin.

No significant change in oxidation state of iron was noted in any of the products under the conditions of acidity employed. Peptonized iron, ferrous gluconate, ferrous glycinate, and iron choline citrate all remained in the ferrous state, whereas the iron-carbohydrate complexes remained in the ferric state. The ferric complexes, as might be predicted, were the more stable and, in one instance, liberated no ionic iron even after treatment with simulated gastric fluid (pH 1.2). With the exception of the ferric-carbohydrate complexes, simulated gastric fluid liberated essentially all of the iron from the complexes studied.

It may be concluded that the more tightly bound ferric complexes are more successful in carrying iron through the gastrointestinal tract to the areas of absorption without loss of iron to pancreatin. Toxicity due to liberation of ionic iron should also be less with the more tightly bound complexes, and

Table I.—Assay Results of Various Iron Preparations

Product	Iron Present As	Oxidation State Found	Amount Recovered, %[a]		
			Hydrochloric Acid[b]	Untreated	Simulated Gastric Fluid
Livitamin with iron	Peptonized iron	+ +	97.00	59.86	108.47
Fergon compound elixir	Ferrous gluconate	+ +	90.00	76.99	90.85
Ferronord	Ferrous sulfate glycine complex	+ +	101.25	99.00	102.5
Imferon	Iron dextran complex	+ + +	92.40	0.0	25.80
Ferrolip	Iron choline citrate complex	+ +	96.00	69.50	94.67
Jefron elixir	Iron carbohydrate complex	+ + +	108.0	0.0	0.0
Saccharated iron oxide	Iron carbohydrate complex	+ + +	74.27	0.0	22.92
Ferrous sulfate[c]	...	+ +	99.63	100.0	97.64
Ferric ammonium sulfate	...	+ + +	99.51	100.0	98.06

[a] The percentages given are based upon the theoretical values given by the manufacturer. Iron concentrations could not be determined in alkaline media of pH 7.5 or simulated intestinal fluid. [b] The percentages given are the average values for a minimum of six determinations. [c] The percentages given are based upon the results of the findings of potassium permanganate assay.

there is already evidence to indicate that chelated iron is less toxic than ionic iron (4). In regard to subsequent distribution and utilization of iron, it may well be the case that chelation is a necessary requirement, since transport of ionic iron, *per se*, through cellular membranes is questionable. Release of iron from administered chelates to form hemoglobin should present no obstacle because of the known extreme affinity of porphyrins to chelate iron (11).

Composition of Gum Turpentines of Pines

Pinus nelsonii and *Pinus occidentalis*

By NICOLAS T. MIROV, EUGENE ZAVARIN†, and JOSEPH G. BICHO†

It was found that the turpentine of *Pinus nelsonii* contained 49.60% *l*-α-pinene, 41.50% *l*-β-pinene, 1.02 dipentene, 0.24% camphene, and 0.01% *n*-heptane. The remainder contained 3.74% of oxygenated substances derived mainly from terpenes (including probably some oxygenated sesquiterpenes); about 0.02% of unidentified, low-boiling materials, pot residue, and losses. The possible occurrence in *P. nelsonii* turpentine of the oxygenated materials should be rechecked, using freshly collected material. The identification of camphene and *n*-heptane must be considered as tentative, only. The turpentine of *Pinus occidentalis* contained 63.8% *d*-, *dl*-α-pinene, 22.2% *l*-β-pinene, 7.7% *d*-Δ³-carene, 1.8% methyl chavicol, 1.1% dipentene, 0.5 % *d*-longifolene, 0.3% linalool, 0.2% camphene, and 0.1% *n*-heptane, with the remaining 2.3% accounted for by unidentified terpenes, pot residue, and losses. The identification of the last four constituents must be considered only tentative.

PINUS NELSONII Shaw is a Mexican piñon or nut pine, growing in a few restricted localities in the desert ranges of Mexican states Tamaulipas, Nuevo Leon, Coahuila, and San Luis Potosí. It is a small bushy tree with long pliant branches, sparse gray-green foliage, and gray bark. Its three cohering needles give the impression of a single, slender needle. A sample of the oleoresin of this pine was received from Aramberri, Nuevo Leon, Mexico. The trees from which the oleoresin was procured grew at an elevation of about 7000 ft. in Valle Hermoso, Miquihuana, Tamaulipas. Herbarium specimens accompanied the oleoresin sample.

Pinus occidentalis Swartz is a pine of the Caribbean area. It grows in eastern Cuba and on the Island of Hispañola, both in the Dominican Republic and in Haiti. It is closely related to *Pinus caribaea* and also to other pines of Mexico and of the southeastern United States. A generous sample of oleoresin of this pine was collected in August of 1960 at Mare Range section of the Pine Forest, Haiti, courtesy of SHADA.

Received March 17, 1962, from the Maria Moors Cabot Foundation, Harvard University (a joint project with National Science Foundation).
Accepted for publication April 30, 1962.
Sincere thanks are extended to Sr. Don Erasmo Cerda of Aramberri, Nuevo Leon, Mexico, for the sample of oleoresin from *Pinus nelsonii* Shaw. We also express appreciation to Mr. Jay H. Hardee of the U. S. Operations Mission to Haiti for his assistance in procuring material of *P. occidentalis*.
† Forest Products Laboratory, University of California, Richmond.

DISCUSSION AND EXPERIMENTAL

Pinus Nelsonii

The turpentine was distilled under reduced pressure. Toward the end of the operation, the pressure was reduced to 2 mm. and the temperature reached 215°. At the end, small quanitities of distillate solidified in the condenser. The pot residue was hard and brittle, showing that all volatile components, including sesquiterpenes and their derivatives, were removed from the oleoresin. Yield of turpentine was 27.8%; its physical characteristics were: density, d_4^{25}, 0.8557; index of refraction, n_D^{25}, 1.4711; and specific rotation, $[\alpha]_{578}^{23}$ −38.5. This was reported by Mirov (1).

A charge of 309.7 Gm. of *P. nelsonii* turpentine was distilled through a 90 cm. long, 12 mm. inside

there is already evidence to indicate that chelated iron is less toxic than ionic iron (4). In regard to subsequent distribution and utilization of iron, it may well be the case that chelation is a necessary requirement, since transport of ionic iron, *per se*, through cellular membranes is questionable. Release of iron from administered chelates to form hemoglobin should present no obstacle because of the known extreme affinity of porphyrins to chelate iron (11).

Composition of Gum Turpentines of Pines

Pinus nelsonii and *Pinus occidentalis*

By NICOLAS T. MIROV, EUGENE ZAVARIN†, and JOSEPH G. BICHO†

It was found that the turpentine of *Pinus nelsonii* contained 49.60% *l*-α-pinene, 41.50% *l*-β-pinene, 1.02 dipentene, 0.24% camphene, and 0.01% *n*-heptane. The remainder contained 3.74% of oxygenated substances derived mainly from terpenes (including probably some oxygenated sesquiterpenes); about 0.02% of unidentified, low-boiling materials, pot residue, and losses. The possible occurrence in *P. nelsonii* turpentine of the oxygenated materials should be rechecked, using freshly collected material. The identification of camphene and *n*-heptane must be considered as tentative, only. The turpentine of *Pinus occidentalis* contained 63.8% *d*-, *dl*-α-pinene, 22.2% *l*-β-pinene, 7.7% *d*-Δ³-carene, 1.8% methyl chavicol, 1.1% dipentene, 0.5 % *d*-longifolene, 0.3% linalool, 0.2% camphene, and 0.1% *n*-heptane, with the remaining 2.3% accounted for by unidentified terpenes, pot residue, and losses. The identification of the last four constituents must be considered only tentative.

PINUS NELSONII Shaw is a Mexican piñon or nut pine, growing in a few restricted localities in the desert ranges of Mexican states Tamaulipas, Nuevo Leon, Coahuila, and San Luis Potosí. It is a small bushy tree with long pliant branches, sparse gray-green foliage, and gray bark. Its three cohering needles give the impression of a single, slender needle. A sample of the oleoresin of this pine was received from Aramberri, Nuevo Leon, Mexico. diameter Todd column packed with $^3/_{32}$-in. diam. glass helices. A 5:1 reflux ratio was maintained throughout the operation. The results of distillation and the physical constants of the fractions are shown in Table I.

An unusual feature of the physical properties was very high levo-rotation of the α-pinene (fractions 1 and 2). Never before have we encountered such a high rotation of α-pinene. After distillation, the 10 fractions and the residue were kept in air-tight containers for $2^1/_2$ years at 5°. No doubt some oxidation and other changes in the material occurred during the storage period, as indicated by the rotation figures in columns 6 and 7. Even so, the specific rotation of fraction 1 has remained rather high.

After $2^1/_2$ years storage, the pot residue of the fractional distillation amounting to 31.8 gm. was distilled under reduced pressure, using a 90 cm. long, 4 mm. inside diameter wire spiral column. A 10:1 reflux ratio was maintained during fractionation. The results are shown in Table II.

Preliminary identification of components and determination of the quantitative composition of all 19 fractions was made by vapor-phase chromatography after the storage period. The Aerograph model A-90-C used was equipped with automatic integrator and with 5 ft. of Silicone 550–20% on chromosorb and 5 ft. Ucon polar 20% on firebrick columns, as recommended by Stanley.[1] Helium was used as the mobile gas phase. The results are shown in Tables III, IV, and VIII. In all cases, samples of known materials were used for comparison of relative retention volumes, which were computed on the basis of the time necessary for α-pinene to appear as equal to 1.0. In quantitative work, the peak areas were assumed to correspond directly to the weight percentages of the individual compounds comprising the fraction under consideration. It was felt that sufficient accuracy was attained as, in most cases, compounds comprising individual fractions did not differ too much structurally. The results are shown in Tables III and IV. In addition to the identified components, unidentified peaks were noted in fractions 1 and 13–19.

The identifications of α-pinene, β-pinene, and dipentene were substantiated by preparation of

[1] Dr. R. G. Stanley, U. S. Forest Service, personal communication.

crystalline derivatives, as given in Table V. *n*-Heptane and camphene were identified only on the basis of relative retention volumes and boiling points, and for this reason their presence must be regarded as established only tentatively.

Of the rather large number of unknown peaks encountered, five were singled out because of either their intensity or their characteristic position in vapor-phase chromatographic experiments.

Peaks A and B from fraction 1 (relative retention volumes of 0.30 and 0.34; Ucon polar column; T = 130°; 29 ml./min.) appear near *n*-heptane and could easily correspond to its homologs.

Peak C from fractions 14 and 15 appeared as a singlet at 210° (17.6 ml./min., Silicone 550), with relative retention volume of 2.13 and as a doublet at 152° (22.0 ml./min., Silicone 550), with relative retention volumes of 3.1 and 3.5. Its infrared spectrum obtained on a smear from the vapor-phase-chromatography condensate indicated, among other groups, the presence of a hydroxyl group (band at 3450 cm.$^{-1}$), a $CH_2 = CR_2$ group (bands at 3100, 1417, and 890 cm.$^{-1}$), a carbonyl group (band at 1715 cm.$^{-1}$, the position agreeing best with a non-conjugated keto group either in straight chain or in six-membered ring), and probably an isopropyl group (doublet at 1390 and at 1374 cm.$^{-1}$). Apparently the material represented a mixture of an alcohol and a ketone. *p*-Nitrobenzoylation of fraction 4 yielded a small amount of *p*-nitrobenzoate, which melted after recrystallization from ethanol at 53–54°. 2,4-Dinitrophenylhydrazone was formed from the same fraction, but in an amount too small for any further work. Examination of all the data obtained indicated that the alcohol in fraction 4 was not identical with any terpene alcohol recorded in pine turpentines.

Peak D, present in fractions 15–18, appeared at a relative retention volume of 4.03 (Silicone 550, 210°, 17.6 ml./min.). The infrared spectrum indicated the presence of a hydroxyl group (band at 3420 cm.$^{-1}$), a double bond (bands at 3050 and 1650–1690 cm.$^{-1}$), and probably an isopropyl group (doublet at 1375 and at 1390 cm.$^{-1}$).

Peak E, present in the same fractions, appeared at the relative retention volume of 5.09 when run under the same conditions. The infrared spectrum indicated the presence of a hydroxyl group (band at

[a] The composition of *P. nelsonii* turpentine, calculated from Tables III and IV, is as follows: 0.01% *n*-heptane; 49.60% α-pinene; 41.50% β-pinene; 0.24% camphene; 1.02% dipentene; traces peak A; 0.02% peak B; 0.63% peak C; 0.68% peak D; 1.41% peak E; 1.02% sum of other high-boiling materials; 3.07% pot residue; 0.80% loss.

TABLE V.—IDENTIFICATION OF THE COMPONENTS OF TURPENTINE FROM *Pinus nelsonii*

Terpene	Derivative	Prepared from Fraction No.[c]	M.p., °C.	Mixed M.p.	Other Identification[a]
n-Heptane[b]	...	..	...	...	...Bp, VP
α-Pinene	Pinonic acid semicarbazone	2	204–205	...	...Bp, n, d, α, VP
Camphene[b]	...	..	...	...	...Bp, VP
β-Pinene	Nopinic acid	10	127.8–128.8	no depression	Bp, n, d, α, VP
Dipentene	Tetrabromide	13	121–122	no depression	Bp, n, d, α, VP

[a] Bp = boiling point, n = refractive index, d = density, α = specific rotation $[\alpha]^{25}_{D}$, VP = vapor-phase chromatography. [b] *n*-Heptane and camphene were identified only on the basis of relative retention volumes and boiling points; thus their presence must be regarded as established only tentatively. [c] See Tables I, II and IX.

3400 cm.$^{-1}$), a $CH_2{=}CR_2$ nonconjugated double bond (bands at 3090, 1635, and 885 cm.$^{-1}$), and possibly an isopropyl group (doublet at 1387 and at 1373 cm.$^{-1}$).

Preparation of hydrochloride from either fraction 15 or fraction 16 resulted only in noncrystallizable oils. Fraction 19 gave a mixture of hydrochlorides melting indenfinitely between 99 and 110°, even after three recrystallizations. Fraction 16 gave a fairly good yield of *p*-nitrobenzoate which, after recrystallization from alcohol and following purification with charcoal, sublimed between 190 and 232°, without melting. As the ester would be expected to have a vapor pressure to high for sublimation, it is possible that *p*-nitrobenzoic acid was eliminated and sublimed during the melting. The ester obtained probably was derived from the compound of Peak E, as the latter is the main constituent of fraction 16.

The infrared spectra of the remaining fractions 17, 18, and 19, all showed the presence of hydroxyl compounds.

As considerable time elapsed after fractionation and the determination of physical constants on the fractions before the vapor-phase chromatographic analysis and characterization of the constituents were performed, the specific rotations of the 10 fractions were redetermined. In all cases, a considerable drop in rotation values was noted. Shaking fractions 2 and 10 with potassium iodide solution liberated iodine. This suggested that air oxidation had taken place during the storage period and cast doubt as to whether the oxygenated terpenes of fractions 14–19 were present in the original turpentine. As no fresh *Pinus nelsonii* turpentine was available to check this point, the work on these materials was abandoned.

The composition of *Pinus nelsonii* turpentine differs considerably from that of the other five piñon pines in that this species contains a large percentage of *l*-β-pinene (1). Its α-pinene possesses unusually high rotatary power. It would be interesting to compare the turpentine of this piñon with the turpentine of the new piñon pine discovered in high mountains of Nuevo Leon, Mexico (2).

Pinus occidentalis

The turpentine was obtained by heating 3.5 Kg. of the oleoresin under reduced pressure, so that at the end of the operation the temperature of the charge reached 190° while the pressure was decreased to 3.4 mm. of mercury.

This operation was performed by the personnel of the Pacific Southwest Forest Experiment Station at Placerville, Calif.

Yield of turpentine was 20.0%; the flask residue (*i.e.*, rosin) was hard and brittle.

The turpentine possessed the following characteristics: density, d_4^{25}, 0.859; index of refraction, n_D^{25}, 1.4688; and specific rotation, $[\alpha]_D^{25}$ + 10.88

A charge of 425 Gm. of the turpentine was fractionated in a 90 cm. long, 25 mm. inside diameter Stedman column. A 10:1 reflux ratio was maintained during fractionation. The results are shown in Table VI.

The preliminary identification of components and determination of the quantitative composition of

[a] Relative retention values.

the fractions obtained was determined by vapor-phase chromatography, as described above. The results are shown in Tables VII and VIII. In addition to identified components, several small unidentified peaks were noted in fractions 13 and 14.

The specific rotations of individual terpenes were computed from the rotation data in Table VI and from vapor-phase chromatography results, considering also the melting points of the prepared derivatives. The compounds were then designated as *d* or *l*, if the optically active material represented at least 80% of the total, and as *d*, *dl* or *l*, *dl* if it was less than 80% and more than 0% of the total. The maximum rotation values for individual terpenes, given in the literature, were used in this computation.

The identification of *d*, *dl*-α-pinene, *l*-β-pinene, *d*-Δ³-carene, dipentene, and methyl chavicol was substantiated by preparation of crystalline derivatives, as given in Table IX. Because of their small amounts, *n*-heptane, camphene, and linalool were identified only on the basis of relative retention volumes and, where possible, of constants from Table VI. For this reason, their identification must be regarded as only tentative. In the case of longifolene, the material was identified by physical constants and relative retention volumes and also by infrared spectrum on the sample collected by condensation of the corresponding fraction separated by vapor-phase chromatography.

The close relationship of *Pinus occidentalis* to *P. caribaea* is manifested by the presence of Δ³-carene in both pines (1).

Structural Studies on the Triterpenes of *Schinus terebinthefolius*

By KRISHAN K. KAISTHA† and LEMONT B. KIER

A second triterpene, schinol (II), has been isolated from the berries in the ether extract. The relationship of II to previously reported terebinthone (I), has been demonstrated. Terebinthone (I) has been proven to be a triketo triterpene and schinol (II) to be a dihydroxy, keto triterpene. A unique type of dehydration has been discovered in II and a possible mechanism is discussed. Structures for I and II are proposed.

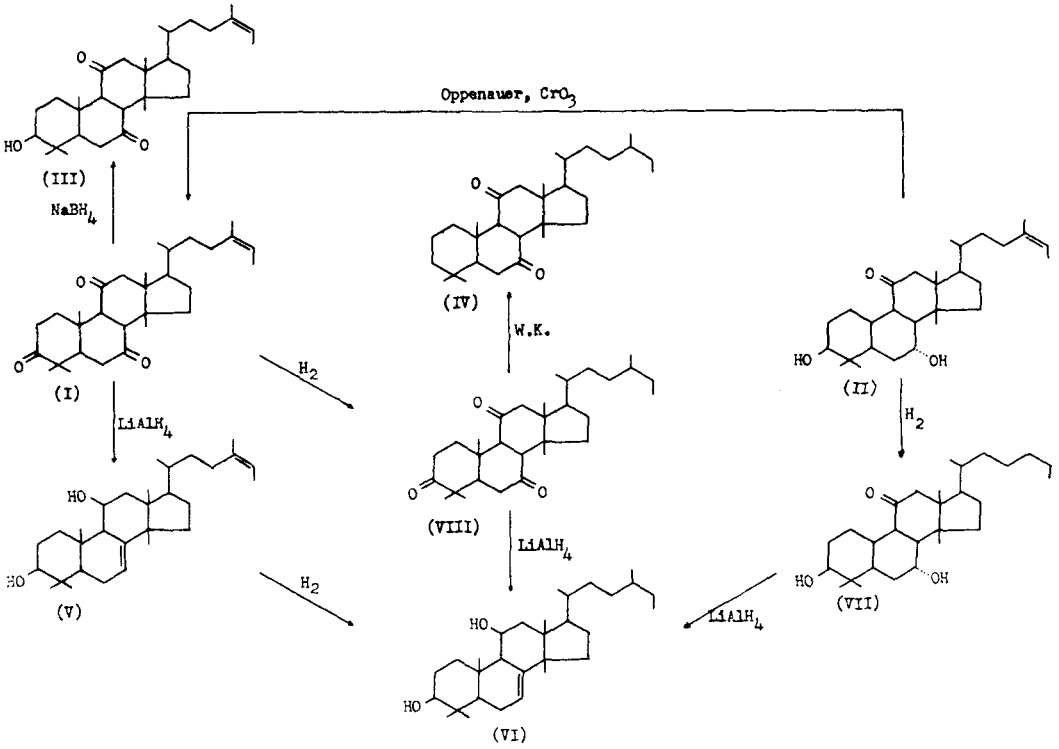
THE partial structural elucidation of a triterpene, terebinthone (I), isolated from the berries of *Schinus terebinthefolius* (Radd.), has been previously described (1). Terebinthone was found to be a 3,11-diketotriterpene with an ethylidene group in the side chain. The nature of a third oxygen function and an element of unsaturation were in doubt but a cyclic ether was proposed. In this present work, the authors have isolated a second triterpene, schinol (II), from this plant and present proposed structures for both compounds.

The triterpene (II), provisionally named schinol from the genus name of the plant, was found to be a $C_{30}H_{50}O_3$ dihydroxy ketone with one reactive double bond. A derivative of the two hydroxyl groups was prepared, but a derivative of the carbonyl group could not be prepared. This indicated that the carbonyl group was in a hindered position. This belief was substantiated by the presence of the carbonyl absorption band at 1690 cm.$^{-1}$ in the infrared which is characteristic for hindered carbonyl groups (2, 3). Except for the hydroxyl and carbonyl group regions, the infrared spectra of schinol (II) and terebinthol (I) were practically identical.

The presence of three carbonyl groups in terebinthone (I) was concluded by comparing the molar absorptivities, ϵ, of the compounds in Table I at 285 mμ. This wavelength was selected as being characteristic of isolated carbonyl groups in cyclohexanones (4). The value of ϵ for schinol was in close agreement with the values reported for one carbonyl group. The two compounds, 3-hydroxy-terebinthone (III) and 3-desoxydihydroterebinthone (IV) had ϵ values corresponding to two carbonyl groups. The ϵ value for terebinthone was in agreement with the presence of three carbonyl groups. These findings indicated that I and II might well be interconvertible or that both might be converted to a common intermediate.

TABLE I.

Compound	Gm./L., Dioxane	ϵ	Estd. No. of C=O
Schinol	4.06	14	1
3-Hydroxy-terebinthone	3.95	28	2
3-Desoxydihydro-terebinthone	4.05	28	2
Terebinthone	4.03	48	3



Oxidation with a chromium trioxide-pyridine complex (5) of II to I was successful though the yield was small. A higher yield was obtained by employing the Oppenauer method (6) with aluminum tertiary-butoxide. This gave conclusive evidence that terebinthone was a triketo compound.

It was necessary to re-examine terebinthol (V) and dihydroterebinthol (IV) since these were previously suspected to be dihydroxy ethers (1). If terebinthone is a triketone then hydride reduction should give a triol. Accordingly V and VI were carefully purified by repeated chromatography until a sharp consistent melting point was obtained. Elemental analyses now gave values which did not agree with those previously reported or those of the expected triol and dihydrol triol. Instead the values obtained for V and VI, $C_{30}H_{50}O_2$ and $C_{30}H_{52}O_2$ indicated that both compounds were missing the elements of water from the expected values. Peracid titration (7) indicated that a new double bond had been introduced in each compound.

In an effort to determine if this unusual mechanism was operative in schinol (II), dihydroschinol (VII), from catalytic hydrogenation of schinol, was subjected to the same lithium aluminum hydride reduction previously reported (1). This gave a diol missing the elements of water from the expected formula. A comparison showed that this compound was identical with VI.

The conversion of I and II to a common product VI conclusively proved that terebinthone (I) and schinol (II) possessed the same ring system, side chain, and location of oxygen

Received February 19, 1962, from the Department of Pharmaceutical Chemistry, College of Pharmacy, University of Florida, Gainesville.
Accepted for publication March 20, 1962.
† Abstracted, in part, from a dissertation for the Ph.D. degree. Winner of a Lunsford-Richardson award.

functions. It was also obvious that the location of the newly introduced double bond in both V and VI would be invaluable in locating the position of the remaining oxygen function, if it was assumed the 3,11 assignment was correct.

Attempts to hydrogenate the new double bond in V and VI were unsuccessful which narrowed the possibilities to the Δ^7 and Δ^8 positions of a tetracyclic triterpene (8, 9, 10). Both V and VI gave negative Tortelli-Jaffe tests specific for a Δ^8 or a Δ^7 which can migrate to a $\Delta^{8,14}$ (11). This latter possibility can be discarded since this migration in a tetracyclic triterpene is prevented by the presence of a 14-methyl group. The nature of this double bond was further studied by plotting its molar absorptivity, ϵ, over the 205–225 mμ region (7). See Fig. 1. Samples of Δ^8-lanostanol and Δ^7-ergostene were used for direct comparison. Both Δ^7-ergostene and VI fell in the same region assigned to trisubstituted double bonds, while Δ^8-lanostanol fell in the same region assigned to tetrasubstituted double bonds (12, 13). Thus, it was concluded that the new double bond introduced in V and VI from hydride reduction is in the Δ^7 position.

In terebinthone (I) the three carbonyl groups must be in the ring system since the only unhindered group is in the 3 position. The infrared spectrum of terebinthone gave no evidence of a carbonyl group in ring D (14) hence the three six-membered rings were the only possible sites. Furthermore, the infrared and ultraviolet spectra of terebinthone (I) showed no absorption due to adjacent carbonyl groups (15) which indicated that the three carbonyl groups must be distributed in rings A, B, and C of the tetracyclic triterpene structure. This is consistent with the assignment of the new double bonds in V and VI to the Δ^7 position since this double bond must have been formed by a reduction of the carbonyl group at C-7 followed by a dehydration.

The possibilities that schinol (II) might be a 3,11-α-dihydroxy-7-keto or 3,11-β-dihydroxy-7-keto triterpene were considered but rejected. If the 11-β-hydroxyl group was present it would be unacylable (1). Schinol formed a derivative of both hydroxyl groups. If the 11-α-hydroxyl group was present a derivative of both hydroxyl groups could be prepared but hydride reduction of dihydroterebinthone (VIII) would not give dihydroschinol (VII) since lithium aluminum hydride reduction of an 11-keto group gives almost exclusively the 11-β-hydroxy compound (16, 17, 18).

These facts present the interesting conclusion that lithium aluminum hydride dehydrates a 7-hydroxyl group in schinol (II) while in terebinthone (I), this reagent first must reduce the carbonyl group to a 7-hydroxyl group then de-

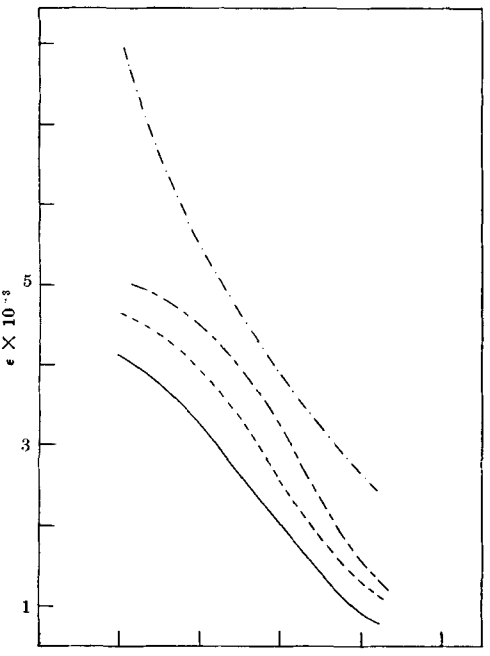


Fig. 1.—Ultraviolet absorption of —— dehydrodihydroschinol (VI), — · — lanostenol, — - — 7-ergostenol, - - - dihydroterebinthol (VI).

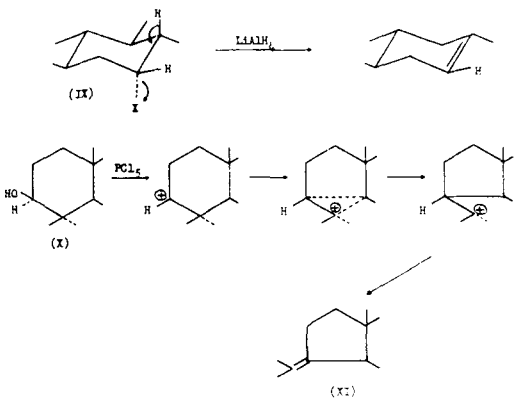
hydrate it by a similar mechanism. There is no precedence for this reaction in the literature though recent work (19), has shown that 3-α-*p*-toluene sulfonates of steroids can be dehydrated with lithium aluminum hydride to Δ^2 compounds very readily. This is a *trans* elimination with the large ester forming the leaving group and the hydride abstracting the adjacent proton. On this basis we would like to propose a similar mechanism (IX) with some form of an aluminum alcoholate forming the leaving group and a second mole of the hydride serving as the proton abstracting base. If this likely mechanism is operative, then the 7-hydroxyl group involved must be α-oriented, for a 7-β-hydroxyl group would be cisoid to the 8-hydrogen and a *cis* elimination mechanism would probably proceed with much more difficulty, if at all, at 36°.

There remained the necessity of proving the orientation of the 3-hydroxyl group of schinol (II). This was determined by treating dihydroschinol (VII) with phosphorus pentachloride. If the 3-β-hydroxyl group is present then X should suffer ring contraction with the formation of an isopropylidene group (XI) (20). Ozonolysis of the product from treatment of VII gave acetone proving a 3-β-hydroxyl group. This assignment of a β orientation is consistent with the fact that hydride reduction of dihydroterebinthone (VIII) should give almost exclusively a 3-β-hydroxyl group (21) which resulted in a compound VI which could also be obtained from schinol (II).



From these findings the authors propose the structures I and II to terebinthone and schinol, respectively.

EXPERIMENTAL[1]

Isolation of Schinol (II).—The hexane marc of the berries of *Schinus terebinthefolius* was extracted with ether in a Soxhlet extractor for 24 hr. The ether was allowed to evaporate leaving a crude crystalline residue. This residue was crystallized several times from ethyl acetate to give a 0.35% yield of schinol, m.p. 145–146.5°, $[\alpha]_D^{23}$ -39.7° (chloroform).

Anal.—Calcd. for $C_{30}H_{50}O_3$: C, 78.55; H, 10.99; 4 C-CH_3, 13.10. Found: C, 78.74; H, 10.74; C-CH_3, 11.98 (Kuhn-Roth).

Schinol was found to be slightly soluble in hexane, ethanol benzene, and chloroform but insoluble in aqueous acid and base. Infrared analysis in nujol showed absorption at 3500^{-1} cm. (hydroxyl), 1700^{-1} cm. (carbonyl), and 1645^{-1} cm. (alkene). The region 1400–650^{-1} cm. was practically identical to that of terebinthone (I). Schinol (II) gave positive Liebermann-Burchard, Salkowski, and tetranitromethane tests but gave negative Zimmermann and Tortelli-Jaffe tests.

Schinol Dibenzoate.—One gram of schinol in 10 ml. of anhydrous pyridine was treated with 2 ml. of benzoyl chloride and the product isolated in the usual way, m.p. 125–127°.

Anal.—Calcd. for $C_{44}H_{58}O_5$: C, 79.24; H, 8.77. Found: C. 79.63; H, 9.11.

Perebenzoic Acid Titration of Schinol (II).—The titration was conducted according to the method previously described (7). The perbenzoic acid consumed was equivalent to 1.2 double bonds.

Dihydroschinol (VII).—A solution of 0.8 Gm. of schinol (II) in 50 ml. of ethyl acetate was hydrogenated at atmospheric pressure using pre-reduced platinum oxide as a catalyst. The consumption of hydrogen was equivalent to 94% of the theoretical amount for one double bond. The ethyl acetate was removed under a vacuum and the residue crystallized from benzene to give 0.78 Gm. of VII, m.p. 148.5–150°, $[\alpha]_D^{23}$-37.3° (chloroform).

[1] All melting points were taken on the Kofler apparatus. Analyses were performed by Galbraith Analytical Laboratories, Knoxville, Tennessee and Weiler and Strauss Microanalytical Laboratories, Oxford, England.

Anal.—Calcd. for $C_{30}H_{52}O_3$: C, 78.20; H, 11.38; two active hydrogens, 0.43. Found: C, 78.53; H, 11.12; active hydrogen, 0.47.

The compound gave no tetranitromethane test and showed no infrared absorption for a double bond.

3-Hydroxy-terebinthone (III).—The method described by Rao (22) was used to reduce 1.5 Gm. of terebinthone (I). The reduction was conducted with sodium borohydride in aqueous dioxane. The crude product was chromatographed on a Celite-magnesium trisilicate (1:1) column, eluting with hexane. The purified compound was crystallized from benzene, m.p. 197–199°, $[\alpha]_D^{23}$ -23.4° (chloroform).

Anal.—Calcd. for $C_{30}H_{48}O_3$: C, 78.89; H, 10.59. Found: C, 78.84; H, 10.73.

The infrared spectrum showed absorption at 3400 cm.$^{-1}$ (hydroxyl) and 1690 cm.$^{-1}$ (carbonyl). The compound gave no Zimmermann reaction.

3-Hydroxy-terebinthone Mono-*p*-nitrobenzoate.—A quantity of III was converted to the *p*-nitrobenzoate in the usual way. The crude product was chromatographed on alumina and crystallized from methanol to give crystals, m.p. 115–117° (capillary).

Anal.—Calcd. for $C_{37}H_{51}NO_6$: N, 2.31. Found: N, 2.55.

The infrared analysis showed no absorption for an hydroxyl group.

Ultraviolet Studies of I, II, III, and IV.—The ultraviolet absorptions of terebinthone (I), schinol (II), 3-hydroxy-terebinthone (III), and 3-desoxy-terebinthone (IV) were measured at 285 mμ using 0.01 molar concentrations in dioxane. The molar absorptivities, ϵ, were calculated. See Table I.

Chromic Acid Oxidation of II to I.—A solution of 1 Gm. of schinol (II) in 20 ml. of anhydrous pyridine was added to a solution of 1 Gm. of chromium trioxide in 20 ml. of anhydrous pyridine. The solution was allowed to stand for 24 hours at room temperature. It was then diluted with 100 ml. of water and extracted with ethyl acetate and this in turn washed with dilute acid. The ethyl acetate was evaporated and the residue chromatographed on a Celite-magnesium trisilicate (1:1) column. A crystalline product weighing 50 mg. was obtained, m.p. 177–179°. A mixed melting point with terebinthone (I) gave no depression and the infrared spectra were identical.

Oppenauer Oxidation of II to I.—A solution of 4 Gm. of schinol (II) and 40 ml. of freshly distilled cyclohexanone in 400 ml. anhydrous toluene was distilled until 150 ml. of toluene was removed. To the remaining solution was added dropwise, 4 Gm. of aluminum tertiary-butoxide in 150 ml. of dry toluene. This solution was refluxed 45 minutes then allowed to stand 12 hours. The reaction mixture was then diluted with water and steam distilled to remove volatile solvents. The precipitate which formed was filtered off then chromatographed on Celite-magnesium trisilicate (1:1). The hexane eluate was recrystallized from ethanol to give 2.5 Gm. of crystals, m.p. 178–179°. A mixed melting point with terebinthone (I) gave no depression and the infrared spectra were identical.

Purification of Terebinthol (V).—A 0.5-Gm. quantity of terebinthol (V), previously prepared, (1) was chromatographed several times on columns of Celite-magnesium trisilicate (1:1) until a fraction was obtained, m.p. 192–193°.

Anal.—Calcd. for $C_{30}H_{50}O_2$: C, 81.39; H, 11.38. Found: C, 81.66; H, 11.44.

Purification of Dihydroterebinthol (VI).—This compound, previously prepared (1), was purified as described for terebinthol (V) until a fraction m.p. 160-161° was obtained.

Anal.—Calcd. for $C_{30}H_{52}O_2$: C, 81.02; H, 11.79. Found: C, 81.14; H, 11.69.

Reduction of Dihydroschinol (VII) to VI.—Dihydroschinol (VII) was reduced with lithium aluminum hydride in ether by the same procedure previously described (1). Purification on a Celite-magnesium trisilicate (1:1) column gave a crystalline product which did not depress the mixed melting point with dihydroterebinthol (VI) and the infrared spectra were identical.

Ultraviolet Analysis of Dihydroterebinthol (VI).—The ultraviolet spectrum of dihydroterebinthol (VI) was obtained in the region 205–225 mμ and compared with the spectra of Δ^8-lanostanol and Δ^7-ergostene. See Fig. 1.

Retropinacol Rearrangement of Dihydroschinol (VII).—A solution of 1.5 Gm. of dihydroschinol (VII) in 150 ml. of methylene chloride was treated with 0.75 Gm. of phosphorus pentachloride. This solution was stirred for 2 hours then refluxed for 1 hour. The reaction mixture was then added to 50 ml. of water and steam distilled to remove the solvent and hydrolyse the phosphorus pentachloride. The residue remaining weighed about 1 Gm. and could not be purified.

Ozonolysis of Crude Retropinacol Products (XI).—One gram of the crude retropinacol product (XI) in 30 ml. of carbon tetrachloride at 0° was treated with a stream of 3% ozonized oxygen for 30 minutes. Water and a few pieces of zinc were then added and the mixture steam distilled into an aqueous acid solution of 2,4-dinitrophenylhydrazine. From this solution was isolated the corresponding acetone derivative, confirmed by a mixed melting point with the authentic compound.

Veratrum Alkaloids L

Structure-Activity Relationships in a Series of Synthetic Hypotensive Analogs of the Protoveratrines

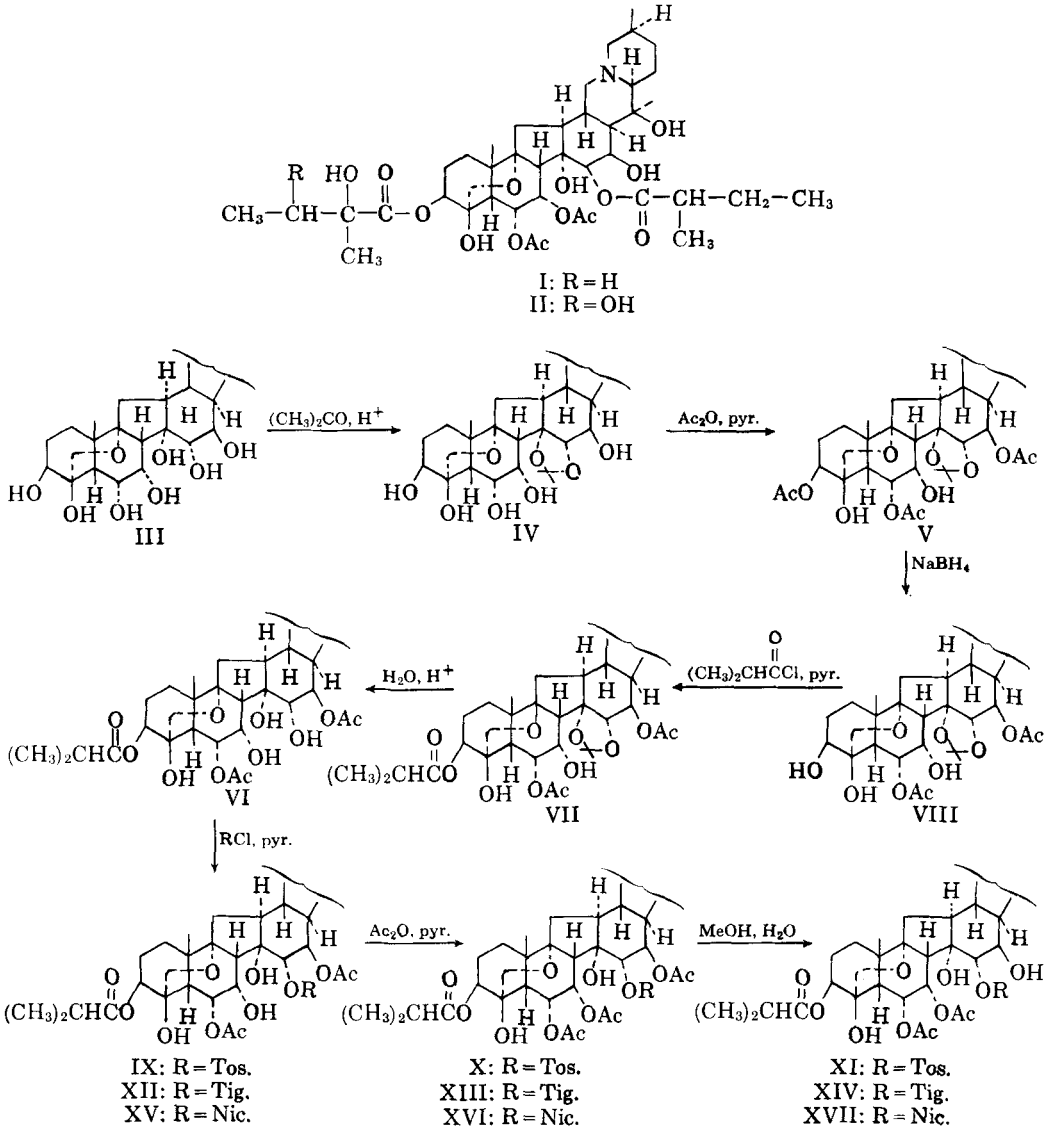
By S. MORRIS KUPCHAN, EIICHI FUJITA, JOHN C. GRIVAS, and LAWRENCE C. WEAVER

A study aimed at further elucidation of the relationship between hypotensive activity and structure among analogs of the protoveratrines is reported. A series of synthetic protoverine tetraesters, which differ from each other only in the nature of the acid residue affixed at C_{15}, have been prepared and subjected to preliminary pharmacological evaluation. The results indicate that alteration in the structure of the ester affixed at C_{15} in analogs of the protoveratrines profoundly affects hypotensive potency.

Two recent developments have stimulated studies involving the synthesis and pharmacological evaluation of analogs of the protoveratrines. On the chemical side, our elucidation of the complete structures and configurations of protoveratrine A (I) and protoveratrine B (II) (1) and several related hypotensive ester alkaloids (2, 3) made feasible the systematic alteration of the molecules. On the clinical side, recent work has demonstrated significant differences between protoveratrine A and protoveratrine B when the substances are administered orally, particularly with regard to hypotensive-emetic relationships (4–6). Since protoveratrines A and B differ only in the nature of the ester moiety at C_3, it was deemed desirable that new protoverine (III) (7) esters, which differ from the protoveratrines solely in the nature of the acid residues, should be prepared and subjected to pharmacological evaluation.

In our previous studies the compounds examined were protoverine derivatives with varying substitution at positions 3, 4, 6, 7, 14, 15, and 16 (8–10). The results supported the following generalizations (*a*) esterification at position 16 with acetate or isobutyrate is accompanied by a profound loss in activity, (*b*) esterification at positions 3 and 15 is required for high activity, (*c*) esterification at position 15 with a branched chain acid is advantageous, (*d*) the ester grouping at position 3 need not be branched, (*e*) positions 6 and 7 need not be esterified for good activity, (*f*) esterification at position 7 with a branched chain acid may be disadvantageous, (*g*) oxidation of the alcohol group at position 16 to a ketone group is accompanied by a loss in activity, (*h*) acetonide formation at positions 14 and 15 is accompanied by a profound loss in activity, (*i*) esterification at position 4 may be disadvantageous, and (*j*) considerable alteration can be made in the structure of the ester affixed at 3 without greatly altering hypotensive potency.

In view of the aforementioned facts that minor differences in the ester affixed at 3 significantly affect the hypotensive-emetic ratio of the protoveratrines and that changes in the structure of the ester at C_3 do not greatly alter hypotensive potency, it was deemed desirable that additional compounds which differ from each other only in the nature of the ester at C_{15} should be prepared and subjected to pharmacological evaluation. The present report details the synthesis and preliminary pharmacological evaluation of three new analogs of the protoveratrines. In the new analogs, the isobutyrate residue, previously demonstrated to be an effective substitute for the naturally-occurring substituted α-methylbutyrate residues (8), is affixed at C_3. Treatment of protoverine (III) with acetone and hydrochloric acid yielded the 14, 15-acetonide (IV), and acetylation then gave protoverine 14, 15-acetonide 3, 6, 16-triacetate (V). Upon treatment with sodium borohydride in *t*-butanol, protoverine 14, 15-acetonide 6, 16-diacetate (VIII) was obtained (7,11). Acylation with isobutyryl chloride in pyridine afforded the 14, 15-acetonide 6, 16-diacetate 3-isobutyrate (VII), and dilute acid gave protoverine 6, 16-diacetate 3-isobutyrate (VI). The latter triester served as the key intermediate for all the further synthesis. Partial acylation with the appropriate acid halide introduced the desired new ester at position 15 (IX, R = tosyl; XII, R = tigloyl; XV, R = nicotinyl). Treatment with acetic anhydride gave



Received February 19, 1962, from the Department of Pharmaceutical Chemistry, University of Wisconsin, Madison, and the Pharmacology Laboratories, Pitman-Moore Co., Division of the Dow Chemical Co., Indianapolis, Ind.

Accepted for publication March 27, 1962.

Presented to the Scientific Section, A.PH.A., Las Vegas meeting, March 1962, as part of a symposium entitled "Biologically Active Natural Products and Derived Synthetic Drugs."

Part XLIX in the series: Kupchan, S. M., Gruenfeld, N., and Katsui, N., *J. Med. Pharm. Chem.*, **5**, 690(1962).

The investigation at the University of Wisconsin was supported in part by research grants from the Wisconsin Alumni Research Foundation and Pitman-Moore Co.

the 3, 6, 7, 15, 16-pentaesters X, XIII, and XVI, and methanolysis selectively removed the 16-acetate to yield the desired 3, 6, 7, 15-tetraesters XI, XIV, and XVII.

The three new protoveratrine analogs XI, XIV and XVII have been investigated for hypotensive activity in the unanesthetized dog and the results are presented in Table I. Adult mongrel dogs unselected as to sex were employed in all experiments described. The femoral artery of the unanesthetized dog was catheterized using locally administered procaine for anesthesia. A mercury manometer and smoked kymogram were used to record mean blood pressure. The dog was placed in an upright position. Test drugs were administered intravenously as freshly prepared aqueous solutions, usually acidic. The effects of these drugs on systemic blood pressure and on emesis production were determined and the results are summarized in Table I. Responses to protoveratrine A and B, and to protoverine 3, 15-diisobutyrate 6,7-diacetate (8) are included for comparison. The 15-isobutyrate was moderately potent as a hypotensive agent, although the activity was appreciably reduced as compared to the protoveratrines. The 15-tiglate (XIV) retained activity, but the order of activity was considerably lower than that of the 15-isobutyrate. When the ester affixed at position 15 was tosylate (XI) or nicotinate (XVII), there was almost complete loss of activity within the doses tested.

It is apparent from the data reported herein that alterations in the structure of the ester moiety affixed at position 15 greatly affect the hypotensive potency. The situation contrasts

TABLE I.—EMETIC AND HYPOTENSIVE ACTIVITIES OF PROTOVERINE DERIVATIVES IN UNANESTHETIZED DOGS

	Mcg./Kg., i.v.	Mean Blood Pressure: No. Dogs	Change, %	Duration, min.	Emesis: No. Vomiting / No. Tested	Onset, min.
Protoveratrine A (I)	1	5	−22	39	1/5	87
	2	3	−37	75	2/3	24, 61
Protoveratrine B (II)	2	6	−33	25	4/6	2, 21

	128	2	−42	1	0/2	

with that of position 3-analogs of the protoveratrines, among which considerable alterations can be made in the structure of the ester without greatly altering hypotensive potency (10).

EXPERIMENTAL

Melting points are corrected for stem exposure. Values of $[\alpha]_D$ have been approximated to the nearest degree. Microanalyses were carried out by Dr. S. M. Nagy and his associates at the Massachusetts Institute of Technology on samples dried under reduced pressure at 110°.

Protoverine 14,15-Acetonide 6,16-Diacetate (VIII).—A mixture of 16.2 Gm. of protoverine 14, 15-acetonide, 3, 6, 16-triacetate (V) (7), 1.52 L. of *t*-butanol and 3.8 Gm. of sodium borohydride was stirred at room temperature for three hours. A 70 ml. quantity of water was added, the solution was allowed to stand for 15 minutes, acidified with 105 ml. of acetic acid and evaporated under reduced pressure. The residue was taken up in water, made alkaline with dilute ammonium hydroxide and extracted with chloroform. The chloroform extract was dried over anhydrous sodium sulfate and evaporated to yield a resin which was chromatographed on 272 Gm. of Merck acid-washed alumina. The column yielded to methanol-chloroform (0.3–1.7%) a resin which was crystallized from acetone as prisms, (8.74 Gm.), m.p. 236–238° decompn. (11). A paper chromatogram[1] indicated that the material was homogeneous.

Protoverine 14, 15-Acetonide 3-Isobutyrate 6, 16-Diacetate (VII).—A 13.73 Gm. quantity of protoverine 14, 15-acetonide 6, 16-diacetate (VIII) was dissolved in 135 ml. of pyridine, cooled in an ice bath, and isobutyryl chloride (6.66 ml., *ca.* 3 mole equivalents) was slowly added with stirring. The flask was protected from moisture with a calcium chloride tube. After completion of the acid chloride addition, the reaction mixture was allowed to stand at room temperature for 24 hours. The solution was treated with ice water, made alkaline with dilute ammonium hydroxide and extracted with chloroform. The chloroform extract was dried over anhydrous sodium sulfate and evaporated to dryness. To remove all of the pyridine, the residue was repeatedly dissolved in benzene and evaporated to dryness, whereupon a yellow resin weighing 14.42 Gm. was obtained. The material was chromatographed on 225 Gm. of Merck acid-washed alumina and yielded to chloroform-benzene (65–80% chloroform), to chloroform, and to methanol-chloroform (0.3–3.3% methanol) a material which was crystallized from ether as prisms, (10.96 Gm.), m.p. 173–178° decompn. A paper chromatogram[1] indicated that the material was homogeneous. A sample was twice recrystallized for analysis from ether to yield prisms, m.p. 175–177° decompn., $[\alpha]_D^{25}$ + 28° (c 1.06, pyr.).

Anal.—Calcd. for $C_{38}H_{57}NO_{12} \cdot H_2O$: C, 61.87; H, 8.00. Found: C, 61.67, H, 7.64.

Protoverine 3-Isobutyrate 6, 16-Diacetate (VI).—A 6.20 Gm. quantity of protoverine 14, 15-acetonide 6, 16-diacetate (VII) was dissolved in 160 ml. of dilute hydrochloric acid (1:4) and the solution was allowed to stand at room temperature for 40 minutes. The reaction mixture was treated with ice, made alkaline with dilute ammonium hydroxide and extracted with chloroform. The chloroform extract was dried over anhydrous sodium sulfate and evaporated under reduced pressure to yield an almost colorless residue. Chromatography on 75 Gm. of Merck acid-washed alumina yielded to chloroform-benzene (35–80%), to chloroform, and to methanol-chloroform (0.5–1.5%), a resin which was crystallized from acetone as rods (5.02 Gm.), m.p. 221–224° decompn. A paper chromatogram[1] indicated that the material was homogeneous. A sample was twice recrystallized from acetone as rods, m.p. 225–226° decompn., $[\alpha]_D^{25}$ − 19° (c 1.15, pyr.).

Anal.—Calcd. for $C_{35}H_{53}NO_{12} \cdot {}^1/_2\ H_2O$: C, 61.04; H, 7.84. Found: C, 60.80; H, 7.48.

Protoverine 3-Isobutyrate 6,16-Diacetate 15-Tosylate (IX).—A 1.9 Gm. quantity of tosyl chloride was added portionwise to a solution containing 679 mg. of protoverine 3-isobutyrate 6, 16-diacetate (VI) in 6 ml. of pyridine cooled in an ice bath. The mixture was allowed to stand at room temperature for 24 hours. The reaction mixture was treated with ice, water, and dilute ammonium hydroxide to

[1] The paper chromatographic system was that of Levine and Fischbach (12): the solution was prepared by adding 1 ml. of formic acid to the separated solvent layer of the system *n*-butylacetate: *n*-butanol: water (10:25:10 ml.).

pH 8.5 and extracted with chloroform. The chloroform extract was dried over anhydrous sodium sulfate and evaporated to dryness. The residue was repeatedly dissolved in benzene and evaporated to dryness to remove pyridine traces. Crystallization of the residue from acetone yielded prisms weighing 506 mg., m.p. 224–226° decompn. Paper chromatographic analysis[2] indicated the material was homogeneous. The product was twice recrystallized from acetone to yield prisms, m.p. 230–231° decompn., $[\alpha]_D^{26}$ − 5° (c 1.37 pyr.).

Anal.—Calcd. for $C_{42}H_{59}NO_{14}S$: C, 60.50; H, 7.08; S., 3.84. Found: C, 60.73; H, 7.01; S, 3.85.

Protoverine 3-Isobutyrate 6,7,16-Triacetate 15-Tosylate (X).—A solution containing 416 mg. of protoverine 3-isobutyrate 6,16-diacetate 15-tosylate (IX) in 3 ml. of pyridine was treated with 12 ml. of acetic anhydride and heated in a water bath at 80° for 2.5 hours. The reaction mixture was treated with ice, water, and dilute ammonium hydroxide to pH 8.5 and extracted with chloroform. The chloroform extract was dried over anhydrous sodium sulfate and evaporated to dryness. The residual resin was crystallized from acetone as prisms, (357 mg.), m.p. 245–247° decompn. A paper chromatogram[2] indicated the homogeneity of the material. Recrystallization from acetone gave prisms, m.p. 245–247° decompn., $[\alpha]_D^{27}$ − 38° (c 1.95, pyr.).

Anal.—Calcd. for $C_{44}H_{61}NO_{15}S$: C, 60.34; H, 6.97; S, 3.65. Found: C, 60.31; H, 7.04; S, 3.44.

Protoverine 3-Isobutyrate 6,7-Diacetate 15-Tosylate (XI).—A solution containing 350 mg. of protoverine 3-isobutyrate 6,7,16-triacetate 15-tosylate (X) in 30 ml. of methanol was allowed to stand at room temperature for 64 hours. Evaporation to dryness left a colorless solid which was crystallized from acetone, to yield prisms, (202 mg.), m.p. 194–195° followed by decomposition at 235–237°. Paper chromatographic analysis[3] indicated the principal product was contaminated with components of lower R_f. Two recrystallizations from acetone yielded prisms weighing 99 mg., m.p. 199–200° followed by decomposition at 215°, $[\alpha]_D^{25}$ − 31° (c 1.14 pyr.), and this material was demonstrated to be homogeneous by paper chromatography.

Anal.—Calcd. for $C_{42}H_{59}NO_{14}S$: C, 60.50; H, 7.08; S, 3.84. Found: C, 60.35; H, 7.19; S, 3.80.

Protoverine 3-Isobutyrate 6,16-Diacetate 15-Tiglate (XII).—A 0.15 ml. quantity of tigloyl chloride was added dropwise to a solution containing 340 mg. of protoverine 3-isobutyrate 6,16-diacetate (VI) in 3.4 ml. of pyridine cooled in an ice bath. The mixture was allowed to stand at 0° for 1 hour and then at room temperature for 18 hours. Workup as described for IX gave a yellow resin which was chromatographed on 12.5 Gm. of Merck acid-washed alumina. The column yielded to chloroform and to methanol-chloroform (0.5–1.5%) a resin which was crystallized from acetone to yield plates: first crop, 155 mg., m.p. 229–230° decompn.; second crop, 29 mg., m.p. 225–226° decompn. Paper chromatography[2] indicated that the first crop was homogeneous and that the second crop was contaminated with a small proportion of a second substance. Recrystallization of a sample of the first crop from acetone yielded plates, m.p. 232–233° decompn., $[\alpha]_D^{27}$ + 13° (c 1.85, pyr.).

Anal.—Calcd. for $C_{40}H_{59}NO_{13}$: C, 63.06; H, 7.75. Found: C, 63.17; H, 7.81.

Protoverine 3-Isobutyrate 6,7,16-Triacetate 15-Tiglate (XIII).—A solution containing 304 mg. of protoverine 3-isobutyrate 6,16-diacetate 15-tiglate (XII) in 2.4 ml. of pyridine was treated with 1.0 ml. of acetic anhydride as described for X. Workup in the usual manner gave a resin which was crystallized from acetone as prisms, (214 mg.), m.p. 260–261° decompn. A second crop weighing 49 mg., m.p. 255–259° decompn., was also obtained. Both crops were shown to be homogeneous by paper chromatography[2]. A sample was twice recrystallized for analysis from acetone to yield prisms, m.p. 264–265° decompn., $[\alpha]_D^{28}$ − 22° (c 1.55, pyr.).

Anal.—Calcd. for $C_{42}H_{61}NO_{14}\cdot H_2O$: C, 61.38; H, 7.67. Found: C, 61.63; H, 7.65.

Protoverine 3-Isobutyrate 6,7-Diacetate 15-Tiglate (XIV).—A solution containing 545 mg. of protoverine 3-isobutyrate 6,7,16-triacetate 15-tiglate (XIII) in 55 ml. of methanol was allowed to stand at room temperature for 27 hours. Evaporation to dryness left a colorless resin which was chromatographed on 11 Gm. of Merck acid-washed alumina. The column yielded to chloroform a resin which was crystallized from ether as prisms (116 mg.). Recrystallization from ether gave prisms weighing 80 mg., m.p. 229–233°, $[\alpha]_D^{28}$ − 22° (c 1.05, pyr.), shown to be homogeneous by paper chromatography.[4]

Anal.—Calcd. for $C_{40}H_{59}NO_{13}$: C, 63.06; H, 7.75. Found: C, 63.06; H, 7.76.

Protoverine 3-Isobutyrate 6,16-Diacetate 15-Nicotinate (XV).—A 0.26 ml. quantity of nicotinyl chloride was added dropwise to a solution containing 679 mg. of protoverine 3-isobutyrate 6,16-diacetate (VI) in 6.8 ml. of pyridine cooled in ice water. After 17 hours at room temperature, the reaction mixture was worked up by the procedure described for IX to yield a resin from chloroform. Crystallization from acetone gave prisms weighing 520 mg., m.p. 200–204° decompn., and a second crop weighing 76 mg., m.p. 195–202° decompn. Both fractions were shown to be homogeneous by paper chromatography.[4] A sample was recrystallized for analysis from acetone to yield prisms, m.p. 200–205° decompn., $[\alpha]_D^{28}$ + 28° (c 1.53, pyr.).

Anal.—Calcd. for $C_{41}H_{56}N_2O_{13}\cdot H_2O$: C, 61.27; H, 7.23; N, 3.49. Found: C, 61.50; H, 6.92; N, 3.62.

Protoverine 3-Isobutyrate 6,7,16-Triacetate 15-Nicotinate (XVI).—A solution containing 770 mg. of protoverine 3-isobutyrate 6,16-diacetate 15-nicotinate (XV) in 6 ml. of pyridine was treated with 2.5 ml. of acetic anhydride as described for X. Workup in the usual manner gave a resin which was crystallized from acetone as prisms weighing 663 mg., m.p. 253–254° decompn. A sample was twice recrystallized from acetone to yield prisms, m.p. 256–257° decompn., $[\alpha]_D^{27}$ − 23° (c 1.79, pyr.).

Anal.—Calcd. for $C_{43}H_{58}N_2O_{14}$: C, 61.98; H, 7.02; N, 3.38. Found: C, 61.80; H, 7.02; N, 3.33.

Protoverine 3-Isobutyrate 6,7-Diacetate 15-Nicotinate (XVII).—A solution containing 346 mg. of

[2] The paper chromatographic system used was *n*-butyl acetate : *n*-butanol : formic acid (25 : 5 : 1 by volume) (12).

[3] The solvent system used was : *n*-butyl acetate : *n*-butanol : formic acid (100 : 1 : 5 by volume), saturated with water.

[4] The solvent system used was: 2,2,4-trimethylpentane: 4-methyl-2-pentanone: pyridine (10:5 : 1 by volume).

protoverine 3-isobutyrate 6,7,16-triacetate 15-nicotinate (XVI) in 57 ml. of methanol was allowed to stand at room temperature for 16 hours. Evaporation to dryness left a resin which resisted attempts at purification by column chromatography, but which yielded to preparative paper chromatography. The resin was dissolved in chloroform and applied to Whatman No. 4 paper (19 sheets, 6 × 18 inches) pretreated with phosphate buffer of pH 3.5. After development for 2.5 hours with the isooctane solvent system[4] and drying, a chloroform solution of Bromphenol Blue was sprayed over the papers as usual. The desired band was cut from the sheets and extracted with 2% methanol-chloroform in a Soxhlet extractor for 2 hours. The extract was shaken with dilute ammonium hydroxide to liberate the free base and remove the dye, and the chloroform solution was washed with water. The chloroform solution was dried over anhydrous sodium sulfate and evaporated to yield a colorless resin weighing 205 mg., which was shown to be homogeneous by paper chromatography.[4] Crystallization from acetone-ether gave colorless prisms weighing 139 mg., m.p. 227–229° decompn. Recrystallization gave prisms, m.p. 229–230° decompn., $[\alpha]_D^{27}$ − 1° (c 1.08, pyr.).

Anal.—Calcd. for $C_{41}H_{56}N_2O_{13} \cdot 1/2\ H_2O$: C, 62.04; H, 7.18; N, 3.53. Found: C, 61.89; H, 7.11; N, 3.84.

Veratrum Alkaloids LI

Hypotensive-Emetic Relationships in the Unanesthetized Dog Among Analogs of the Protoveratrines

By LAWRENCE C. WEAVER†, W. RALPH JONES†, and S. MORRIS KUPCHAN

A study aimed at elucidation of the relationship between hypotensive and emetic activities in the unanesthetized dog among synthetic analogs of the protoveratrines is reported. Preliminary data indicate that a partial dissociation of hypotensive and emetic activities is demonstrable.

VERATRUM and related plants have been used for medicinal purposes for hundreds of years. Galenical preparations were used in the Middle Ages for purposes of sorcery and mystical rites. Subsequently, the crude extracts have been used in the treatment of fevers, as local counterirritants in neuralgia, as cardiac tonics, as emetics, as crow poisons, and as insecticides (1, 2). The use of veratrum in the control of hypertension, at least in the United States, dates from the report of Baker in 1859 (3). Several attempts were made to introduce the use of veratrum extracts into medical practice during the second half of the nineteenth century, but these attempts were unsuccessful. The treatments during this period continued to employ crude extracts containing many alkaloids. The results achieved with these crude extracts were erratic and the treatments fell into disrepute. Some 50 years later, during the late 1930's, purified alkaloidal preparations responsible for the hypotensive activity of veratrum became available for the first time. Poethke in Germany (4) and Jacobs and Craig in the United States (5) improved the extraction and purification procedures and made available the first crystalline powerfully hypotensive alkaloid preparation, protoveratrine. Careful pharmacological investigation of the crystalline preparations, spearheaded by Krayer and his associates, demonstrated that the drugs were suitable for clinical trials (6). These clinical

I, R = H II, R = OH

trials were followed by introduction of protoveratrine and related preparations into clinical use in the treatment of certain types of hypertension (7–9). The limiting factor in the clinical use of these drugs has been the narrow dosage range between hypotensive and emetic effects.

In 1952–1953, four groups reported almost simultaneously that protoveratrine was not a homogeneous entity, but a mixture of two closely related ester alkaloids, protoveratrine A and protoveratrine B (10–13). Subsequent clinical studies have established significant differences between protoveratrine A and protoveratrine B when the substances are administered orally (14–16). Protoveratrine A is a potent hypotensive agent with a narrow therapeutic dosage range. Protoveratrine B, on the other hand, is inactive orally in doses several times the hypotensive doses of protoveratrine A. However, studies of divided doses of more than 10 mg. a day have indicated that protoveratrine B has strong hypotensive activity, which may be prolonged and not accompanied by emetic effects (14–16).

Structural studies culminated in 1960 with elucidation of the complete structures and configurations of the alkamine protoverine and of the tetraesters protoveratrine A (I) and protoveratrine B (II) (17, 18). It is evident that the structures of the two protoveratrines are exceedingly similar, and, indeed, differ only in the nature of the acid moiety of the ester at C_3. In view of the aforementioned pronounced difference in activity which accompanies this minor difference in structure, it was deemed desirable that new analogs of the protoveratrines should be prepared and subjected to pharmacological evaluation. It was hoped that such a study might point the way to the preparation of new protoverine derivatives with more favorable hypotensive-emetic ratios.

To study the relationship between hypotensive activity and structural isomerism among polyesters of protoverine, the first phase of the program involved the synthesis of all the possible protoverine 3,6,7,15-tetraesters which contain one, two, or three isobutyryl residues, and in which the remaining acyl groups are acetyl (19). Pharmacological evaluation of the synthetic esters in *anesthetized* dogs led to formulation of the following generalizations: (*a*) esterification at position 16 with acetate or isobutyrate is accompanied by a profound loss in activity, (*b*) esterification at positions 3 and 15 is required for high activity, (*c*) esterification at position 15 with a branched-chain acid is advantageous, (*d*) the ester grouping at position 3 need not be branched, (*e*) positions 6 and 7 need not be esterified, and (*f*) esterification at position 7 with a branched-chain acid may be disadvantageous.

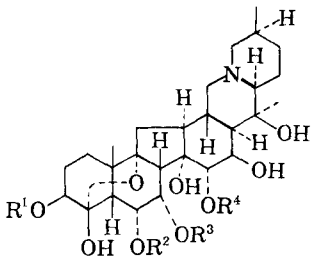
Our second study involved a broader group of structural variants, and the results supplemented and extended earlier generalizations (20). New relationships which evolved from the second study were: (*g*) oxidation of the alcohol group at position 16 to a ketone group is accompanied by a loss in activity, (*h*) acetonide formation at positions 14 and 15 is accompanied by a profound loss in activity, and (*i*) esterification at position 4 may be disadvantageous.

In our third study, 25 new protoverine tetraesters which differ from the protoveratrines solely in the nature of the acid residue affixed at position 3 were described (21). Pharmacological evaluation in anesthetized dogs indicated that considerable alterations can be made in the structure of the ester affixed at position 3 without greatly altering hypotensive potency.

The most recent study involved the synthesis and evaluation of a series of protoverine tetraesters which differ from each other only in the nature of the acid residue at position 15. Pharmacological evaluation of the new protoverine tetraesters showed substantial diminution in hypotensive activity when compared to the protoveratrines (22).

METHODS

The present report is concerned with an evaluation of selected active compounds in the *unanesthetized* dog. Adult mongrel dogs, unselected as to sex, were used for these studies. Mean blood pressure was recorded on a smoked kymogram from the catheterized femoral artery of the dog maintained in a standing position. All drugs were administered rapidly as aqueous solutions, usually acidic, by the intravenous route. The dogs were observed for approximately 2 hours to determine duration of changes in systemic blood pressure and signs of emesis. It should be emphasized that only one dose of one drug was given to any dog. Thus, tolerance or cumulation were not variables. When evaluating compound effects, one should consider hypotensive degree and duration, as well as the presence or absence of emesis.



RESULTS AND DISCUSSION

Ten of the synthetic protoverine tetraesters of the "first study" showed activity in anesthetized dogs in dosages less than 128 mcg./Kg. i.v. (19). These compounds have been studied in the unanesthetized dog and the results are presented in Table I. The compounds are numbered as in ref. 19 in order to make comparisons with data in anesthetized dogs convenient. Generally, the compounds at equivalent dosages had less hypotensive effect than was observed in the anesthetized dog. This is not unexpected, since a barbiturate was the anesthetic agent used in the early studies. Only compound VI had a margin between hypotensive and emetic effects greater than protoveratrine A or B; it is questionable whether this margin is significant. It should be pointed out that when emesis occurred, the duration of the hypotensive response as recorded was frequently decreased because of the changes in blood pressure secondary to this emesis. The hypotensive-emetic ratio of the other compounds appeared similar to those of the protoveratrines.

None of the compounds from the "second study" exhibited sufficient activity to qualify them for investigation in unanesthetized dogs.

All of the 26 new protoveratrine analogs of the

"third study," *i.e.*, the compounds differing from the protoveratrines solely in the nature of the ester at position 3, showed significant hypotensive activity in anesthetized dogs at dosages of 128 mcg./Kg. i.v. or less (21). The results obtained with the latter compounds when administered to unanesthetized dogs is presented in Table II. The compounds are numbered as in ref. 21 to make comparisons with data in anesthetized dogs convenient. Further, an "a" is added (*e.g.*, Ia) to prevent confusion with compounds mentioned earlier in this report. The data for escholerine (IIIa) are included, as well. As was noted above in comparing data obtained from anesthetized and unanesthetized dogs, differences were usually in the direction of lesser activity in the unanesthetized dog. Test compounds were less active than protoveratrine A and B in most cases. Exceptions were compounds IVa, VIa, XIa, XVIIIa, XXIIa, and XXVIa. Increased hypotensive-emetic ratios or margins of safety appeared to be present with compounds IXa and XIVa. Thus, preliminary data indicate that a partial dissociation of hypotensive and emetic activities among synthetic analogs of the protoveratrines is demonstrable in the unanesthetized dog. Compounds XXa, XXIVa, and XXIXa failed to show hypotensive activity at the doses tested, although emesis was evoked. The latter results may be considered to constitute support for the thesis that hypotensive-emetic ratios can be altered. Several of the new analogs will be investigated in human hypertensives to determine whether the improved margin is demonstrable in man as well.

Probability and Complexation: A New Approach

By LLOYD KENNON and KUO-SIN CHEN†

A method is proposed which considers the ability of the ionic atmosphere surrounding a drug in solution to form "probability complexes" with the drug. These complexes are detectable both mathematically and physically. The method is described and illustrated with a study of the behavior of three solutions of phenothiazine derivatives with saccharin.

WHAT is a complex? For about the last ten years this question has been asked, with particular interest being expressed in the components of pharmaceutical solutions. When one attempts to answer this question with various mechanistic concepts, it is found that exact quantitation and definition may be somewhat elusive. However, an explanation which is unencumbered by mechanisms and, hence, probably completely uncontroversial is this: A and B are complexed when there are more A species around and/or closer to B species than a random distribution of A's and B's would bring about. It is such a concept which this communication seeks to explore and discuss.

THEORY AND BACKGROUND

Although the ordered state of crystalline solids, with their units locked into symmetrical and repeating patterns, and the disordered, randomized state of gas molecules have received much attention and investigation and are relatively well understood, the amorphous solid state (including glasses) and liquids have not been so explicitly characterized. At one time the latter two states had in general been considered to be somewhat similar, in that they are both structureless and amorphous. It is now well-known that both dissolved solutes and liquid solvents *per se* behave as if they have at least transitory structures.

The concept of incomplete dissociation, even with complete ionization resulting in nondistinguishable, truly unionized molecules and associated ion-pairs, is well accepted with regard to solutes. Fuoss and Kraus (1) have postulated the existence of ion triplets in addition to the pairs. The Debye-Hückel-Onsager treatments of the theory of electrolytic solutions which were made during their development of the interionic attraction concepts recognize that each ion is surrounded by its own ionic atmosphere of opposite charge. These phenomena, of course, more readily exist in solvents having lower dielectric constants. Also, Brady (2, 3) has demonstrated by X-ray measurements that ionic solutions have structure, *i.e.*, a large degree of local order. Other authorities such as Bailar (4) and Martell and Calvin (5) have drawn attention to chelation processes, coordination compounds, complex inorganic compounds such as amines, hydrates, and double salts, and olation and oxolation. Olation, whereby metal atoms are linked together by OH bridges, can cause the formation of polymers which may reach colloidal size when the olation process does not terminate early. Oxolation, conversion of *ol* groups to *oxo* groups by proton loss, can function similarly. Schlenk and Sand (6) have shown that even clathrates or inclusion compounds can exist in the liquid phase.

Solvents themselves are also capable of sustaining a structure, at least instantaneously. This has been recognized by workers such as Bernal (7–9). Even though the neighbors of a liquid's molecules appear to lie at apexes of various kinds of polyhedra, the highly condensed nature of liquids and their lack of long range order has made the problem of constructing realistic geometric models for mathematical analysis very difficult.

It is known that complexation concepts have explained some of the behavior noted in pharmaceutical solutions. For example Higuchi and Lachman (10) in their first paper on the inhibition of ester hydrolysis have shown that benzocaine does not hydrolyze in solution when it is present as a complex with caffeine. This, and similar observations along with the structure-in-liquids concepts, leads one to believe that another pharmaceutical observation may be explicable and studied as outlined in this paper. The observation is this: Often in pharmaceutical development it appears that different salts of the same compound exhibit not only different solubility characteristics but also differing stability properties. As a literature example we may cite the work of Macek (11) and Bird and Shelton (12) who noted differences in the stabilities of the hydrochloride and nitrate salts of thiamine.

These and similar results found in the course of pharmaceutical development work are somewhat surprising, because at any given pH the same fractions of the possible drug species exist in solution regardless of the acid salt used. Of course, some cases are not surprising and are more readily understood. Epinephrine fumarate or its equivalent has been shown by Romanian workers (13) to be more stable than epinephrine hydrochloride; a British patent (14) was issued to the Rhone-Poulenc Corp. on the use of chlorpromazine fumarate (or maleate, citraconate, itaconate, *etc.*) as preferred to the hydrochloride. These and similar cases may be explained by noting that an oxidizable olefinic linkage has been introduced and would be expected to impart some antioxidant properties. In fact, the Lindsey-Maxwell process (15) for stabilizing edible fatty oils is similar in that citric acid is added

to the oil and then deliberately decomposed to form unsaturated, easily oxidized acids.

The thesis of this paper is that the surprising results mentioned above are due to the fact that the ionic environment *per se* plays a decisive role in the stability picture. This is true because the ions form a protective molecular overcoat—a loose ionic atmosphere complex—which is detectable both mathematically and physically and which may be reasonably termed a "probability complex." Thus, a probability complex mathematically just approaches the definition of a complex mentioned in the introduction; because of its physically demonstrable existence, we may say it does fit the definition.

Formulation work done in our laboratories by Gulesich and Marlino (16) showed that the presence of sodium saccharin in some chlorpromazine hydrochloride[1] ampul and syrup formulations surprisingly enhanced the light stability of the drug. Subsequent work indicated that saccharin also improved the stability to light of other phenothiazine derivatives such as prochlorperazine ethanedisulfonate[1] and trifluoperazine dihydrochloride.[1] These observations also supported the view that certain ions in solution may affect the stability of drugs. The aim of the experimental work was to show the existence of, isolate, and identify if possible the postulated probability complexes. The next section describes the probability method as part of the experimental work.

EXPERIMENTAL

Chlorpromazine and Saccharin.—The initial work was aimed at forcing the saccharin complexes out of solution. This was done by determining the maximum concentrations at which the phenothiazine derivative and sodium saccharin together would form a clear solution. The following illustration of the procedure will use chlorpromazine as the first example. It was found that the maximum permitted concentrations of the two components were 0.00625 *M* chlorpromazine hydrochloride and 0.00332 *M* sodium saccharin; this is a chlorpromazine: saccharin ratio of 1.88:1.00. The phenothiazine must be surrounded by both Cl and saccharin (S) species. At S = 1, Cl = 1.88, so the total possibilities of this (mutually exclusive) situation = 2.88. Therefore, the probability of the drug being in the saccharin form = Ps = 1/2.88 = 0.348; the probability of it being in the Cl form = PCl = 1.88/2.88 = 0.653. The sum of these two is 1.00 as, of course, the drug must be in either one or the other form. The total moles of drug in the just-clear liter of solution being 0.00625 as stated, the molar amount as drug-saccharate would be 0.00625 × 0.348 = 0.00217 moles. Postulating a 1:1 interaction, the molecular weight of the chlorpromazine saccharate = 502. Therefore, the grams of this complex per liter would be 502 × 0.00217 = 1.09 Gm./L.; this then should be the solubility of the complex. A solution containing both components at a concentration of 0.05 *M* each (17.7 Gm. drug hydrochloride plus 12.06 Gm. of sodium saccharin, *q.s. ad* 1 L.) was made so that the complex would be forced out of solution. The grams of complex possible would be 0.05 × 502 = 25.10 Gm.; 1.09 Gm. would be soluble as shown. Thus 24.01 Gm. should settle out; 24.0 Gm. was actually found.

Trifluoperazine and Saccharin.—Similarly to the above, the trifluoperazine dihydrochloride and saccharin case was treated probability-wise. This case differs somewhat from the chlorpromazine situation in that two moles of anion will surround the drug and the possibilities are altered. The drug may be surrounded by Cl-Cl, S-S, Cl-S, or S-Cl. Therefore, having found that the maximum permitted concentrations of the two components were 0.005 *M* drug and 0.00788 *M* saccharin (a drug:saccharin ratio of 1:1.576), the probabilities are: P_{Cl} = 1/2.576; Ps = 1.576/2.576. Hence the probabilities of the double combinations would be: $P_{Cl-Cl} = (1/2.576)^2 = 0.151$; $P_{S-S} = (1.576/2.576)^2 = 0.375$; $P_{Cl-S} = 2[1.576/(2.576)^2] = 0.474$. These probabilities again add up to 1.00, as the drug must be in the four mentioned forms; actually there are only three forms, ehnce the factor of 2 indicating that we could not distinguish between the Cl-S and S-Cl species. The total moles of drug in the just-clear liter of solution being 0.005, the molarity of drug-saccharate would be 0.005 × 0.375 = 0.001875 *M*. Postulating a 2:1 saccharin to drug interaction, the molecular weight of the trifluoperazine disaccharate = 774. Therefore, the grams of this complex per liter, *i.e.*, the solubility, would be 774 × 0.001875 = 1.45 Gm./L. A liter of solution containing 0.05 moles of trifluoperazine dihydrochloride (24.02 Gm.) and 0.10 moles of sodium saccharin (24.12 Gm.) was made. The grams of complex possible would be 0.05 × 774 = 38.7 Gm.; 1.45 Gm. would be soluble as shown. Thus, 37.25 Gm. should settle out; when the solution was made, 38.0 Gm. was actually found.

Before describing the work with prochlorperazine ethanedisulfonate and saccharin, which proved to be the most interesting case, some other comments are appropriate. All the complexes came out of solution as wet oils which when dried became hard glasses which could not be crystallized. [Incidentally, Japanese workers (17) were able to crystallize both mono- and di-saccharinates of thiamine. However, Hamilton and Turnbull (18) prepared many amine saccharinates, *i.e.*, substituted ammonium salts of saccharin, and found them generally difficult or impossible to crystallize.] An attempt to show that the complexes really existed in addition to their probability existence at concentrations lower than their maximum solubility was not successful. The method of continuous variations was employed, using the refractive indices of appropriate binary solutions as the characteristic property followed. The individual sodium saccharin and drug solutions *per se* exhibited easily measured changes in refractive index, but the binary solutions studied showed simple additive effects with no maxmin. This observation also supports the concept that the complexes in solution are somewhat elusive and consist essentially only of a certain ionic environment.

Prochlorperazine and Saccharin.—The probability analysis and subsequent precipitation study, in agreement in the two cases above, did not present a coherent picture in the prochlorperazine ethanedisulfonate–sodium saccharin case. It was evident

[1] Marketed as Thorazine, Compazine, and Stelazine, respectively, by Smith Kline & French Laboratories, Philadelphia, Pa.

that we were postulating the oil to be something that it was not. Therefore, it was decided to investigate in detail the composition of the oil.

The complex oil was made by mixing 0.3-*M* solutions of each component, separating the oil formed and drying it at 85°, whereupon it became a transparent, hard glass. The material was soluble in water and in alcohol with a strong acid reaction; it was insoluble in ether or chloroform. When a portion of the mass was dissolved in water and then neutralized with sodium hydroxide, a brown liquid which was acid- but not water-soluble separated. The physical appearance and solubility behavior paralleled those of prochlorperazine base. When two different aqueous complex solutions made from the glass were spectrophotometrically analyzed, the per cent of drug base in the oil was found to be 56.42% and 56.50%, for an average of 56.46%. Upon treating a small amount of the mass with dilute hydrochloric acid, a white, sweet precipitate was produced. The material melted in the range 227–230° and was obviously saccharin. Quantitative analysis for saccharin was done as follows: A sample of drug complex (1.519 Gm.) was dissolved in water, acidified (HCl), and extracted with chloroform-alcohol (9:1). The extract was evaporated to dryness, dissolved in water, neutralized with sodium hydroxide, and extracted with ether. The aqueous layer, containing the sodium saccharin and the sodium chloride, was evaporated, acidified, and extracted with chloroform-alcohol. The extract was evaporated to dryness and the residue taken up in water and titrated with 24.55 ml. of 0.0973 *N* sodium hydroxide. The per cent saccharin in the sample is then: $24.55 \times 0.0973 \times 183.2 \times 100/1519 = 28.82\%$.

Thus, it appeared that there was about 15% of a third component in the drug-saccharin complex. Evidence was soon obtained which indicated that there was another acid in the product: When the complex in water was titrated with base in the presence of ether (to remove the organic base), the amount of alkali needed was much more than that required for neutralization of the 29% saccharin. Naturally, the conclusion was that ethanedisulfonic acid was also present in the oil; this was verified, as will be shown.

The various possible drug-acid-saccharin interaction products were now considered. The one that fit the data was a complex consisting of 2 moles of saccharin, 2 moles of prochlorperazine, and 1 mole of ethanedisulfonic acid; this would contain about 57% drug, 28% saccharin, and 15% ethanedisulfonic acid. A titration made as described in the last paragraph indicated, after adjusting for the theoretical amount of saccharin in the postulated complex, that the ethanedisulfonic acid comprised about 12.5% of the complex. A further check on the acid content was made by mixing 5.64 Gm. (0.01 mole) of prochlorperazine ethanedisulfonate with 2.41 Gm. (0.01 mole) of saccharin sodium. After complex formation, the aqueous solution should contain 1.17 Gm. of disodium ethanedisulfonate; experimentally we recovered 1.02 Gm. of a white powder which was soluble in water, insoluble in alcohol, neutral to litmus paper as an aqueous solution, and had an equivalent weight of 116.5 (theoretical = 117.1). The equivalent weight was determined by running the sample alongside a known sample of disodium ethanedisulfonate through an analytical grade of cation exchange resin[2] and titrating the eluate with alkali. The known gave an equivalent weight of 116.8, the unknown, 116.5. The presence of the acid in solution corroborated the chosen composition of the complex, as it was consistent with the rest of the data, and it eliminated some alternate possibilities. Thus it appears that one molecule of ethanedisulfonic acid connects two prochlorperazine-saccharin interaction products.

As mentioned, the product defied all attempts to crystallize it. However, it was possible to obtain a powder (amorphous) by freeze-drying a solution. The material thus obtained was then checked for carbon-hydrogen and, for a compound which would not crystallize and must be obtained as a wet oil initially, the agreement is quite satisfactory.

Anal.—Calcd. for $C_{56}H_{64}Cl_2N_8O_{12}S_6$: C, 51.56; H, 4.95. Found: C, 53.44, 53.65; H, 4.95, 5.26.

CONCLUSIONS

The nature of the ionic atmosphere around a drug in solution may explain why different salts of the same drug can exhibit different stability characteristics.

The composition of the ionic atmosphere may be determined by examining the concentrations of all the species involved and using simple probability mathematics; the species involved may be changed and thus studied by varying the salt types in the solution.

Although the ionic atmosphere forms what may be termed a "probability complex" detectable only mathematically, these probability complexes can be forced out of solution and their composition verified.

Substituted Salicylanilides II

Further Antimicrobial and Other Studies with Halonitrosalicylanilides

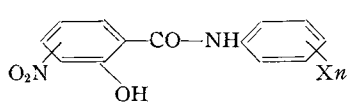
By ROBERT G. TABORSKY† and ROLAND J. STARKEY

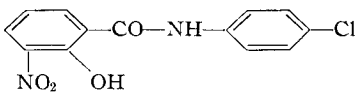
A detailed examination of the general antimicrobial spectra of halonitrosalicylanilides previously reported upon is described together with some general observations. Some other biological data are also presented.

THE OBSERVATION of antimicrobial activity among certain halonitrosalicylanilides has been previously reported (1). These compounds can be represented by the general formula shown in Fig. 1.

Since that report, a more detailed examination of the general spectra of antimicrobial action of the series has been made. In addition, data have also been obtained upon some areas of the general biological activity of these compounds together with further toxicity data. These results are reported below, together with some general observations.

It was of interest to determine the potencies of one of the more active members of each of the 3-nitro and the 5-nitro series of compounds against a variety of fungi and bacteria. 4′-Chloro-3-nitrosalicylanilide (I) from the former series and 4′-bromo-5-nitrosalicylanilide (II) from the latter series were chosen (see Fig. 2).





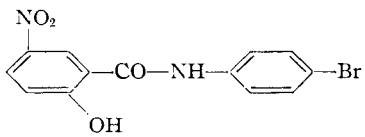


Fig. 1.—General formula for halonitrosalicylanides where X is Br, Cl, F or I and n = 1, 2, or 3.

(I)

(II)

Fig. 2.—Structural formulas for the two compounds studied.

These two compounds were evaluated against a number of interesting microorganisms by determining the minimum concentrations required to cause inhibition of their growth. The data are presented in Table I.

On the basis of these data, it can be seen as had already been observed in the preliminary study that with only a few exceptions, the 5-nitro compound is a more potent antimicrobial than the 3-nitro compound.

In vivo, activity of 4′-chloro-5-nitrosalicylanilide against *Mycobacterium leprae* was determined in mice. The results of the study with a streptomycin control are presented in Table II.

A degree of activity was clearly evident. However, the activity was of lesser magnitude than the control antimicrobial.

In a further study with two related organisms, *Mycobacterium tuberculosis* and *Mycobacterium avium*, and comparison with *Salcide*, employing the serial broth dilution method, threshold values of 5 mcg./ml. were obtained. *Salcide* is a commercial preparation containing approximately equal amounts of 3′-chloro-3-nitrosalicylanilide, 3′-chloro-5-nitrosalicylanilide, 4′-chloro-3-nitrosalicylanilide, and 4′-chloro-5-nitrosalicylanilide.

Thirteen of the halonitrosalicylanilides were then compared in activity against two Gram-positive and one Gram-negative bacteria and a fungus. A mixture of two of the anilides was also examined. These results are shown in Table III. Several interesting facts become apparent upon studying the data. In the first place, as had been initially observed to a limited degree, the compounds were more potent against the Gram-positive organisms than the particular strain of *E. coli* used.

Manifestation of synergism is seen upon comparison of the value against *Aspergillus niger* for the mixture with the values for the unmixed materials. Similar synergisms were encountered with other mixtures and are referred to below. Comparison of the values for the 3-nitro and 5-nitro compounds unequivocally demonstrates the consistently higher potencies of the latter. Finally, it was possible to select on the basis of these results, the most active and interesting members of the series for further study. These were 3′-chloro-5-nitrosalicylanilide, 4′-chloro-5-nitrosalicylanilide, and 4′-iodo-5-nitrosalicylanilide.

To further our knowledge about the halonitrosalicylanilides and to learn more about the synergism between some of the members, several experiments were designed involving mixtures of the compounds. Because of the many combinations possible with all 13 of the active halonitrosalicylanilides, only those exhibiting the highest degree of activity were selected

Received March 5, 1962, from the Ben Venue Laboratories, Inc., Bedford, Ohio.

Accepted for publication June 6, 1962.

We wish to extend our gratitude to Dr. John Erlich of the Parke Davis Company, who carried out some of the antimicrobial determinations and to Dr. Y. T. Chang of the Public Health Service, who screened several of the halonitrosalicylanilides against *Mycobacterium leprae* in mice. Our appreciation is also extended to the National Cancer Screening Service for their screening of the halonitrosalicylanilides for antitumor activity.

† Present address: Cleveland Clinic Foundation, Cleveland 6, Ohio.

TABLE I.—QUANTITATIVE ANTIMICROBIAL DETERMINATIONS FOR TWO HALONITROSALICYLANILIDES BY SERIAL BROTH DILUTION

	Antifungal *in Vitro* Test Results[a] (Broth Dilution)

Treatment of the Animals	Dose	Leprosy Score in Mesentery[a]
Leprosy control untreated	...	4.7
Streptomycin	2 mg. subcutaneously	2.7
4′-Chloro-5-nitrosalicylanilide	0.1% in the diet	3.5

[a] The score is based upon a count of the number of infected cells in the mesentery (2).

for the synergistic studies. Quite by accident, a mixture exhibiting a very high degree of synergistic action was initially prepared consisting of 3 parts of 3′-chloro-5-nitrosalicylanilide and 1 part of 4′-iodo-5-nitrosalicylanilide. In an initial experiment, the threshold inhibition values were determined for each of the two unmixed materials and for the three-to-one mixture against six different microorganisms. The results of this study are summarized in Table IV. It can be seen that the synergism appears to be exhibited against fungi, but not against bacteria. A particularly resistant strain of *E. coli* had been used in these studies for the sake of detecting any synergistic action.

Other mixtures were examined in order to determine whether any generalizations about the types of structural combinations exhibiting synergism might be possible. The three-to-one mixture was adhered to rather arbitrarily since initially a high degree of synergism had been observed with that ratio. *Aspergillus niger* was used throughout as the test organism since it had exhibited the greatest response to the initial synergistic ratio tried in preliminary studies. The results are presented in Table V.

4′-Chloro-5-nitrosalicylanilide	3	>600
4′-Iodo-5-nitrosalicylanilide	1	

[a] In all cases, the unmixed components had values of over 600 mcg./ml.

The most interesting conclusion obtained from Table V is the great specificity of the various components of the mixtures for synergism. In this limited current study of synergism, it can be generalized that only mixtures of halo-5-nitrosalicylanilides where one component has a halogen in the 3′-position and the other in the 4′-position exhibit any appreciable degree of synergistic activity.

Our investigations with the halonitrosalicylanilides then took another direction in an attempt to discover some more general biological characteristics of the materials. It was of interest to determine the fate of the material when introduced into an animal by the oral route. The rabbit was selected as a suitable animal and suspensions of 3′-chloro-5-nitrosalicylanilide in gum acacia were administered orally. In these studies, gross symptoms of toxicity such as emesis, diarrhea, or weight loss were not detected at daily dosages of 1 Gm. per Kg. for a 1-week period.

Pooled feces of the rabbits were extracted with dimethylformamide, a solvent in which 3′-chloro-5-nitrosalicylanilide is extremely soluble. The extractions were filtered and evaporated to dryness and tested for antimicrobial activity *vs. Staphylococcus aureus*, one of the organisms very sensitive to this series. No trace of antimicrobial activity was detected for the residue. Thus the conclusion is reached that either the substituted salicylanilide is chemically modified in the gastrointestinal tract or else is very slowly absorbed into the system at sublethal levels.

In our original publication and in subsequent studies, we had found that generally the LD_{50} in the rat, for the halo-3-nitrosalicylanilides by the intraperitoneal route was in the order of 35 mg. per Kg. and that this value was 125 mg. per Kg. for the halo-5-nitrosalicylanilides. The oral feeding study mentioned above was carried out upon only one animal. Therefore, it cannot by any means, be considered a toxicity study. However, it does serve as an indication that the oral doses which are tolerated are many times greater than the intraperitoneal dose.

Because antimicrobial materials, particularly antibiotic broths, have often exhibited antitumor activity, all of the halonitrosalicylanilides prepared in our studies were submitted to the National Cancer Screening Service for a primary antitumor screening against four tumor systems in mice.

Some of the members exhibited varying degrees of antitumor activity in these tests. 4′-Iodo-5-nitrosalicylanilide qualified for further examinations but its activity was not considered consistent enough for more extensive studies. The results of that study are shown in Table VI.

TABLE VI.—REDUCTION OF TUMOR WEIGHT BY 4′-IODO-5-NITROSALICYLANILIDE[a]

Experiment	Daily Dose, mg./Kg.	Survivors	Tumor Weight—Medicated Animals	Tumor Weight—Non-medicated Animals	Reduction, %
I	113	6/6	5.5	8.2	67
II	113	6/6	1.2	7.7	15
III	113	4/6	8.2	7.8	105
IV	113	5/6	1.5	6.4	23
V	113	5/6	4.3	8.6	50
VI	113	3/6	4.5	8.8	51
VII	113	8/10	7.7	7.6	101

[a] The Erlich Ascites Tumor was used throughout.

DISCUSSION AND SUMMARY

The spectra of certain halonitrosalicylanilides have been investigated to show that they possess bactericidal and fungicidal activity against a large variety of microorganisms.

Upon comparing the members among themselves against five organisms, 3′-chloro-5-nitrosalicylanilide (I), 4′-chloro-5-nitrosalicylanilide (II), and 4′-iodo-5-nitrosalicylanilide (III) emerged as the three most active compounds. It was further of interest, to discover that mixtures of I and III and of II and III had activities as great as 30 times that of the unmixed materials against *Aspergillus niger* and *Memnoniella echinata*. The synergism was observed against fungi in general, but not bacteria. It was,

however, exhibited by several other mixtures to some degree, but only the above-mentioned combinations had a very high degree of activity in this respect.

In further studies upon general biological activity, it was found that the oral toxicity of 3′-chloro-5-nitrosalicylanilide may be many times less than by intraperitoneal administration.

An attempt to correlate pKa and antimicrobial activity for several different salicylanilides has been made (3). The hypothesis put forth was that pKa would be a measure of chelating ability and that, in effect, a correlation of pKa and activity was a correlation of chelating power and activity. In our own studies it was demonstrated that indeed the halonitrosalicylanilides were powerful chelating agents. Upon taking a solution of 5-nitrosalicylic acid and adding ferric chloride solution, a brilliant blood-red chelate complex is formed. However, when EDTA is added to the solution, the color is immediately discharged indicating the transferral of Fe^{+++} to form an EDTA-Fe^{+++} relatively colorless complex. However, when this was repeated with 4′-chloro-5-nitrosalicylanilide, the red color that formed could not be discharged by means of EDTA indicating the former to be a better chelater of iron than EDTA. It must be remembered, on the other hand, that excellent chelating agents such as EDTA do not exhibit general antimicrobial activity and that chelation alone does not give rise to antimicrobial activity. Furthermore, among some of the original halonitrosalicylanilides prepared by ourselves were a series of halo-3,5-dinitrosalicylanilides whose phenolic hydrogens would have a higher pKa than those of the mono-nitrated products. However, these compounds were completely devoid of activity against bacteria or fungi. Thus it is suggested that the requirements for a substituted salicylanilide to possess activity could logically involve its chemical functionality, general solubility, and size and shape of the molecule. These factors could affect its migration across physiological barriers and its ability to seat in enzyme sites which in addition to chelating ability, could determine or influence antimicrobial activity.

Currently, new substituted salicylanilides are being prepared with the idea of exploring some of the molecular requirements for activity. In these studies, particular emphasis is being placed upon investigating the relationship between chelating ability and activity together with some of the other considerations mentioned above. Also, because of the very specific type of synergism observed, a further investigation is underway in attempting to further determine its limitations and to theorize upon its origin. It is hoped that from these investigations more information may be obtained regarding the mechanistic and theoretical aspects of the antimicrobial action of variously substituted salicylanilides.

EXPERIMENTAL

Quantitative *in Vitro* Antibacterial Assays.—These were conducted turbidimetrically by the serial broth dilution method. Inhibition of growth was reported as complete, 50%, and incomplete and measured as the mcg./ml. concentration to cause the inhibition. In some instances absolute bactericidal end points were determined visually but confirmed by streaking replicate sections of nutrient agar plates with several dilutions from the test series.

Stock solutions of halonitrosalicylanilides were prepared by dissolving 100 mg. in 100 ml. of distilled water and adjusted to pH 7.3 with 0.1 *N* sodium hydroxide with some compounds requiring heating to 50° to obtain complete solubilization. The solutions were then sterilized in serum vials at 15 pounds pressure for 15 minutes.

One milliliter aliquots were removed with tuberculin syringes equipped with #22 gauge needles and aseptically transferred to vials containing 9.0 ml. of fluid thioglycollate (BBL). Subsequent dilutions were made in a similar manner. Each test series included viability and media controls.

The inoculum was prepared by making a minimum of three transfers of the test organism in fluid thioglycollate and inoculating 0.05 ml. of the test organism into each vial following 18 hours incubation at 37°. Readings were made at the conclusion of 24 and 72 hours of incubation.

Quantitative *in Vitro* Antifungal Assays.—These were conducted by the broth dilution turbidimetric and agar-dilution linear-growth methods. The former assay was performed in a manner similar to that described for determining antibacterial activity, but with the exception of using fluid dextrose Sabouraud throughout.

In the linear-growth technique, dilutions of the appropriate stock solution (0.001 Gm./ml.) were added to sterile plastic Petri dishes (100 x 15 mm.), and the final volume adjusted to 10 ml. with Sabouraud dextrose agar.

Following solidification, one drop of a concentrated spore suspension was placed in the center of each plate with a 1.0-ml. serological pipet. Controls consisted of untreated Sabouraud agar, though inoculated with the test fungus.

Diameter of the fungus on untreated plates was compared for 7 days with those treated with varying concentrations of a halonitrosalicylanilide. All plates were incubated at room temperature with complete antifungal activity expressed in micrograms per milliter.

Oral Fate of 3′-Chloro-5-nitrosalicylanilide.—A 2.9 Gm. quantity of 3′-chloro-5-nitrosalicylanilide was suspended in 40 ml. of a 10% suspension of gum acacia. This was slowly administered to a 2.9 Kg. rabbit by gastric intubation and was repeated on 5 consecutive days. Side effects or other indications of acute toxicity were not observed.

All of the feces collected during this period, approximately 200 Gm. were extracted by a total of 1.0 L. of dimethylformamide. Portions were combined, vacuum filtered, and evaporated to dryness in a small glass still at 60° and 5 mm. A 30% concentration of the residue was prepared in distilled water and screened against *Staphylococcus aureus* by the cup-plate method. No antimicrobial activity was observed. Controls of 3′-chloro-5-nitrosalicylanilide (0.001 Gm./ml.) elicited conspicuous zones of inhibition.

False-Positive Alkaloid Reactions Obtained with Extracts of *Piper methysticum*

By A. R. FURGIUELE, N. R. FARNSWORTH, and J. P. BUCKLEY

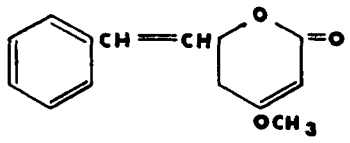
Piper methysticum Forst. (Piperaceae) has been reported by several investigators to contain alkaloids. Several screening methods utilized in this study substantiated these findings; however, after comparing a variety of test procedures, these "positive" alkaloid tests were shown to be due to certain non-nitrogenous α-pyrone compounds. The α-pyrones were also demonstrated to react with a modified Dragendorff spray reagent, after thin-layer chromatography on silica gel G plates. The orange color produced after spraying these α-pyrones was typical of the usual alkaloid positive result, but the color persisted for less than 24 hours. The use of heat to dissolve extracted residues in 1% hydrochloric acid for testing was shown to intensify the alkaloid-like reactions. The results are discussed relative to the screening methods employed.

A NUMBER of reference sources have indicated that the common alkaloid precipitating reagents (Mayer's, Wagner's, Dragendorff's, Sonnenschein's, Hager's, *etc.*) are capable of precipitating certain nonalkaloid materials from solution. Certain proteins, amino acids, glycosides, tannins, betaines, choline, carbohydrates, and ammonium salts have most frequently been implicated as substances present in plants that will give such false-positive reactions (1–11).

Piper methysticum Forst. is a plant indigenous to many islands of the South Pacific. The roots of this plant have been used in the form of a beverage, known as Kava, Kawa, or Awa, by natives of many of these islands to allay anxiety and reduce fatigue (12). Other uses claimed for Kava have been as an aphrodisiac, antiseptic, tonic, anodyne, sudorific, diuretic, stimulant, and intoxicant (13). Local application of the drug is reported to produce a burning pain followed by loss of sensitivity (14). Perhaps the most significant biological effects produced by extracts of this plant are the induction of intoxication of a silent and drowsy nature, accompanied by incoherent dreams when large doses are ingested (13).

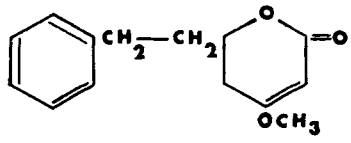
Six α-pyrone compounds have been isolated from Kava. They are kawain (*K*), dihydrokawain (*DHK*), methysticin (*M*), dihydromethysticin (*DHM*), yangonin (*Y*), and desmethoxyyangonin (*DMY*), (15–20). See Fig. 1. Methysticin and dihydromethysticin have been demonstrated to be the most effective sedative compounds of the six pyrones isolated to date (20). Recently, Hansel, *et al.* (21), have isolated two new compounds, flavokawin *A* and flavokawin *B* from Kava, but these were shown to be devoid of sedative properties. In addition, gum, starch, sugar, resins, glucosides (22), and alkaloids (22–24) have been reported to be present in Kava.

Since the alkaloids reported present in this plant had not been thoroughly investigated, our initial studies were directed to the isolation, separation, and identification of these compounds. The present report is concerned with evidence pointing to a class of non-nitrogenous chemical substances present in *P. methysticum* that render alkaloid-positive reactions with a number of common alkaloid-detecting reagents.



EXPERIMENTAL

Materials.—The plant material used in this investigation was collected in Hawaii during the fall of 1959 and consisted of the roots of *Piper methysticum* Forst. (Piperaceae).[1] The *Hamamelis virginiana* L. and *Prunus serotina* Ehrh. used as alkaloid negative controls were obtained commercially as powdered leaves and bark, respectively.[1] Thin-layer chromatography experiments were conducted using the DeSaga apparatus,[2] designed to prepare a 200 μ matrix on 200 x 200 mm. glass plates. The adsorbent matrix was prepared from silica gel G[2] with all prepared plates activated at 105° for 30 minutes, followed by cooling to room temperature in a soda-lime desiccator. All solvents and chemicals used in this investigation were of reagent grade quality unless otherwise specified.



Comparison of Screening Methods.—All attempts made to isolate crude alkaloids from Kava by the usual methods employed in phytochemical studies were unsuccessful. Since the possibility existed that alkaloids were not present, small samples were screened for alkaloids according to the methods of Wall, *et al.* (25, 26), Wall method; Kiang and Douglas (27), Kiang method; and Swanholm, *et al.* (24), Swanholm method. Using the reagents to detect alkaloids that were recommended for each method, it was found that pre-

liminary tests for the alkaloids using the Wall method were positive, while confirmatory tests were negative. The Kiang method indicated that alkaloids were present corresponding to *ca.* 0.01% (as brucine hydrochloride). This is in general agreement with the reported occurrence of alkaloids in Kava of 0.022% by Winzheimer (22) and 0.012% by Scheuer and Horigan (23). The methods utilized for alkaloid estimation were not indicated by these investigators. Both Swanholm methods (direct hydrochloric acid extraction and Prollius extraction) gave results indicative of the presence of alkaloids in this plant.

Since the confirmative test by the Wall method was negative, and the methods of Kiang and Swanholm were indicative of the presence of alkaloids, a series of experiments were designed to clarify these conflicting results. Preliminary experiments had led us to believe that the material possibly responsible for the positive tests was chloroform-soluble. Therefore, it was decided to simultaneously compare the results obtained by screening *P. methysticum* and two plants known to be devoid of alkaloids, or alkaloid-like material, but to which chloroform extracts of *P. methysticum* had been added.

The Swanholm method was utilized and the leaves of *H. virginiana* and the bark of *P. serotina* were included as controls. It was necessary to include controls in this study since extraneous plant materials (resins, pigments, *etc.*) present in the extracts could alter the separation and/or resolution of the α-pyrones present in the *P. methysticum* chloroform extractives. Four 5-Gm. samples of finely powdered *P. methysticum* roots were continuously extracted with chloroform for 3 hours in suitable Soxhlet

extractors. Two of these chloroform extracts were mixed with separate 5-Gm. samples of finely powdered *H. virginiana* leaves and two were mixed with separate 5-Gm. samples of powdered *P. serotina* bark. These four samples were then heated to dryness on a steam bath.

One set of samples consisting of 5 Gm. each of *P. methysticum*, *H. virginiana* treated with *P. methysticum*, *H. virginiana*, *P. serotina* treated with *P. methysticum*, and *P. serotina* was screened by the Swanholm method utilizing direct 1% hydrochloric acid extraction. The samples were mixed with sufficient 1% hydrochloric acid to form a slurry, macerated at 80° for 4–6 hours, cooled to room temperature and filtered. Each filtrate was adjusted to 2 ml. by passing 1% hydrochloric acid through the marc on the filter paper.

A duplicate group of 5-Gm. samples was extracted with *ca.* 30 ml. of Prollius fluid (ether/chloroform/ethanol/ammonia) (25:8:2.8:1)(v/v) for 56 hours at room temperature in tightly stoppered flasks. After the maceration period, each sample was filtered and the residue on each filter paper was washed with an additional 20 ml. of Prollius fluid. The filtrates were then evaporated to dryness on a steam bath. Each residue was then mixed with *ca.* 4 ml. of 1% hydrochloric acid and allowed to macerate at 80° for 1 hour with occasional stirring. After cooling to room temperature, the extracts were filtered and sufficient 1% hydrochloric acid added to each sample to make 2 ml.

The samples were each tested for alkaloids by the addition of 0.1 ml. of reagent to 0.2 ml. of extract (equivalent to 0.5 Gm. of dried plant material). Mayer's, Wagner's, picric acid, Dragendorff's, Sonnenschein's, and silicotungstic acid reagents were used. The results are presented in Table I and clearly indicate the presence of material in the chloroform-soluble *P. methysticum* extracts that produce precipitates with the reagents indicated.

Since most alkaloids are known to exist in plants as chloroform-insoluble salts, the presence of chloroform-soluble, nonalkaloid material as being responsible for the alkaloid-like reactions was further suspected.

For comparative purposes, duplicate samples of *P. methysticum* were screened by the Prollius extraction method with one sample treated as previously described, using heat to aid in dissolving the Prollius residue in 1% hydrochloric acid. The second sample was treated in a similar manner; however, no heat was applied. This evaluation was considered necessary since the original Webb method (11) was found to give positive alkaloid tests with *P. methysticum* by direct acid extraction (heat applied at 60° for 1/2 to 1 hour), but negative tests by the Prollius method in which heat was not applied. When *P. methysticum* was screened by the Arthur modification (28) of the Webb method, negative results were obtained with the direct acid extraction (no heat) as well as with the Prollius extraction (no heat). The results of this study are indicated in Table II and point out the effect of heat on increasing the false-positive alkaloid reactions with these reagents.

Thin-Layer Chromatography Studies.—It is common practice in many laboratories to detect alkaloids in plant material by means of chromatographic methods using a modified Dragendorff spray reagent. After chromatograms are treated with the Dragendorff spray, the appearance of typical yellow-orange to orange spots is generally accepted as good evidence of the presence of alkaloids in the material chromatographed. Since the standard Dragendorff reagent produced a visible alkaloid-like reaction with extracts of *P. methysticum* in test tube experiments, it was decided to determine the effect of the Munier and Macheboeuf modified Dragendorff spray reagent (29) on chromatograms prepared from the previously described Prollius extracts, in addition to certain controls.

An additional aid in allowing us to verify that chloroform-soluble *P. methysticum* extracts contained material responsible for false-positive alkaloid reactions was found in treating chromatograms of these extracts with sulfuric acid. Chloroform extracts of *P. methysticum*, in addition to the known α-pyrones isolated from this plant (chloroform-soluble), were found to react with sulfuric acid to produce red or yellow colors.

Silica gel G plates were spotted with separate solutions containing 1γ/1λ of each of the known α-pyrones (kawain, dihydrokawain, methysticin, dihydromethysticin, desmethoxyyangonin, yangonin) in chloroform. In addition, a solution containing a mixture of 1γ/1λ of each was prepared. Ten lambda of each solution was applied and a mixture of Skelly B/ethyl acetate (1:1) was used as the eluent. After proper development, the plates were removed from the chambers, air-dried and sprayed with sulfuric acid. The areas of color formation were quickly traced and the colors noted. All compounds reacting with sulfuric acid to produce a yellow color quickly faded, while those components producing red colors were more permanent. The result of this chromatographic separation is illustrated in Fig. 2. A suitable solvent system for the complete resolution of the six α-pyrones could not be devised, but in mixtures of appropriate concentration, differences in migration, combined with the sulfuric acid color reaction, were sufficient to allow detection of desmethoxyyangonin (yellow) and yangonin (yellow) from mixtures of kawain (yellow)-dihydrokawain (yellow) and methysticin (red)-dihydromethysticin (red).

Several dilutions of the known α-pyrones were prepared, applied to duplicate silica gel G plates, and chromatographed as previously described. One set of plates was sprayed with sulfuric acid and the other set with the Munier and Macheboeuf-Dragendorff spray in order to ascertain the minimal quantities detectable with each reagent. The results are indicated in Table III.

The initial reaction of the α-pyrones to the Dragendorff spray was quite similar to that produced by known alkaloids; however, it should be pointed out that the reaction was not of long duration. The initial orange color faded to yellow within 1 hour and, dependent on concentration, was usually rendered colorless after standing for 24 hours. This is in sharp contrast to most alkaloids that we have treated in a similar manner, in which the orange color has been observed to persist for several weeks.

Duplicate silica gel G plates were prepared for thin-layer chromatography, by the application of 100λ each of the 1% hydrochloric acid solutions of the Prollius residues, prepared as previously described. These solutions included *P. methysticum*, *H. virginiana* treated with *P. methysticum*, *H. virginiana*, *P. serotina* treated with *P. methysticum*, *P. serotina*, *P. methysticum* chloroform-soluble extract in 1% hydrochloric acid (unheated), and *P. methysticum* chloroform-soluble extract in 1% hydrochloric acid (heated). In addition, 20λ of a chloroform extract of *P. methysticum* containing the equivalent of 1 Gm. of drug in 50 ml., and 20λ of the α-pyrone mixture (1γ/1λ) in chloroform were applied. Both plates were eluted with Skelly B/ethyl acetate (1:1) as previously described and were air-dried. One plate was sprayed with sulfuric acid and the duplicate plate with the Munier and Macheboeuf-Dragendorff spray. The results are illustrated in Figs. 3 and 4 and point out that the known α-pyrones, present in chloroform extracts of *P. methysticum*, react with Dragendorff's spray reagent. Sufficient quantities of these compounds are soluble in heated 1% hydrochloric acid, as indicated by the chromatographic results, to account for the previously described alkaloid-like reactions

using Prollius extracts prepared with heat. Extracts prepared without the use of heat were only slightly soluble in 1% hydrochloric acid as evidenced by these results and undoubtedly the concentrations present in these Prollius extracts were too low to be detected by the precipitating agents employed in this study.

DISCUSSION

The results of this investigation clearly indicate that certain α-pyrone derivatives in *P. methysticum* can induce false-positive alkaloid reactions with several of the common alkaloid precipitating reagents. In addition, these compounds can react to produce similar results on chromatograms treated with the modified Dragendorff spray reagent. A critical analysis of the methods used to detect alkaloids in plant material can aid in the prevention, as well as in the interpretation of these false-positive reactions. If the Swanholm, Webb, or Kiang methods are to be utilized, heat should be avoided, or an additional purification step, as included in the Wall method, should be considered. The appearance of orange spots on chromatograms after treatment with the modified Dragendorff spray reagent should be

considered indicative of the presence of alkaloids only when the suspected alkaloid spot persists for several hours, since compounds of the α-pyrone type, and perhaps others, will not retain the typical alkaloid-positive orange color with this reagent.

From the data presented, it is reasonable to assume that the occurrence of alkaloids in *P. methysticum*, as reported by several investigators, has been brought about through observations of the reactions due to the nonalkaloid α-pyrone constituents in this plant. These observations have prompted us to investigate other structurally related non-nitrogenous compounds, synthetic as well as naturally occurring, in order to gain additional information concerning the limitations of alkaloid detecting reagents as used in phytochemical studies. These results will be published at a later date.

SUMMARY

1. The nonalkaloid α-pyrone compounds present in *P. methysticum* have been shown to exhibit alkaloid-like reactions with several common alkaloid precipitating reagents.

2. The use of heat in alkaloid testing procedures increases the solubility of the α-pyrone compounds. This increased solubility is sufficient to allow detection of them with standard alkaloid reagents.

3. The α-pyrones present in *P. methysticum* will produce alkaloid-like color reactions on chromatograms treated with the Munier and Macheboeuf modified Dragendorff spray reagent. This effect is discussed and the sensitivity of the reaction on thin-layer chromatograms of the α-pyrones is reported.

4. The color reactions and sensitivity of kawain, dihydrokawain, methysticin, dihydromethysticin, yangonin, and desmethoxyyangonin after thin-layer chromatography and subsequent sulfuric acid spray, is reported.

5. Alkaloids have been shown to be absent from *P. methysticum*. Previous reports concerning the presence of alkaloids in this plant have been evaluated and discussed in view of the experimental results from this investigation.

Complex Formation Influence on Reaction Rate I

Effect of Caffeine on Riboflavin Base-Catalyzed Degradation Rate

By DAVID E. GUTTMAN

The rate of the base-catalyzed decomposition of riboflavin was investigated in aqueous solution in the absence and presence of caffeine at a number of different temperatures. It was found that at all temperatures the apparent velocity of the reaction was decreased by the presence of caffeine and that the magnitude of this effect was dependent on the concentration of caffeine in the system. A mathematical relationship, expressing the relative degree of stabilization as a function of the caffeine concentration and the dissociation constant for the complex, was derived by assuming that a 1:1 complex formed and that the complexed riboflavin did not undergo reaction with the base. Dissociation constants which were calculated for the complex from the kinetic data were found to be in close agreement with values previously obtained by nonkinetic techniques. Free energy, enthalpy, and entropy changes which characterize the association were calculated to be −2,000 cal., −5,750 cal., and −12 e.u., respectively. The energy of activation for the degradative reaction was found to be the same in the presence of caffeine as in its absence.

A NUMBER of investigations have demonstrated that molecular complex formation can influence the rate at which participating species undergo chemical reaction. For example, the rate of the coupling reaction between β-naphthol and *p*-diazobenzenesulfonic acid was found by Overbeek, Vink, and Deenstra (1) to be lowered by the addition of caffeine to the reaction medium. The lowering of the reaction velocity was explained on the basis of lowered reactivities of the reactants in the complexed forms since both phenol and the sulfonic acid were shown to form 1:1 complexes with caffeine. Similarly, Higuchi, Lachman, Ravin, and Guttman (2,3,4) showed that the rates of hydrolysis of local anesthetic esters were substantially reduced by the addition of complexing agents to their aqueous solutions. Their investigations indicated that the esters, in the complexed forms, did not undergo hydrolytic cleavage at the ester linkage.

Pharmaceutical interest in this particular manifestation of complex formation is quite naturally derived from the possibility of utilizing such behavior to stabilize labile medicinal agents. More comprehensive studies of this phenomenon would, therefore, be of value in amplifying and extending this interest and could, in addition, be of more fundamental importance in providing further insights into the nature of the bonding forces responsible for molecular associations. The extent to which the reactivity of a compound is affected by complexation might serve as an indication of the type of interactive mechanism that is primarily operant. Correlation and comparison of such studies with results obtained by nonkinetic methods might also serve to pinpoint functional groups as sites of contact between components in the complex. Alternatively, it is possible that a kinetic approach to the determination of the energetics of complex formation might be more direct and preferred in some cases to many of the classical approaches which are commonly used.

This communication summarizes the results of a preliminary investigation of the effect of mo-

Complex Formation Influence on Reaction Rate I

Effect of Caffeine on Riboflavin Base-Catalyzed Degradation Rate

By DAVID E. GUTTMAN

The rate of the base-catalyzed decomposition of riboflavin was investigated in aqueous solution in the absence and presence of caffeine at a number of different temperatures. It was found that at all temperatures the apparent velocity of the reaction was decreased by the presence of caffeine and that the magnitude of this effect was dependent on the concentration of caffeine in the system. A mathematical relationship, expressing the relative degree of stabilization as a function of the caffeine concentration and the dissociation constant for the complex, was derived by assuming that a 1:1 complex formed and that the complexed riboflavin did not undergo reaction with the base. Dissociation constants which were calculated for the complex from the kinetic data were found to be in close agreement with values previously obtained by nonkinetic techniques. Free energy, enthalpy, and entropy changes which characterize the association were calculated to be −2,000 cal., −5,750 cal., and −12 e.u., respectively. The energy of activation for the degradative reaction was found to be the same in the presence of caffeine as in its absence.

A NUMBER of investigations have demonstrated that molecular complex formation can influence the rate at which participating species undergo chemical reaction. For example, the rate of the coupling reaction between β-naphthol and *p*-diazobenzenesulfonic acid was found by Overbeek, Vink, and Deenstra (1) to be lowered by the addition of caffeine to the reaction medium. The lowering of the reaction velocity was explained on the basis of lowered reactivities of the reactants in the complexed forms since both phenol and the sulfonic acid were shown to form 1:1 complexes with caffeine. Similarly, Higuchi, Lachman, Ravin, and Guttman (2,3,4) showed that the rates of hydrolysis of local anesthetic esters were substantially reduced by the addition of complexing agents to their aqueous solutions. Their investigations indicated that the esters, in the complexed forms, did not undergo hydrolytic cleavage at the ester linkage.

Pharmaceutical interest in this particular manifestation of complex formation is quite naturally derived from the possibility of utilizing such behavior to stabilize labile medicinal agents. More comprehensive studies of this phenomenon would, therefore, be of value in amplifying and extending this interest and could, in addition, be of more fundamental importance in providing further insights into the nature of the bonding forces responsible for molecular associations. The extent to which the reactivity of a compound is affected by complexation might serve as an indication of the type of interactive mechanism that is primarily operant. Correlation and comparison of such studies with results obtained by nonkinetic methods might also serve to pinpoint functional groups as sites of contact between components in the complex. Alternatively, it is possible that a kinetic approach to the determination of the energetics of complex formation might be more direct and preferred in some cases to many of the classical approaches which are commonly used.

This communication summarizes the results of a preliminary investigation of the effect of mo-

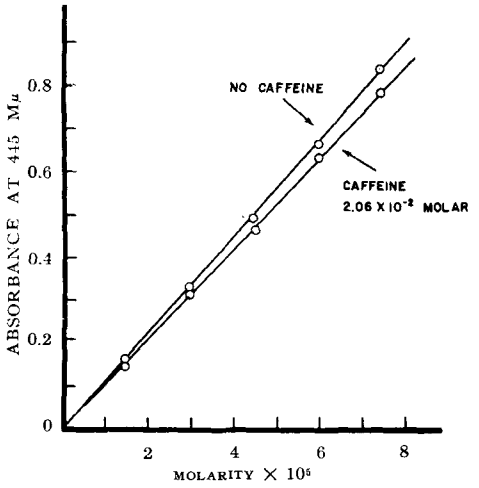

Fig. 1.—The relationship between absorbance and concentration for solutions of riboflavin.

lecular interactions on the velocities of reactions involving riboflavin. It is anticipated that riboflavin-containing systems will be useful models for the accumulation of pertinent information because of the well-known interactive tendencies of isoalloxazine derivatives and because the many modes of degradation and reaction of the vitamin will provide the opportunity to investigate the influences of complexation on the rates of reactions possessing quite different mechanisms. The specific objective of the present study was to investigate the influence of caffeine on the rate of the base-catalyzed conversion of riboflavin to urea and 1,2-dihydro-6,7-dimethyl-2-keto-1-D-ribityl-3-quinoxaline-carboxylic acid (5). No attempt was made to derive a mechanistic picture of the degradative reaction or a mechanistic explanation at the molecular level of the observed influence of complex formation on reactivity. The study will show, however, that the vitamin in its complexed form possessed negligible reactivity towards alkaline hydrolysis and that, consequently, pertinent information concerning energy changes which resulted from complexation could be obtained from kinetic studies.

EXPERIMENTAL[1]

Reaction systems were formulated in 0.05 *N* sodium hydroxide to contain approximately 1 × 10^{-4} moles $L.^{-1}$ of riboflavin and the desired concentration of caffeine. The reaction flasks were maintained at a constant temperature by immersion in a Sargent Thermonitor constant temperature bath. Five-milliliter samples were withdrawn from the flasks at various time intervals and immediately treated with exactly 5 ml. of 1 *N* acetic acid to quench the reaction. The absorbance of each sample was then determined at 445 mμ utilizing a Beckman model DU spectrophotometer. Studies were conducted in a similar manner on reaction systems containing 0.1 *N* sodium hydroxide. All riboflavin-containing solutions were protected from light at all times. The disappearance of riboflavin was thus followed by noting the decrease in absorbance at 445 mμ. The spectrophotometric assay appeared to be specific for the intact vitamin. Completely degraded solutions yielded negligible absorbance values at the selected wavelength. Although it has been shown by Harbury and Foley (6) that caffeine does affect the spectral characteristics of riboflavin in aqueous solution, preliminary studies which are illustrated in Fig. 1 showed that a direct proportionality existed between absorbance at 445 mμ and the concentration of the vitamin in both the absence and presence of caffeine. The absorbance values were, therefore, used directly in all of the kinetic plots as being representative of the vitamin concentrations.

RESULTS

Results typical of those obtained throughout the course of this study are graphically illustrated in Fig. 2. Here, semi-log plots are shown for two reaction systems formulated with and without caffeine. It can be seen that in both cases a pseudo first-order disappearance of the vitamin occurred. A number of studies showed that the linearity of the plots extended over time periods many times the half-life of the vitamin. Figure 2 makes apparent that the reaction occurred at a significantly reduced rate in the presence of caffeine. Similar studies were conducted at various temperatures and at various concentrations of caffeine. In all cases the data fit first-order plots and from such plots first-order rate constants

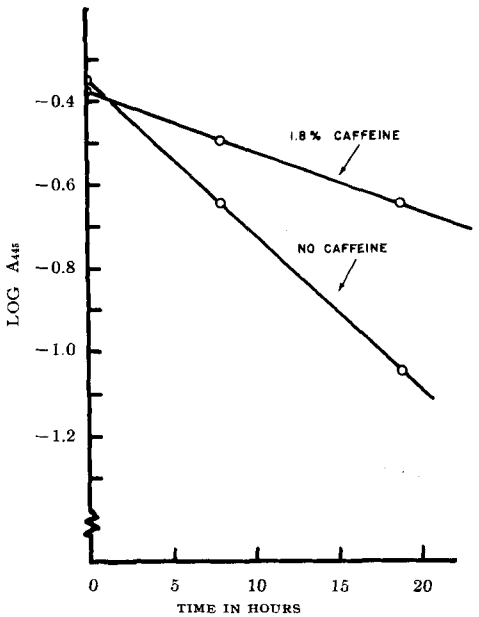

Fig. 2.—The first-order decomposition of riboflavin in 0.05 *N* sodium hydroxide at 35°.

were estimated. The results are summarized in Table I. Here, for each temperature investigated, are tabulated the molar concentration of caffeine in the system, the apparent rate constant observed for that system, and the ratio of the rate constant found in the absence of caffeine, k, to that found in the presence of caffeine, k_{app}. It can be seen that this ratio, which is indicative of the apparent reduction in vitamin reactivity in the presence of caffeine, is proportional to the caffeine concentration in the system.

DISCUSSION

A reasonable explanation for the decreased rate of vitamin disappearance effected by the presence of caffeine is that riboflavin in the complexed state possessed either a decreased or negligible reactivity toward the catalyst. If it is assumed that the latter was the case, then the overall mechanism for the process in the presence of caffeine is

$$\text{riboflavin:caffeine} = \text{caffeine} + \text{riboflavin}$$
$$\downarrow \text{OH}^-$$
$$\text{products}$$

Accordingly, the rate of disappearance will depend not on the stoichiometric concentration of riboflavin in the system but rather on the concentration of the noncomplexed specie.

If, as is indicated by the postulated mechanism, a 1:1 complex is formed, then it can be shown that the concentration of noncomplexed riboflavin is related to its stoichiometric concentration by the expression

$$R_f = \frac{K}{K + C_f} R_t \qquad \text{(Eq. 1)}$$

where R_f = molar concentration of noncomplexed riboflavin, K = dissociation constant for the complex, C_f = concentration of noncomplexed caffeine, and R_t = stoichiometric molar concentration of riboflavin. Since the rate equation for the decomposition reaction in the absence of caffeine is

$$-dR_t/dt = kR_t \qquad \text{(Eq. 2)}$$

then based on the preceding assumptions, in the presence of caffeine, it will be

$$-dR_t/dt = k \frac{K}{K + C_f} R_t \qquad \text{(Eq. 3)}$$

The apparent rate constants evaluated for reaction systems containing caffeine are thus related to the "true rate" constant by

$$k_{app} = k \frac{K}{K + C_f} \qquad \text{(Eq. 4)}$$

or more conveniently,

$$k/k_{app} = 1 + C_f/K \qquad \text{(Eq. 5)}$$

Because caffeine was maintained at a much higher concentration than riboflavin in all of the present studies, its stoichiometric concentration can be used as a close approximation of the C_f term in Eq. 5.

Equation 5 predicts a linear relationship between the ratio k/k_{app} and the molarity of caffeine and thus serves as a means to check the validity of the assumptions made. A plot of this relationship for three different temperatures is shown in Fig. 3. It is seen that, at least at lower concentrations of caffeine, a linear relationship existed. As the molarity of caffeine was increased, deviations from linearity became more pronounced. It is felt that this behavior does not negate the postulated mechanism but rather resulted from the self-complexing of caffeine which becomes increasingly significant at higher concentrations. This possibility is supported by the decreased curvature observed at higher temperatures and by the fact that a previous study on the solubilization of riboflavin by caffeine (7) yielded deviations of the same nature and of the same magnitude. It should be noted that the 35° curve of Fig. 3. includes experimental points obtained at two different concentrations of hydroxide ion. The close agreement obtained between the two different concentrations emphasizes that the stabilization did not result from neutralization or inactivation of catalyst by caffeine.

Dissociation constants for the complex were graphically estimated from the slopes of the curves obtained by the plot illustrated in Fig. 3. The initial straight-line portion of the curves were used for

this purpose. The values obtained at various temperatures are tabulated in Table II.

The values obtained are in reasonable agreement with values derived by other workers who utilized different experimental methods. For example, the value for 20° was interpolated from this study to be 0.024 mol./L. as compared to a value of 0.019 mol./L. obtained by the spectrophotometric study of Yagi and Matsuoka (8) at the same temperature. Similarly, the solubility study at 30° of Guttman and Athalye (7) yielded a value of 0.0345 as compared to 0.0286 in the present study.

The temperature dependency of the dissociation equilibrium is graphically illustrated by the semi-log plot of Fig. 4. The enthalpy change $\Delta H°$ resulting from the association of caffeine with riboflavin was calculated to be −5.74 Kcal. The free energy change $\Delta F°$ and the entropy change $\Delta S°$ for the interaction at 35° were calculated to be −2.04 Kcal. and −12.0 e.u., respectively.

The temperature dependency for the degradative reaction, under the conditions used in this study, is shown by the Arrhenius plot of Fig. 5. Plotted here as a function of reciprocal absolute temperature are rate constants obtained at different temperatures for systems free of caffeine and also those obtained at corresponding temperatures for systems containing two different concentrations of caffeine. The apparent energy of activation was graphically estimated to be approximately 20.0 Kcal. in all cases. This observation gives further support to the assumption that the complexed form of riboflavin does not degrade at a perceptible rate.

This investigation has provided another example of a manifestation of complex formation that has possible practical and theoretical importance. In addition, the possibility of gaining information about the energetics of molecular interactions from kinetic studies has been demonstrated. Although quite equivocal, one might speculate that the reduction in the reactivity of riboflavin as well as the rather large

negative entropy change resulting from complexation supports the previously suggested involvement of a charge-transfer interactive mechanism with caffeine acting as a donor and riboflavin as the acceptor (6, 9). Such an interaction would possibly reduce the electrophilicity of riboflavin and might, therefore, reduce its reactivity by discouraging the nucleophilic attack of hydroxide ion, an attack undoubtedly involved in the hydrolytic cleavage of the isoalloxazine ring.

Effect of Deuterium Oxide on Local Anesthetic Activity of Procaine

By S. V. SUSINA, F. D. HITER, F. P. SIEGEL, and M. I. BLAKE

Deuterium oxide was used as a solvent for procaine and the effect on the stability and local anesthetic activity was noted. The ED_{50} was determined by the method of Chance and Lobstein and comparison was made with aqueous procaine solutions. In water the ED_{50} was 1.8% while in deuterium oxide it was 1.0%. The LD_{50} was determined by intraperitoneal injection in mice. There appears to be no significant difference in the toxicity of procaine in either solvent. Stability studies indicate that procaine is more stable in deuterium oxide at pH and "apparent" pH values of 8.0, 8.5, and 9.0.

THE THERAPEUTIC efficacy of drugs instilled into the eye depends, among other factors, on the pH of the solution in which the drug is administered and on the stability of the drug under such conditions. Procaine is a typical example. These relationships may be adduced from kinetic data and pharmacological studies. Higuchi, *et al.* (1), have studied the influence of pH and temperature on the rate of procaine decomposition in aqueous solutions. It is apparent from their work that procaine deteriorates rapidly in the alkaline pH range. Inhibition of procaine decomposition by complex formation has also been studied (2).

Topical anesthetic activity of procaine depends primarily on the extent of availability of free base. At pH values below 7.0 procaine is relatively inactive topically. Hind and Goyan (3) have shown that at this pH the per cent of procaine free base is less than 1, and even at pH 7.4 it increases only to 3.4%, but at pH 9.0 it becomes 58.5%. The lipoid nature of the corneal epithelium controls the rate at which absorption of procaine will occur in the cornea. The greater the concentation of procaine free base in the lacrimal fluid, the greater should be the extent of procaine penetration and absorption from the cornea which should result in greater and more prolonged local anesthetic activity.

The present study was undertaken to determine the effect of deuterium oxide on the stability of procaine solutions at "apparent" pH values comparable to those in protium oxide (distilled water). In addition, comparison was made of the local anesthetic activity in both systems over the pH range 5.0 to 9.0.

The toxicity of deuterium oxide in biological systems was described by Morowitz and Brown (4). Katz (5) has reviewed the literature dealing with the chemistry and biology of deuterium oxide. Algae and other microorganisms have been cultured in 99.6% deuterium oxide (6). It has been demonstrated (5) that mice and rats can survive when up to about one-third of their body water is replaced by deuterium oxide. When the blood serum approaches about 20% deuterium oxide content, toxic manifestations become evident. Since it appears that deuterium oxide is toxic in animals only when the concentration

in the body fluids reaches high levels, and since deuterium oxide resembles the common solvent protium oxide more closely than any other, it seems appropriate to explore possible pharmaceutical applications of this solvent.

EXPERIMENTAL

Toxicity Study.—The effect of deuterium oxide on the toxicity of procaine was studied by determining the LD_{50} in this solvent. This was conducted on BDF-1[1] strain mice weighing about 25 Gm. Two per cent procaine hydrochloride solutions were prepared in water and deuterium oxide. The doses administered varied from 165 mg./Kg. to 200 mg./Kg. The route of administration was by intraperitoneal injection and each of the four dose levels was administered to a group of 10 mice. See Table I. The LD_{50} was determined by use of the method of Miller and Tainter (7).

TABLE I.—TOXICITY OF PROCAINE IN WATER AND IN DEUTERIUM OXIDE

Procaine in Water		Procaine in Deuterium Oxide	
Dose, mg./Kg.	Death, %	Dose, mg./Kg.	Death, %
165	20	170	10
175	30	180	40
190	50	190	50
200	60	200	60

Determination of ED_{50}.—The cornea provides an ideal site for testing surface anesthesia. It is free of special sensory cells and the free, unsheathed nerve endings are imbedded in the corneal layers. Therefore, the drug has a single uniform membrane to penetrate after which it is in direct contact with sensory nerve fibers. The cornea is also free of fluid channels and blood vessels. It has been shown (8) that the guinea pig elicits a more regular reflex response than the rabbit. In this investigation a modification of the method of Chance and Lobstein (8) was employed.

The local anesthetic potency of procaine in water and deuterium oxide was determined on the cornea of guinea pigs weighing 225–250 Gm. Each animal was held immobile in plastic restraining cages which allowed easy access to the eyes for the instillation of solution. Aqueous procaine solutions were freshly prepared prior to use by dissolving procaine hydrochloride in 0.1 *M* phosphate buffer (pH 7.0) in concentrations ranging from 0.5 to 2.0%. The concentrations of procaine in deuterium oxide ranged from 0.25 to 1.0% and were prepared in a deuterated phosphate buffer solution (pD 7.4). Two drops of the solution were placed on the cornea filling the space between the eyelids. The resulting clearly visible film of solution was allowed to remain in contact with the cornea for 15 seconds. After this period the excess fluid was removed by initiating a blink reflex. At the end of 45 seconds, a stimulus was applied to the cornea of the eye by means of a single thick horsehair which was pressed against the center of the cornea. The same amount of pressure was applied with each stimulation. This was repeated at 1-minute intervals for a period of 1 hour. A failure to respond to the stimulus (the blink reflex) indicated effective anesthesia. The anesthetic effect, recorded as per cent protection, was calculated from the number of minutes in which the blink reflex did not occur out of the 60-minute study period. A minimum of 12 animals or 24 test sites was used for each test solution and the reported value, expressed as a percentage, is the average value for that number of determinations. The logarithm of the concentration of procaine was plotted *vs.* the probit of the per cent protection (Fig. 1). The concentration of procaine solution which produced 50% protection was then determined from the curve. This value is the effective $dose_{50}$ (ED_{50}).

Effect of pH and pD on Anesthetic Activity.—One per cent procaine solutions were buffered at pH 5.0, 6.0, 7.0, 8.0, and 9.0. One-tenth molar buffer solutions were prepared with KH_2PO_4 and sodium hydroxide for pH values 5.0 to 8.0. A sodium borate and hydrochloric acid buffer system was used for pH 9.0. The concentration of procaine in deuterium oxide was 1/2%. The deuterium oxide buffer systems were prepared from the same reagents except that all replaceable hydrogen was exchanged with deuterium. All buffers in deuterium oxide were adjusted to an "apparent" pH corresponding to the pH of the aqueous buffer solutions. The "apparent" pH was measured with a Beckman pH-meter (model H-2) and an appropriate correction (9) to the reading was made to obtain pD.

The corneal reflex test described earlier was used to determine the per cent protection at the different pH and pD values. The data are shown graphically in Fig. 2.

Procaine Stability Study.—The decomposition of procaine in protium oxide and deuterium oxide solutions was studied by the method described by Higuchi, *et al.* (1). The time required for procaine to decompose to 50% of the original concentration (half-life) was determined at pH 8.0, 8.5, and 9.0

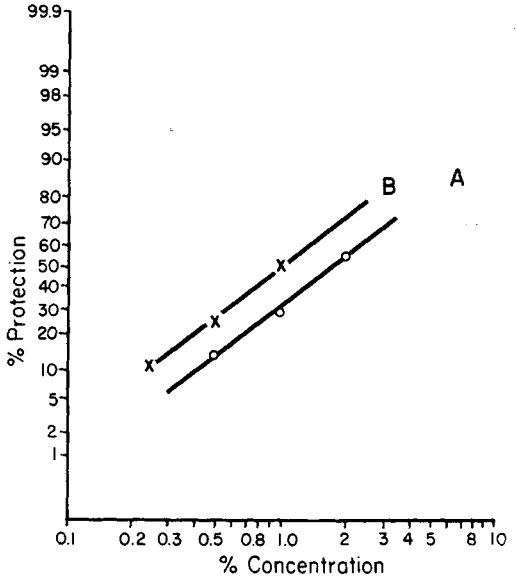

Fig. 1.—Per cent protection plotted in probits; concentration of procaine plotted as logarithm. Curve *A*, procaine in water; curve *B*, procaine in deuterium oxide.

in aqueous buffer solutions and at corresponding pD values for the deuterated system. The replaceable hydrogens in procaine hydrochloride were not exchanged with deuterium prior to the study in the deuterium oxide solutions. The hydrogen introduced in this way did not appreciably affect the hydrogen content of the deuterium oxide. This was verified by analyzing the reaction mixture for deuterium content. The data for these studies are recorded in Table II.

RESULTS AND DISCUSSION

The LD_{50} for procaine hydrochloride in water was 190 ± 12 mg./Kg. and for procaine in deuterium oxide was 190 ± 8 mg./Kg. The data for the LD_{50} studies are shown in Table I. There does not appear to be any significant difference in the toxicity of procaine in either solvent system as determined by intraperitoneal injection in mice.

An appropriate dose of procaine which produced a measurable local anesthetic effect was obtained from a dose response curve (Fig. 1) for procaine in both protium and deuterium oxide solutions. The ED_{50} for procaine in water (curve *A*) is 1.8% ± 0.8%. For procaine in deuterium oxide (curve *B*) the ED_{50} is 1.0% ± 0.5%. The pH of the aqueous procaine solution was 7.0 and that of the procaine in deuterium oxide solution was an "apparent" pH of 7.0 or a pD of 7.4. It appears that the ED_{50} of procaine in deuterium oxide is about one-half of the ED_{50} for procaine in water.

In the study dealing with the effect of pH and pD on the local anesthetic activity concentrations of 1.0% procaine in water and 0.5% procaine in deuterium oxide were used. Per cent protection as a function of pH and pD is shown graphically in Fig. 2. At pH values below 7.0 the per cent protection was low. This in agreement with the findings of Hind and Goyan (3) and Swan (10) who showed that at a pH below 7.0 the per cent of free base is less than 1%. Poor anesthetic activity is expected since it is only the free base which is capable of producing this effect. As the pH is increased to 7.5 the per cent protection increased to 30% and at pH values of 8.0 and 9.0 it increased to 35% and 60%, respectively. At pD 7.4 the per cent protection was 32% and at pD 8.4 and 9.4 the protection increased to 51% and 75%, respectively. At comparable pH and "apparent" pH values the deuterium oxide system offers greater protection than an aqueous system. While per cent protection was approximately the same, the concentration of procaine in deuterium oxide was one-half of that in the aqueous system.

The stability studies indicate that procaine is more stable in deuterium oxide solutions as compared to aqueous solutions at the same pH and "apparent" pH. Increased local anesthetic activity of procaine in deuterium oxide may be accounted for by the fact that procaine free base is more stable in deuterium oxide solutions or that at the same pH and "apparent" pH, a deuterium oxide solution of procaine will contain more free base than in the corresponding aqueous solution.

A simple pH effect is ruled out by the fact that much higher ratios of half-lives are obtained when pH and pD are compared. For example, when aqueous procaine at pH 8.0 is compared with procaine in deuterium oxide at "apparent" pH 8.0, the ratio of half-lives is 3.0. See Table II. However, when an aqueous solution of procaine at pH 8.5 is compared to procaine in deuterium oxide at pD 8.4, the ratio $T^1/_2\ D_2O / T^1/_2\ H_2O$ becomes 8.8.

The availability of deuterium oxide at a reasonable cost has stimulated much research with this solvent in recent years. However, a review of the literature indicated that pharmaceutical applications of this solvent have not been explored. It was the purpose of this investigation to observe the effect of deuterium oxide on the stability of procaine in alkaline solutions and to note the influence on local anesthetic activity. Further studies are currently in progress in which other labile drugs are being investigated. In addition to the effect of this solvent on the stability and activity of certain drugs, it is hoped that information may be obtained that will better explain the mechanisms of drug action and decomposition.

Chromatography and Electrophoresis of Phenothiazine Drugs

By THEODORE J. MELLINGER and CLYDE E. KEELER

Three separation techniques for various phenothiazine tranquilizers are reported in this paper. Electrophoresis with suitable buffer systems and proper voltage permitted fast and distinctive migration of these phenothiazine bases, but tailing interfered with the usefulness of this technique. Paper chromatography with salt solutions as solvents proved to be a valuable and easy procedure for the separation of this group of drugs. Thin-layer chromatography with silica gel showed the most accurate separation of phenothiazine compounds. Combination of chromatography with color reaction or fluorescence permitted good differentiation of the various phenothiazine tranquilizers.

INCREASING INTEREST in the therapy of mental disorders has led to widespread use of phenothiazine derivatives, that are on the market under various names and chemical modifications. There is an immense clinical literature concerning these drugs but little is known about their separation or identification by means of chromatographic procedures or electrophoresis. Three kinds of techniques have been explored and are reported in this paper: electrophoresis, paper chromatography, and thin-layer chromatography. They were tested upon 23 drugs in the search for well reproducible separation methods with variation in R_f values as well as distinctive spots or zones devoid of tailing.

METHODS

Electrophoresis was carried out with buffer systems proposed by Werum, *et al.* (1). The 23 drugs were applied side by side along the starting line on a strip of Whatman 3 MM paper 30 cm. in width. Several strips were run with each buffer system. A Gordon-Misco apparatus for horizontal paper electrophoresis was used. The average potential difference between the electrodes was 500 to 800 v.

Paper chromatography was carried out with Whatman 3 MM filter paper. The dissolved substances were applied in amounts of 5 to 10 mg. in thin streaks along the starting line and were developed in the ascending direction.

Thin-layer chromatography was run on glass plates 20 × 20 cm. coated with a layer of 500 μ of silica gel G Merck. The coated plates were dried overnight in an incubator at 38°. After spotting the drugs, the chromatograms were developed in the ascending direction.

To locate the drugs, their fluorescence was examined under an ultraviolet lamp with a peak emission at 253 mμ and one at 360 mμ. To produce color reactions, 40% sulfuric acid was sprayed upon the developed chromatograms.

RESULTS

Electrophoresis.—Because all phenothiazine drugs in this study are bases, and therefore positively charged molecules, they migrate toward the negative end of the paper. With appropriate buffer systems and a proper potential difference between the two poles, migration of the drugs was accomplished in 40 to 60 minutes. With the new organic buffers proposed by Werum, *et al.*, the migrating phenothiazine compounds could be followed easily by their fluorescence under ultraviolet light. These new buffers do not quench the fluorescence of the drugs as barbiturate buffers do. When the buffer solutions were modified by leaving out the formamide, the same migration was obtained and the color reactions were more distinctive.

Table I presents the electrophoretic values of 19 phenothiazine compounds and of four other substances closely related to the phenothiazine tranquilizers. The migration values of the drugs are shown in the vertical columns, as they were run on the same paper. However, the values for each substance cannot be compared exactly on the horizontal lines, since they were not run together. In spite of this, there can be seen a general trend in most of the substances to decrease the speed of migration with increasing pH, possibly due to decreasing ionization at higher pH. This is less apparent for the three sulfoxidized phenothiazines, imipramine, and the two thypendyl compounds. It cannot be ascertained from these experiments whether the deviations of the latter compounds are merely due to physico-chemical differences, or are

Prothypendyl	6.0	6.2	5.8	5.5	7.9	7.4

the result of chemical interaction with some of the organic buffer substances used.

With most buffer systems, the drugs migrated at very similar speeds when compared vertically in Table I. Buffer pH 8 permitted the best separation. A drawback of paper electrophoresis was excessive tailing of most compounds, except phenothiazine sulfoxides, when concentrations over 10 mg. per spot were applied.

Paper Chromatography.—When the conventional solvent systems of lower alcohols with water or acidic or basic solutions are used, all phenothiazine drugs run with or near the front, and form tails. Low affinity of the drugs for the stationary phase is probably the cause. Although this paper chromatographic technique is so unsatisfactory, it is the most frequently cited.

When the lipid solvents were omitted and salt solutions were used as solvents, the picture changed, and a satisfactory separation of all phenothiazine drugs could be carried out on paper chromatography. Small amounts of acids or lower alcohols added to these salt mixtures, not exceeding 10% of the total volume, permitted a further variation of R_f values. Table II shows the solvents used and the wide variety of R_f values for the phenothiazine compounds. When these solvent systems were studied, they appeared to be similar to "reverse phase techniques" since substances with higher lipid solubility showed lower R_f values.

Another method using mineral oil treated paper with methanol as the solvent gave very satisfactory separations without tailing, especially when used in circular chromatography to distinguish the original phenothiazine drugs from their metabolites in urine or bile. When the differentiation of one original phenothiazine derivative from another is concerned, it was not as suitable since the drugs developed nearly the same R_f of about 0.60 to 0.70.

Thin-layer Chromatography.—Although several techniques for the separation of lipids similar to paper chromatographic procedures had been described before (2–4), the introduction of thin-layer chromatography by Stahl (5–7), constituted real progress in the separation of lipid soluble substances. Reproducible standard conditions of a uniformly distributed layer of the absorbent is attained. Several substances or mixtures together with reference compounds can be developed and compared on the same chromatogram. We tested this technique for the separation of phenothiazine drugs that are all nitrogenous bases with relatively high fat solubility resembling, in this property, many of the alkaloids, antihistaminics, and synthetic narcotics.

When silica gel G Merck was used as the thin layer, all phenothiazine derivatives showed a strong absorption to silica gel. Chloroform, ether, hexane, or other lipid solvents did not move the substances from their starting line even after many hours of running the chromatogram. However, when an appropriate mixture of lipid solvent and water was used, the drugs migrated with a variety of quite distinctive R_f values. This is shown in Table III. The average time of development required in the ascending direction was 2 hours. This separation method was superior to that obtained by paper chromatography with salt solutions where a spreading out of the spots often takes place. The sensitivity or detectability of the spots moving in sharply defined zones was increased. Figure 1 shows the sharp separation of a thin-layer chromatogram compared with the spots of electrophoresis. Even when some of the drugs have nearly similar R_f values with one solvent system they can be distinguished by their fluorescences, their color reactions, or by a two-dimensional chromatogram. This property makes the method especially suitable for testing the purity or decomposition of phenothiazine drugs. The silica gel thin-layer technique proved to be, by far, the best procedure for any phenothiazine drug.

Location of the Drugs.—Since all phenothiazine

derivatives of this study showed a visible fluorescence of varying intensity under ultraviolet irradiation, this locating method was very satisfactory. An ultraviolet lamp having a maximum intensity at 263 mμ was superior to one with 360 mμ for this purpose. The sensitivity of this procedure was in many cases higher than with color reactions. Compounds having a chlorine on position 2 of the phenothiazine nucleus, such as chlorpromazine, perphenazine or perchlorperazine, or agents without substitution on this position, such as promazine and mepazine showed the least fluorescence or appeared often as quenched zones on the slightly fluorescent background of the paper or silica gel. This happened especially in solvent systems containing acids. It was found that the combination of acid solvent and ultraviolet or daylight easily decomposed the phenothiazine drugs, usually decreasing their visible fluorescence. Acidic solvent systems had to be used in light-protected tanks and avoided whenever possible.

When the phenothiazine drugs were run together on the same chromatogram, it could be easily observed that each emitted a fluorescent color according to its substitution on position 2 on the phenothiazine nucleus. For instance, drugs with a trifluomethyl group, as triflupromazine, trifluoperazine, or fluphenazine, emit the same bluish-yellow fluorescence. They could not be differentiated from each other by this method, but they could be distinguished easily from acylated compounds like acetophenazine, proketazine, or butyrylperazine, that showed an orange-to-brick-red fluorescence. Thioridazine showed a blue fluorescence which was strongly intensified by potassium permanganate spray. The fluorescent colors of the various phenothiazine drugs are shown in Table IV together with their color reactions.

All phenothiazine drugs responded to 40% sulfuric acid spray with various color reactions that distinguish them according to their radicals on position 2. As with the fluorescence, this color test did not permit any further differentiation between drugs with different radicals on position 10. When ferric chloride or ferric nitrate was added to 40% sulfuric acid spray, no difference was observed in color variation or intensity except the velocity of color development. These catalysts are useful in colorimetry of phenothiazines but superfluous in spray reagents for chromatograms. Adding 1% *p*-dimethylaminobenzaldehyde in 25% sulfuric acid did not show any further color difference, but later

[a] Dark zone on slightly fluorescent background. [b] Visible blue after adding $KMnO_4$ or bromine. [c] Increased blue-green fluorescence after 40% H_2SO_4 spray. [d] Brick fluorescence after 40% H_2SO_4 spray.

the spots turned to a green-blue tint. The palladium chloride reaction (8), despite its good sensitivity, showed the least color differentiation.

COMMENTS

The described procedures have revealed that the phenothiazine compounds examined in our experiments cannot be recognized completely by their color reactions or fluorescent properties. Only chromatography and electrophoresis made it possible to distinguish between substances giving the same color reactions or fluorescence but with a different radical on position 10 of the phenothiazine nucleus. This combination of chromatographic techniques with color reactions was of great help in many analyses in our laboratory concerned with the identification of phenothiazine drugs in toxicological investigations, in drug metabolism studies, in purification procedures, and in purity tests of commercial preparations.

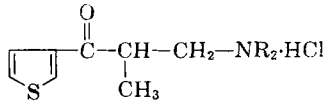
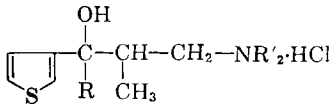
New 3-Thiophene Derivatives as Sedative Agents



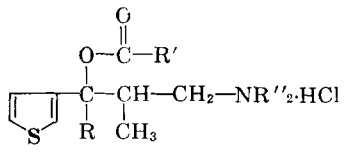
By HEINO A. LUTS† and W. LEWIS NOBLES

A group of compounds prepared from 3-propionylthiophene has been synthesized for pharmacological evaluation. Preliminary studies indicate that some of these agents combine sedative and stimulating properties in an unusual manner.



IN A SEARCH for compounds possessing possible analgetic activity, a program designed to produce certain Mannich bases and their derivatives from 3-propionylthiophene has been carried out. It has been noted that in many cases the 3-thienyl analog often has greater activity than the corresponding 2-thienyl compound (1–5). In fact, Campaigne (5) has suggested that, based on available data, it is impossible to predict the activity of the 3-thienyl isomer from a knowledge of the activity of the corresponding 2-isomer. Furthermore, Campaigne suggests that in any program in medicinal chemistry involving thiophene analogs, the 3-isomer should always be included since there is a high probability that it will be active and a good chance that it will be more active than the 2-isomer.

Previously, we (6) reported on the preparation of 2-substituted analogs of *d*-propoxyphene. In line with this and the above statements of Campaigne, it appeared quite logical to extend this work to the preparation of the corresponding 3-isomers.



In our work, three general types of compounds were prepared. These are

Type I

Type II

Type III

The compound designated as Type I was prepared using the standard conditions normally employed in the Mannich reaction (7). Type II compounds were formed by the conventional Grignard reaction on the preceding Mannich base; also, the Mannich base was reduced to the

the spots turned to a green-blue tint. The palladium chloride reaction (8), despite its good sensitivity, showed the least color differentiation.

COMMENTS

The described procedures have revealed that the phenothiazine compounds examined in our experiments cannot be recognized completely by their color reactions or fluorescent properties. Only chromatography and electrophoresis made it possible to distinguish between substances giving the same color reactions or fluorescence but with a different radical on position 10 of the phenothiazine nucleus. This combination of chromatographic techniques with color reactions was of great help in many analyses in our laboratory concerned with the identification of phenothiazine drugs in toxicological investigations, in drug metabolism studies, in purification procedures, and in purity tests of commercial preparations.

corresponding secondary alcohol by the use of sodium borohydride. A Type III compound was synthesized by means of refluxing the sodium salt of the alcohol with propionyl chloride in dioxane.

The general synthetic scheme utilized in the preparation of these agents follows

GENERAL SCHEME OF SYNTHESIS

Preliminary information (8) indicates that one of the compounds, 3-dimethylamino-2-methyl-1(3-thienyl)-1-phenylpropanol hydrochloride, combined sedative and stimulating properties in a most interesting manner.

EXPERIMENTAL

Type I Compounds

3 - Dimethylamino - 2 - methyl - 1 - (3 - thienyl)-1-propanone Hydrochloride.—By the usual procedure for the preparation of a Mannich base from a ketone, 13.8 Gm. (0.1 mole) of 3-propionylthiophene, 3 Gm. of paraformaldehyde, and 8.1 Gm. (0.1 mole) of dimethylamine hydrochloride were refluxed in 25 ml. of ethanol. After refluxing for 29 hours, the solution was filtered while hot; it was then cooled. Subsequently, a mixture of 15 ml. of acetone and 85 ml. of dry ether was added. The solid obtained was removed by filtration and recrystallized to analytical purity from a solution of ethanol-ether to produce a yield of 9.1 Gm. (42%) of a compound, m.p. 158–160°.

Anal.—Calcd. for $C_{10}H_{16}ClNOS$: C, 51.40; H, 6.90; S, 13.72. Found: C, 51.37; H, 6.96; S, 13.86.

3-(3-Dimethylamino-2-methyl-propanoyl) thiophene.—This free base was obtained by making an aqueous solution of the above hydrochloride alkaline with ammonium hydroxide and ether extracting the resulting product. The ether extract was dried over Drierite and distilled in the range of 104–105°/0.3 mm.

Anal.—Calcd. for $C_{10}H_{15}NOS$: C, 60.85; H, 7.66; S, 16.02. Found: C, 60.73; H, 7.52; S, 16.13.

Type II Compounds

3 - Dimethylamino - 2 - methyl - 1 - (3 - thienyl)-1-propanol Hydrochloride.—Four hundred milligrams of sodium borohydride was added to 50 mg. of 50% methanol at 18–20°. Two and three-tenths grams (0.01 mole) of 3-(3-dimethylamino-2-methylpropanoyl) thiophene hydrochloride in 50% methanol was added dropwise at 20–22°. After the addition, the reaction mixture was warmed to 30°, maintained at this temperature for 30 minutes, and then heated to 50° for 15 minutes. Methanol was removed *in vacuo*. The residue was made basic with 6 *N* sodium hydroxide, extracted with ether, and dried over Drierite. Anhydrous hydrogen chloride was bubbled in. Recrystallization from an ethanol-ether mixture yielded 1.5 Gm. (60%) of a compound which melted in the range of 154–157°.

Anal.—Calcd. for $C_{10}H_{18}ClNOS$: C, 51.10; H, 7.72. Found: C, 51.33; H, 7.83; IR: OH, 303 μ.

3 - Dimethylamino - 2 - methyl - 1 - (3 - thienyl)-1-phenyl-propanol Hydrochloride.—Phenylmagnesium bromide was prepared from 3.16 Gm. (0.2 mole) of bromobenzene, 730 mg. (0.03 mole) of magnesium turnings, and anhydrous ether. The Grignard solution was stirred at room temperature during the dropwise addition of 2.95 Gm. (0.015 mole) of 3-(3-dimethylamino-2-methylpropanoyl) thiophene in 25 ml. of ether. The reaction mixture was stirred and refluxed for 1 hour; the mixture was then decomposed by the addition of 7 ml. of water. The ether layer was separated, the reaction mixture was extracted with two 25-ml. portions of ether, and the ether layers were combined and dried over Drierite. The hydrochloride was prepared in ether solution, using anhydrous hydrogen chloride. Recrystallization from an ethanol-ether mixture yielded 3.7 Gm. (81%) of a compound which melted in the range of 210–212°.

Anal.—Calcd. for $C_{16}H_{22}ClNOS$: C, 61.80; H, 7.13. Found: C, 61.79; H, 7.06.

3 - Dimethylamino - 2 - methyl - 1 - (3 - thienyl)-1- cyclohexyl - 1 - propanol Hydrochloride.—Cyclohexylmagnesium bromide was prepared from 3.2 Gm. (0.02 mole) of bromocyclohexane, 730 mg. (0.03 mole) of magnesium turnings, and anhydrous ether. The Grignard solution was stirred at room temperature during the dropwise addition of 2.95 Gm. (0.015 mole) of 3-(3-dimethylamino-2-methylpropanoyl)thiophene in 25 ml. of dry ether. The reaction mixture was stirred and refluxed for 1 hour and then decomposed by the addition of 7 ml. of water. The ether layer was separated, the reaction mixture was extracted with two 25-ml. portions of ether, and the ether layers were combined and dried over Drierite. The hydrochloride was prepared in ether solution, using anhydrous hydrogen chloride. A yield of 3.6 Gm. (76%) of the compound which melted in the range of 233–234° was obtained after recrystallization from an ethanol-ether mixture.

Anal.—Calcd. for $C_{16}H_{28}ClNOS$: C, 60.57; H, 8.80; N, 4.39. Found: C, 60.46; H, 8.72; N, 4.10. U.V. max. 233 mμ (5110); 238 mμ shed (5900); 245 mμ shed (3020).

3 - Dimethylamino - 2 - methyl - 1 - (3 - thienyl)-1-benzyl-1-propanol Hydrochloride.—Benzylmagnesium bromide was prepared from 3.4 Gm. (0.02 mole) of benzyl bromide, 730 mg. (0.03 mole) of magnesium turnings, and anhydrous ether. The Grignard solution was stirred at room temperature during the dropwise addit on of 2.9 Gm. (0.015 mole) of 3-(3-dimethylamino-2-methylpropanoyl) thiophene in 25 ml. of dry ether. The reaction mixture was stirred and refluxed for 1 hour; it was then decom posed by the addition of 7 ml. of water. The ether layer was separated, the reaction mixture was extracted with two 25-ml. portions of ether, and the ether layers were combined and dried over Drierite. The hydrochloride was prepared as indicated above. After recrystallization from an ethanol-ether mixture, a yield of 3.8 Gm. (78%) of a compound which melted at 207° was obtained.

Anal.—Calcd. for $C_{17}H_{24}ClNOS$: C, 62.46; H, 7.40; N, 4.29. Found: C, 62.12; H, 7.19; N, 4.38.

3 - Dimethylamino - 1 - propyl - 1 - (3 - thienyl)-2-methyl-1-propanol Methiodide.—Three hundred and ninety-four milligrams (0.002 mole) of 3-(3-dimethylamino-2-methylpropanoyl) thiophene was treated with an equal molar quantity of propylmagnesium bromide in 15 ml. of dry ether; this mixture was refluxed for 2 hours and then decomposed with the addition of water. The ether .ayer was separated and extracted with two 10-ml. portions of ether. The ether layers were combined, dried over Drierite, and then evaporated to dryness. The residue was dissolved in 10 ml. of acetone. The quaternary salt of the free base was formed by the addition of 1 ml. of methyl iodide; 5 ml. of ether was added to precipitate the salt. A yield of 5.2 Gm. (68%) of the methiodide, m.p. 120–127°, was thus obtained.

Anal.—Calcd. for $C_{14}H_{26}INOS$: C, 43.87; H, 6.84. Found: C, 43.38; H, 6.56.

Type III Compound

4 - Dimethylamino - 1 - phenyl - 2 - (3 - thienyl)-3-methyl-2-propanoyloxybutane Hydrochloride.—To 20 ml. of dry dioxane, 46 mg. (0.002 mole) of sodium metal was added, and the mixture was stirred and heated at reflux temperature until sodium sand resulted. Five hundred and eighty milligrams (0.002 mole) of 3-dimethylamino-2-methyl-1-(3-thienyl)-1-benzyl-1-propanol was added slowly and refluxed for 6 hours. The solution was cooled, and 186 mg. (0.0022 mole) of propionyl chloride was added. After refluxing for 6 hours, the mixture was cooled, water was added, and the mixture was made basic to litmus with sodium carbonate. The solution was extracted three times with 20-ml. portions of ether; the combined extracts were dried over anhydrous potassium carbonate, and the compound was converted in the usual manner to the hydrochloride. A yield of 297 mg. (39.4%) of a compound, m.p. 217°, was thus obtained.

Anal.—Calcd. for $C_{20}H_{28}ClNO_2S$: C, 62.89; H, 7.39; N, 3.67. Found: C, 62.61; H, 7.33; N, 3.73.

Quantitative Fluorometric Determination of Methandrostenolone

By F. TISHLER, P. B. SHETH, M. B. GIAIMO, and W. J. MADER

A fluorometric procedure is described for the determination of methandrostenolone (17α-methyl-17β-hydroxyandrosta-1,4-dien-3-one). The method is based on the flluorogen formed when the steroid is heated with hydrochloric acid at 100°. In order to determine the selectivity of this reaction, a number of related steroids has been studied.

METHANDROSTENOLONE[1] is a new tissue-building compound prepared in these laboratories. Its structural formula is illustrated:

Quantitative Fluorometric Determination of Methandrostenolone

By F. TISHLER, P. B. SHETH, M. B. GIAIMO, and W. J. MADER

A fluorometric procedure is described for the determination of methandrostenolone (17α-methyl-17β-hydroxyandrosta-1,4-dien-3-one). The method is based on the flluorogen formed when the steroid is heated with hydrochloric acid at 100°. In order to determine the selectivity of this reaction, a number of related steroids has been studied.

METHANDROSTENOLONE[1] is a new tissue-building compound prepared in these laboratories. Its structural formula is illustrated:

Received March 22, 1962, from the Research Department, Ciba Pharmaceutical Co., Summit, N. J.
Accepted for publication April 11, 1962.
[1] Ciba's trade name for methandrostenolone is Dianabol.

The ultraviolet spectrum of methandrostenolone in methanol appears in Fig. 1 and can be used for the quantitative determination of the compound; however, ultraviolet analysis in methanol cannot be employed when methyltestosterone is present as an impurity since each steroid exhibits a maximum around 241 mμ.

Fluorometry offers a means to the qualitative and quantitative determination of microgram amounts of steroids. Sulfuric acid has been employed by many workers (1–4) to form the fluorogen used for the determination of various steroids. Recently Touchstone and Murawec (5) found that certain steroids exhibited a greater fluorescent intensity when heated with a 2*N* methanolic potassium hydroxide solution prior to being dissolved in sulfuric acid than when dissolved in sulfuric acid alone. The use of hydrochloric acid to induce fluorescence in steroids has also been reported (6–8).

It has been observed in these laboratories that when methandrostenolone is heated at 100° with hydrochloric acid a fluorogen is formed, which is the basis of the method of analysis to be described. Under the same conditions, methyltestosterone exhibits no fluorescence, thereby offering a means of determining methandrostenolone in which methyltestosterone might be present as an impurity. Optimum conditions for the hydrochloric acid-induced fluorescence have been determined and a number of related steroids have been studied in order to determine the selectivity of this reaction.

EXPERIMENTAL

Apparatus.—All measurements are made on an Aminco-Bowman spectrophotofluorometer with a quartz cell having a 1-cm. light path using a $^1/_{16}$-in. defining slit (band pass = 6 mμ) and an RCA 1-P-21 photomultiplier. The excitation and fluorescent spectra are obtained on an Electro model 101 XY recorder. The instrument is calibrated against a quinine solution by the method of Sprince and Rowley (9). Absorbance measurements are made with a Cary recording spectrophotometer.

Reagents.—All steroids used in the study are of reference standard quality, either assayed by phase solubility (10) or purchased from the U.S.P. as reference standards. All other reagents are reagent grade. Standard methandrostenolone solutions are prepared containing 2.5, 5.0, 7.5, 10.0, 12.5, and 15.0 mcg./ml. in methanol.

Procedure.—Weigh a counted number of not less than 20 tablets and reduce them to a fine powder. Transfer an accurately weighed portion of the powder, equivalent to 10 mg. of methandrostenolone, to a 100-ml. volumetric flask. Add 75 ml. of methanol, shake for 10 minutes, dilute to volume with methanol, and mix well. Centrifuge a portion of the mixture. Transfer a 5.0-ml. aliquot sample of the clear solution to a 100-ml. volumetric flask, dilute to volume with methanol, and mix well. (Concentration = 5.0 mcg./ml.)

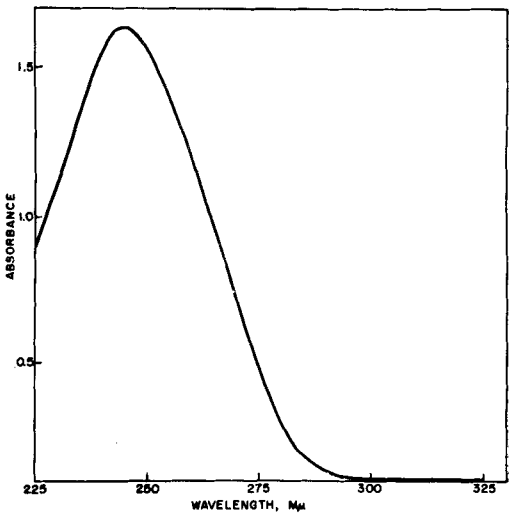

Fig. 1.—Ultraviolet absorption spectrum of methandrostenolone in methanol, 0.01 mg./ml.

Pipet 2.0 ml. of the sample preparation, 2.0 ml. of a standard solution (5.0 mcg./ml.), and 2.0 ml. of methanol into separate 25-ml. volumetric flasks. Add 5 ml. of concentrated hydrochloric acid and heat in an oven at 100°. After 20 minutes, wash down the sides of the volumetric flasks with 2 ml. of methanol and continue heating for an additional 20 minutes. Cool the flasks to room temperature, dilute to volume with methanol, and mix well. Read the fluorescent intensity of the blank, sample, and standard solutions at an excitation of 280 mμ and a fluorescence of 345 mμ after setting the photometer sensitivity to full and the meter multiplier to 0.03. Calculate the amount of methandrostenolone in each tablet by the following formula

$$\frac{A_o - A_b}{A_s - A_b} \times 10 \times \frac{Wt}{Ws} =$$

mg. of methandrostenolone/tablet

where Ao = fluorescent intensity of the sample, As = fluorescent intensity of the standard, Ab = fluorescent intensity of the blank, Wt = average weight per tablet in Gm., and Ws = weight of sample in Gm.

DISCUSSION

When exhibited, excitation and fluorescent maxima were obtained for all steroids used in this study. The excitation and fluorescent spectra for methandrostenolone appear in Fig. 2. In order to determine the optimum conditions for the formation of the fluorogen, the fluorescence of the final solution as a function of time and milliliters of hydrochloric acid added was investigated. From Figs. 3 and 4 it can be seen that at 100°, a constant maximum fluorescence is obtained after 20 minutes using 4 ml. of hydrochloric acid. To be sure of maximum fluorescent intensity, 5 ml. of acid was used in the procedure. It was found that, due to evaporation of the solvent over the required heating period, reproducible results were not always obtained be-

cause of unreacted methandrostenolone on the sides of the flask. For this reason, a second heating period was employed after washing the flasks with 2 ml. of methanol. A plot of fluorescent intensity *vs.* concentration was found to be linear up to 30 mcg./25 ml. of final solution (Fig. 5).

Temperatures below 100° were unsatisfactory, and at room temperature the fluorogen was not formed. Dilution with water or dilute hydrochloric acid rather than methanol decreased the fluorescent intensity in all cases.

As a test of the applicability of the fluorometric procedure to pharmaceutical preparations, several

lots of tablets containing methandrostenolone were analyzed by both the proposed method and by ultraviolet analysis. The results appear in Table I. The results on several commercial lots, performed in triplicate, showed a precision of ±2%.

Common tablet excipients did not interfere with the fluorescent technique. In order to determine whether methyltestosterone interfered with the fluorometric procedure, several samples of methandrostenolone containing up to 10% of methyltestosterone were assayed for methandrostenolone. Methyltestosterone itself showed no fluorescence

TABLE I.—COMPARISON OF TABLETS BY FLUORESCENT AND ULTRAVIOLET PROCEDURES

Sample	Description and Declaration, mg.	Methandrostenolone Found, mg. Fluorescent	Ultraviolet
1	2.5	2.47	2.49
2	2.5	2.48	2.50
3	5.0	4.94	5.02
4	1.0 with 9α-fluoro-16α-methylprednisolone[b]	1.05	1.04[a]

[a] A preliminary extraction and separation is necessary before U.V. analysis can be employed. [b] Ciba's trade name for 9α-fluoro-16α-methylprednisolone is Gammacorten.

with hydrochloric acid but when present in concentrations greater than 8%, complete development of the fluorogen was inhibited.

A number of related steroids was studied in order to determine the selectivity of the reaction and the effect of various groups on the molecule (see Table II). Of the various steroids studied, only methandrostenolone, ethinyl estradiol, 17α-methylestradiol, and 17α-ethyl-17β-hydroxyandrosta-1,4-dien-3-one showed fluorescence under the conditions employed. The excitation spectrum which is the same for ethinyl estradiol and 17α-methylestradiol appears in Fig. 6. From Figs. 2 and 6, it can be seen that methandrostenolone can be readily distinguished from ethinyl estradiol and 17α-methylestradiol as the latter compounds show no maximum at 310 mμ; however, methandrostenolone cannot be distinguiushed from 17α-ethyl-17β-hydroxyandrosta-1,4-dien-3-one as both excitation and fluorescent spectra are very similar.

It is, therefore, indicated that hydrochloric acid-induced fluorescence is applicable only to methandrostenolone and certain structurally related steroids. The reaction appears to be selective for $\Delta^{1,4}$-dien-3-one or $\Delta^{1,3,5,(10)}$-trien-3-ol steroids which have both a 17β-hydroxy and 17α-alkyl or alkyne substitution. Further studies are being carried out to determine the chemistry of the reaction of hydrochloric acid-induced fluorescence and to determine the effect of various other substitutions at the 17α-, 17β-, and 3-positions.

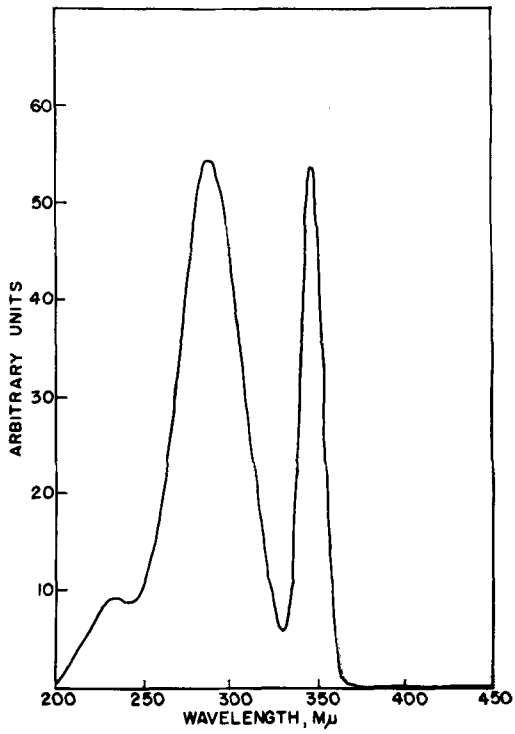

Fig. 6.—Excitation spectrum for both ethinyl estradiol and 17α-methylestradiol, fluorescence held at 345 mμ.

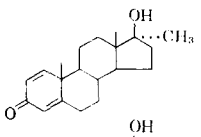
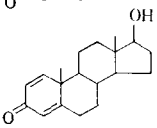
SUMMARY

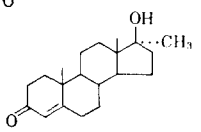
1. A method is described for the quantitative fluorometric determination of methandrostenolone.

2. A number of related steroids is studied to determine the selectivity of hydrochloric acid-induced fluorescence

TABLE II.—FLUORESCENCE OF 17α-METHYL-17β-HYDROXYANDROSTA-1,4-DIEN-3-ONE AND SOME RELATED COMPOUNDS

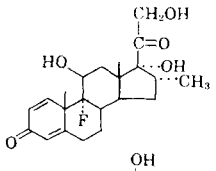


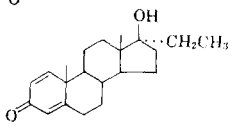


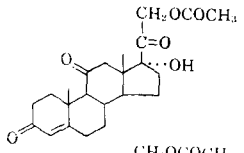


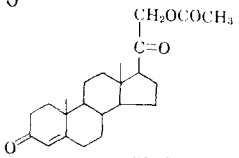
Compound	Structure	Relative Fluorescent Intensity
17α-Methyl-17β-hydroxyandrosta-1,4-dien-3-one		100
17β-Hydroxyandrosta-1,4-dien-3-one		Nil
Methyltestosterone		Nil

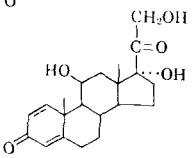
TABLE II (*Continued*)

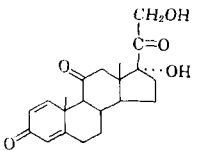


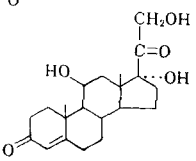


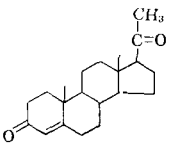


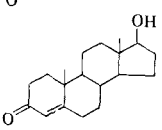


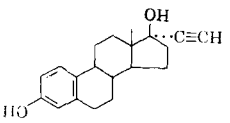


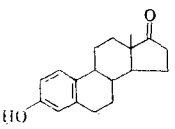


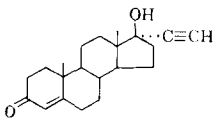


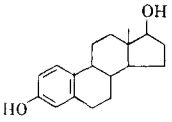


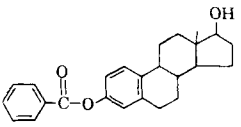


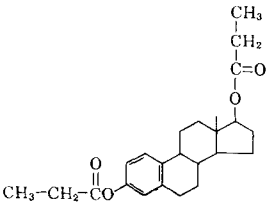


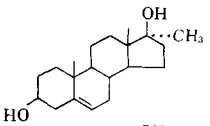


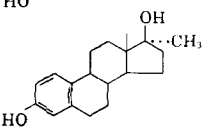












Compound	Structure	Relative Fluorescent Intensity

A Punch and Die Control Program and Its Contribution to Tableting Technology

By C. J. SWARTZ, S. WEINSTEIN†, J. WINDHEUSER‡, and J. COOPER

The necessity for a comprehensive quality control program for tableting tools is discussed and the establishment of tool specifications and inspection facilities are described. Several experiments are presented leading to the evaluation of steels, tool shapes, tolerances, granulations, and tool maintenance on the effective life span of the tableting tools.

IN RECENT years tablets have become the most widely employed mode of administering drugs orally. As a result, the techniques involved in their preparation have been under the intensive scrutiny of pharmaceutical researchers to a continually greater degree. The spirit of criticism and inquiry which has developed in this important area of technology has produced many new innovations in techniques and equipment for tableting operations. The latter developments have included multilayer and compression coating machinery as well as increasingly higher speed presses equipped with induced or forced feeders.

Although these more complex devices have undergone considerable study, the important area of tableting tools has been left relatively untouched by both the tablet machinery manufacturers and the industries which employ them. An awareness of this deficit has recently been referred to in two articles published by the tableting tool industry. Gaskell (1) has stated that "the quality of the finished product depends in no small measure on the quality of the tools which actually compress the powders." It is not difficult to realize that with machines with outputs of 3000 to 6000 tablets/min., many tooling difficulties never previously encountered could be anticipated. Heavy losses in productivity resulting from poor quality punches and concurrent frequent tool replacement certainly must be avoided. If the critical variables cannot be adequately controlled, the utility of the high-speed machinery is seriously hampered. Bobbitt (2) has further noted that "mechanical perfection as well as selection of the proper tooling materials are both necessary precursors to permit modern presses to deliver the precision performance and large volume output that has been engineered into them."

Despite commentary such as the above from punch and die manufacturers indicating the need for exacting and reproducible tool quality, experiences at Ciba disclosed a definite need for the initiation of a routine quality control program for incoming tableting tools. To substantiate this, a few specific examples might be of value.

Aside from the normal processing errors that were encountered in dealing with suppliers, numerous problems have developed of which the following are representative: oversized and undersized punch heads, shank diameter irregularities, oversized punch tips, improper punch face finish including surface polish, monogram irregularities, nonuniformity of steel hardness throughout tool, overall punch length variations, and nonconcentricity of die bore and punch tip.

Prior to the initiation of an inspection program, our concept of the causes of the tooling problems which beset us was limited. However, inspection of incoming punches and dies revealed a vast array of nonconformance to specifications set up by the tool suppliers themselves. Certainly no comment is required relevant to the potential difficulties which would be encountered when using unsatisfactory tooling as described above.

It might be advantageous to dwell in greater depth on the subject of punch face characteristics. An example of an unsatisfactory finish on a punch face can be observed in Fig. 1, the obvious irregularities being readily apparent. It takes little imagination to appreciate what effect a punch finish such as this would have on the tablets compressed from it. The results obtained when these punches were returned to the manufacturer for corrective action can be seen in Fig. 2. The faces have been overbuffed and, although the buffing considerably improved the appearance of

Fig. 1.—Punch tip showing surface irregularities.

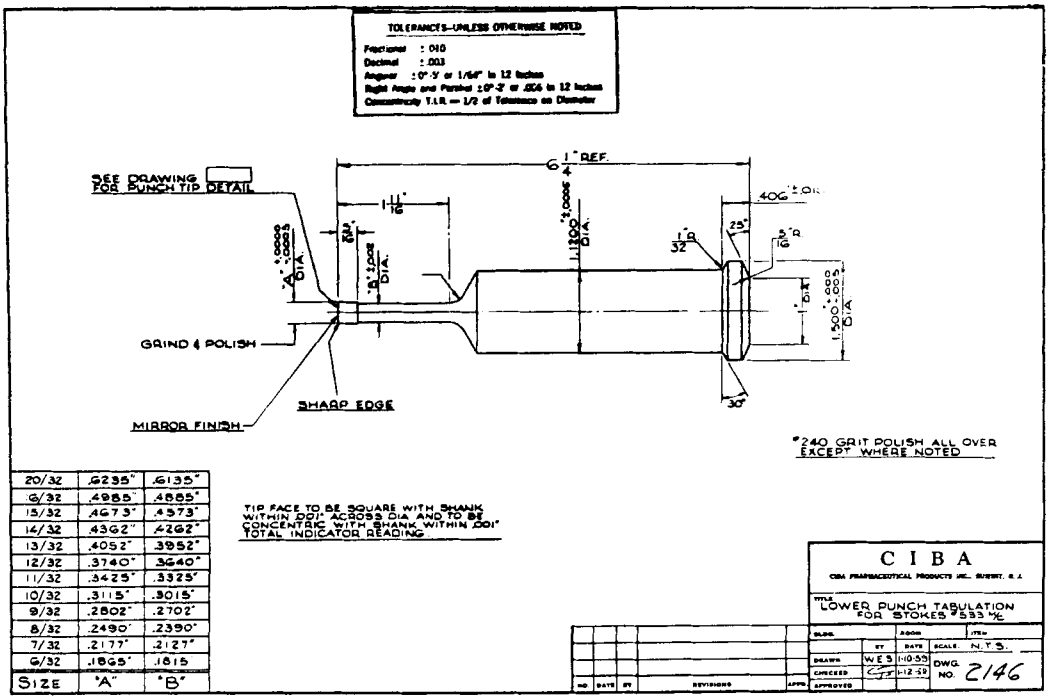
the face of the punch, it also removed a significant amount of the embossed monogram, particularly the letter A. These punches were rejected a second time. Unfortunately, the above was not an isolated example of unsatisfactory tools obtained from the punch and die manufacturers.

In the pharmaceutical industry controls are established over all aspects of manufacturing procedures. Since tooling is one of the major factors governing the quality of finished tablets, a program of inspection must be considered to be in the category of other necessary incoming material inspections, such as packages and chemicals. Since machine problems often cause considerable production delays as well as postponement of product introductions, we felt that it was important to initiate a more comprehensive quality control program for our tableting tools. As a result, studies were undertaken to develop a standardized program for tool purchase and control.

DESIGN OF THE CONTROL PROGRAM

The objective of a control program for punches and dies, as in any other quality control program, was to define clearly and precisely the tooling desired and subsequently to maintain this high quality of tooling through careful inspection. The first step toward our objective involved the establishment of tool specifications and tolerances for all punches and dies acceptable both to Ciba and the tool suppliers.

Development of Specifications.—The development of satisfactory tool specifications required the combined efforts of several divisions, including Pharmaceutical Manufacturing, Plant Engineering, Purchasing and Pharmacy Research, as well as the cooperation of the tool manufacturer. The specifications established were based upon the requirements of the machines used, the products being manufactured, and the working tolerances of the tool manufacturers. To obtain maximum flexibility, a system of drawings was developed encompassing monograms, punch blanks, punch tips, dies, and special shaped punch and die sets.



Preliminary drawings of all tools used were developed and eventually assumed the form seen in Fig. 3. This representative example is a typical punch body drawing with carefully evaluated tolerances on all critical dimensions. All specification drawings include tooling size ranges from $^{6}/_{32}$ to $^{20}/_{32}$ inch by the use of appropriate tabulations. Separate punch tip detail drawings define tip shape, depth of concavity, types of monogram, and the length of the tools. In order to reproduce the quality of the punch face it was necessary to control the quality of the hobs being used by the manufacturer. This required the preparation of monogram drawings which defined tolerances for every facet of the monogram, including spacing, depth, and overall length of each of the letters. Further, in consideration of recent tablet counterfeiting attempts, it is evident that the development of such precisely controlled monograms would facilitate the detection of these criminal acts.

Fig. 2.—Punch tip after buffing.

Inspection Program.—The establishment of specifications as described above did not, in itself, solve the problem of tool control. The initiation of a 100% inspection program for incoming punches and dies was found to be necessary. Engineers and mechanics, utilizing appropriate instruments, developed standard techniques for checking all critical dimensions. Figure 4 presents a view of the inspection area showing the equipment used for checking all critical dimensions. Present are measuring tools, including indicating micrometers, gauge blocks, an indicating bore gauge, and a master form gauge. This precision equipment can measure to an accuracy range of ±0.0001 in. The inspector checks the dimensions against the drawings which were sent with the tool order to the manufacturer. Other inspection devices include a depth measuring stereomicroscope to measure punch face characteristics. A steel hardness tester is also available, so that punches and dies may be checked not only for conformance to specifications, but also for uniformity of steel temper throughout each tool. The steels currently used for tooling are based upon the suppliers' recommendations.

If the complete set of punches or dies meets all the standards, they are then accepted and etched

with a control number for identification. Should the tools fail to meet specifications, they are rejected and returned to the manufacturer for reprocessing or replacement.

Considering aspects of the inspection procedure, all the dimensions defined are important and are checked. However, through our experience, several areas have been found to be of more critical concern and limits of ±0.0005 in. have been established for them. These regions include head thickness, overall punch length, and shank diameter. Justification for this may best be described by way of example. During compression, the influence of variation in overall length of the lower punches will affect weight variation between tablets, thus altering the dose finally administered to the patient. Hardness of the tablets will not be uniform and the mechanics of compression coating operations may be seriously affected. Tapered and oversized punch shanks can lead to seizing of the punch body in the head of the machine, with resultant severe turret damage. The concentricity of the die bore, in relation to the concentricity of the punch tip, if not within specified tolerances can seriously affect continuous machine operation.

After the first year of the program we were surprised to see that 33.8% of all incoming tooling was rejected as not conforming to specifications. This was particularly disturbing since these standards were set up in conjunction with our tooling suppliers, using their working tolerances. Since then, as can be noted in Fig. 5, we have experienced a steady reduction in the total number of tools returned to the fabricators. It is felt that a paramount factor in this reduction has been the establishment and maintenance of our vigorous inspection program. The continued progress achieved in this area is indicated by the further reduction of rejections to a level of 4.0% of all tooling received during 1961. While the decrease in the total number of rejections during the fourth year of the program is heartening and demonstrates positive action on the part of our suppliers, the continuing appreciable number of unsatisfactory punches and dies points to the need for maintenance of total inspection as it is presently being carried out.

Recording Tool Life History.—The establishment of specifications and subsequent quality control of the tools will insure a uniform high quality in the tools purchased. But, at our present level of knowledge in this area, we cannot be certain that the quality of tooling now used, however uniform, is the most satisfactory for uninterrupted production. So that we might obtain such information, a system for recording the life of the various tools has been developed which enables us to know the total number of tablets compressed with any given set of tools. In addition, information on the products prepared, machines the tools were used with, and the reason that the tools were eventually discarded is recorded. The careful evaluation of the facts obtained from these records will be useful in purchasing tooling with optimum wear characteristics and will result in a better finished product at reduced cost.

The tool life information is recorded on specially prepared cards. They may disclose the merits of refacing procedures, in those instances where refacing is feasible. The records will also show whether misuse by operators, excessive wear by the machine, or a particular granulation was the principal reason that the tools are no longer suitable for use. Since, for the purpose of accurate wear records it is necessary to employ tools only as complete sets, the record cards give the extra benefit of an auditing control of each set of punches for inventory purposes.

RESEARCH AND DEVELOPMENT ASPECTS

Over and above the advantages derived from a quality control viewpoint, the tableting tool control program as just outlined has been responsible for a number of benefits, of both a general and specific character, in tablet manufacturing at Ciba. The acquisition of tooling of desired specifications can now be assured regardless of the source of supply. From the point of view of research and development, the secondary benefits of the program allow the planning and execution of experiments leading to the evaluation of the effects of steels, tool shapes, tolerances, granulation, and tool maintenance on the effective life span of the tableting tools.

Although the program is of recent origin, a number of interesting projects are being pursued and will be discussed below.

Effect of Steel on Tool Life.—From intuitive and cursory evaluation of steels based on data gathered prior to the introduction of the punch and die program, it appeared evident that the type and hardness of steel used in the punches had a profound effect on the life of the tools being used. To accelerate the development of more basic scientific knowledge in this area, an experiment was devised in which a set of punches was prepared from four different types of steels, each being tempered to the same hardness. The test conditions were kept constant by the utilization of a 35-station tableting press and a single product, the only variable being the steel employed for the punches.

Although this study is still in progress, preliminary examination of punches by photomicrography indicates that there are definite differences in the wear qualities of each of the steels used, even though all have the same hardness. Upon completion of this study, or ones of similar design, one will be able to arrive at a scientific conclusion as to the relative merits of the various steels, based upon experimental data rather than speculation. It must be

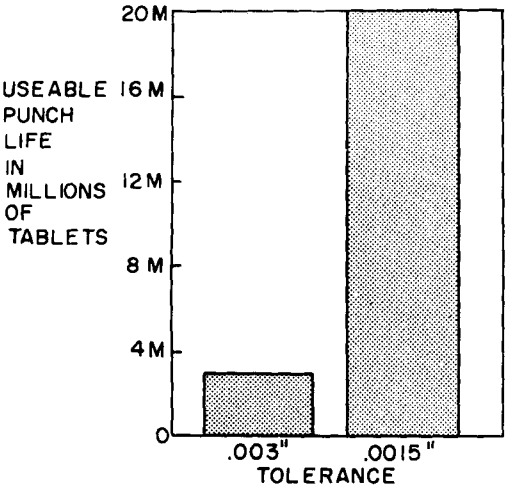

Fig. 7.—Added tool life attributed to closer tolerances.

emphasized that these results can only be accepted as valid in respect to the product tested as it has been shown that different formulations of the same product may possibly alter punch life characteristics.

Effect of Punch Shape.—As was noted earlier, evaluation of the records obtained to date indicated that the shape or geometry of punch tips had a marked influence on the life of punches. The following shapes commonly employed in the manufacture of pharmaceutical tablets are listed in an order of the most durable to the least durable shape: flat, shallow concave, standard concave, flat beveled, deep concave, modified ball punches.

The reason for the order, which has been established from examination of our records, can be explained on the basis of edge strength. It has been found, upon study of unsatisfactory punches, that a common reason for discarding them is the development of a rolled-in burr. It is readily apparent that a modified ball punch tip which, by design, has extremely sharp and narrow edges would be much more prone to this type of deformation than the flat punch, all other shapes fitting somewhere in between. It has been found that the shape of punch tips is also important with respect to misalignment or poor fit in the tableting press itself. This will be discussed in the next section.

Effects of Machine Tolerances.—During the evaluation of data it was noted that, in some cases, a marked decrease in the expected life of the tools resulted when tools were used on certain machines. It was found in all instances that the reduction of tool life was due to damage to the upper punches in the form of a rolled-in lip or burr. Stroboscopic examination of the machine in operation at production speeds indicated that enough clearance existed between the punch shank and machine bore to allow considerable "run out" of the tool at the die table during the compression cycle. This "run-out" results from the eccentric force exerted by the upper pressure roller which forced the tool out of line to as much as 0.010 inch off center at the point of entry into the die. This constant contact with the die edge very rapidly resulted in the lapped condition observed. The solution to this dilemma was a cooperative effort between ourselves and the manufacturer who prepared a new head for the machine in question utilizing tighter clearances for the upper punch, as noted in Fig. 6. Calculations indicated that reducing the clearances between the punch shank and the bore to 0.0015 in. from the 0.003 in. normally allowed on the machine would be the most suitable solution to the problem. Following the receipt of a head, machined to the dimensions specified, experiments were conducted to determine the influence of the turret with these closer tolerances on the actual wear characteristics of the punches in question. As evidenced in Fig. 7 there is no question about the added tool life which can be attributed to closer tolerances. The graph clearly illustrates that, to date, we have obtained at least six times greater usable life from the punches by the application of closer tolerances. It is readily apparent that although the original program was not intended to study the compression machines, *per se*, the availability of accurate, recorded data on punch life enabled us to become aware of a machine problem and to facilitate its solution readily. The economic advantages of a scientific approach to tableting are obvious in this instance.

Effect of Granulations.—Up to this point we have dwelled mainly upon the mechanical aspects of the program, but any tableting operation can be considered a three-component system consisting of the machine, the tools, and the granulation. All things being equal, the active agent and/or excipients of the granulations exert a profound effect on the life of the tools being used. Again, from experiences prior to the initiation of this program, it was our impression that the marked variations in the length of tool life were directly related to the products compressed. Examination of the records of discarded sets having been controlled and used under the conditions of the program indicated our conjec-

ture to be well founded. This can be most dramatically illustrated by the following: glutethimide (Doriden, Ciba) tablets are prepared utilizing $^{15}/_{32}$ in. flat beveled punches. Records indicate that, under the conditions of manufacture and using what will be called formula A, a yield of approximately 25,000,000 tablets per set of punches could be expected on a 35-station machine. For other technical reasons it became necessary to modify the formulation to formula B. Concurrently with this, a new set of punches meeting the same specifications as those previously used were ordered and used exclusively with formula B. The completed report on these tools indicates that 114,000,000 tablets have been compressed on the same machine under the same conditions. This 4.5-fold increase in the life of the tools is a significant change and can be wholly attributed to modification of the granulation components. Although a replacement set is still being used, a check at this date indicates that 80,000,000 tablets have been produced so far from this second set without deleterious effects on the tools. This would suggest that the initial results with the new formulation will be substantiated by the second set of punches now in use.

Relationship of Dies to the Life of Punches.—Our consideration thus far has been mainly devoted to the life of the punch due to the relative costs involved. Inasmuch as one would be prone to examine punches more thoroughly than dies, it should be pointed out that in the majority of our trials, carbide lined dies have been utilized. No data are available as yet on the length of service of controlled sets of these dies as the carbide lining appears impervious to normal wear, with the exception of damage brought about by sudden shocks. It has been noted that in the cases of modified ball, deep concave, and flat beveled punch tips, carbide dies, acting as honing surfaces, have a tendency to wear the edges of the punches rapidly.

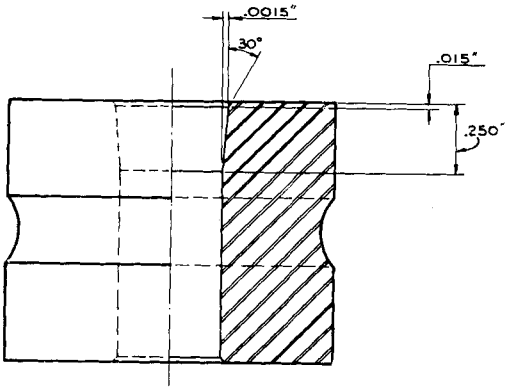

Fig. 8.—Die with tapered bore.

An interesting facet examined is the use of tapered dies. In these dies the bore is not a uniform cylinder but gradually tapers, as shown in Fig. 8, or is gradually tapered completely through the bore. It has been suggested that the tapering would reduce die wall friction during the ejection cycle by virtue of the increase in die diameter anywhere above the compression point. It was felt that if this were true it could be demonstrated by differences between edge

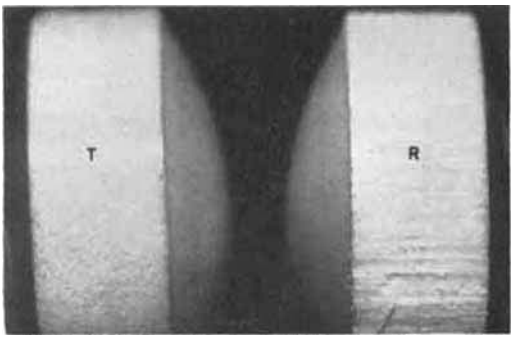

Fig. 9.—Tablets prepared using tapered (T) and regular (R) dies showing edge characteristics.

characteristics of tablets compressed in standard or tapered dies. Figure 9 shows the results of an experiment carried out at Ciba comparing tapered and standard dies. The test substance consisted of granulated magnesium oxide (granulated with sucrose solution) and stearic acid *q.s.* The amount of stearic acid was reduced successively until binding occurred in standard bore dies. At this point, tapered dies were substituted and the same granulation compressed. The different edge characteristics noted upon examination of Fig. 9 showing the regular signified by "R" and the "T" signifying tapering dies, clearly indicated that tapered dies prevented binding. It is fully recognized that this is a qualitative rather than a quantitative analysis, but it does indicate the possible value of the substitution of tapered dies in selected problem products. The reduction of binding by the tapered dies allows the use of lower concentrations of lubricants which, as shown by Strickland, *et al.* (3), generally results in lowering of disintegration time of tablets.

CONCLUSION

The comprehensive integration of pharmaceutical requirements and tool technology under the program has been found to be a valuable stimulus to investigation of tableting problems. It is impossible to contemplate research projects in tableting without a thorough understanding of the influence exerted by the tooling on the resultant data. It is obvious that marked variations of the tooling from established specifications could invalidate conclusions drawn from otherwise closely controlled experiments.

For years pharmaceutical manufacturers have accepted the expense of nonuniform punches and dies, fearing that a program to improve their caliber would be even more costly. It has been found that the ability to introduce new products on schedule, elimination of severe machine damage, and prolonging of tool life more than compensates for the costs involved. Aside from the technical and financial aspects, there is no question that well prepared tooling helps insure uniformity of finished tablets which is, after all, the paramount aim of our science.

Acceptance Sampling of Finished Pharmaceutical Products

By H. LATHAM BREUNIG and E. P. KING

In this paper we describe some problems inherent in acceptance sampling of finished pharmaceuticals, and provide an expository account of the power and effectiveness of modern statistical methods in the solution of these problems.

STATISTICAL techniques form an integral part of every effective quality control program. Sound statistical procedures for accepting or rejecting batches of finished product based on evidence obtained from samples were given tremendous impetus during World War II through their recognition and application by military procurement agencies. Since that time, these methods have enjoyed a continually expanding circle of usage in the chemical and process industries.

On the other hand, criteria currently used for acceptance sampling of medicinal products, based upon chemical or biological assay, are susceptible to considerable improvement. It would further appear that as this need for improvement becomes recognized and as changes in the sampling procedures are proposed, even these revisions do not incorporate the efficient statistical methods now available.

The sampling procedures of today are probably the result of a natural process of evolution. For many years the majority of active drugs were dispensed in the form of fluid extracts and solutions. The first official sampling procedure to appear in the United States Pharmacopeia (1) pertained to the assay of crude drugs which were to be extracted. Because the liquid extract was recognized as homogeneous, it was natural that attention be shifted from the finished product and focused on accurately estimating the amount of active principle in a shipment of crude drug. It was logical to strive for a "representative sample" of the shipment, ignoring variation from portion to portion within a shipment, because the entire shipment would ultimately be extracted as one unit to form a homogeneous fluid. Hence the procedure called for taking core samples, compositing, quartering, and the like.

However, as time passed, new dosage forms came into prominence. Tablets and filled capsules replaced fluid extracts and solutions. Since this was a gradual process, the sampling procedures for crude drugs were carried over unchanged to the new forms. Unfortunately, however, the problem had changed. Unit-to-unit variation among finished tablets or capsules from the same batch is inherently greater than the variation from one portion of a fluid to another. A thoroughly mixed fluid is homogeneous throughout, but two tablets from the same batch can differ in potency because of composition variation in granulation and because of weight variation among the tablets after compression.

Both physician and patient are concerned with whether or not the amount of drug in a single dose conforms to label claim. Estimating the average amount of drug per unit weight in the parent batch is only a first step. The older sampling methods, aimed at assessing the amount of active ingredient in a crude drug shipment, simply cannot be depended upon to provide information about unit-to-unit differences in tablets and filled capsules. Hence the "representative sample" approach, although adequate for its original purpose, must now make room for techniques which concentrate on individual units of finished product; methods which are concerned not only with average drug content but also with variation in potency from unit to unit. Such a program is given further impetus by the development, in recent years, of analytical methods which permit

accurate assay for the relatively small amount of active ingredient in each unit.

The need for this type of change has been recognized by many responsible individuals—both within the Food and Drug Administration and within the pharmaceutical industry. Reports such as that by Pernarowski and co-workers (2) have discussed dosage variation among single tablets of several items. However, some of the proposals which have been made still fall far short of the effectiveness that could be achieved through the use of statistical methods of acceptance sampling. Furthermore, reference to sampling plans in *Interim Federal Standard No. 00140 (Navy-Bu Med)* (3) concerning procurement of tablets for medicinal purposes underlines the need for an understanding of the properties of such plans. Our purpose in the following expository discussion is to illustrate the advantages to be had through the application of these modern statistical principles.

Inherent Variation.—The inescapable fact upon which statistical sampling plans are built is that there is inherent variation in the output of any manufacturing process. No two ball bearings have precisely the same diameter. No two capsules, tablets, or ampules will contain exactly the same amount of active ingredient. Even if it were possible to produce two identical units of product, we could never verify that they were exactly alike because there is no test procedure known to modern science which is capable of producing absolutely error-free measurements. The widespread belief that each tablet in a bottle contains exactly the same amount of active ingredient is every bit as erroneous as the notion that every male child in the United States will attain exactly the same weight at his fifth birthday. The difference is not one of kind—only of degree.

Hence, the problem of constructing an efficient acceptance sampling procedure is not simply one of determining whether or not each unit of product contains exactly the amount of active ingredient specified on the label. The problem is rather one of assuring that a "sufficiently large" percentage of the units falls "sufficiently close" to label claim.

Components of Variation.—In the discussion which follows, when we refer to the variation exhibited by a series of measurements we will be referring to *total* variation, unless otherwise specified. This total variation is not attributable to the product alone nor to the method of assay alone; it is actually the composite result of several variables simultaneously exerting their influences. For example, if a random sample of several tablets is drawn from a parent batch of a particular pharmaceutical product and an individual assay performed on each tablet, the observed variation among the resulting determinations represents the joint contribution of the following major factors: (*a*) differences in weight from tablet to tablet; (*b*) differences in the proportion of active ingredient from one tablet to another, resulting from inhomogeneous mixing of the drug with inert excipients in the granulation from which the tablets are compressed or molded; and (*c*) variation in assay, reflecting not only the precision of the measurement process but also such laboratory variables as sample preparation, equipment, and analysts.

In addition to the above, a lot-to-lot component of variation can reflect such additional factors as variation in raw material potency and variation in raw material assays.

A Typical Statistical Sampling Problem.—In order to illustrate the effectiveness of a statistical plan, together with the rationale behind it, let us take a realistic sampling problem and sketch the steps in its solution. Suppose an acceptance sampling procedure is required for finished lots of a particular tablet item. In other words, we wish to develop an efficient method for classifying a given production lot as "acceptable" or "unacceptable," basing this decision solely upon the information obtained from a small random sample of tablets drawn from the lot.

The first step is to arrive at explicit meanings for the terms "acceptable" and "unacceptable." If the product were an automobile tire, acceptable quality would be defined to reflect the mileage requirements of the consumer under typical driving conditions. If the product were an incandescent lamp, quality standards would incorporate the length of life that should be expected in normal usage. Similarly, quality requirements for an ethical drug should bear a close relationship to the therapeutic needs of the patient. If the range between the minimum effective dose and a toxic dose is small, tolerances on the product should tend to be narrow. On the other hand, if there is a broad dose range within which each dose is nontoxic and of equal therapeutic effect, the tolerances on the product should tend to be broad. By contrast, it appears that present official tolerances on drugs are frequently based, instead, upon the precision and accuracy that is attainable with current assay procedures. It may well be that more reasonable standards should reflect both factors.

A statistical sampling plan normally requires that four quality standards be specified: (*a*) an acceptable quality level (*AQL*), (*b*) an unacceptable quality level (*UQL*) (*c*) the risk of misclassifying an acceptable quality lot, sometimes referred to as the "Producer's Risk"(R_p), and (*d*) the risk of misclassifying an unacceptable quality lot, sometimes referred to as the "Consumer's Risk" (R_c).

When these four basic standards have been established, the corresponding sampling plan is completely determined. If the *AQL* and *UQL* are quite far apart and high risks of misclassification can be tolerated, as might well be the case with sodium chloride tablets, the plan will call for very few units in the sample. If the *AQL* and *UQL* are close together and very small risks of misclassification must be maintained, as on potent steroids, a large sample will normally be required.

In terms of our example, let us set up hypothetical quality standards that might be considered reasonable for a particular tablet product. We will assume that the unit of product from the point of view of the patient is a single tablet. Let us further assume that the definition of acceptable quality shown in Fig. 1 conforms to the therapeutic requirements for this item.

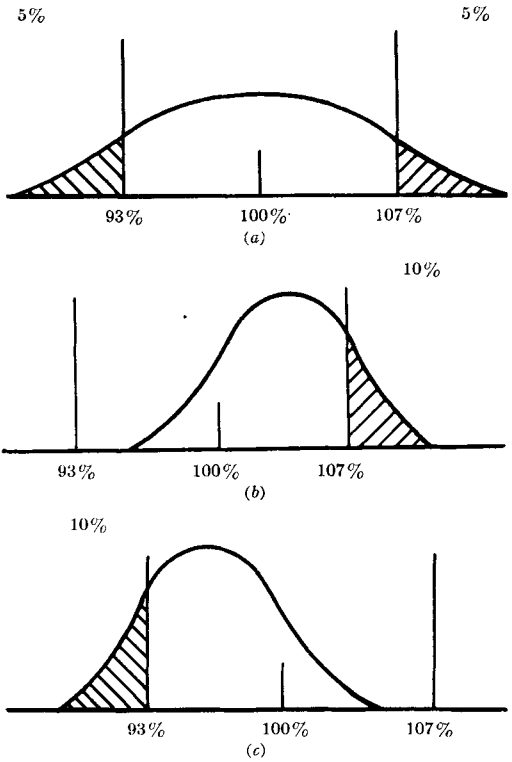

Fig. 1.—Distributions of single tablet assay values, acceptable quality, showing shifts in mean (*a*), mean at label claim; (*b*), upward shift; (*c*) downward shift.

A very large number of single tablet assay values should, when tabulated, distribute themselves under a bell-shaped curve in such a way that, for example, 90% of the tablets would fall within ±7% of label claim. This corresponds to an $AQL = 10\%$. In an analogous fashion let us define UQL as a lot of finished tablets with, say, 40% of its units outside of ±7% of label claim. Examples could be of the types illustrated in Fig. 2.

Let us assume further that we can tolerate misclassifying an acceptable lot no more than 10% of the time and an unacceptable lot no more than 10% of the time. We now have the four required standards: AQL, 10% of units outside ±7% of label claim; UQL, 40% of units outside ±7% of label claim; R_n, Producer's Risk = 10%; and R_c, Consumer's Risk = 10%.

It should be emphasized that we have chosen the numerical values for these standards quite arbitrarily for purposes of illustration. In actual practice this choice would, of course, rest with whatever official group was responsible for this type of policy decision.

Operating Characteristic Curve.—We have pointed out that R_p and R_c, the producer's and consumer's risks, are inherent in any sampling plan. A convenient graphical way of presenting these risks is through the operating characteristic (OC) curve.

In preparing to graph an OC curve, we take for the horizontal scale running from zero to 100%, the quality of submitted lots expressed as per cent defective, *i.e.*, the percentage of units in a lot which falls outside of the official tolerances for the product. On the vertical scale, also running from zero to 100%, is the percentage of lots of a given quality which is expected to be accepted if submitted to the sampling plan.

In an ideal situation, if we agree that a manufacturer is doing a good job if he submits to the sampling plan batches containing 10% defective units, we would accept all batches containing this proportion (or less) of defectives, and reject every batch containing 10.1% or more defectives (Fig. 3).

Such a plan would exhibit perfect discrimination. But it would be unrealistically stringent, for it would make no allowance for batch-to-batch variation about the 10% figure. What we want is a plan which will pass a high percentage of acceptable batches but at the same time guard against poor quality by accepting only a small proportion of bad lots if submitted. This would lead to a plan such as is shown in Fig. 4.

If we still concede that the manufacturer is doing a good job in submitting material containing 10% defective units ($AQL = 10\%$), we may want to be reasonably sure of passing this quality 95% of the time ($R_p = 5\%$). On the other hand, we may decide that 20% defective is intolerable ($UQL = 20\%$), and

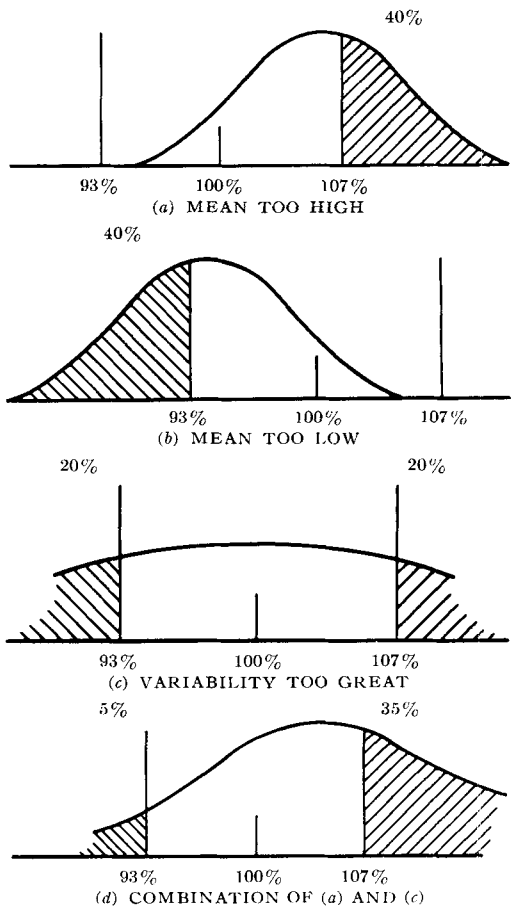

Fig. 2.—Distributions of single tablet assay values, unacceptable quality, showing shifts in location and dispersion.

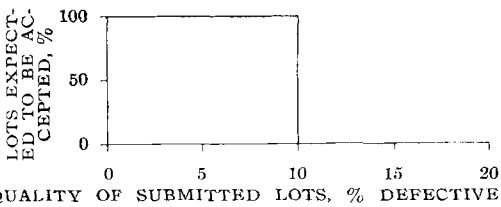

Fig. 3.—Ideal operating characteristic (*OC*) curve illustrating perfect discrimination but unrealistic stringency.

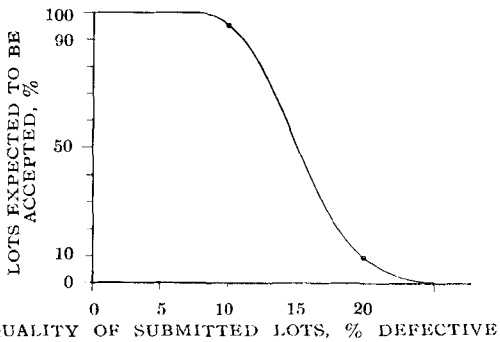

Fig. 4.—Typical *OC* curve from MIL-STD-414 (5), p. 27, illustrating $AQL = 10\%$; $UQL = 20\%$; $R_p = 5\%$; $R_c = 10\%$; $n = 85$.

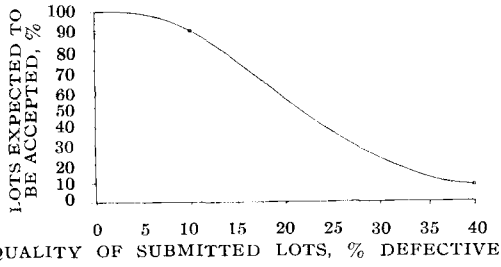

Fig. 5.—*OC* curve for tablet example, from MIL-STD-414 (5), p. 11, illustrating $AQL = 10\%$; $UQL = 40\%$; $R_p = 10\%$; $R_c = 8\%$; $n = 10$.

rarely want to pass this, certainly not more than 10% of the time ($R_c = 10\%$). Such a scheme, in practice, would be fair to both the manufacturer and to the patient.

Once these four characteristics of a plan have been agreed upon, the sample size is automatically determined. For the example cited, the sample size would be $n = 85$. Various *OC* curves for different values of sample size and per cent defective may be drawn, and judgment made as to properties of various sampling plans before agreeing upon one which balances the producer's and consumer's risks against the cost of assay. This balance has been discussed by Davies (4).

Construction of the Plan.—For single characteristics which may be measured on a continuous scale, and for which quality may be expressed in terms of per cent defective, the Military Standard 414 [MIL-STD 414 (5)] is an appropriate source of statistical plans if the measurements may be considered random, independent observations from a normal (bell-shaped) distribution. The mathematical and statistical principles underlying Military Standard 414 are described in a document of the same name (6). This reference also contains the specific methods used in computing the various tables and *OC* curves. In the case of pharmaceutical products we have defined per cent defective as that percentage of single dosage units which may be expected to fall above or below specified tolerances, such as those stated in the several individual monographs of the official compendia.

To illustrate the application of MIL-STD-414 (5), we refer again to our example for which tolerances were set at 93–107% of the labeled amount. Suppose this corresponds to 16.2 ±1.13 mg. of pure drug per tablet, *i.e.*, 15.07–17.33 mg./tablet. An inspection lot of tablets is presented for examination. We have previously specified $AQL = 10\%$; $UQL = 40\%$; $R_p = 10\%$; and $R_c = 10\%$. Searching through the operating characteristic curves of MIL-STD-414 (5) for the curve which most nearly corresponds to these requirements (Fig. 5), we find it associated with "Sample Size Code Letter F."

This *OC* curve tells us that lots of $AQL = 10\%$ (10% or less tablets outside of 15.07–17.33 mg./tablet) will be accepted 90% of the time (R_p). This is shown in Fig. 5 where the curve crosses the 10% abscissa at the 90% ordinate. We also see that lots of $UQL = 40\%$ will be accepted only 8% (R_c) of the time, *i.e.*, where the curve crosses the 40% abscissa at the 8% ordinate.

Referring to the appropriate master table for double specification limits, variability unknown, in MIL-STD-414 (5), we find the sample size corresponding to Code Letter F to be $n = 10$, and that the "acceptability criterion," estimated per cent defective, which balances the risks is 21.06%.

The final statistical plan then takes the following form: Select 10 tablets at random from an inspection lot and individually assay each tablet. Estimate the per cent defective in the lot from these 10 determinations. If this estimate does not exceed 21.06% defective, accept the lot. Otherwise, reject it.

Suppose that we obtain the following values: 16.20, 16.18, 15.70, 15.80, 16.05, 15.54, 16.19, 16.40, 17.00, 15.90 mg./tablet.

The details of computation are spelled out in Appendix I. In this instance the total estimated per cent defective is zero and the lot would be passed. Incidentally, the lot would also be passed on the basis of this sample if $AQL = 1\%$; $UQL = 11\%$; $R_p = 10\%$; $R_c = 20\%$.

Current Sampling Practices.—Let us now compare the discriminating ability of the above procedure with that of the typical plan currently specified in the U.S.P. (1) for a tableted product. The latter stipulates that a single assay on a composite sample of n tablets shall fall within $\pm y\%$ of the declared value. We are not concerned here with whether or not the numerical values of n and y are chosen properly. Our purpose is rather to point out that even with ideal choices of n and y, a plan of this type cannot be as effective as a statistical plan. The detailed derivations for this section are given in Appendix II.

Recalling the basic (but arbitrary) requirements specified for our example, and choosing $n = 10$ as the sample size in order to obtain an unbiased com-

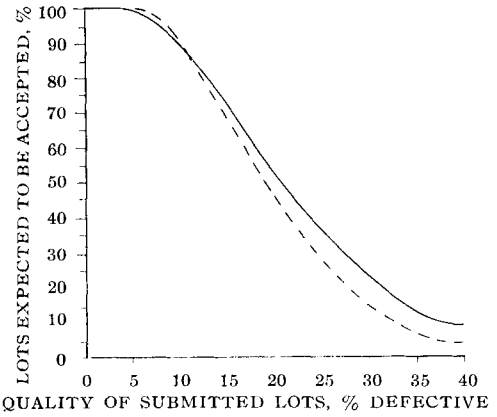

Fig. 6.—Comparison of *OC* curve for statistical plan (Fig. 5) with a curve computed for current plan (dashed line) when mean shifts.

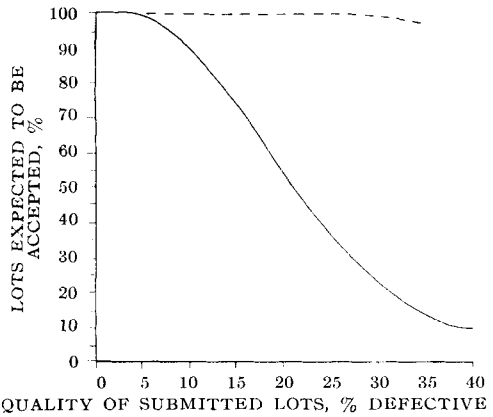

Fig. 7.—Comparison of *OC* curve for statistical plan (Fig. 5) with curve computed for current plan (dashed line) when variation becomes excessive.

parison with the statistical plan just derived, we find the ideal value for y to be approximately 5%. In other words, we have chosen the following specific plan: Perform a single assay on a composite sample of 10 randomly selected tablets and accept the parent lot only if the result falls within ±5% of the decleared value. The *OC* curve for this plan is shown in Fig. 6 for the situation in which inferior quality results from shifts in mean only. Note that this plan provides comparable discrimination to the statistical plan.

If the parent lot has mean potency low enough to force 10% of the tablets below 93% of label claim, both plans will pass this lot approximately 90% of the time. If 40% of the tablets in a lot fall below 93% of label claim because the mean potency of the lot is too low, the statistical plan will accept this type of lot about 8% of the time; the current type plan will accept it about 3% of the time.

Figure 7 shows the *OC* curve for the current plan when inferior quality results from increase in variation from tablet to tablet, the mean always at label claim.

It is clear that the plan is practically powerless to detect this type of trouble. For example, if 40% of the tablets in a lot fall outside ±7% of the declared value (and the lot mean is at 100%), this lot will be passed by the current plan about 94% of the time. The statistical plan, however, because it takes into account both mean and variation, will pass this lot only about 8% of the time, as before.

In actual practice one would expect unsatisfactory lots to exhibit some combination of simultaneous shift in mean and increase in variation. The power of the current plan varies considerably with the type of combination present. Two examples are shown in Fig. 8. The performance of the current plan is clearly inferior to the statistical plan for these combinations.

The reason for poor performance is clear. Because the current method relies on a single assay on a composite sample, it provides no way of estimating the variability in the amount of active ingredient from one tablet to another.

Recent Revisions.—The above shortcoming has been recognized; revisions in the official compendia have been recently proposed which take tablet-to-tablet variation into account. These proposals employ two separate criteria, one for detecting shift in mean only and another for detecting increase in variation only. Revisions of this type are certainly a step in the right direction, but they are still unable to compete with statistical plans because they cannot readily detect the unacceptable lot which has both difficulties operating simultaneously.

Using our example, a specific proposal might read as follows: Select 10 tablets at random from the inspection lot and accept the lot if the following two conditions hold. (*a*) the average drug content of the 10 individually assayed tablets falls within ±5% of the declared value, and (*b*) of the 10 results, not more than two shall differ from the average by more than ±7%.

Let us now examine the performance of this "2-step" plan relative to the statistical plan. If a lot of the quality shown in Fig. 9 is submitted, both the "2-step" plan and the statistical plan will accept it 90% of the time. Since this lot is, by definition,

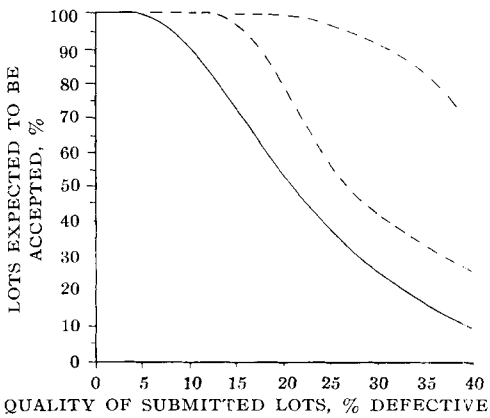

Fig. 8.—Comparison of *OC* curve for statistical plan (Fig. 5) with curves computed for proposed "2-step" plan (dashed line) for detecting shifts in (*a*) location and (*b*) dispersion.

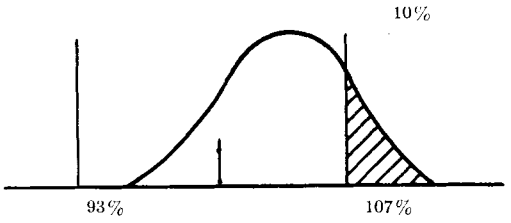

Fig. 9.—Distribution of single tablet assay values for lots expected to be accepted by both the statistical plan and proposed "2-step" plan. Upward shift in mean.

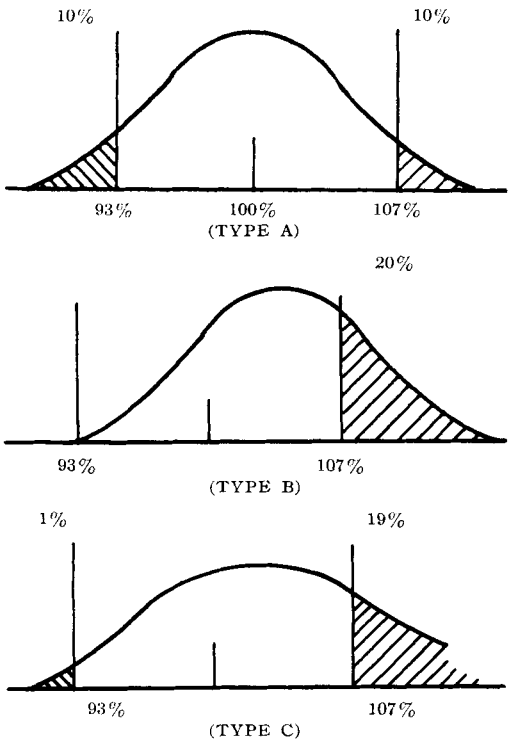

Fig. 10—Distribution of single tablet assay values for unacceptable quality lots of types shown in Table I. Type A, excessive variation; Type B, upward shift in mean; Type C, combination of excessive variation and upward shift in mean.

an acceptable quality lot, both plans are performing as desired. Next, let us consider three different types of lots, each having 20% of its tablets outside limits as illustrated by Fig. 10.

In Table I are shown the percentages of lots containing 20% defective tablets which we would expect to be accepted by each of the two plans, depending upon the type of distribution of the defective tablets outside the postulated official tolerances.

TABLE I.—PER CENT OF LOTS ACCEPTED

	Type A %	Type B %	Type C %
"2-Step" plan	74	50	86
Statistical plan	53	53	53

It is evident from Table I that the "2-step" plan is quite ineffective in detecting a lot of Type *C*, even though this lot has the same proportion of its tablets outside limits as do the other two. The shift in mean in lot *C* is not sufficient to be detected on this basis alone, the variation from tablet to tablet is not sufficient to be detected on this basis alone, and the plan cannot take into account the simultaneous operation of both. See Appendix III for details. By contrast, the statistical plan has the same effectiveness on all three lots.

Advantages of Statistical Plan.—It is clear from the preceding discussion that a statistically designed acceptance sampling plan has many advantages over a plan of any other type.

(*a*) It provides performance that is equal or superior to other plans using the same number of units of product in the sample. This is a result of efficient utilization of the information contained in the sample.

(*b*) Its performance can be studied in advance of its use, by examination of its operating characteristic curve. One can determine beforehand the quality levels that will be consistently accepted and those that will be consistently rejected, when stipulating appropriate risks. It aids in evaluation of official tolerances, not only from these standpoints, but also from that of practical economics in the determination of reasonable sample sizes.

(*c*) The statistical plan lends itself not only to the need of the manufacturer for sound acceptance sampling of his production lots, but also to that of the regulatory agencies who, having little information concerning in-plant quality controls, must perforce base their decisions on packages picked up in the market place. (It should be pointed out that such a package may not be expected to contain units which are randomly chosen from an entire production lot but will represent, rather, a small random sublot.)

The Contrasting Functions of Acceptance Sampling and Process Control.—We feel that this discussion would be incomplete without a word of caution regarding acceptance sampling in general. One characteristic common to all sampling programs is that a lot consisting of a large number of units is accepted or rejected on the basis of information obtained from a very small number of units. It is quite unreasonable to expect even the most efficient statistical plans to guarantee that practically all accepted lots will be of the desired quality. Although such a plan can be quite effective in detecting an occasional bad lot when all others are of high quality, it should be borne in mind that this is basically a checking device. A little reflection should convince even the most confirmed skeptic that an inspection operation which utilizes no prior information and which examines a very small percentage of the total output of a production process could easily overlook moderate departures from ideal quality a large percentage of the time. (For example, the statistical sampling plan discussed in this paper would accept lots containing 20% of their tablets outside tolerance limits about 53% of the time. If we wished to develop a plan which accepted lots of this quality only 1% of the time, it would require a prohibitively large number of units in the sample.) If a process were producing unacceptable quality consistently, acceptance sampling of the finished product would be singularly ineffective in preventing

units of inferior quality from reaching the consumer.

A reputable pharmaceutical manufacturer must maintain production methods capable of sustaining the desired quality level and a quality control system which continuously monitors each process from raw material to finished product. This alone assures acceptable quality in the long run. The practice of sampling finished products serves as a check to insure that such a system is actually in use by detecting gross departures from desired quality if they occur.

APPENDIX I

Example of the Application of MIL-STD-414.—Table II shows a specimen protocol which includes details of computation of estimated per cent defective tablets in the lot from which were taken the tablets of our example. The particular situation deals with symmetrical double specification limits about the mean [(5) p. 69]. Other examples are given (5) where per cent defective beyond a single specification limit either above or below the mean may be estimated and also for double specification limits which are not symmetrical about the mean.

Since the procedure is spelled out in such detail, it may appear at first glance to be inordinately long. In practice, however, computation of quality indices and looking up the corresponding estimated per cent defective in Table C-5 (5) takes approximately 3 minutes.

Entries No. 1, 5, 6, 7, and 13 would normally be made in advance of the assay.

APPENDIX II

Operating Characteristic Curves for Current Plan.—The OC curves for the current plan were derived under the assumption that a sufficiently replicated assay of a composite sample of n tablets is equivalent to the average of n individual tablet assays. The mathematical formulation then takes the following form:

Let $x_1, x_2, \ldots, x_{10}$ be independently and identically distributed random variables, each having a normal distribution with mean μ and variance σ^2. Compute their arithmetic mean, $\bar{x}$. If $0.95\ \mu_0 < \bar{x} < 1.05\ \mu_0$, accept the parent lot; otherwise, reject it.

Let $P_A(\mu, \sigma)$ denote the probability of acceptance. Then we have

$$P_A = P_r\left\{0.95\,\mu_0 < \bar{x} < 1.05\,\mu_0\right\} = P_r\left\{\frac{0.95\,\mu_0 - \mu}{\sigma/\sqrt{10}} < u < \frac{1.05\,\mu_0 - \mu}{\sigma/\sqrt{10}}\right\} = F\left(\frac{1.05\,\mu_0 - \mu}{\sigma/\sqrt{10}}\right) - F\left(\frac{0.95\,\mu_0 - \mu}{\sigma/\sqrt{10}}\right) \quad \text{(Eq 1)}$$

where

$$u = \frac{\bar{x} - \mu}{\sigma/\sqrt{10}} \quad \text{and} \quad F(t) = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{t} e^{-y^2/2}\,dy$$

The per cent defective (% outside $\mu_0 \pm 0.07\ \mu_0$) which corresponds to $P_A\ (\mu, \sigma)$ can be expressed as

$$p(\mu, \sigma) = p_u + p_L$$

where

$$\begin{cases} p_u = \%\text{ above upper limit} = 1 - F\left(\dfrac{1.07\,\mu_0 - \mu}{\sigma}\right) \\ p_L = \%\text{ below lower limit} = F\left(\dfrac{0.93\,\mu_0 - \mu}{\sigma}\right) \end{cases}$$

The OC curve for shift in mean only (Fig. 6) was obtained by plotting $P_A(\mu, \sigma)$ *vs.* $p(\mu, \sigma)$ for various values of μ, keeping σ fixed at $\sigma = \sigma_0$. The curve for increase in variation only (Fig. 7) was obtained in analogous fashion by varying σ with μ fixed. Finally, the curves in Fig. 8 were obtained by simultaneous variation of μ and σ.

APPENDIX III

Performance Characteristics of Revised Plans.—The "2-step" plan described in *Recent Revisions* can be defined as follows:

Compute the arithmetic mean, $\bar{x}$, of the 10 sample values and accept the lot if the following conditions hold: (A) $0.95\ \mu_o < \bar{x} < 1.05\ \mu_o$, and (B) $|x_i - x| < 0.07\ x$ for at least 8 of the 10 samples values, x_i.

In the notation of the previous section, the probability that condition (A) holds is simply $P_A(\mu, \sigma)$, as given in Eq. 1. The probability, $P_B(\mu, \sigma)$ that condition (B) holds can be approximated by assuming that $x_i - \bar{x}$ and $x_j - \bar{x}$ are statistically independent when $i \neq j$. Letting $h = P_r\ [|x_i - \bar{x}_1| < 0.07\ \bar{x}]$ we obtain for P_B the binomial type expression

$$P_B(\mu, \sigma) = \sum_{r=8}^{10} \binom{10}{r} h^r (1-h)^{10-r}$$

where $h = 2F(0.0738\ \mu/\sigma) - 1$.

The value in Table I corresponding to a particular normal distribution was obtained by first computing μ, σ, $P_A(\mu, \sigma)$, $P_B(\mu, \sigma)$, and then approximating the probability of acceptance for the revised plan as $P'_A(\mu, \sigma) = P_A(\mu, \sigma)\, P_B(\mu, \sigma)$.

Notes

The Occurrence of *iso*Pelletierine in *Withania somnifera*

By K. L. KHANNA, A. E. SCHWARTING, and J. M. BOBBITT

INVESTIGATION of the root alkaloids of *Withania somnifera* Dunal has resulted in the delineation of the alkaloid complex by paper partition chromatography (1), the isolation of tropine and pseudotropine (2), and the isolation and characterization of a new alkaloid, anaferine (3). Compound VII of the chromatogram, cited above, is *dl-iso*pelletierine. The occurrence of this alkaloid in the *Solanaceae* was first reported (4) for the leaves of *Duboisia myoporoides* R. Br.; the previously acknowledged occurrence being the root of *Punica granatum* L., family *Punicaceae*. This finding amplifies the known biochemical heterogeneity of the *Solanaceae* and extends a lysine related alkaloid to yet another genus in the plant kingdom.

EXPERIMENTAL [1]

The alkaloid was isolated from an ethanol extract of the defatted granulated root (81 Kg.). The concentrated extract diluted with water and adjusted to pH 4.7 was adsorbed on a column of Amberlite IRC-50-Na resin and was eluted by a gradient acid-buffer method. The fraction containing *iso*pelletierine hydrochloride was further purified by chromatography on acid alumina (Woelm, grade 1) using ethyl acetate as the eluent. The alkaloid salt (5.67 Gm.) was recrystallized from ethyl acetate.

***iso*Pelletierine Hydrochloride.**—The infrared spectrum was identical to that of a synthetic sample[2] and a natural sample;[3] m.p. 145°, undepressed in admixture with each of the above samples; $[\alpha]_D^{2.5} = 0.00$ (0.21% in ethanol).

Anal.—Calcd. for $C_8H_{16}ClN$: C, 54.07; H, 9.07; Cl, 19.95; N, 7.88. Found: C, 54.38; H, 9.59; Cl, 20.21; N, 7.67.

***iso*Pelletierine Picrate.**—The compound was prepared from the hydrochloride and was crystallized from ethanol; m.p. 148.5 to 149.5°, reported 149–150°. The melting point of a mixture with the picrate of an authentic sample[2] was undepressed.

***iso*Pelletierine 2,4-Dinitrophenylhydrazone Hydrochloride.**—The compound was prepared from the hydrochloride and was crystallized from ethanol-ethyl acetate; m.p. 240–241.5° (decompn.), lit. 242°.

APPENDIX III

Performance Characteristics of Revised Plans.—The "2-step" plan described in *Recent Revisions* can be defined as follows:

Compute the arithmetic mean, $\bar{x}$, of the 10 sample values and accept the lot if the following conditions hold: (A) $0.95\ \mu_o < \bar{x} < 1.05\ \mu_o$, and (B) $|x_i - x| < 0.07\ x$ for at least 8 of the 10 samples values, x_i.

In the notation of the previous section, the probability that condition (A) holds is simply $P_A(\mu, \sigma)$, as given in Eq. 1. The probability, $P_B(\mu, \sigma)$ that condition (B) holds can be approximated by assuming that $x_i - \bar{x}$ and $x_j - \bar{x}$ are statistically independent when $i \neq j$. Letting $h = P_r\ [|x_i - \bar{x}_1| < 0.07\ \bar{x}]$ we obtain for P_B the binomial type expression

$$P_B(\mu, \sigma) = \sum_{r=8}^{10} \binom{10}{r} h^r (1-h)^{10-r}$$

where $h = 2F(0.0738\ \mu/\sigma) - 1$.

The value in Table I corresponding to a particular normal distribution was obtained by first computing μ, σ, $P_A(\mu, \sigma)$, $P_B(\mu, \sigma)$, and then approximating the probability of acceptance for the revised plan as $P'_A(\mu, \sigma) = P_A(\mu, \sigma)\, P_B(\mu, \sigma)$.

Notes

The Occurrence of *iso*Pelletierine in *Withania somnifera*

By K. L. KHANNA, A. E. SCHWARTING, and J. M. BOBBITT

INVESTIGATION of the root alkaloids of *Withania somnifera* Dunal has resulted in the delineation of the alkaloid complex by paper partition chromatography (1), the isolation of tropine and pseudotropine (2), and the isolation and characterization of a new alkaloid, anaferine (3). Compound VII of the chromatogram, cited above, is *dl-iso*pelletierine. The occurrence of this alkaloid in the *Solanaceae* was first reported (4) for the leaves of *Duboisia myoporoides* R. Br.; the previously acknowledged occurrence being the root of *Punica granatum* L., family *Punicaceae*. This finding amplifies the known biochemical heterogeneity of the *Solanaceae* and extends a lysine related alkaloid to yet another genus in the plant kingdom.

EXPERIMENTAL [1]

The alkaloid was isolated from an ethanol extract of the defatted granulated root (81 Kg.). The concentrated extract diluted with water and adjusted to pH 4.7 was adsorbed on a column of Amberlite IRC-50-Na resin and was eluted by a gradient acid-buffer method. The fraction containing *iso*pelletierine hydrochloride was further purified by chromatography on acid alumina (Woelm, grade 1) using ethyl acetate as the eluent. The alkaloid salt (5.67 Gm.) was recrystallized from ethyl acetate.

***iso*Pelletierine Hydrochloride.**—The infrared spectrum was identical to that of a synthetic sample[2] and a natural sample;[3] m.p. 145°, undepressed in admixture with each of the above samples; $[\alpha]_D^{2.5} = 0.00$ (0.21% in ethanol).

Anal.—Calcd. for $C_8H_{16}ClN$: C, 54.07; H, 9.07; Cl, 19.95; N, 7.88. Found: C, 54.38; H, 9.59; Cl, 20.21; N, 7.67.

***iso*Pelletierine Picrate.**—The compound was prepared from the hydrochloride and was crystallized from ethanol; m.p. 148.5 to 149.5°, reported 149–150°. The melting point of a mixture with the picrate of an authentic sample[2] was undepressed.

***iso*Pelletierine 2,4-Dinitrophenylhydrazone Hydrochloride.**—The compound was prepared from the hydrochloride and was crystallized from ethanol-ethyl acetate; m.p. 240–241.5° (decompn.), lit. 242°.

Quantitative Determination of Dehydrocholic Acid in Tablets

By VISHNU DAS GUPTA

Quantitative recovery of dehydrocholic acid from the tablets can be accomplished by first extraction with chloroform and subsequent titration as given in the U.S.P. XVI. Results are reported to indicate that the residue obtained is of pure acid.

THE U.S.P. XVI (1) procedure for the estimation of dehydrocholic acid appears to be satisfactory for pure samples of acid but reproducible results are obtained only with difficulty for some of the commercial preparations. Some samples require stirring for periods up to 1 hour on the magnetic stirrer before solutions are effected in order to obtain quantitative recoveries; without stirring there is a marked tendency to obtain premature end points which are difficult to distinguish from the true end point. The addition of 100 ml. of water as prescribed shortly before the end point is reached may also lead to low results if added too soon. This is probably caused by some of the acid going out of solution. Crisafio and Chatten (2) of the National Food and Drug Laboratories, Ottawa (Ontario) have reported similar difficulties.

EXPERIMENTAL

Not less than ten tablets were reduced to a fine powder and a portion of the powder, representing about 300 mg. of dehydrocholic acid was accurately weighed and transferred to a dry 100-ml. volumetric flask with the aid of reagent grade chloroform. Sufficient chloroform was added to make exactly 100 ml. of the mixture and the flask was agitated. The mixture was allowed to stand for 1 minute and rapidly filtered through dry rapid filter paper. The first 20 ml. was rejected and the next 50 ml. of the filtrate was collected in a dry 50-ml. volumetric flask which was transferred to a 250-ml. Erlenmeyer flask or a 100-ml. tared beaker if the residue was to be weighed. The flask was washed with two 5-ml. portions of chloroform and mixed with the filtrate. Chloroform was removed by evaporation; 2 ml. of dehydrated alcohol was then added and also removed by evaporation. The residue was cooled and assayed by U.S.P. method (1) for dehydrocholic acid, using 0.02 *N* sodium hydroxide. Each milliliter of 0.02 *N* sodium hydroxide is equivalent to 8.05 mg of anhydrous dehydrocholic acid. If the tablets were known to contain no chloroform-soluble excipients such as stearic acid, then the residue was dried at 100° for 15 minutes, cooled in a desiccator, and weighed. Twice the weight of the residue represented the amount of dehydrocholic acid contained in the portion of the powder taken. The melting point of the residue and the U.S.P. method (1) for determining the dehydrocholic acid confirmed that the residue was a pure form of the dehydrocholic acid. Results are recorded in Table I.

SUMMARY AND CONCLUSION

1. A study was designed to develop a method for 100% recovery of dehydrocholic acid from the tablets.

2. The method described required 20 minutes (actual working time) for each analysis with 100% recovery. The solvent used is available in every laboratory.

3. Assay results appear to confirm the accuracy of the method.

TABLE I.—ASSAY RESULTS FROM DEHYDROCHOLIC ACID TABLETS

Sample No.	Recovery, U.S.P. Method	Recovery, Proposed Method	M.p. of Residue	Percentage Found in the Residue by U.S.P. Method

Observations on the Structure of Argemonine

Sir:

Our interest in certain of the *Argemone* alkaloids (1–3) recently led us to postulate three tentative aporphine structures for argemonine (4). All of these structures adopted a 2:3 placement for two of the methoxyl groups with the other two vicinally placed in the 8:9, 9:10, or 10:11 positions. The 9:10 position was favored, largely on the basis of negative oxidative evidence that had failed to indicate the presence of isolable *o*-hemipinic acid (3,4-dimethoxyphthalic acid) in the oxidation residues with only *m*-hemipinic acid (4,5-dimethoxyphthalic acid) being observed. Thus, structure I was suggested as being the most reasonable structure for argemonine with the evidence in hand at that time. Since then, Shamma (5) has postulated two additional structural possibilities (II and III) in an attempt to reconcile our low ultraviolet extinction coefficients for argemonine and its related alkaloids. His reasoning was that 1:11 methoxyl interaction would accentuate the known twist of the biphenyl moiety in the aporphine nucleus, thereby reducing coplanarity with resultant reduction in absorption. On this basis, he found it necessary to adopt a *non-vicinal* arrangement of methoxyls in ring *D* to implement his arguments. His reasoning for a 1:2 placement of the ring *A* methoxyls was based on the observation (6) that all known naturally-occurring aporphine alkaloids have the 1:2 arrangement. Our recent oxidative experiments have shown that Shamma's assumptions are unfounded.

We have ethylated the monophenol, norargemonine[1], with diazoethane and oxidized the resultant ethylnorargemonine without further purification, other than removal of unreacted norargemonine, with manganese dioxide in dilute sulfuric acid by the same procedure as we had previously oxidized argemonine (4). The neutral fraction from this oxidation yielded a small amount of N-methyl-*m*-hemipinimide, m.p. 261–262°, identified by mixed melting point with authentic material prepared by the usual method from authentic *m*-hemipinic acid. The acidic fraction from the above oxidation, on being treated with ethylamine and subsequently heated to 180° and sublimed, yielded N-ethyl-4-ethoxy-5-methoxyphthalimide, m.p. 202–203°. The identity of this product was established by mixed melting point determination and comparison of X-ray powder diffraction patterns, ultraviolet, and infrared spectra with the authentic compound prepared by permanganate oxidation of boldine that had been completely ethylated with diazoethane, followed by the usual treatment to obtain the desired phthalimide derivative. The above findings, assuming an aporphine ring system, show that the phenolic group in norargemonine is on ring *D* rather than on ring *A* and, therefore, indicate that the placement of the methoxyl groups in ring *D* of argemonine is *vicinal* and must be the same as that found in glaucine, namely 9:10. Ring *A* obviously could bear the methoxyls in the 1:2 or 2:3 positions because the necessary *o*-decarboxylation to yield N-methyl-*m*-hemipinimide does not indicate the placement unequivocally but could have arisen from either arrangement. The 1:2 placement, however, could not be entertained as a possible structure because this is the arrangement in glaucine, an isomer of argemonine, which is not identical with the latter alkaloid. Thus, structure I is the only remaining possibility for argemonine.

We previously had referred (4) to the recent elucidation of the structure of crebanine (9) in which a biogenetically unacceptable 8:9 placement of vicinal methoxyls was found in ring *D* and a normal 1:2 placement in ring *A*. If our structural arguments are valid, argemonine, on the other hand, represents a biogenetically acceptable 9:10 placement in ring *D* but an abnor-

[1] Manske and Ashford (7) have suggested that norargemonine "could be partly racemic isocorypalmine." Our own experience in methylating it to argemonine and the similar findings of Boit and Flentje (8) indicate that the above statement is without basis and that norargemonine can be considered a homogeneous entity related to argemonine as a monophenol to its methyl ether.

mal 2:3 placement in ring A. To our knowledge, this would be the first example of such an aporphine alkaloid and, together with the crebanine structure, illustrates the necessity for extreme caution when applying biogenetic principles to solving structural problems in the aporphine group.

We are carrying out presently the synthesis of argemonine to further implement our structural assignment. This work will be the subject of a future communication.

The Absolute Antipodal Activity of Analgesics in the Basic Anilide Series

Sir:

The influence of absolute configuration on the activity of potent analgesics possessing one asymmetric center has been demonstrated by Beckett and co-workers (1). These experiments have shown that most of the analgesic activity resides in the enantiomorph possessing the D-configuration. A hypothesis was advanced which attempted to define an analgesic receptor surface on the basis of three points of contact. This implies that the orientation of the methyl group on the asymmetric carbon of the methadones and thiambutenes is held in a favorable position only in those compounds having the D-configuration. In an effort directed at testing this hypothesis we have determined the absolute configuration of diampromid (II) (2), a member of a new class of analgesics of the basic anilide type.

The D-(−)-N-methyl-N-benzyl compound (I) (3), which has been related to D-alanine, was catalytically hydrogenolyzed with palladium on carbon according to the procedure of Wright, Brabander, and Hardy (2). The resulting debenzylated intermediate was then phenethylated with phenethyl bromide to give D-(−)-diampromid (II), $[\alpha]_D^{28°}$ −26.4° (c 5% in ethanol), b.p. 159–163° (0.1 mm.). The infrared spectrum is identical with that of racemic II (2). Wright, Brabander, and Hardy (4) have independently prepared (+) and (−)-diampromid. Their physical constants are in close agreement with our data.

The (+) and (−) enantiomers of compound I and of diampromid (II) were tested (5) subcutaneously on rats by a modification of the rat-tail heat response method. The L-(+)-isomers of I and II possess analgesic activity comparable to that of morphine, whereas the D-(−)-isomers are substantially less active. These pharmacological results are quite unexpected since it has been demonstrated that the more active enantiomorphs of methadone-type and thiambutene-type analgesics have the D-configuration (1). The potent analgesic action and addictive properties of I and II suggest that they are acting by a mechanism similar to that of methadone and other potent analgesics in spite of the fact that the more active enantiomorphs

The Absolute Antipodal Activity of Analgesics in the Basic Anilide Series

Sir:

The influence of absolute configuration on the activity of potent analgesics possessing one asymmetric center has been demonstrated by Beckett and co-workers (1). These experiments have shown that most of the analgesic activity resides in the enantiomorph possessing the D-configuration. A hypothesis was advanced which attempted to define an analgesic receptor surface on the basis of three points of contact. This implies that the orientation of the methyl group on the asymmetric carbon of the methadones and thiambutenes is held in a favorable position only in those compounds having the D-configuration. In an effort directed at testing this hypothesis we have determined the absolute configuration of diampromid (II) (2), a member of a new class of analgesics of the basic anilide type.

The D-(−)-N-methyl-N-benzyl compound (I) (3), which has been related to D-alanine, was catalytically hydrogenolyzed with palladium on carbon according to the procedure of Wright, Brabander, and Hardy (2). The resulting debenzylated intermediate was then phenethylated with phenethyl bromide to give D-(−)-diampromid (II), $[\alpha]_D^{28°}$ −26.4° (c 5% in ethanol), b.p. 159–163° (0.1 mm.). The infrared spectrum is identical with that of racemic II (2). Wright, Brabander, and Hardy (4) have independently prepared (+) and (−)-diampromid. Their physical constants are in close agreement with our data.

The (+) and (−) enantiomers of compound I and of diampromid (II) were tested (5) subcutaneously on rats by a modification of the rat-tail heat response method. The L-(+)-isomers of I and II possess analgesic activity comparable to that of morphine, whereas the D-(−)-isomers are substantially less active. These pharmacological results are quite unexpected since it has been demonstrated that the more active enantiomorphs of methadone-type and thiambutene-type analgesics have the D-configuration (1). The potent analgesic action and addictive properties of I and II suggest that they are acting by a mechanism similar to that of methadone and other potent analgesics in spite of the fact that the more active enantiomorphs

of these compounds are related to L-(+)-alanine. The apparent inversion of antipodal activity on passing from the methadones to the basic anilides suggests that in addition to the orientation of the methyl group on the asymmetric carbon of I and II, other factors may also exert a profound influence on the absolute antipodal activity of the basic anilides.

We are presently investigating the configurations of other basic anilide analgesics and methadone-type compounds.

Book Notices

Methods of Biochemical Analysis. Vol. 10. Edited by DAVID GLICK. John Wiley & Sons, Inc., Interscience Division, 440 Park Ave. South, New York 16, N. Y., 1962 xi + 399 pp. 15 × 23 cm. Price $14.50.

This tenth volume in a series concerned with methods of biochemical analysis contains sections on Separation of carbohydrate derivatives by gas-liquid partition chromatography, Determination of-SH groups in proteins, Measurement of sodium and potassium by glass electrodes, Measurement of UDP-Enzyme systems, Determination of dissociation constants for two-substrate enzyme systems, Dialysis, Countercurrent distribution, Partition methods for fractionation of cell particles and macromolecules, Determination and microscopic localization of cholesterol, and Chemical determination of flavins. Subject and author indexes for this volume as well as a cumulative index for the entire series enhance the value of the series as a reference source. Numerous literature references follow each section which should be an aid to workers employing the methods and techniques described.

Plante Medicinali, Chimica Farmacologia e Terrapia. Vol. 1. By BENIGNI C. CAPRA, and P. E. CATTORINI. dott. Inverni & Bella Beffa S.p.a., Via Ripamonti n. 99, Milano, Italy, 1962. vi + 730 pp. 16 × 23 cm. Price L. 8000.

This is a reference work (in Italian) on medicinal plants which covers chemical, pharmacologic, and therapeutic aspects of these substances. Volume 1 is apparently the first of a series since this volume includes plant names in the A-G group. The book is arranged alphabetically by plant name in monograph form. Each monograph includes identifying characteristics, extracts, and usual preparations with formulas as well as good, frequently extensive, literature references. An index is appended.

Analyze des Stéroïdes Hormonaux. Méthodes générales. Tome 1. Vol. 1. By M. F. JAYLE. Masson et Cie Editeurs, 120 boulevard Saint-Germain, Paris VI e, France, 1961. 276 pp. 16.5 × 24.5 cm. Price 45 NF.

This volume (in French) is one of a three volume set dealing with steroids and hormones. Volume 1 concerns itself with the structure, nomenclature, physical constants, hydrolysis, extraction, and purification of steroids. It also covers the analysis of conjugated steroids and spectophotometric and chromatographic analysis of steroids.

Précis de Botanique. Tome 1. Vol. 1. Morphologie et Reproduction des Plantes Vascularies, Systematique des Cryptogames, Vascularies et des Gymnospermes. By P. CRÉTÉ. Masson et Cie, Editeurs, 120 boulevard Saint-Germain, Paris VIe, France, 1962. viii + 348 pp. 16.5 × 21.7 cm. Price 34 NF.

This first volume of a two volume set on pharmaceutical botanicals (in French) includes materials on the morphologie and reproduction of vascular plants and contains a section dealing with the classification of these plants.

Gas Chromatography. By C. AMBROSE and BARBARA A. AMBROSE. D. Van Nostrand Co., Inc., 120 Alexander St., Princeton, N. J., 1962. vii + 220 pp. 13.5 × 21.5 cm. Price $6.75.

This book is designed as a survey of the literature on gas chromatography, including information to enable the reader to construct the necessary apparatus and utilize it intelligently. After a chapter dealing with the method generally, the book discusses retention parameters, effects on separations of solute-solvent interactions, and column performance, among other topics. A directory of equipment manufacturers is appended.

of these compounds are related to L-(+)-alanine. The apparent inversion of antipodal activity on passing from the methadones to the basic anilides suggests that in addition to the orientation of the methyl group on the asymmetric carbon of I and II, other factors may also exert a profound influence on the absolute antipodal activity of the basic anilides.

We are presently investigating the configurations of other basic anilide analgesics and methadone-type compounds.

College of Pharmacy
University of Minnesota
Minneapolis 14, Minn.

Received September 6, 1962.
Accepted for publication October 1, 1962.
The author gratefully acknowledges the cooperation of Dr. Robert A. Hardy, Jr., of Lederle Laboratories, in supplying physical data for comparison purposes, and in being instrumental in informing us of the pharmacological results.

Book Notices

Methods of Biochemical Analysis. Vol. 10. Edited by DAVID GLICK. John Wiley & Sons, Inc., Interscience Division, 440 Park Ave. South, New York 16, N. Y., 1962 xi + 399 pp. 15 × 23 cm. Price $14.50.

This tenth volume in a series concerned with methods of biochemical analysis contains sections on Separation of carbohydrate derivatives by gas-liquid partition chromatography, Determination of-SH groups in proteins, Measurement of sodium and potassium by glass electrodes, Measurement of UDP-Enzyme systems, Determination of dissociation constants for two-substrate enzyme systems, Dialysis, Countercurrent distribution, Partition methods for fractionation of cell particles and macromolecules, Determination and microscopic localization of cholesterol, and Chemical determination of flavins. Subject and author indexes for this volume as well as a cumulative index for the entire series enhance the value of the series as a reference source. Numerous literature references follow each section which should be an aid to workers employing the methods and techniques described.

Plante Medicinali, Chimica Farmacologia e Terrapia. Vol. 1. By BENIGNI C. CAPRA, and P. E. CATTORINI. dott. Inverni & Bella Beffa S.p.a., Via Ripamonti n. 99, Milano, Italy, 1962. vi + 730 pp. 16 × 23 cm. Price L. 8000.

This is a reference work (in Italian) on medicinal plants which covers chemical, pharmacologic, and therapeutic aspects of these substances. Volume 1 is apparently the first of a series since this volume includes plant names in the A-G group. The book is arranged alphabetically by plant name in monograph form. Each monograph includes identifying characteristics, extracts, and usual preparations with formulas as well as good, frequently extensive, literature references. An index is appended.

Analyze des Stéroïdes Hormonaux. Méthodes générales. Tome 1. Vol. 1. By M. F. JAYLE. Masson et Cie Editeurs, 120 boulevard Saint-Germain, Paris VI e, France, 1961. 276 pp. 16.5 × 24.5 cm. Price 45 NF.

This volume (in French) is one of a three volume set dealing with steroids and hormones. Volume 1 concerns itself with the structure, nomenclature, physical constants, hydrolysis, extraction, and purification of steroids. It also covers the analysis of conjugated steroids and spectophotometric and chromatographic analysis of steroids.

Précis de Botanique. Tome 1. Vol. 1. Morphologie et Reproduction des Plantes Vascularies, Systematique des Cryptogames, Vascularies et des Gymnospermes. By P. CRÉTÉ. Masson et Cie, Editeurs, 120 boulevard Saint-Germain, Paris VIe, France, 1962. viii + 348 pp. 16.5 × 21.7 cm. Price 34 NF.

This first volume of a two volume set on pharmaceutical botanicals (in French) includes materials on the morphologie and reproduction of vascular plants and contains a section dealing with the classification of these plants.

Gas Chromatography. By C. AMBROSE and BARBARA A. AMBROSE. D. Van Nostrand Co., Inc., 120 Alexander St., Princeton, N. J., 1962. vii + 220 pp. 13.5 × 21.5 cm. Price $6.75.

This book is designed as a survey of the literature on gas chromatography, including information to enable the reader to construct the necessary apparatus and utilize it intelligently. After a chapter dealing with the method generally, the book discusses retention parameters, effects on separations of solute-solvent interactions, and column performance, among other topics. A directory of equipment manufacturers is appended.

of these compounds are related to L-(+)-alanine. The apparent inversion of antipodal activity on passing from the methadones to the basic anilides suggests that in addition to the orientation of the methyl group on the asymmetric carbon of I and II, other factors may also exert a profound influence on the absolute antipodal activity of the basic anilides.

We are presently investigating the configurations of other basic anilide analgesics and methadone-type compounds.
