tion in the rate of metabolism of methotrimeprazine was noted among the individual animals during the first 2 hr. The variation is less marked at 4 and 24 hr. after the drug injection. It can be noted that the initial part of the curve falls steeply and that after 60 min. about 70% of the injected dose has already disappeared. However, after the initial rapid decline the rate of disappearance of methotrimeprazine tends to level off, and the curve flattens out between 1 and 2 hr. After 24 hr., 7 and 8% methotrimeprazine was still recovered from two mice, respectively. Contamination of body levels by any drug in bladder urine was negligible since the amount of the drug present in the bladder urine at various time intervals in 8 of 23 mice was barely detectable, and the total 24-hr. excretion reflected less than 1% of the injected dose.

Methotrimeprazine "Analgesia"—Table II shows the mean values of the reaction time and their mean deviations obtained by injecting 2, 4, 8, and 15 mg./Kg. methotrimeprazine in 51 mice. The mean value of the control reaction time of the untreated mice was found to be 1.2 ± 0.04 sec.

While there appears to be a slight increase in the reaction time at the three dose levels and at 20, 40, and 60 min. after the administration of the drug, this increase is more apparent than real. The individual values varied considerably and the intensity of the responses correlated poorly with increasing doses of the compound. In fact with the highest dose, 15 mg./Kg. of methotrimeprazine, the reaction

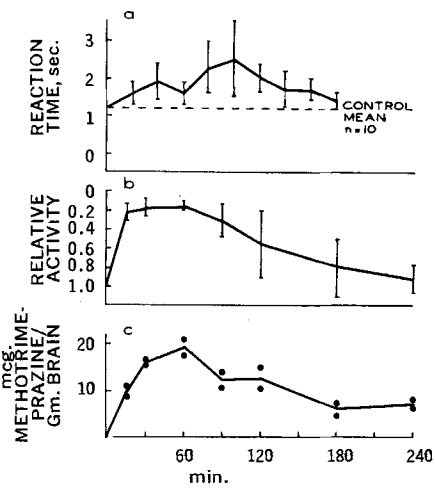

Fig. 3—Time response curves for mice receiving methotrimeprazine and assessed for (a) *"analgetic" activity (15 mg./Kg. dose);* (b) *loss of motor coordinating ability (4 mg./Kg. dose); and* (c) *brain levels of the drug (4 mg./Kg. dose).*

time was found to be almost the same or even less than that of lower dosages. Figure 3, a, represents the reaction time in seconds obtained with this dosage over a 3-hr. period with animals tested at 20-min. intervals. The mean deviations plotted in the same figure demonstrate the marked variation at each time interval. Despite the fact that little "analgesia" was noted, the mice appeared heavily sedated and exhibited little physical activity even at the lowest dose (2 mg./Kg.) of methotrimeprazine.

Coordinated Motor Ability—Figure 3, b, represents the average values of the relative activity of 10 mice when given 4 mg./Kg. of methotrimeprazine subcutaneously. It is apparent from the curve that the coordinated motor ability of the animals was reduced about 80% during the first hour. The mice gradually recovered, and by the end of the 4-hr. period there was only a 5% reduction in the relative activity of the mice. Subjectively, however, the animals still appeared very sedated and moved only when prodded.

Brain Levels of Methotrimeprazine—Figure 3, c, represents the concentration of methotrimeprazine as mcg./Gm. brain over the 4-hr. period after the administration of 4 mg./Kg. subcutaneously. The concentration in the brain increases gradually with time and reaches a peak level at 60 min. and then the drug concentration slowly declines. Significant amounts of methotrimeprazine were still present in the brain at the end of the 4-hr. period. The brain concentrations appeared to correlate with the coordinated motor ability of the mice to remain on the rotating rod.

DISCUSSION

The prolonged sedation and rather persistent tissue levels of methotrimeprazine observed in the mouse are in agreement with what is known concerning the duration of action and rate of metabolism of phenothiazine compounds in other animal species.

The psychotropic effects of chlorpromazine in humans have been reported to be maintained for 1 to 2 weeks after its discontinuation (5), and excretion of the drug in trace amounts in the urine may last for weeks (5, 12). Salzman and Brodie reported a relatively slow rate of biotransformation of chlorpromazine in dogs, and attribute the slow rate partly to extensive localization of the drug in various organs with consequent lesser immediate availability of the drug to metabolizing enzymes (6).

The studies on the organ distribution of methotrimeprazine in the rat (13) indicate that there is also rapid uptake of the drug by organ depots, especially parenchymatous tissues, and this is consistent with findings on most basic compounds (15). In the case of methotrimeprazine, organ levels of the drug may still be appreciable 12 hr. after its administration. Ultimately, however, the drug is extensively biotransformed. Less than 1% of the unchanged drug is excreted in the urine, but a variety of metabolic products, including sulfoxide metabolites, are detectable in varying amounts (13); similar findings have been reported for humans (5).

To what extent the biotransformation products of methotrimeprazine may contribute to the sum total of pharmacologic effects remains a question. The prolonged half-life of the drug indicates that adequate amounts of the original substance are available for eliciting drug effects. A reasonable degree of parallelism was noted for the curve for concentration of drug in the brain and that for coordinated motor ability. Such a correlation suggests that the parent substance is principally mediating the pharmacologic effects under observation, but whether loss of motor coordination is accompanied by analgesia cannot be answered by our experiments.

The failure to obtain a good correlation with "analgesia" resulted from the inability to establish a clear-cut response with methotrimeprazine by the test procedure. This is not surprising and was in part anticipated. Agents other than the narcotic analgetic type yield erratic effects in prolonging the tail reaction time to thermal stimulus and in our hands methotrimeprazine proved to be no exception to the rule. In view of the established effectiveness of the compound as a potent analgetic clinically (2–4), the tail flick procedure obviously would be a poor screening method for other compounds in this series. These findings are not consistent with an earlier report (14), and we have no explanation for the discrepancy. There is still clearly a need to establish a suitable test procedure for surveying non-narcotic type analgetics.

Effect of γ Radiation on Selected Pharmaceuticals

By LAWRENCE J. RASERO, JR.*, and DONALD M. SKAUEN

Aqueous solutions of chlorobutanol, theophylline, and sodium carboxymethylcellulose (CMC) were irradiated with γ radiation from a ^{60}Co source. Solutions were irradiated in glass and polyethylene containers. Chlorobutanol solutions were analyzed for appearance, pH changes, chlorobutanol degradation, and production of chlorine, acetone, and hydrogen peroxide. Theophylline solutions were analyzed for appearance, pH changes, theophylline degradation, and production of hydrogen peroxide. CMC solutions were analyzed for viscosity changes. All systems showed pronounced changes, even at low radiation levels.

THE ABILITY of γ radiation to destroy microorganisms without an appreciable temperature rise in the substrate offers an attractive means of sterilizing pharmaceuticals. The possibility of side effects must be considered, however, as γ radiation has the capacity to create highly reactive chemical species in any matter through which it passes. This can lead to an alteration of the physical properties of materials and to the production of numerous chemical changes.

Willis (1) and Proctor and Goldblith (2) have published review articles on the effects of radiation on pharmaceuticals. Although much valuable information has appeared in the literature, the majority of the published reports are confined

Effect of γ Radiation on Selected Pharmaceuticals

By LAWRENCE J. RASERO, JR.*, and DONALD M. SKAUEN

Aqueous solutions of chlorobutanol, theophylline, and sodium carboxymethylcellulose (CMC) were irradiated with γ radiation from a ^{60}Co source. Solutions were irradiated in glass and polyethylene containers. Chlorobutanol solutions were analyzed for appearance, pH changes, chlorobutanol degradation, and production of chlorine, acetone, and hydrogen peroxide. Theophylline solutions were analyzed for appearance, pH changes, theophylline degradation, and production of hydrogen peroxide. CMC solutions were analyzed for viscosity changes. All systems showed pronounced changes, even at low radiation levels.

THE ABILITY of γ radiation to destroy microorganisms without an appreciable temperature rise in the substrate offers an attractive means of sterilizing pharmaceuticals. The possibility of side effects must be considered, however, as γ radiation has the capacity to create highly reactive chemical species in any matter through which it passes. This can lead to an alteration of the physical properties of materials and to the production of numerous chemical changes.

Willis (1) and Proctor and Goldblith (2) have published review articles on the effects of radiation on pharmaceuticals. Although much valuable information has appeared in the literature, the majority of the published reports are confined

to the study of the active ingredients in the system, and usually only indicate which products may or may not be successfully radiation sterilized. Reports concerning the effects of radiation on pharmaceutical adjuncts, as for example, preservatives or suspending agents, are few. Detailed studies showing degradation curves and degradation products are also lacking.

Few reports have been published which investigate the effects of the type container used in the systems studied. Hills and Johnson (3) have shown that the type container used in radiation studies may influence the final result. For irradiation of distilled water with γ radiation, they reported that the samples became more acid, an effect which was greater in polyethylene containers than in glass. They also noted that with dextrose and fructose solutions the coloration produced was more pronounced for the solutions packaged in glass containers.

The object of this investigation was to study the effect of γ radiation from a ^{60}Co source on aqueous solutions of chlorobutanol, theophylline, and sodium carboxymethylcellulose packaged in glass and polyethylene containers.

EXPERIMENTAL

Equipment—The irradiation facility used in this investigation was a ^{60}Co source.[1] A calibration certificate supplied by the company indicated a dose rate of 5.5×10^5 rad/hr. on May 17, 1962. The measuring technique was by ferrous chemical dosimetry. A check of the calibration was made using the ASTM Tentative Method of Test for Absorbed Gamma Radiation Dose in the Fricke Dosimeter (4).

A Beckman DU,[2] model 2400, spectrophotometer with attached Beckman DU power supply was used for colorimetric and ultraviolet analysis.

A Will 80–100 sec. 2-ml. Ostwald viscometer[3] was used for all viscosity determinations, except the 2% sodium carboxymethylcellulose (CMC) solution. For this CMC solution, the viscometer employed was a Haake Rotovisco,[4] with an attached Haake Ultra-Thermostat, type NBS.

A Beckman Zeromatic pH meter,[2] number 9500, with standard electrodes was used for all pH measurements.

Containers—Two types of containers were used in this investigation. One was a 4-oz., 0.95 d., amber polyethylene container.[5] The second type was a 4-oz. amber glass container.[6] Screw type lined, plastic caps were used for both containers.

PROCEDURES

The solutions were prepared, packaged in glass and polyethylene containers, irradiated for varying lengths of time, and analyzed within 24 hr. Irradiation was performed at room temperature. Air was not evacuated from the containers.

Analysis of chlorobutanol was by the colorimetric method of Rehm and Mader (5). Hydrogen peroxide was determined by the colorimetric method of Eisenberg (6). Acetone produced in chlorobutanol solutions was determined by the method of Greenberg and Lester (7). Chlorine was determined with *o*-tolidine reagent using the procedure described by Boltz (8). Theophylline was determined by the spectrophotometric method of Comer and Hiltz (9).

All viscosity determinations were made at 100° F. For the Ostwald viscometer 4-ml. aliquots of the solution were pipetted into the lower bulb of the viscometer, and allowed to stand 15 min. for the temperature to equilibrate. The liquid was then drawn into the second bulb and to a position about 5 mm. above the first timing mark. The time required for the meniscus to pass from the first timing mark to the second was then measured with a stopwatch.

The Haake viscometer was used to follow the change in the characteristic flow curve of the 2% CMC solution. The measurements were made at 100° F., using the MV-11 cup and bob system.

The increase in the viscosity of a polymer solution over that of the pure solvent can be expressed as specific viscosity (10)

$$\eta_{sp} = \frac{\eta - \eta_0}{\eta_0}$$

where η = viscosity of the solution,
η_0 = viscosity of the pure solvent,
η_{sp} = specific viscosity.

If η_{sp}/concentration is plotted against concentration, the point of intercept at zero concentration is known as the intrinsic viscosity $[\eta]$. The intrinsic viscosity is related to the molecular weight by two constants (K and a) in the equation $[\eta] = KM^a$ (11), so any change in the intrinsic viscosity should be indicative of a change in the molecular weight.

For the molecular weight changes, a 0.25% solution of sodium CMC was irradiated for 0, 5, 10, and 20 min. Each sample was then diluted 5, 10, 50, and 100 times, and the viscosities were determined with the Ostwald viscometer, as described previously. The η_{sp} was then calculated and plots were made of η_{sp}/C *versus* C.

RESULTS AND DISCUSSION

Chlorobutanol Solutions—Visual observation of the chlorobutanol solutions showed the development of an amorphous, yellow precipitate during irradiation. No attempt was made to identify the composition of the precipitate.

Analysis for chlorine showed that no chlorine was produced in a 0.5% chlorobutanol solution irradiated up to 6.8×10^6 rads.

Measurement of pH changes showed that irradiated chlorobutanol solutions suffered severe drops in pH after very short periods of irradiation. Table I presents the change in pH of a 0.5% chlorobutanol solution. It can be seen that a dose of only 6.1×10^3 rads causes a pH drop of more than 1 unit. Measurements of irradiated distilled water

[1] Gammacell 200. Atomic Energy of Canada Limited, Commercial Products Division, Ottawa, Ontario, Canada.

[3] Will Scientific, Inc., New York, N. Y.
[4] Brinkmann Instruments, Inc., Great Neck, N. Y.
[5] Monsanto Co., Packaging Division, Hartford, Conn.
[6] Armstrong Co., Lancaster, Pa.

showed no change in pH over the same dose range as the chlorobutanol solution. This indicates that the drop in pH is due to the degradation of the chlorobutanol. Similar pH drops have been reported by others for heated chlorobutanol solutions (12, 13).

TABLE I—pH OF 0.5% CHLOROBUTANOL SOLUTION

9.1×10^4	2.90
1.8×10^5	2.68
3.7×10^5	2.37

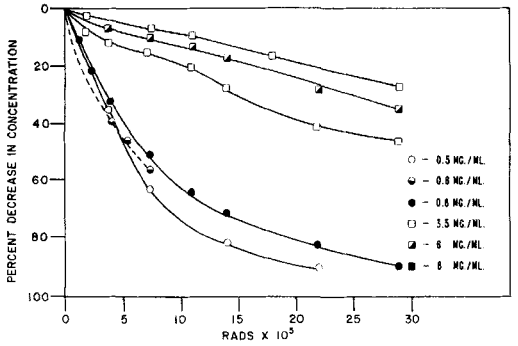

Fig. 1—Per cent decrease of chlorobutanol solutions.

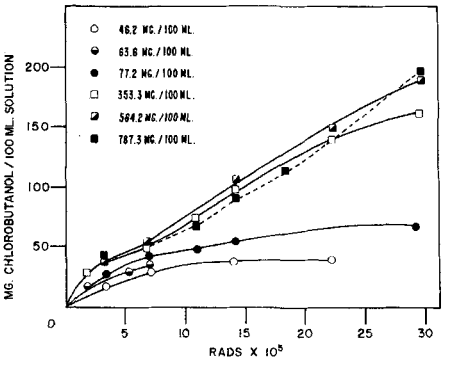

Fig. 2—Milligram loss curve for chlorobutanol solution.

Figure 1 shows the per cent decrease in irradiated chlorobutanol solutions, and Fig. 2 presents the total milligram loss for the same solutions. Figure 1 shows that those solutions containing a higher concentration of chlorobutanol have less per cent decomposition, and this appears to indicate that the more concentrated solutions are more stable to γ radiation. If, however, the total milligram loss is plotted for each solution of chlorobutanol, it is found that the total milligram loss at first increases as the concentration increases, until a limiting factor is reached. These results support the indirect action theory which states that in dilute aqueous solutions the major effect of radiation is on the water molecules, and the degradation of the solution is due to a secondary reaction. Since the number of water molecules remains relatively constant, the same amount of chlorobutanol should be degraded in each case. The apparent discrepancy which occurs in the chlorobutanol solutions of low concentration may be due to the fact that a large percentage of the chlorobutanol is degraded, and this in turn limits the total milligram loss.

The production of hydrogen peroxide in chlorobutanol solutions presents a most unusual result (Fig. 3). The data show that more concentrated solutions produce higher levels of hydrogen peroxide. However, in every instance the level of hydrogen peroxide increases rapidly, reaches a peak, and then suffers a reduction in concentration. The point of maximum hydrogen peroxide concentration occurs at about the time the precipitate becomes evident. One possible explanation for this unusual result is that the peroxide may be used up during formation of the insoluble material. It is impossible, however, to suggest appropriate mechanisms without knowing all the degradation products produced during irradiation.

Analysis of the data for acetone production (Fig. 4) shows that as the concentration of chlorobutanol increases, so does the level of acetone. The amount of acetone produced is less than would be expected if each mole of chlorobutanol degraded formed 1 mole of acetone.

For all the assay procedures used, there was no difference in results due to the container.

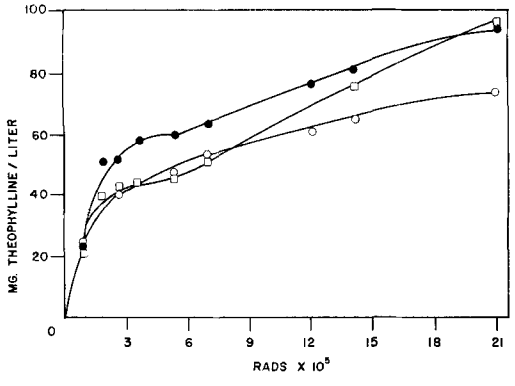

Fig. 6—Milligram loss curve for theophylline solutions. Key: ○, 0.1 Gm./L.; ●, 0.5 Gm./L.; □, 1.0 Gm./L.

Theophylline Solutions—Visual observations of theophylline solutions showed that irradiation causes a slight yellowing to develop in the solution. This yellow tint was more pronounced the higher the concentration of the solution, and the longer the irradiation time.

Unlike chlorobutanol solutions, the pH of theophylline solutions remain relatively constant, even after prolonged periods of irradiation (Tables II and III).

The degradation of theophylline solutions is very similar to chlorobutanol solutions (Figs. 5 and 6). The more concentrated solutions have less degradation, on a per cent basis, than the more dilute solutions. But, once again, it may be seen that the milligram loss for all solutions remains relatively constant. This, as explained previously, is an indication of an indirect effect on the theophylline molecule.

The curves for hydrogen peroxide levels (Fig. 7) are of a much simpler nature than those for chlorobutanol solutions. For more concentrated solutions of theophylline, there is a higher production

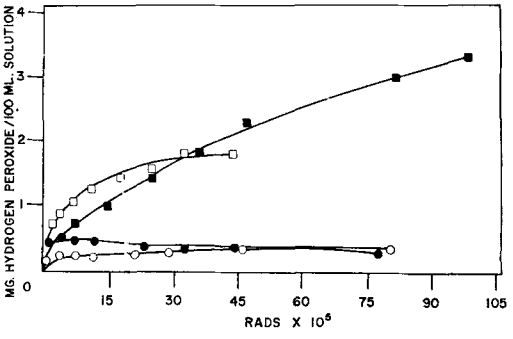

Fig. 7—Hydrogen peroxide levels of theophylline solutions. Key: ○, distilled water; ●, 0.1 Gm./L.; □, 0.5 Gm./L.; ■, 5.0 Gm./L.

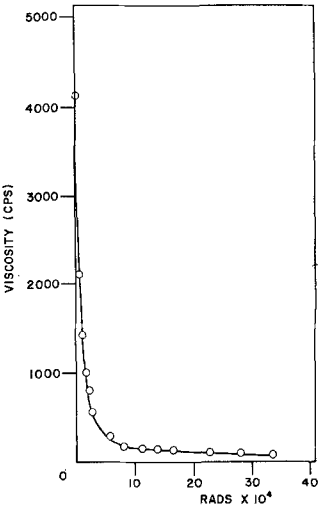

Fig. 8—Viscosity decrease of 0.5% sodium carboxymethylcellulose at 100° F.

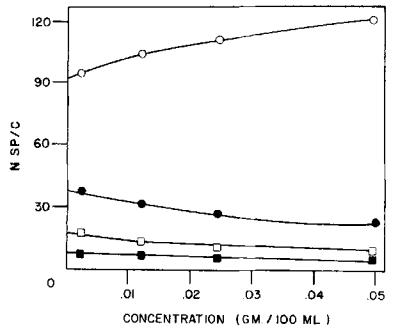

Fig. 9—Effect of irradiation on η_{sp}/C versus C curves for 0.25% sodium carboxymethylcellulose at 100° F. Key: ○, control; ●, 2.8 × 10⁴ rads; □, 5.7 × 10⁴ rads; ■, 1.1 × 10⁵ rads.

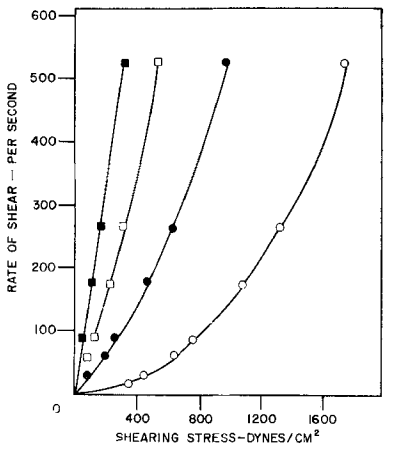

Fig. 10—Effect of irradiation on flow curves of 2% sodium carboxymethylcellulose at 100° F. Key: ○, control; ●, 2.8 × 10⁴ rads; □, 5.7 × 10⁴ rads; ■, 8.5 × 10⁴ rads.

of hydrogen peroxide, but there is no decrease in the level after a certain point, as was the case with chlorobutanol solutions.

There was no difference in effects due to the containers used for the theophylline solutions.

Sodium Carboxymethylcellulose Solutions (CMC)—Ostwald viscometer measurements of 0.125%, 0.25%, and 0.5% CMC solutions indicated that irradiation with γ rays causes a severe and immediate drop in viscosity. As little as 5.7 × 10^3 rads caused a decrease in viscosity of 48 to 66% for the solutions. Figure 8 presents the decrease for the 0.5% solution. The curves for the 0.125% and 0.25% solutions were very similar.

The results of intrinsic viscosity determination (Fig. 9) indicate a profound reduction in molecular weight. As discussed previously, the intrinsic viscosity is related to the average molecular weight.

Analysis of the total flow curve for a 2% CMC solution shows that irradiation causes the curve to change from a pseudoplastic flow curve to a nearly Newtonian system, after a dose of 8.5 × 10^4 rads (Fig. 10). This loss of pseudoplastic behavior is another indication of the reduction in length of the polymer chain which occurs during irradiation.

No container effect was noted for the CMC solutions.

CONCLUSIONS

Gamma irradiation of aqueous solutions of chlorobutanol, theophylline, and sodium carboxymethylcellulose caused severe degradation in all three systems.

These results indicate that γ irradiation is not a suitable method for sterilizing aqueous solutions of these products.

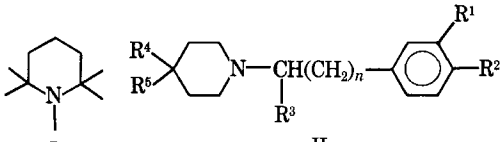
Preparation of Some *N*-Benzylpiperidines

By JOSEPH SAM and DOROTHY M. NOBLES*

A number of *N*-(*p*-substituted benzoyl)piperidines was prepared. The reduction of the amides with lithium aluminum hydride provided the corresponding *N*-(*p*-substituted benzyl)piperidines. Isobutyric anhydride and 3,4,5-trimethoxybenzoyl chloride were used to prepare several esters of *N*-(*p*-hydroxybenzyl)piperidines. Several of the compounds were tested in mice for their general behavioral effects and in dogs for pharmacodynamic activity.

EXTENSIVE INVESTIGATIONS have been conducted in a search for hypotensive agents and a number of useful compounds have been produced (1).

The need for agents with greater safety characteristics and different limits of tolerance prompted an investigation into the preparation of some *N*-benzylpiperidines (III). The hypotensive properties exhibited by 1,2,2,6,6-pentamethylpiperidine (I) and related compounds (2), and the observations of Somers and Handley (3) that 1-aralkyl-4,4-dialkylpiperidines (II) possess substantial hypotensive activity, added impetus to this work.



I

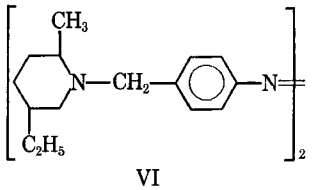
II

DISCUSSION

The synthesis of *N*-(*p*-substituted benzyl)piperidines (III) was accomplished primarily *via* reduction of the corresponding benzoylpiperidines (IV). (Scheme I.)

The intermediate *N*-(*p*-substituted benzoyl)-piperidines (IV) (Table I) were prepared by the reaction of a substituted benzoyl chloride with a substituted piperidine.

The reduction of IV with lithium aluminum hydride, with one exception, provided the corresponding benzyl derivatives (III) (Table II). The reduction of *N*-(*p*-nitrobenzoyl)-2-methyl-5-ethylpiperidine yielded the azo derivative (VI). The formation of azo compounds *via* lithium aluminum hydride reduction of nitro groups is not uncommon (4). The *N*-(*p*-aminobenzyl)-2-methyl-5-ethylpiperidine is obtained if, preceding lithium hydride reduction, the nitro group is reduced with palladium-carbon.



VI

The synthesis of *N*-(*p*-hydroxybenzyl)piperidines (Table II) ultimately was effected by the following methods: (*a*) demethylation of *N*-(*p*-methoxybenzyl)piperidines, (*b*) debenzylation of *N*-(*p*-benzyloxybenzyl)piperidines, (*c*) utilization of a modified Wallach reaction, and (*d*) reduction of *N*-(*p*-acetoxybenzoyl)piperidines.

Demethylation was accomplished using refluxing hydriodic acid in glacial acetic acid (5) and debenzylation was performed by hydrogenolysis with palladium-carbon.

A modified Wallach reaction (6) was utilized for the preparation of *N*-(*p*-hydroxybenzyl)piperidine. The maximum yield, however, never exceeded 10%. Increasing the length of reaction time did not increase the yield.

The *N*-(*p*-acetoxybenzoyl)piperidines were prepared by condensing *p*-acetoxybenzoyl chloride with an appropriately substituted piperidine and were employed without purification in subsequent lithium aluminum hydride reductions.

The esterification of the *N*-(*p*-hydroxybenzyl)-piperidines to V was accomplished using isobutyric anhydride and 3,4,5-trimethoxybenzoyl chloride. The esters of both of these acids are prevalent in the veratrum series (7). Table III lists the esters prepared.

Preliminary studies in mice indicated that the amides (Table I) in general exhibit weak central nervous system (CNS) depressant properties. Cheymol and associates (8) noted hypnotic properties of *o*-(piperidinothiocarbonyl)phenol. The amines (Table II) in general exhibited weak CNS stimulant activity. Preliminary studies of the esters (Table III) in dogs showed transient depressor responses.

EXPERIMENTAL[1]

p-Benzyloxybenzoyl chloride (9), *p*-acetoxybenzoyl chloride (10), and *p*-nitrobenzoyl chloride (11) were prepared according to reported procedures. Commercially available anisoyl chloride was utilized.

N-(p-Substituted Benzoyl)piperidines (Table I)—*Method A*—A cooled solution of 0.07 mole of the

Received February 6, 1967, from the Department of Pharmaceutical Chemistry, University of Mississippi, University, MS 38677

Accepted for publication March 14, 1967.

Presented to the Medicinal Chemistry Section, A.PH.A. Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

Abstracted in part from a thesis submitted by Dorothy M. Nobles to the Graduate School, University of Mississippi, in partial fulfillment of Doctor of Philosophy degree requirements.

Supported in part by the Mississippi Heart Association and McNeil Laboratories, Fort Washington, Pa.

[a] A, acetone; E, ether; B, benzene; Ea, ethyl acetate.

appropriate piperidine in 50 ml. of anhydrous ether was treated dropwise with 0.03 mole of anisoyl or *p*-benzyloxybenzoyl chloride. The reaction mixture was allowed to stand 15 min. and then treated with 25 ml. of ice water. The ether solution was washed with two 50-ml. portions of 10% sodium bicarbonate and two 50-ml. portions of 10% hydrochloric acid, respectively. The ether was evaporated and the residual material either distilled or recrystallized from a suitable solvent.

In the case of the *N*-(*p*-acetoxybenzoyl)piperidines, the final ethereal layer was dried over anhydrous magnesium sulfate and evaporated to dryness. The residual product was used in subsequent reduction reactions.

Method B—To a solution of 38 Gm. (0.3 mole) of 2-methyl-5-ethyl piperidine in 150 ml. of pyridine was added slowly 28 Gm. (0.18 mole) of *p*-nitrobenzoyl chloride. The reaction mixture was heated 45 min. on a steam bath. The solution was cooled and then washed with two 50-ml. portions of 10% sodium bicarbonate and two 50-ml. portions of 10% hydrochloric acid, respectively. The residual oil was extracted with ether, dried, and then distilled.

Method C—A solution of 18.6 Gm. (0.07 mole) of *N*-(*p*-nitrobenzoyl)-2-methyl-5-ethyl piperidine in 50 ml. of ethanol was hydrogenated with 10% palladium-carbon at 40 p.s.i. for 2 hr. The product was isolated in the usual manner.

Method D—To 7 Gm. (0.03 mole) of *N*-(*p*-methoxybenzoyl)-2-methyl piperidine was added 100 ml. of glacial acetic acid and 100 ml. of 57% hydriodic acid. The mixture was refluxed 6 hr., cooled, and treated with 100 ml. of water. The solution was decolorized with sodium bisulfite and extracted with two 50-ml. portions of ether. The ether was extracted with 50 ml. of 10% sodium hydroxide. The aqueous layer was separated and acidified with 10% hydrochloric acid. The acid solution was extracted with 50 ml. of ether. Evaporation of the ether yielded the product.

N-(p-Substituted Benzyl)piperidines (Table II)—*Method E*—The procedure outlined by Sommers (12) for lithium aluminum hydride reductions was modified and used. A stirred slurry of 18.2 Gm. (0.4 mole) of lithium aluminum hydride and 100 ml. of anhydrous tetrahydrofuran was treated dropwise with 0.1 mole of the amide in 50 ml. of anhydrous tetrahydrofuran. The mixture was stirred and refluxed 24 hr., cooled, and cautiously decomposed with 200 ml. of ethyl acetate. The reaction mixture was filtered and the solvent distilled. The residual oil was converted to the hydrochloride in the usual manner and recrystallized from the appropriate solvent.

Method F—To a solution of 20 ml. of 57% hydriodic acid in 20 ml. of glacial acetic acid was added 4.3 Gm. (0.02 mole) of *N*-(*p*-methoxybenzyl)-2-methylpiperidine and the whole refluxed 6 hr. The cooled solution was treated with 100 ml. of water, made alkaline with solid sodium bicarbonate, and extracted with ether. The ether layer was dried over anhydrous magnesium sulfate. The hydrochloride was prepared in the usual manner.

Method G—A solution of 29.5 Gm. (0.1 mole) of *N*-(*p*-benzyloxybenzyl)-4-methylpiperidine in 90% ethanol was hydrogenated with 10% palladium-carbon catalyst at 42 p.s.i. for 12 hr. The catalyst was removed by filtration and the ethanol distilled under reduced pressure. The oil was extracted with 50 ml. of 10% sodium hydroxide; the latter was washed with ether and then neutralized with solid carbon dioxide. The product was extracted with ether and converted to the hydrochloride in the usual manner.

Method H—Following a modified procedure of Staple and Wagner (6), 16 Gm. (0.2 mole) of piperidine and 4.6 Gm. (0.1 mole) of formic acid (90%) were heated on a steam bath for 30 min. The mixture was cooled, treated with 12.2 Gm. (0.1 mole) of *p*-hydroxybenzaldehyde, and thereafter heated in an oil bath at 110–120° for 14 hr. The mixture was cooled, treated with 100 ml. of 10% sodium bicarbonate, and extracted with ether. The hydrochloride was prepared in the usual manner.

Method I—The *N*-(*p*-acetoxybenzoyl)piperidines (prepared according to method *A*) were reduced with lithium aluminum hydride according to the procedure outlined in method *E* to *N*-(*p*-hydroxybenzyl)piperidines.

Esters of N-(p-Hydroxybenzyl)piperidine (Table III)—*Method J*—The procedure outlined by Behrend (13) and Hudson and Dale (14) was followed. A solution of 0.004 mole of the requisite *N*-(*p*-hydroxybenzyl)piperidine hydrochloride in 20 ml. of pyridine was treated with 3.2 Gm. (0.02 mole) of isobutyric anhydride and stirred 12 hr. The pyridine was distilled under reduced pressure and the residue was recrystallized from an appropriate solvent.

Method K—A modified procedure of Counsell and Soine (15) was employed. A solution of 1 Gm. (0.005 mole) of *N*-(*p*-hydroxybenzyl)-4-methylpiperidine in 25 ml. of anhydrous benzene was treated with 2.3 Gm. (0.01 mole) of commercial 3,4,5-trimethoxybenzoyl chloride and 2 Gm. (0.02 mole) of triethylamine. The mixture was refluxed 12 hr., cooled, and washed with 10% sodium hydroxide and water, respectively. The product was isolated in the usual manner and converted to a hydrochloride.

Constituents from *Gymnema sylvestre* Leaves II

Nitrogenous Compounds

By JOSEPH E. SINSHEIMER and HUGH M. MCILHENNY*

The leaves of *Gymnema sylvestre* were examined for the presence of alkaloids through the establishment of quaternary and nonquaternary nitrogenous fractions. A trace amount of an alkaloidal substance was isolated from a nonphenolic nonquaternary fraction and partially characterized. The plant bases choline, betaine, and adenine were isolated and identified in a combined yield of 0.04 per cent and would appear to be primarily responsible for the positive alkaloid tests previously reported for the leaves. The amino acids leucine, isoleucine, valine, alanine, and γ-amino-*n*-butyric acid were also detected. Of particular interest was the isolation (0.0003 per cent of leaf) and firm identification of trimethylamine oxide which has not been previously reported in plant material.

LEAF EXTRACTS of *Gymnema sylvestre* R. Br. (*Asclepiadaceae*) have an extensive history of pharmacological activity in Indian medicine (1–5) including use as an agent for the treatment of glycosuria and diabetes. It became the objective in these laboratories to examine the chemical nature of plant constituents with potential medicinal importance and to make them available for biological evaluation. The present study describes the isolation and identification of nitrogenous compounds during an investigation of dried *G. sylvestre* leaf for the reported presence (6, 7) of alkaloids.

EXPERIMENTAL

Dried *G. sylvestre* leaf processed during this investigation was commercially supplied by Prachi Gobeson Co., Calcutta, India, and in the later stages by the Himalaya Drug Co., Bombay, India.

Melting points were obtained with the Kofler micro hot stage and are corrected unless noted. An F&M carbon hydrogen nitrogen analyzer model 180 was used to follow nitrogen enrichment in alkaloid-containing fractions and as a deductive lead to structural characterization, but not to confirm a proposed structure. Spectra were determined on Perkin-Elmer models 137B and 337 infrared, Beckman DK-2A ultraviolet, Varian A-60 NMR, and Bendix-Time-of-Flight model 14 mass spectrometers. Neutral alumina, grade 1, Woelm, and silicic acid, 100 mesh (powder) (Mallinckrodt) were used for column chromatography. Silica gel G and alumina G supports and equipment supplied by Warner-Chilcott Laboratories were used for TLC. Continuous extractions of alkaloids were performed with a rotary film liquid-liquid extractor, Rinco VE-4000-x. The adjustments of pH were followed with a Beckman Zero matic pH meter.

Separation Methods

Methanol–Ammonia Extraction—A series of individual extractions was performed with portions (2.4–2.8 Kg.) of finely ground *G. sylvestre* leaf by maceration with methanol saturated with ammonia. The total maceration period was 10 days and included two fresh solvent exchanges. The combined extract was concentrated under reduced pressure to a thick, dark concentrate and diluted with an equal volume of 5% hydrochloric acid. Evaporation to original volume precipitated plant acids which were separated by filtration. The dark filtrate was continuously extracted with chloroform for 48–96 hr. to remove residual plant acids, pigment, and other nonalkaloidal impurities. The acidic aqueous system was made alkaline to pH 11.5 with cold 5 *N* sodium hydroxide and continuously extracted with chloroform for 48 hr. The chloroform extract was washed, dried over sodium sulfate, and evaporated to a brown nitrogenous semisolid, fraction A (0.023% of leaf), as the nonquaternary nonphenolic alkaloid fraction (positive Dragendorff's test). The alkaline solution after chloroform extraction was adjusted to pH 8 with cold 10% hydrochloric acid and continuously extracted with chloroform for 48 hr. The extract was separated, washed, dried over sodium sulfate, and reduced to a semisolid nitrogenous residue, fraction B (0.013% of leaf), as the nonquaternary phenolic alkaloid fraction (positive Dragendorff's test).

Aqueous layers after chloroform extraction were combined (representing 23.58 Kg. of leaf) and processed for the recovery of quaternary alkaloids. The system was concentrated to 8.2 L. in a flash evaporator (40°), adjusted to pH 2 with cold 10% hydrochloric acid, and refrigerated for 24 hr. After separation from an insoluble residue, the dark concentrate (9 L.) was treated with a saturated aqueous solution of Reinecke salt to completion of precipitation (3 L.). The reineckates were separated by filtration after chilling 24 hr. and washed with *n*-propanol (3.3 L.) to remove impurities. To the remaining solids on the filter was added acetone until the disappearance of color in

Abstracted in part from a dissertation submitted by Hugh M. McIlhenny in partial fulfillment of Doctor of Philosophy degree requirements.

This investigation was supported by grant AM 06224 from the National Institutes of Arthritis and Metabolic Diseases, U. S. Public Health Service, Bethesda, Md.

The authors are indebted to Liggett and Myers Tobacco Co., Durham, N. C., through Dr. P. Manni, for providing NMR and mass spectrometric data and to Mr. Lee Below and Mr. Michael Donahue for technical assistance.

* Fellow of the American Foundation for Pharmaceutical Education, 1963–1965. Trainee under grant GM 1367 from the Department of Health, Education, and Welfare, U. S. Public Health Service, Bethesda, Md., 1965–1966. Present address: Chas. Pfizer & Co., Inc., Groton, CN 06340

Previous paper: Manni, P. E. and Sinsheimer, J. E., *J. Pharm. Sci.*, **54**, 1541(1965).

the filtrate (2.5 L.). The reineckates in acetone solution were diluted with an equal volume of methanol and applied to a column of ion-exchange resin[1] (1075 ml., 3 cm. × 126 cm.), flow rate ≤12 ml./min. Column effluent and washes of acetone–methanol (1:1) were collected until a negative reineckate test was given (6.5 L.) and concentrated under reduced pressure to a solid fraction of quaternary bases.

The crude bases were dissolved in 2 L. of water and passed through a column of resin[2] (250 ml., 2.5 cm. × 211 cm.), flow rate 8 ml./min. Column effluent was concentrated to dryness *in vacuo* (50–60°) to give 3.1 Gm. of a tan residue as fraction C. The column[2] had assumed a dark coloration and was therefore removed and slurried batchwise with water. The dark aqueous supernatant was separated by filtration, evaporated, and dried to yield 1 Gm. of a brown residue as fraction D. The washed resin[2] was returned to the column and eluted with 1 *N* hydrochloric acid until a negative reineckate test was given in the column discharge (2 L.). Eluate was concentrated to dryness *in vacuo* (50–60°) to give tan solids as fraction E.

Aqueous Extraction—A solution resulting from a hot aqueous percolate of 403 Gm. of defatted ground leaf was applied to a column containing 500 ml. of ion-exchange resin.[3] The percolate prior to application to the column was kept under a layer of toluene. The effluent was discarded, and the resin was slurried with water to remove precipitated plant acids. Elution with 2.5 L. of 1 *N* ammonium hydroxide gave six fractions. Fractions 1–3 (1.3 L. of eluate) were reduced to dryness, extracted with hot ethanol, and filtered collectively through a 5-Gm. column of alumina. The yellow filtrate and ethanol washings were combined (200 ml.) and evaporated to a brown residue (1.2 Gm.) giving positive ninhydrin and picrate tests.

A 0.885-Gm. sample was dissolved in 50 ml. of water and freed of impurities by extraction with ether (3 × 25 ml.). To the aqueous layer was added a saturated aqueous solution of picric acid to completion of precipitation. The picrate was recovered and dissolved in 130 ml. of 0.1 *N* hydrochloric acid. Extraction with ether (5 × 65 ml.) removed picric acid and left an aqueous layer which upon repeated concentrations from water *in vacuo* (50°) gave 49.3 mg. of a yellow hydrochloride powder, fraction F.

The supernatant remaining after picrate precipitation was concentrated to 45 ml. and diluted to 50 ml. with 1 *N* hydrochloric acid. Picric acid was extracted with ether (8 × 25 ml.), and the aqueous layer was reduced to a yellow gum, fraction G.

Purification and Characterization

Nonquaternary Alkaloids—A 2.67-Gm. quantity of nonquaternary nonphenolic residue fraction A (representing 13.18 Kg. of leaf) was freed of water-soluble impurities and successively extracted with portions of 2% hydrochloric acid until reineckate spot tests were negative. The extract was treated with a saturated aqueous solution of Reinecke salt until precipitation was completed (60 ml.). After a 16-hr. refrigeration period, the reineckate derivative was filtered and recovered in 50 ml. of acetone. Regeneration of amine hydrochlorides by the classical method (8) gave a residue which was converted to free base form in methanol on a column of ion-exchange resin.[1] Collection of effluent and 80 ml. of methanol wash gave a brown residue, 0.145 Gm., as the purified nonquaternary nonphenolic alkaloid fraction (0.001% of leaf). Alumina column chromatography gave 7.5 mg. of the major component 5[4] from chloroform eluates, as a brown solid, m.p. 60–70°.

Anal. (CHN analyzer)—C, 68.01; H, 8.41; N, 7.26.

The substance gave a positive Dragendorff's test, was homogeneous by TLC on alumina in 2% methanol in benzene (blue fluorescence), and was soluble in chloroform, ethanol, methanol, benzene and ether and insoluble in water. Neither hydrochloride nor 2,4-dinitrophenylhydrazone derivatives could be prepared. A picrate, exhibiting a crystalline sublimate at 212° and m.p. 260°, indicated a molecular weight of 221 for the conjugate base by a spectrophotometric (Zeiss model PMQ II) method (9). An infrared spectrum (neat) showed $\nu_{max.}$ 3400 cm.$^{-1}$, 2950 cm.$^{-1}$, 1650 cm.$^{-1}$. The ultraviolet spectrum revealed $\lambda_{max.}^{ethanol}$, 231 mμ (*a* 39.68), 250(sh) (24.63), 281 (14.10), 288 (18.35); $\lambda_{max.}^{0.1\ N\ HCl\text{-}ethanol}$ 250 mμ (*a* 27.79), 302–303 (16.48).

A 1-mg. sample of component 5 purified by silica gel chromatography with 5% ethanol in chloroform as eluant gave an NMR spectrum which showed τ 9.10, 9.01, 8.74, 8.16, 3.15. A Varian C-1024 time-averaging computer was used to enhance the signal-to-noise ratio. A mass spectrum revealed the following peaks in order of decreasing intensity: *m/e* 28, 32, 168, 43, 41, 55, 57, 29, 18, 69, 71, 83, 14, 84.

Betaine—Fraction C was reconstituted in 25 ml. of ethanol, filtered from an insoluble residue, and washed with ethanol (3 × 5 ml.). To the solution in an ice bath was added cold concentrated hydrochloric acid, dropwise, until precipitation of base hydrochloride solids was completed (3 ml.). Solids were removed by filtration and washed with portions of ether and dried in vacuum over calcium chloride to give 1.8 Gm. of crude base hydrochloride. TLC on silica gel in methanol–28% ammonium hydroxide (75:25) showed a single zone with a modified Dragendorff's reagent (10) and was similar to a reference sample of betaine hydrochloride prepared from betaine (Nutritional Biochemical). Repeated recrystallization from 95% ethanol deposited a white crystalline solid, m.p. 264–285° dec.

Anal.—Calcd. for $C_5H_{12}ClNO_2$: C, 39.09; H, 7.87; N, 9.12. Found:[5] C, 39.37; H, 8.01; N, 8.73.

An infrared spectrum (KBr) of the substance was identical with that of reference betaine hydrochloride, m.p. 254–265° dec. The plant compound formed a picrate, m.p. 186° [lit. (11) m.p. 180–181°], and chloroaurate, m.p. 207.5–208.5° [lit. (11) m.p. 200–209°], derivatives which were identical with similarly prepared samples of reference betaine

compounds, by melting point, mixed melting point, and infrared (KBr) analyses.

Trimethylamine Oxide—A 1% aqueous solution of fraction D was acidified to pH 2.5 with 5 *N* acetic acid, filtered, and treated with 70 ml. of 0.1 *M* sodium tetraphenylboron (aqueous). The precipitate was separated and converted to its chloride salts by passage through a column of ion-exchange resin.[6] Reduction of the effluent to dryness gave a residue which was fractionated by alumina column chromatography. Elution with 2% ethanol in chloroform (1.2 L.) gave 70.8 mg. of a hygroscopic white solid (0.0003% of leaf) which could be crystallized from ethanol–ether as needles, m.p. 80–81°. The addition of a 5% solution of oxalic acid dihydrate (0.6 ml.) to a 5.5% solution of the isolated compound in ethanol (0.5 ml.) gave crystals upon chilling. Recrystallization from ethanol gave needles (8.8 mg.), m.p. 119°, which showed a single peak in an NMR (D_2O) spectrum, τ 8.12.

Anal. (CHN analyzer)—C, 36.40; H, 7.05; N, 7.99.

Reference trimethylamine oxide (TMAO) di-

[6] Marketed as Amberlite IRA 401(Cl⁻) by Rohm and Haas Co., Philadelphia, Pa.

hydrate (K & K Laboratories) showed an infrared spectrum (KBr) that was superimposable with the isolated substance and gave an oxalate, which was identical with the unknown oxalate by mixed melting point, infrared (KBr), and NMR analyses.

Anal. (reference TMAO oxalate)—Calcd. for $C_3H_9NO \cdot C_2H_2O_4$: C, 36.36; H, 6.67; N, 8.48. Found:[7] C, 36.55; H, 6.80; N, 8.31.

A picrate derivative, m.p. 208.5–209.5° dec., indicated a molecular weight of 72 for the conjugate base of a monopicrate, by a spectrophotometric (Zeiss model PMQ II) method (9). This picrate derivative was subsequently shown to be identical in melting point, mixed melting point, and infrared (KBr) to reference TMAO picrate.

Residues from chromatographic fractions 4 and 5 of the aqueous extraction procedure (see under *Aqueous Extraction*) representing 1.3–2.0 L. of 1 *N* ammonium hydroxide eluate, were extracted with hot ethanol, combined, and filtered over 2 Gm. of alumina. The colorless filtrate and ethanol washings were collected (50 ml.) and evaporated to a white scale. Thin-layer chromatography on alumina G in methanol–carbon tetrachloride–acetic acid (10:30:1) revealed a zone (iodine vapors) that corresponded to that of trimethylamine oxide when developed side by side. Response to modified Dragendorff's reagent (delayed orange coloration) was the same with each sample.

Choline—Fraction E was separated from considerable inorganic chloride content by reconstituting the fraction in 200 ml. of ethanol and concentrating to a small volume. The dark supernatant was decolorized[8] and concentrated to dryness *in vacuo* (60°) which left a yellow semisolid (0.02% of leaf). A 0.500-Gm. quantity of crude base chloride was chromatographed over alumina to yield 0.211 Gm. which was recrystallized from ethanol–ether to give 0.177 Gm. of needles, m.p. gradual dec. above 250°. Paper chromatography in three solvent systems (10, 12) gave R_f values and characteristic color responses with modified Dragendorff's and Levine Chargaff reagents consistent with reference choline chloride (Eastman recrystallized). The infrared spectra (KBr) of plant base chloride and authentic choline chloride were similar. Chloroaurate derivatives of the plant compound and reference choline were identical with m.p. 230.5–232.5°[9] and by mixed melting point and infrared (KBr) analyses. The melting point of tetraphenylborate derivatives of the plant isolate, reference choline chloride, and a mixture of the two were identical at 227–229°. [Lit. (14) m.p. 219–221° uncorrected.] The infrared spectra (KBr) of these derivatives as well as a reineckate from the isolated plant base were identical with the spectra of the corresponding derivatives from reference choline chloride.

Adenine—Ether addition to a concentrated methanolic solution of fraction F afforded a flocculent precipitate which dried to 33 mg. of an off-white powder (0.008% of leaf), m.p. 280–292° dec., uncorrected. It gave a weakly positive Dragendorff's test for alkaloids, did not form a reineckate, and yielded a picrate, m.p. 284–288° dec., uncorrected, and picrolonate, m.p. 256–259°. An infrared spectrum (KBr) of the powder was similar to that of adenine·HCl·$3H_2O$. A picrate derivative, m.p. 284–288° dec., uncorrected [lit. m.p. 279–281° (15), 292° (16)], was prepared from reagent adenine sulfate (Nutritional Biochemical) and converted to adenine hydrochloride, m.p. 280–292° dec., uncorrected, in the same manner as was the amine picrate of plant origin. A reference sample of adenine picrolonate, m.p. 256–259° [lit. (15) m.p. 265°], was prepared from the hydrochloride. Mixed melting points of reference picrate and picrolonate derivatives of adenine were not depressed with the corresponding derivatives of plant origin; the infrared spectra (KBr) of reference adenine hydrochloride, picrate, and picrolonate were superimposable with the respective samples derived from the plant compound.

Amino Acids—Fraction G (positive ninhydrin and negative picrate tests) as a 0.5% aqueous solution was applied successively to two ion-exchange resin columns.[2, 10] No basic or acidic amino acids could be recovered from these columns. However, the final effluent passing through both columns was reduced to a yellow semicrystalline residue, 0.545 Gm. (0.23% of leaf), as the purified neutral amino acid fraction. The residue was examined by paper (17) and silica gel thin-layer (18) chromatography with a series of naturally occurring reference L-amino acids. Agreement of R_f values in three paper chromatographic systems and a two-dimensional thin-layer pattern with reference mixtures run in parallel and in admixture revealed the presence of leucine, isoleucine, valine, alanine, and γ-amino-*n*-butyric acid as the major amino acid constituents of the plant fraction.

RESULTS AND DISCUSSION

The methanol–ammonia extraction for alkaloids from *G. sylvestre* (Scheme I) gave residues of nonquaternary nitrogenous substances. After nitrogen enrichment by acid exchange resin adsorption and binary phase extraction, TLC indicated that both phenolic and nonphenolic fractions contained only small amounts of a complex mixture of alkaloid positive constituents (0.001% of leaf) and considerable nonalkaloidal impurities. Thus, interest was limited to the isolation of the major alkaloid of the nonquaternary nonphenolic fraction A. Several milligrams of the base (5×10^{-6}% of leaf) were made available by alumina column chromatography as a brown solid, m.p. 60–70°. The fluorescent substance formed a picrate from which a molecular weight of 221 was estimated for the base by a spectrophotometric method (9). A mass spectrum did not substantiate this value and showed a peak of highest mass at *m/e* 168, suggesting the presence of a stabilized fragment ion from the intact molecule. The base had ultraviolet absorption characteristics of an aniline derivative, particularly the indoline chromophore (19), but exhibited a bathochromic shift in acid and lacked the features of aromatic structure from infrared and mass spectrometric data. NMR and mass spectra

indicated significant aliphatic nature. Efforts to isolate sufficient quantities of the alkaloid substance for further characterization are in progress.

The major alkaloid-positive constituents of *G. sylvestre* were detected in quaternary base fractions and were indicated as the biological amines choline and betaine (combined yield, 0.03%) by chromatography and infrared data. The compounds were isolated by reineckate precipitation and separated by an exchange resin technique. Firm identification was established by analysis of choline as reineckate, tetraphenylborate, and chloroaurate derivatives, and betaine as chloroaurate and picrate derivatives.

During the separation process of choline and betaine, minor amounts of a third alkaloid-positive component were isolated (0.0003% of leaf). The substance was identified as trimethylamine oxide (TMAO) by NMR, infrared, molecular weight, and elemental analyses, and by agreement of oxalate and picrate derivatives with reference samples. The oxalate of TMAO has not been described previously in the literature. However, the ease with which a crystalline, nonhygroscopic compound with sharp melting point was obtained makes trimethylamine oxide acid oxalate an excellent derivative for characterization of TMAO.

Aqueous leaf extractions removed an alkaloid-positive substance which was separated by adsorption on a strong acid exchanger and isolated as an insoluble picrate derivative. Conversion to the amine hydrochloride (fraction F) and precipitation gave a compound (0.008% of leaf) which was similar to adenine·HCl·$3H_2O$ by infrared analysis. A picrate of reference adenine sulfate was processed in the same manner to give a hydrochloride with similar chromatographic and melting point characteristics as the plant product. Their infrared spectra were superimposable. Picrate and picrolonate derivatives of both reference and plant samples of adenine were identical by melting point and infrared analysis. The occurrence of compounds such as adenine in plants and their relationship to nucleic acids is discussed by Markham (20).

The supernatant remaining after precipitation of adenine from aqueous extracts contained a series of neutral amino acids (0.23% of leaf). The possibility that an uncommon amino acid of potential pharmacological significance (*e.g.*, as a hypoglycemic agent) might reside in this fraction prompted the characterization of major constituents by paper and thin-layer chromatographic methods. By agreement of R_f values with reference mixtures in a series of solvent systems, the amino acids leucine, isoleucine, valine, alanine, and γ-amino-*n*-butyric acid were detected. A two-dimensional thin-layer chromatogram confirmed these results.

Identification of the protoalkaloids (21), choline and betaine, and the pseudoalkaloid (22), adenine, offers an explanation for Webb's report of positive alkaloid tests from 1% hydrochloric acid extracts of *G. sylvestre* leaves (7). Phosphomolybdic acid, the only reagent in Webb's survey that showed appreciable alkaloid content, affords heavy precipitates with betaine, choline, and adenine. Minor amounts of complex alkaloid mixtures in nonquaternary plant fractions exclude *G. sylvestre* as a true alkaloid-bearing plant in taxonomic terms, which require an accumulation of 0.01% alkaloid from dried tissue (23). Hooper's original alkaloid-positive extract (6) most likely contained this group of trace nonquaternary alkaloidal substances. The level of occurrence of all nitrogenous compounds found in *G. sylvestre* and the chemical identity of major constituents show essentially no correlation with pharmacological activity of the plant.

The occurrence of TMAO in dried leaves was reaffirmed when direct aqueous extractions, which minimized artifact production by chemical and bacterial influences, gave chromatographic evidence for the presence of the oxide. The natural occurrence of TMAO in plant tissue has not been previously described in the literature. However, the biogenesis of TMAO in biological systems has been discussed by Guggenheim (24). Also, evidence has recently been presented for the ability of alfalfa (25) and *Chenopodium vulvaria* (26) seedlings to convert radioactive trimethylamine to TMAO *in vivo*, while inherent oxidative mechanisms are proposed for the biogenesis of amine oxides in the seeds of *Piptadenia* species (27). It would be of particular interest to examine fresh *G. sylvestre* leaves for the natural occurrence of TMAO, and to explore the conversion of trimethylamine to TMAO in this plant.

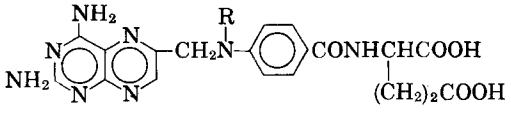
Irreversible Enzyme Inhibitors LXXXVI

Hydrophobic Bonding to Dihydrofolic Reductase VIII. Substituted-1-aryl-4,6-diamino-1,2-dihydro-2,2-dimethyl-*s*-triazines

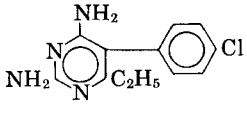
By B. R. BAKER, BENG-THONG HO, and GERHARDUS J. LOURENS

A series of 1-phenyl-4,6-diamino-1,2-dihydro-2,2-dimethyl-*s*-triazines (IV) bearing a phenylalkyl group on the *m*- or *p*-position of the 1-phenyl moiety was synthesized for enzymic evaluation with dihydrofolic reductase. The largest increment in binding was observed with a *m*-phenylbutyl group (XIV) which gave a fortyfold increment in binding; activity was not increased by substitution of one or two chlorines on the terminal phenyl group. The most active compound (XIV) was complexed one-third as well as the potent aminopterin, that is, XIV had 95 per cent of the free energy of binding shown by aminopterin. The potential use of XIV and related compounds for treatment of tumors with an impaired active-transport system for folic acid and aminopterin is discussed.

AMETHOPTERIN (I) has been useful for the treatment of leukemia in children for a number of years (1); unfortunately, only about 20% of the cases respond, and then only a temporary remission occurs. Amethopterin (I) and aminopterin (II) pass through a cell wall by active-transport (2–8), presumably by the same active-transport system used by a cell for folic acid. By use of tritiated amethopterin, Bertino (9) has been able to correlate the 20% of patients responding to amethopterin with ability of the patients' leukemic cells to take up the drug; the 70% showing no response to amethopterin had virtually no uptake of amethopterin in their leukemic cells.



I, R = CH_3
II, R = H



III

Citrovorum factor (5-formyl-tetrahydrofolic acid, CF) is used as an antidote for amethopterin toxicity, since CF can be utilized by a cell in place of tetrahydrofolic acid—the product of the reaction catalyzed by folic reductase which is blocked by amethopterin; presumably CF also enters the cell by the active-transport system used for the uptake of folic acid. It should therefore be theoretically possible to treat those leukemic patients with an impaired leukemic active-transport system with a potent folic reductase inhibitor that enters the cell by passive diffusion; by pre- and post-treatment with the antidotal CF, those cells with an impaired active-transport system would take up less CF and therefore not be protected as well by CF. Folic reductase inhibitors, such as 2,4-diaminopyrimidines of the pyrimethamine type (III), enter cells by passive diffusion (2, 10); presumably 4,6-diamino-1,2-dihydro-*s*-triazines of type VII (Table I) also enter cells by passive diffusion. If an inhibitor of the 4,6-diamino-1,2-dihydro-*s*-triazine type could be found that approached the potency of amethopterin for blocking folic reductase, it would be useful to investigate such a passive transport inhibitor of folic reductase in conjunction with CF treatment. Such an approach has been previously suggested (11); the results of a search for such potent inhibitors is the subject of this paper.

DISCUSSION

Both amethopterin (I) and aminopterin (II) have a strong pH dependence as inhibitors (12, 13), the optimum inhibition being close to pH 6 (13). The far less inhibition at pH 5.5 or 6.5 is dramatic (13), but the difference in inhibition between pH 6.5–7.4 is only nominal. Since few if any cells attain a pH of 6.0, a more reasonable comparison of inhibitors with aminopterin should be made at pH 6.5–7.4; the authors have selected pH 7.4 primarily because almost all previous work was at this pH. Aminopterin (II) (Table I) requires a concentration of 1×10^{-9} *M* for 50% inhibition in our system at pH 7.4.

The most potent compounds of the passive diffusion type observed on the pigeon liver enzyme are the 3-chloro (V) and 3,4-dichloro (VI)-1-phenyl-*s*-

Previous paper: Baker, B. R., Lourens, G. J., and Jordaan, J. H., *J. Heterocyclic Chem.*, **4**, 39(1967). Previous paper on hydrophobic bonding to dihydrofolic reductase: Baker, B. R., and Ho, B.-T., *J. Pharm. Sci.*, **55**, 470(1966).

triazines (Table I); these two compounds are still $^1/_{10}$ to $^1/_{15}$ so effective as aminopterin (II), but about 7–9 times more effective than the parent 1-phenyl-*s*-triazine (IV). It was noted in earlier studies that substitution of benzyl (VIII) or phenethyl (IX) on the 3-position (14) or benzyl (X) at the 4-position (15) of the 1-phenyl group gave three- to sixfold enhanced binding. Therefore, a study of longer aralkyl groups at the 3-position was initiated first. The phenylpropyl (XIII), phenylbutyl (XIV), and phenylamyl (XV) were all more potent than the phenethyl (IX) group at the 3-position of the 1-phenyl moiety; optimum activity appeared to be at phenylbutyl (XIV), which was fortyfold more potent than the parent 1-phenyl-*s*-triazine (IV) and approached the potency of aminopterin (II) within a factor of three.

That there was some hydrophobic bonding by a 3-alkyl group was indicated by the 3-methyl (XVII) and 3-*n*-butyl (XII) groups, the latter being 3 times as effective as the parent 1-phenyl-*s*-triazine (IV). The presence of this hydrophobic bonding area near the 3-position (15) of the 1-phenyl group was also indicated by evaluation of the more polar anilinomethyl (XVI) and *n*-propoxy (XVIII) groups; the 3-anilinomethyl group (XVI) was about threefold less effective than the 3-phenethyl group (IX), while the 3-*n*-propoxy group (XVIII) was fiftyfold less effective than the 3-*n*-butyl group (XII).

Since phenyl binding to a receptor can sometimes be increased by halogenation (for example, VI *versus* IV) halogen derivatives of the 3-phenylbutyl group of XIV were investigated; no increased binding was observed by substitution of 3,4-dichloro (XIX), 2,4-dichloro (XX), 2,6-dichloro (XXI), or 2-chloro (XXII) substituents, but the binding was within a factor of two of the parent phenylbutyl group (XIV).

The 4-position of the 1-phenyl triazine was then investigated. 4-Phenethyl (XXIII) was as good an inhibitor as 3-phenethyl (IX) and the 2,4-dichlorophenylbutyl group at the 3-position (XX) and 4-position (XXIV) were equivalent. Therefore, XXV was synthesized to see if the ninefold increment in binding seen by introducing a 3-chloro group (V) on on the parent phenyl triazine (IV) would be additive with the 4-phenylbutyl side chain; that this additivity was not achieved can be seen by comparison of XXV and XXVI.

Although the most potent compound (XIV) in this study is less potent than aminopterin (II) by a factor of three, XIV is still sufficiently potent to warrant animal studies on tumor lines with an impaired active-transport system for amethopterin (I) (6). It can be estimated from the concentration of aminopterin required for 50% inhibition at pH 7.4 that $K_i \cong 1 \times 10^{-10}$ *M*, or a free energy of binding of 14 Kcal./mole. Since XIV only binds threefold less than aminopterin, the difference in binding energies is about 0.7 Kcal./mole. Therefore, at pH 7.4 XIV has about 95% of the free energy of binding of aminopterin.

The technical assistance of Maureen Baker, Barbara Baine, and Karen Smith is acknowledged. [a] Dihydrofolic reductase was a 45–90% saturated ammonium sulfate fraction from pigeon liver prepared and assayed with 6 μ*M* dihydrofolate and 12 μ*M* TPNH at pH 7.4 as previously described (21). [b] Inhibitors were dissolved in 1 m*M* hydrochloric acid and dilutions were made with the same solvent. Solutions of some inhibitors at concentrations below 0.1 μ*M* lost appreciable inhibitory activity after 1–2 hr. at room temperature; since more concentrated solutions in the range of 0.1–1.0 m*M* were stable, the loss of inhibitor in highly dilute solution may have been due to adsorption on the glass. Consistent results were obtained by frequent dilution from a master solution of inhibitor at 0.31 m*M* so that solutions below 0.1 μ*M* were not aged for more than 30 min. CHEMISTRY

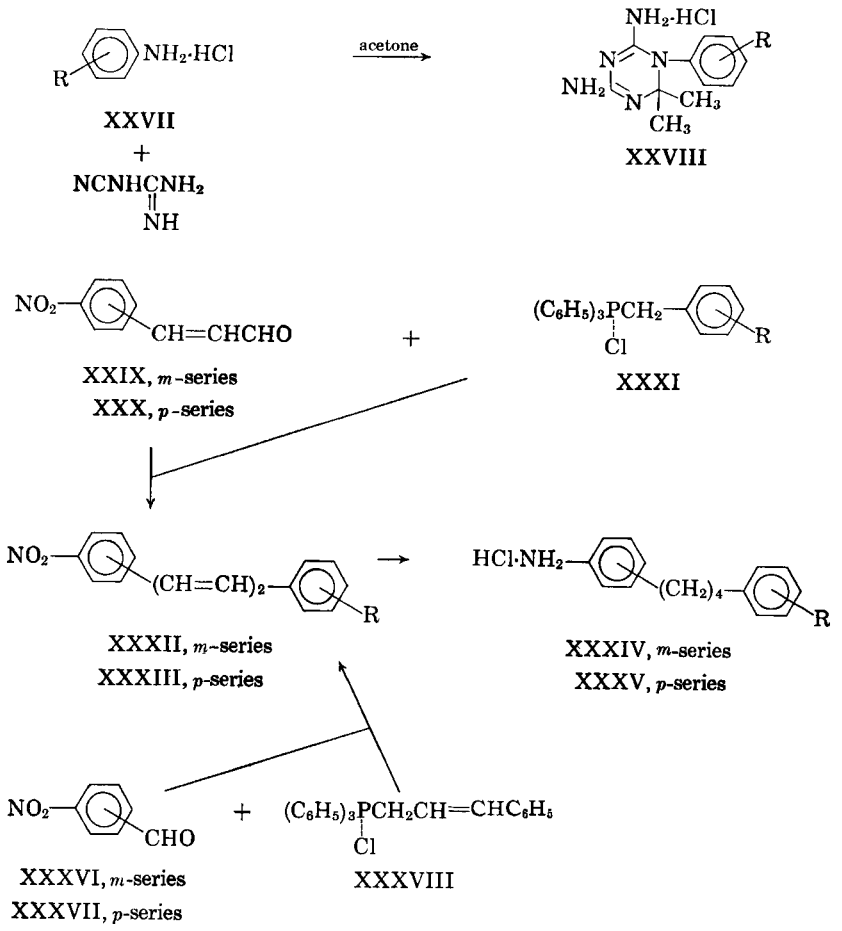
Synthesis

All of the substituted-1-phenyl-*s*-triazines (XXVIII) (Tables I and V) were synthesized by the three-component method of Modest (16), where the appropriate arylamine hydrochloride (XXVII) was condensed with cyanoguanidine in acetone. The synthesis of the requisite *m*- or *p*-aralkylanilines could be divided into three classes: (*a*) those where the alkyl was tetramethylene, (*b*) those where the alkyl was trimethylene or pentamethylene, and (*c*) miscellaneous.

The *m*-(XXXIV) and *p*-phenylbutylanilines (XXXV) were prepared by catalytic reduction of the appropriate 1,4-diphenylbutadiene (XXXII or XXXIII); the dienes were synthesized by the Wittig reaction. If the aralkyl group contained no other substituent, as in series *a*, the 1,4-diphenylbutadiene (XXXII*a* and XXXIII*a*) were conveniently synthesized by condensation of the Wittig reagent from cinnamyl chloride (XXXVIII) with the appropriate isomer of nitrobenzaldehyde (XXXVI or XXXVII). When the aralkyl had halogen substituents (series *b–e*), the appropriate benzyl chloride was converted to the Wittig reagent



Series:

a, R = H
b, R = 3,4-Cl_2
c, R = 2,4-Cl_2
d, R = 2,6-Cl_2
e, R = 2-Cl

Scheme I

(XXXI), then condensed with the *m*-isomer (XXIX) or *p*-isomer (XXX) of nitrocinnamaldehyde. In many cases, the 1,4-diphenylbutadienes melted over a wide range; since these crude materials gave good yields of 1,4-diphenylbutanes (XXIV, XXV) on hydrogenation, they were probably mixtures of *cis*- and *trans*-isomers. The yields obtained by the Wittig reaction were far better than those obtained by the older Meerwein and Perkin reactions. (Scheme I.)

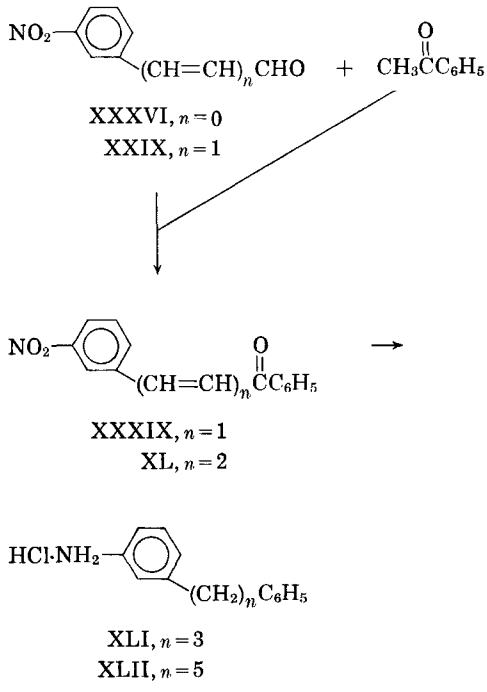
The second class of *m*-aralkylanilines containing an odd number (3 or 5) of methylene groups was synthesized in two steps. Condensation of *m*-nitrobenzaldehyde (XXXVI) or *m*-nitrocinnamaldehyde (XXIX) with acetophenone in aqueous ethanol containing sodium hydroxide gave the chalcones (XXXIX and XL) (17); catalytic reduction of the nitro, vinyl, and carbonyl groups with a palladium charcoal catalyst in glacial acetic acid containing ethanesulfonic acid (14) afforded the required *m*-aralkylanilines (XLI and XLII) in good yield. (Scheme II.)

In the miscellaneous class of 1-phenyl-*s*-triazines were the *m*-(*n*-butyl) (XII), the *p*-phenethyl (XXIII), *m*-anilinomethyl (XVI), and *m*-(*n*-propoxy) (XVIII) derivatives, which were synthesized from the known amines.

Methods

Melting points were determined in capillary tubes on a Mel-Temp block and those below 230° are corrected. Infrared spectra were determined in KBr pellet with a Perkin-Elmer 137B or 337 spectrophotometer. Ultraviolet spectra were determined with a Perkin-Elmer 202 spectrophotometer.

(3,4-Dichlorobenzyl)triphenylphosphonium Chloride (XXXIb)—*Method A*—A solution of 18 Gm. (0.07



Scheme II

mole) of triphenylphosphine and 13.7 Gm. (0.07 mole) of α,3,4-trichlorotoluene in 36 ml. of benzene was refluxed with magnetic stirring for 15 hr.; within 15 min., the product began to separate. The product was collected on a filter and washed with benzene; yield, 21.3 Gm. (66%) of white crystals, m.p. 305–306°. Recrystallization of a sample from absolute ethanol–ether gave white crystals, m.p. 309–310°. $\nu_{max.}$ 1580, 1550 (C=C); 1430, 1105 cm.$^{-1}$ (P-C). (See Table II for additional data.)

1 - (m - Nitrophenyl) - 4 - phenyl - 1,3 - butadiene (XXXIIa)—*Method B*—To a stirred solution of 10.1 Gm. (24 mmoles) of XXXVIII (18) and 3.02 Gm. (20 mmoles) of *m*-nitrobenzaldehyde (XXXVI) in 50 ml. of reagent methanol was added 1.62 Gm. (30 mmoles) of solid sodium methoxide; a yellow solid immediately separated. After being stirred for 20 hr. at ambient temperature protected from moisture, the mixture was filtered. The product was washed successively with methanol, water, and methanol; yield, 2.0 Gm. (40%), m.p. 146–147°. The combined filtrate and washings deposited another 1.46 Gm. (total 69%) of product, m.p. 146–147°, after about 18 hr. at −15°. An analytical sample of unchanged melting point was obtained by recrystallization from methanol as yellow crystals; $\nu_{max.}$ 1600, 1560 (C=C); 1505, 1340 cm.$^{-1}$ (NO_2); $\lambda_{max.}$ (EtOH): 331, 345 mμ (inflection). (See Table III for additional data.)

This compound has been prepared by the Meerwein reaction in 12% yield and melting points of 146° (19) and 145° (20) have been recorded.

1 - (3,4 - Dichlorophenyl) - 4 - (m - nitrophenyl) - 1,3 - butadiene (XXXIIb)—*Method C*—Condensation of 0.885 Gm. (5 mmoles) of *m*-nitrocinnamaldehyde (XXIX) with 2.74 Gm. (6 mmoles) of XXXI*b* in methanol, as described under *Method B*, gave 0.900 Gm. (56%) of product, m.p. 112–124°, that was suitable for the next step. One crystallization from petroleum ether (b.p. 60–110°) gave 0.451 Gm. (28%) of yellow crystals, m.p. 129–136°. A second recrystallization afforded 0.315 Gm. (20%), m.p. 138–141°. $\nu_{max.}$ 1600, 1560 (C=C); 1520, 1345 cm.$^{-1}$ (NO_2); $\lambda_{max.}$ (EtOH) 338 mμ with shoulders at 325 and 353 mμ.

α-(m-Nitrobenzal)acetophenone (XXXIX)—To a stirred solution of 2.1 Gm. (0.055 mole) of sodium hydroxide in 20 ml. of water was added 10 ml. of ethanol and 5.2 Gm. (0.043 mole) of acetophenone. Then 6.5 Gm. (0.043 mole) of *m*-nitrobenzaldehyde was added in one portion; the temperature was maintained at 20–25° by occasional cooling. After being stirred an additional 2 hr., the thick mixture was kept at 4° for about 18 hr. The product was collected on a filter, then ground in a mortar with water; the solid was collected by filtration. The grinding with water in a mortar was repeated until the final washing was neutral. The product was then washed with cold ethanol; yield, 10.9 Gm. (100%), m.p. 143–144°. Recrystallization from ethanol afforded 7.81 Gm. (72%) of beige-colored crystals, m.p. 145–146°. $\lambda_{max.}$ (EtOH): 294 mμ; $\nu_{max.}$ 1650 (C=O); 1600, 1570 (C=C); 1525, 1340 cm.$^{-1}$ (NO_2).

[a] All compounds had infrared spectra in agreement with their assigned structures. [b] Recrystallized from isopropyl alcohol–ether. [c] The crude hydrochloride could not be crystallized and was therefore converted directly to the corresponding *s*-triazine in Table V. [d] The free base has been previously described (19). [e] Recrystallized from absolute ethanol–ether. [f] Hemihydrate. [g] The starting 4-nitrostilbene was obtained by the Meerwein method (19). [h] Free base from petroleum ether; a m.p. of 48° has been recorded by von Braun, J., Deutsch, H., and Koscielski, O., *Chem. Ber.*, **46,** 1511(1913). Considerable *p*-aminostilbene, m.p. 139–142°, insoluble in petroleum ether, was obtained as a by-product.

hyde, as described for the preparation of XXXIX, was obtained 1.43 Gm. (51%) of recrystallized product, m.p. 152–154°. For analysis a sample was recrystallized once more from ethanol to give crystals, m.p. 156–159°. $\lambda_{max.}$ (EtOH): 333 mμ; $\nu_{max.}$ 1640 (C=O); 1570 (C=C); 1500, 1335 cm.$^{-1}$ (NO_2).

Anal.—Calcd. for $C_{17}H_{13}NO_3$: C, 73.1; H, 4.69; N, 5.01. Found: C, 72.9; H, 4.65; N, 5.05.

Pfeiffer *et al.* (17) have recorded m.p. 157–158° for this compound.

1 - (p - Aminophenyl) - 4 - (2,4 - dichlorophenyl)-butane Hydrochloride (XXXVc)—*Method D*—A mixture of 2.2 Gm. (6.8 mmoles) of XXXIIIc, 200 ml. of absolute ethanol, and 100 mg. of platinum oxide catalyst was shaken with hydrogn at 2–3 Atm. until reduction was complete (3.5 hr.). The filtered solution was evaporated *in vacuo*. The oily residue was dissolved in 25 ml. of reagent ether, then the solution was treated with hydrogen chloride gas. The product was collected on a filter and washed

Interaction of Sodium and Calcium Salicylates with Cationic Surfactants

By LUCY S. C. WAN

Sodium and calcium salicylates have been found to interact with surfactants of the quaternary ammonium type in much the same way as salicylic acid, as stated in a previous report. The interaction produces a marked change in viscosity which increases with salicylate concentration until the system becomes a gel. This increase in viscosity is not related to pH and is reduced with a rise in temperature. This complex interaction is probably due to attraction between the salicylate ion and the cation of the surfactant molecule leading to an increase in size of the surfactant molecule resulting in a rise in viscosity. The change in viscosity is further enhanced by an increase in the electrical charges in the system brought about by the addition of sodium salts, the order of effectiveness of the anion being as follows: citrate > phosphate > sulfate > carbonate > bromide > (except at low concentration) chloride, and by the addition of various sulfates, the order of effectiveness of the cation being as follows: sodium > potassium > ammonium > magnesium > zinc. Phenyl, ethyl, and methyl salicylates fail to show this complex interaction due to the absence of salicylate ion in aqueous solution. In addition, sodium lauryl sulfate and cetomacrogol 1000 do not demonstrate any change in viscosity in the presence of both salicylates.

COMPLEX INTERACTIONS play an increasingly important role in pharmaceutical formulations today. Interaction of quaternary ammonium bactericides with various compounds including anionic and nonionic surfactants, dyes, and polymeric compounds have been studied by various workers (1–4). Cationic drugs have been shown to form complexes with sodium carboxymethylcellulose (5), and sodium salicylate has been reported to interact with polyvinylpyrrolidone (6) and with oxytetracycline dihydrate and tetracycline trihydrate (7) forming complexes. The factors involved in complexation and the postulations offered for the mechanisms of complexation are many and varied (8–12). As salicylic acid is the only one of the substituted benzoic acids which interact with the quaternary compounds (13), it will be interesting to discover if the salicylates behave in like manner and it is hoped to learn more of the possible mechanism of this highly specific interaction.

EXPERIMENTAL

Materials—Sodium salicylate (British Drug Houses Ltd.) and calcium salicylate (E. Merck, Darmstadt) were used as supplied by the manufacturers. Phenyl salicylate, 42–43°; ethyl salicylate, density 1.140; methyl salicylate, density 1.184 (Hopkin and Williams, Ltd.); the chloride and bromide of sodium and potassium (May and Baker, Ltd.); sodium citrate, carbonate, and phosphate, and the sulfates of sodium, potassium, magnesium, zinc, and ammonium (British Drug Houses Ltd.) were used without purification. The cationic surfactants, dodecyltrimethylammonium bromide, tetradecyltrimethylammonium bromide (Glovers Chemicals Ltd.), cetyltrimethylammonium bromide, (Imperial Chemical Industries), sodium lauryl sulfate (Sipon Products Ltd.), and cetomacrogol 1000 B.P.C,[1] were the same as those described in a previous paper (13). The approximate molecular weights of dodecyltrimethylammonium, tetradecyltrimethylammonium, and cetyltrimethylammonium bromides are 314, 342, and 370, respectively.

Apparatus—Portable Ferranti viscometer, Pye tropical universal pH meter.

Measurement of Viscosity—The required amounts of salicylate were weighed into a series of 100-ml. volumetric flasks containing the required concentration of surfactant. The flasks were allowed to rotate in a thermostatically controlled water bath at 25 ± 0.1° for 24 hr. For the study of the effect of addition of salts, the required volume of a concentrated salt solution was incorporated and then equilibrated in like manner. The viscosities of the solutions were measured using the Ferranti portable viscometer placed in a thermostatically controlled water bath at 25 ± 0.5°. The shear rates employed ranged from 78.56 to 483.0 sec.$^{-1}$. An interval of 30 sec. was allowed between readings.

RESULTS AND DISCUSSION

Viscosity Measurements—Figures 1 and 2 show the effect of sodium salicylate on the viscosity of cetyltrimethylammonium bromide and tetradecyltrimethylammonium bromide solutions at 25°. A marked change in viscosity is observed with increased concentration of sodium salicylate; this change is seen with all five of the different shear rates used. This viscosity effect occurs in all surfactant concentrations studied, ranging from 0.05 to 0.18 moles/L., but is much less prominent in dodecyltrimethylammonium bromide systems. Similarly, calcium salicylate exerts this viscosity effect when dispersed in the same quaternary surfactants (Figs. 3 and 4).

Salicylic acid has been shown to demonstrate this viscosity effect (13) but unlike the salicylates it does not gel the system even after it has become saturated with the acid. However, the salicylates produce a

gel of the system at a particular concentration, probably due to the presence of the sodium or calcium ion. Gelling is taken as the state in which the viscosity cannot be determined by the Ferranti viscometer because the dial readings continually fluctuate. The molar concentration at which gelling occurs is greater for sodium salicylate than for calcium salicylate, and in addition the amount required for

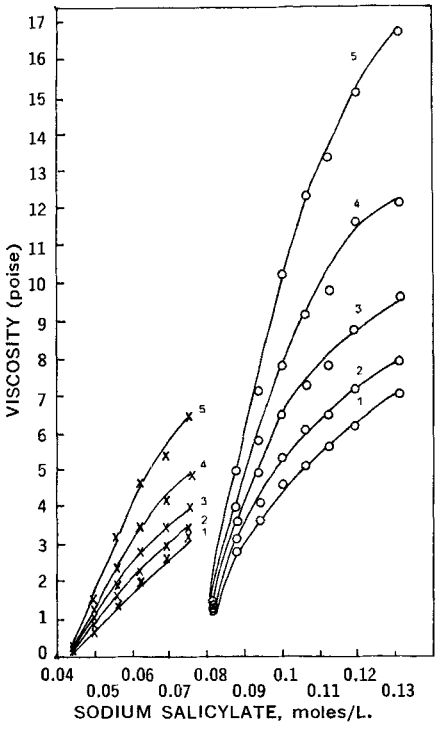

Fig. 1—Effect of sodium salicylate on the viscosity of cetyltrimethylammonium bromide solution at 25°. Key: ×, 0.081 M; ○, 0.162 M. Shear rate: 1, 234.6 sec.$^{-1}$; 2, 195.9 sec.$^{-1}$; 3, 155.1 sec.$^{-1}$; 4, 117.35 sec.$^{-1}$; 5, 78.56 sec.$^{-1}$.

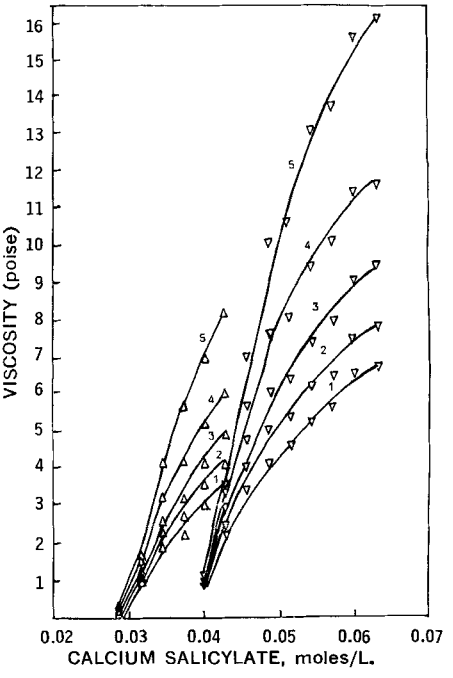

Fig. 3—Effect of calcium salicylate on the viscosity of cetyltrimethylammonium bromide solution at 25°. Key: △, 0.108 M; ▽, 0.162 M. Shear rate: 1, 234.6 sec.$^{-1}$; 2, 195.9 sec.$^{-1}$; 3, 155.1 sec.$^{-1}$; 4, 117.35 sec.$^{-1}$; 5, 78.56 sec.$^{-1}$.

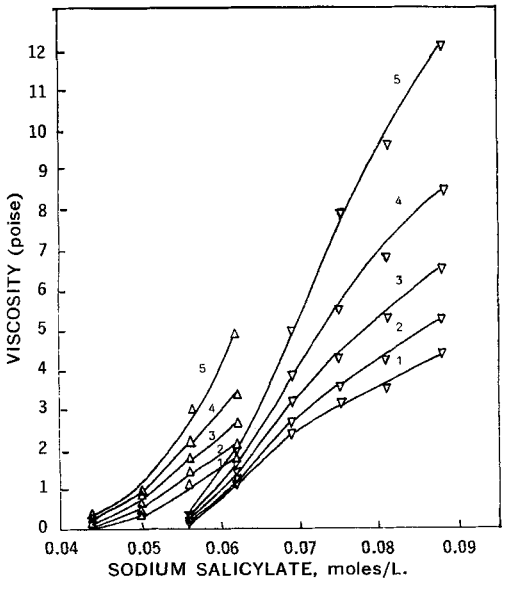

Fig. 2—Effect of sodium salicylate on the viscosity of tetradecyltrimethylammonium bromide solution at 25°. Key: △, 0.117 M; ▽, 0.1754 M. Shear rate: 1, 234.6 sec.$^{-1}$; 2, 195.9 sec.$^{-1}$; 3, 155.1 sec.$^{-1}$; 4, 117.35 sec.$^{-1}$; 5, 78.56 sec.$^{-1}$.

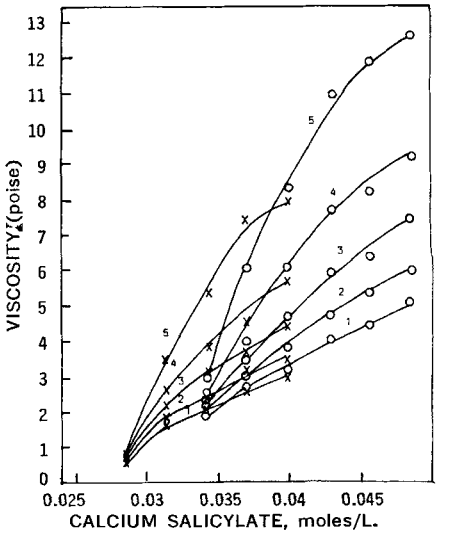

Fig. 4—Effect of calcium salicylate on the viscosity of tetradecyltrimethylammonium bromide solution at 25°. Key: ×, 0.1462 M; ○, 0.1754 M. Shear rate: 1, 234.6 sec.$^{-1}$; 2, 195.9 sec.$^{-1}$; 3, 155.1 sec.$^{-1}$; 4, 117.35 sec.$^{-1}$; 5, 78.56 sec.$^{-1}$.

gelling by sodium salicylate is approximately twice that required by calcium salicylate (Table I). This could be due to the fact that the calcium salicylate molecule produces twice as many salicylate ions as the sodium salicylate molecule. The ratios of salicylate to surfactant concentration at which the system becomes a gel decrease with increasing concentration of the quaternary compound, indicating that as the number of surfactant molecules increases following increased concentration of surfactant less salicylate molecules are required to produce a gel, and that probably at high surfactant concentration, the molecules interact less with the salicylates because of the extremely viscous nature of the system in which the surfactant molecules may find their movement restricted or are less mobile. Hence, they do not interact to the same degree as at low concentration of surfactant. From a graphical representation of the data presented in Table I, the amount of salicylate that has to be added to a given concentration of the quaternary compound to produce a gel or maximal measurable viscosity can be calculated.

Effect of Temperature—Figure 5 shows the effect of increasing temperature on the viscosity of sodium salicylate dispersed in cetyltrimethylammonium bromide solution. There is a sharp decrease in viscosity followed by a gradual fall. The viscosity decreases with increasing shear rates but approaches the same value at about 42°, after which there is practically no change with further rise of temperature, suggesting the conversion to a Newtonian liquid. At about 49° and above the viscosity is about the same as that of a solution of cetyltrimethylammonium bromide without the salicylate at 25°. With increased Brownian motion arising from high temperatures, the system offers less resistance to shear.

Effect of pH—Table II shows the pH of sodium salicylate and calcium salicylate dissolved in cetyltrimethylammonium bromide solutions. There is a small difference in pH for both systems and a gradual increase in pH with increasing concentration of salicylate. The effect of additives on the pH of solutions of cetyltrimethylammonium bromide containing sodium salicylate is seen in Table III. Generally a slight change in pH is observed with increased concentration of the additive. pH seems to have no effect on the viscosity change.

Effect of Anion—The addition of sodium chloride, bromide, citrate, phosphate, sulfate, and carbonate to a cetyltrimethylammonium bromide solution containing sodium salicylate further enhances the viscosity effect as seen in Fig. 6. This is true for different shear rates used. The order of effectiveness of the anion is: citrate > phosphate > sulfate > carbonate > bromide > (except at low concentration) > chloride. The valency of the charge on the anion appears to determine the effectiveness on the enhancement as the higher the valency the greater is the additional increase in viscosity. For the sodium halides the effect is different in that a much higher concentration of the corresponding salt is required to effect an additional increase in viscosity in which case the increase is also gradual. In addition, up to a concentration of 1.8 moles/L. of the salt the system does not become a gel, in contrast to the other sodium compounds, all of which form a gel at about 0.7 to 0.75 moles/L. of the salt concentration. Sodium iodide has been included in the investigation but it forms a white precipitate and the viscosity of the system decreases because the surfactant has been removed by precipitation and thus is not available for interaction with the salicylate. Potassium chloride and bromide also show an enhanced viscosity effect similar to that produced by the corresponding sodium compounds, the potassium salts exerting a relatively larger effect on the viscosity. Since the above-mentioned salts form insoluble compounds with calcium salicylate, only sodium citrate, chloride, bromide, and potassium chloride and bromide were added to aqueous solutions of cetyltrimethylammonium bromide containing calcium salicylate. The additives also increase the viscosity of the system similar to that in the systems containing sodium salicylate (Fig. 7). Here again the concentration of sodium citrate required to gel the system is the same as that containing sodium salicylate. The viscosity of cetyltrimethylammonium bromide solutions containing the sodium or potassium compound in the absence of the salicylate remains unaffected.

Effect of Cation—Figure 8 shows the effect of adding the sulfates of ammonium, sodium, potassium, magnesium, and zinc to a solution of cetyltrimethylammonium bromide containing sodium salicylate. The order of enhanced viscosity effect is sodium > potassium > ammonium > magnesium > zinc. This order seems to be related to the valency of the charge on the cation and is the reverse of that observed with the effect of anions in that the smaller the valency of the charge of the cation, the greater the enhancement. A higher concentration of potassium sulfate could not be used since it became insoluble in the system at above 0.5 moles/L.

The results of this investigation indicate that sodium and calcium salicylates interact with the quaternary surfactants in much the same way as salicylic acid itself. They further confirm that the salicylate ion is of prime importance in the interaction, since phenyl, ethyl, and methyl salicylates do not demonstrate any viscosity effect. The complex interaction of salicylates with the quaternary surfactants may be due to a strong attraction between the salicylate ion and the bulky cation of the surfactant, thus enlarging its size and leading to an increase in viscosity. The attraction is enhanced by the addition of anions such as chloride, bromide, citrate, phosphate, sulfate, and carbonate and also by the addition of cations such as sodium, potassium, magnesium, ammonium, and zinc since they reinforce the electrical charges in the system. No change in viscosity is observed either with dispersions containing any of the salts investigated and a salicylate in the absence of the surfactant or with dispersions containing any of the salts studied and the surfactant in the absence of the salicylate. Hence the anions and cations only affect the viscosity in the presence of the complex formed by the interaction of salicylate and the surfactant.

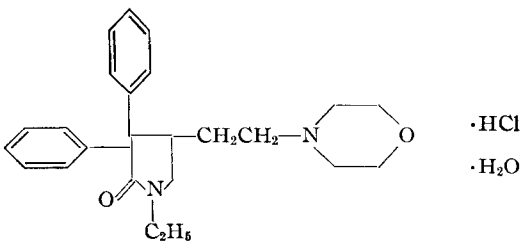
Qualitative and Quantitative Tests for Doxapram Hydrochloride

By EDWARD F. SALIM* and A. EDWIN MARTIN†

Provisional, unofficial monographs are developed by the Drug Standards Laboratory, in cooperation with the manufacturers of the drug concerned, for publication in the *Journal of Pharmaceutical Sciences*. The ready availability of this information affords discriminating medical and pharmaceutical practitioners with an added basis for confidence in the quality of new drug products generally, and of those covered by the monographs particularly. Such monographs will appear on drugs representing new chemical entities for which suitable identity tests and assay procedures are not available in the published literature. The purity and assay limits reported for the drugs and their dosage forms are based on observations made on samples representative of commercial production and are considered to be reasonable within expected analytical and manufacturing variation.

1-ETHYL-4-(2-MORPHOLINOETHYL)-3,3-DIPHENYL-2-PYRROLIDINONE HYDROCHLORIDE HYDRATE; $C_{24}H_{30}N_2O_2 \cdot HCl \cdot H_2O$; mol. wt. 433.00. The structural formula of doxapram hydrochloride may be represented as



Physical Properties—Doxapram hydrochloride occurs as a white to off-white, odorless, crystalline powder and melts within a range of 2° between 217° and 221° (U.S.P., class I). It is sparingly soluble in water and in alcohol, soluble in chloroform, and practically insoluble in ether. The pH of a solution of doxapram hydrochloride in carbon dioxide-free water (1 in 100) is between 3.5 and 5.0.

Identity Tests—A 1 in 2500 solution of doxapram hydrochloride in water exhibits ultraviolet absorbance maxima at about 252 mμ, 258 mμ [absorptivity (a) about 1.1], and 264 mμ and absorbance minima at about 244 mμ, 254 mμ, and 262 mμ. The spectrum is shown in Fig. 1.

The infrared spectrum of a 0.5% dispersion of doxapram hydrochloride in potassium bromide, in a disk of about 0.82 mm. thickness, is shown in Fig. 2.

Purity Tests—Dry about 1 Gm. of doxapram hydrochloride, accurately weighed, at 105° for 2 hr.: it loses not more than 4.5% of its weight.

Char about 1 Gm. of doxapram hydrochloride, accurately weighed, in a tared platinum crucible, cool the residue, add 1 ml. of sulfuric acid, heat cautiously until evolution of sulfur trioxide ceases, ignite, cool, and weigh: the residue does not exceed 0.3%.

Dissolve 1.0 Gm. of doxapram hydrochloride in 25 ml. of water by gentle warming, and cool: the heavy metals limit determined by U.S.P. method I is 20 p.p.m.

Assay—*Chloride*—Transfer about 300 mg. of doxapram hydrochloride, accurately weighed, to a 250-ml. iodine flask, and dissolve in 50 ml. of water. Add 25.0 ml. of 0.1 N silver nitrate, 3 ml. of nitric acid, 5 ml. of nitrobenzene, and 2 ml. of ferric ammonium sulfate T.S. Shake well, and titrate the excess silver nitrate with 0.1 N ammonium thiocyanate. Each milliliter of 0.1 N silver nitrate is equivalent to 3.545 mg. of chloride (Cl). The amount of chloride found is not less than 7.90% and not more than 8.30% of the weight of the sample taken.

Doxapram Hydrochloride—Transfer about 800 mg. of doxapram hydrochloride, accurately weighed, to a 200-ml. tall form beaker, add 50 ml. of glacial acetic acid, and stir until the sample is completely dissolved. Add 10 ml. of mercuric acetate T.S., 1 drop of crystal violet T.S., and titrate with 0.1 N perchloric acid to a blue-green end point. Perform a blank titration and make any necessary correction. Each milliliter of 0.1 N perchloric acid is equivalent to 43.30 mg. of $C_{24}H_{30}N_2O_2 \cdot HCl \cdot H_2O$. The amount of doxapram hydrochloride found is not less than 98.0% and not more than 100.5% of the weight of the sample taken.

DOSAGE FORMS OF DOXAPRAM HYDROCHLORIDE

Doxapram Hydrochloride Injection

Physical Properties—Doxapram hydrochloride injection is a sterile aqueous solution with chlorobutanol present as a preservative. The pH of the solution is between 3.5 and 5.0.

Received December 20, 1966, from the *Drug Standards Laboratory, AMERICAN PHARMACEUTICAL ASSOCIATION FOUNDATION, Washington, DC 20037

Accepted for publication February 10, 1967.

† A. H. Robins Co., Inc., Richmond, VA 23220. A. H. Robins Co., Inc., has cooperated by furnishing samples and data to aid in the development and preparation of this monograph.

The Drug Standards Laboratory gratefully acknowledges the assistance of Miss Carolyn Damon and Miss Hannah Klein.

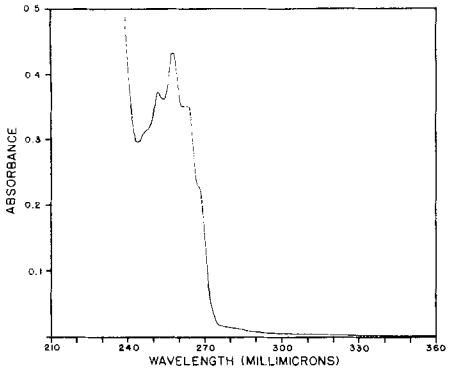


Fig. 1—Ultraviolet absorption spectrum of doxapram hydrochloride in water (400 mcg./ml.); Beckman model DK-2A spectrophotometer.

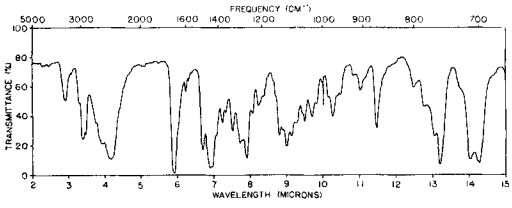

Fig. 2—Infrared spectrum of doxapram hydrochloride in potassium bromide disk (0.5%); Perkin-Elmer model 21 spectrophotometer, sodium chloride prism.

Identity Test—The solution prepared by dilution of the injection in the *Assay* exhibits absorbance maxima and minima at the same wavelengths as the doxapram hydrochloride standard solution.

Assay—Pipet a volume of doxapram hydrochloride injection, equivalent to 100 mg. of doxapram hydrochloride, into a 250-ml. volumetric flask, dilute to volume with water, and mix. Concomitantly determine the absorbance of this solution and of a standard solution of doxapram hydrochloride, in water, at a concentration of about 400 mcg./ml., in 1-cm. cells, at the maximum at about 258 mμ, with a suitable spectrophotometer, using water as the blank. Calculate the quantity, in milligrams, of $C_{24}H_{30}N_2O_2 \cdot HCl \cdot H_2O$ in each milliliter of injection, by the formula $0.25 \times (C/V) \times (A_u/A_s)$, in which C is the exact concentration of the standard solution, in micrograms per milliliter, V is the volume, in milliliters, of the injection taken, A_u is the absorbance of the sample solution, and A_s is the absorbance of the doxapram hydrochloride standard solution. The amount of doxapram hydrochloride found is not less than 95.0% and not more than 105.0% of the labeled amount.

DISCUSSION

U.S.P. and N.F. terminology for solubility, melting range, reagents, *etc.*, has been used wherever feasible.

Doxapram hydrochloride[1] is a respiratory stimulant which acts primarily to increase tidal volume and secondarily to increase respiratory rate. It is particularly effective following general anesthesia to prevent postanesthetic respiratory depression or hypoventilation.

Quantitative Methods—The assay for chloride determines the nonactive portion of the molecule but serves as a control on the purity of the bulk material. Analysis of doxapram hydrochloride by the indicator titration method gave an average value of 8.18 ± 0.09%[2] chloride (Cl). The calculated value for chloride content is 8.19%.

The nonaqueous titrimetric procedure for doxapram hydrochloride gave an average value of 99.4 ± 0.3%.[2] The indicator end point was determined by simultaneous indicator and potentiometric observation during the titration. The electrode system employed was glass *versus* calomel modified by replacement of the aqueous salt bridge with 0.02 *N* lithium chloride in glacial acetic acid.

Analysis of commercial doxapram hydrochloride injection by the spectrophotometric method gave an average value of 99.6 ± 0.5%[2] of the labeled amount of doxapram hydrochloride. This approach can be used for analysis of bulk doxapram hydrochloride provided suitable reference standard material is available for absorbance measurement.

[2] Maximum deviation from the mean value.

Lubricity of Dilute Solutions of Hydrocolloids

By T. WERNER SCHWARZ

To determine relative lubricity of hydrocolloids at low viscosities, the friction values of dilute solutions of seven hydrocolloids were measured with the lubrimeter. At very low viscosities, hydrocolloids impart no lubricity to water. A certain consistency appears to be a prerequisite for hydrocolloid dispersions to be effective as lubricants, except for a high molecular weight polymer of ethylene oxide.

IN A PREVIOUS paper on lubricity (1) it was shown that, in the case of hydroxypropyl methylcellulose gels, lubricity was not a function of viscosity. Rather, lubricity was directly related to the solid content of the dispersion regardless of the viscosity grade of the methylcellulose. Thus, dispersions of equal concentrations of two hydroxypropyl methylcelluloses[1] had identical lubricity values (but quite different viscosities).

The lubrimeter, with which the decrease in friction was measured (2), consists basically of two cylinders separated by a film of lubricant. The lower cylinder is rotated at a constant speed; the upper one, to which a spring is attached, rests on the lower cylinder and its motion is activated by the turning of the lower one. The extent of the rotation of the upper cylinder depends on the friction between the surfaces of the two cylinders. If friction is high, the upper cylinder is pulled along up to half of its circumference thereby stretching the spring until the restoring force of the extended spring equals the pull of the upper cylinder. The extension of the spring is a measure of the friction value, which is expressed in grams. The greater the stretch, the greater the friction, and *vice versa*.

The movements of the two cylinders in the lubrimeter facilitate the formation of a converging fluid wedge along the line of nearest approach of the cylinders. This fluid wedge, which is an essential feature of hydrodynamic lubrication, increases the flow velocity of the lubricant and subjects it to great shear, which, in turn, decreases the apparent viscosity of hydrocolloids. Thus the lubricant effect of hydrocolloid gels, all of which have non-Newtonian flow characteristics, may not parallel empirical impressions of lubricity. By rotating the driving cylinder at a slow speed, however, this effect on the viscosity was decreased. Although it was established that lubricity was not simply related to viscosity, at least in the case of methylcellulose, viscosity is, nevertheless, a contributing factor to lubricity. A comparison of different hydrocolloid gels with regard to their lubricity might well be invalidated by the distortion of viscosities. Since no quantitative expression exists for lubricity of aqueous systems, such as Petroff's equation for friction and lubricity in metal bearings (3), the contribution of viscosity to the lowering of friction remains shrouded.

Very dilute solutions of hydrocolloids have low viscosities and they approach, furthermore, Newtonian flow characteristics as the concentration of hydrocolloid decreases. The effect of viscosity on the measurement of lubricity in such dilute solutions would be minimal. In addition to the fundamental aspects of such a study, practical applications are also conceivable. Although medicinal lubricants are usually of gel consistency, mobile solutions, as used for irrigations, enemas, and lotions, can be improved by the addition of a water-soluble lubricant.

Among the several hydrocolloids which were studied were representatives of the natural plant gums, semisynthetic cellulose ethers, and totally synthetic products. Where several viscosity grades of a product existed, a low viscosity type was selected. Except for one hydrocolloid, only solutions with viscosities of less than 1000 cps. were incorporated in the study.

EXPERIMENTAL

Materials—Commercially available hydrocolloids were used except for a polyethylene glycol resin of very high molecular weight[2] and hydroxyethyl cellulose,[3] samples of which had been furnished by their manufacturers. Naturally occurring hydrocolloids were represented by nonionic guar gum[4] and anionic carrageenin.[5] Three cellulose derivatives were used: nonionic hydroxypropyl methylcellulose,[6] anionic sodium carboxymethylcellulose,[7] and nonionic hydroxyethylcellulose.[3] Representatives of the synthetic hydrocolloids were anionic neutralized carboxy vinyl polymer[8] and nonionic polyethylene glycol resin.[2]

Received October 6, 1966, from the School of Pharmacy, San Francisco Medical Center, University of California, San Francisco, CA 94122

Accepted for publication April 5, 1967.

This investigation was supported in part from research funds of the Academic Senate, University of California.

The author wishes to dedicate this paper to Dean T. C. Daniels, whose leadership at the University of California has done so much to raise the standards of education and research in the pharmaceutical sciences.

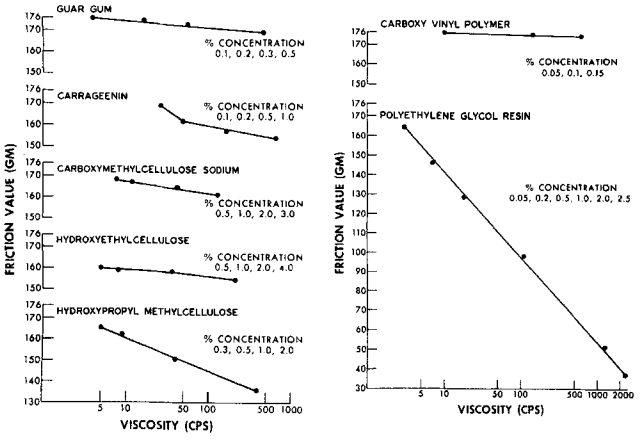

Fig. 1—The effect of hydrocolloid concentration on lubricity and viscosity.

Apparatus and Procedure—The lubrimeter and its use were described previously (2). A single spring was used which covered the whole range of lubricities examined. Its total range was somewhat less than the range of lubricities covered with several springs and, therefore, the difference between extremes of high and low friction was less than in previous experiments. Thus water had a friction value of 176 Gm. as compared with previous readings of 203 and 210 Gm., respectively. Glycerin gave a reading of 29 Gm. (previously 22.7 Gm.). All measurements were carried out at room temperature, which fluctuated between 21° and 24°. Otherwise, the same procedure was followed as described previously.

Viscosity determinations were made with the Brookfield viscometer, model LVF, at temperatures of 22° ± 1° and spindles No. 1 and No. 3. Each hydrocolloid solution was measured at speeds of 6, 12, and 30 r.p.m. and the scale readings were converted to cps. Up to about 500 cps. differences in apparent viscosities, if any, were small. The viscosities used for the purpose of comparison were based on the scale readings at 12 r.p.m. At very low viscosities (up to about 8 cps.) the instrument's readings were erratic; such low viscosity values may, therefore, be inaccurate.

RESULTS AND DISCUSSION

Figure 1 illustrates the results for each of the hydrocolloids examined. All but one exhibit little or no lubricity. This was not unexpected since in aqueous systems generally only full fluid or hydrodynamic lubrication is effective. This type of lubrication requires a substantial layer of lubricant between the opposing surfaces which remains in place by virtue of its viscosity. It could not be taken for granted that the lubrimeter, which was designed to measure hydrodynamic lubrication in aqueous systems as applied in a physiological environment was capable of measuring also lubricity when viscosity, a basic condition of hydrodynamic lubrication, was practically absent or very low.

The friction value of water, 176 Gm., was used as the upper limit. Actually, water itself has a lubricating effect, but the addition to it of any hydrocolloid could only lower its friction value. Very low concentrations of a hydrocolloid, as in the case of the carboxy vinyl polymer, have no effect whatever on the friction value. Even at a viscosity of more than 2000 cps. for a 0.2% solution of this neutralized hydrocolloid—not included in Fig. 1—the friction value was only slightly less than that for the 0.05% solution. A higher concentration of solute, in general, produced a reduction in friction, which was in line with the conclusion of a previous report (1) that the solid content of the solution has a direct bearing on the friction reducing effect. Yet when compared with a known lubricant, such as glycerin, even 3% of one of the hydrocolloids in solution, carboxymethylcellulose, produced no significant lubrication. Its 3% solution had only slightly less friction value than a 0.5% solution. Guar gum, which forms much more viscous systems than carboxymethylcellulose at equal concentrations, had about the same friction value at 0.5% concentration as carboxymethylcellulose. Some of the hydrocolloids had, at low concentrations, a slight effect on the lubricity of their aqueous solutions, others practically none. Only hydroxypropyl methylcellulose, aside from polyethylene glycol resin, improved the lubricity of water at low concentrations and low viscosities.

It was, therefore, surprising to observe a very marked lubricity in polyethylene glycol resin in concentrations comparable to those of other hydrocolloids. At a concentration of 0.5%, the friction value of this resin was already lower than that of any other hydrocolloid tested regardless of concentration. And the slope representing the decrease in friction value with increasing viscosity was considerably steeper than that for methylcellulose, which showed somewhat better lubricity than any of the other five hydrocolloids. Extending the measurements of polyethylene glycol resin to still higher concentrations resulted in a continuing increase of lubricity. Viscosity increased proportionally with the increase of lubricity. At the highest concentration tested, the consistency approached that of a thin gel which was non-Newtonian. Nevertheless, the slope remained the same. However, there was no corresponding further change in lubricity when the concentration was increased beyond 2.5%, only a marked change in viscosity (not indicated on the graph.) The friction value of a 2.5% solution of polyethylene glycol resin was almost as low as that of 95% glycerin (29 Gm.).

The extraordinary reduction of friction by low concentrations of polyethylene glycol resin in water begs an explanation. Aqueous solutions of this resin are non-Newtonian; their apparent viscosities decrease with increasing shear except at very low concentrations. Other liquids having consistencies similar to those of polyethylene glycol resin solutions such as glycerin, or polyethylene glycol of low molecular weight, have also very low friction values. It is worth noting that of three polyols previously measured (1), polyethylene glycol had the lowest friction value and even at a dilution of one part with four parts of water, it raised the lubricity of water significantly.

Hydrodynamic lubrication depends on the inherent viscosity of the lubricant. With decreasing viscosity, hydrodynamic lubrication changes to boundary lubrication, in which a very thin film of only a few layers of the lubricant molecules may separate the surfaces. Solutions and gels of polyethylene glycol resin are apparently effective lubricants at any concentration. It is suggestive to attribute the striking lubricating effect to the linearity and the size of the resin macromolecules; among the most effective lubricants in engineering are linear hydrocarbons (4). At low viscosities, partial hydrodynamic and boundary lubrication coexist because no liquid wedge can be sustained under the pressure of opposing surfaces. If the lubricant film is only a few molecules thick, it must strongly adhere to one or both surfaces or it will be worn away. Solutions of polyethylene glycol resin are very slippery to the touch and stretch fiber-like when being removed from the main body of the liquid. This resistance to being pulled apart is defined as tack (5). The cohesiveness together with adhesion to opposing surfaces distinguish polyethylene glycol resin from the other hydrocolloids and may be partly responsible for its lubricity even in low concentrations. Measurements of adhesiveness of hydrocolloids, with a tackmeter (5, 6) may well contribute to further elucidation of the nature of lubrication with hydrocolloids.

The relationship between friction value and viscosity appears to be linear in the semilog graph. However, a mathematical analysis was not attempted because of too many variables inherent in the lubrimeter. Although the elasticity of various springs could readily be calibrated, friction values of the same lubricant obtained with different springs but identical plastic sheets and by the same operator were different. The plastic sheets, with which one cylinder of the lubrimeter was covered, gave different results, which necessitated averaging a minimum of 6 measurements. The deviations from the average were always less than 5% and were largest at low friction values. Sheets cut from a different piece of the same type of ribbed polyethylene did not match previous results. Nevertheless, the instrument is capable of comparing quantitatively friction values under carefully controlled conditions.

It is of historical interest that the first instrument to measure the "sliding ability" of pharmaceutical preparations was described more than 30 years ago in the *Journal of the American Pharmaceutical Association* (7); an improved version was described more recently (8).

SUMMARY

The lubricity of several dilute solutions of hydrocolloids was measured with the lubrimeter.

Only a high molecular weight polyethylene glycol resin reduced the friction values of water markedly.

The experimental results were discussed and evaluated.

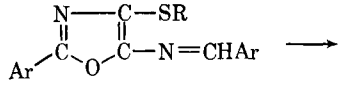
Somnifacient Action of α-Methylmercaptohippuramide

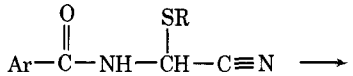
By ARNOLD R. MARTIN*, F. H. MEYERS, and ROGER KETCHAM

α-Methylmercaptohippuramide has an LD_{50} in mice of 670 ± 20 mg./Kg. Sublethal doses produce sleep but not anesthesia. In preliminary tests on a dog, the drug showed no effect on the autonomic system, nor did it alter the normal responses to the autonomic drugs or histamine. Its pharmacology appears to be similar to that of trimeglamide and thalidomide to which it is structurally related.

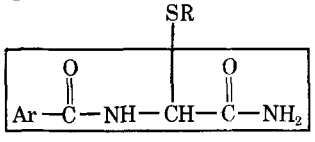
DURING THE COURSE of chemical studies on the oxazole condensation products (I) from *S,S'*-dialkyl or diaryl dithioöxaldiimidates and aromatic aldehydes (1), it was found that these oxazole derivatives are rapidly hydrolyzed by acids to open chain nitriles (II), or, under only slightly more vigorous conditions, to the corresponding amides (III).



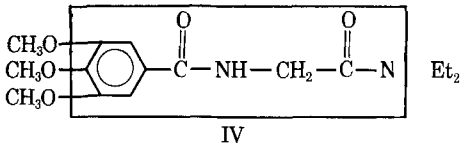
I



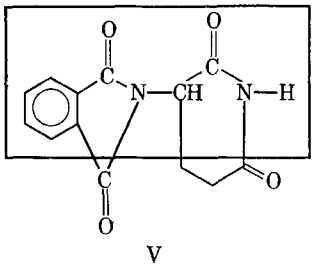
II



IIIa, R = CH_3, Ar = C_6H_5



IV



V

Scheme I

The structural similarity of these amides (III) to trimeglamide (IV) and thalidomide (V), which is pointed out in Scheme I, suggested that these sulfur-containing hippuramides might possess similar biological properties. Compound IIIa was therefore subjected to preliminary pharmacological testing.

EXPERIMENTAL

Experiments with Mice—Male Swiss albino mice, weighing 19–23 Gm., were injected (i.p.) with a suspension containing 25 mg./ml. of IIIa in 20% glycerin in water with 0.1% polysorbate 80[1] as a suspending agent. Ten mice at each dose level were treated in a group and observed periodically in a well-lighted room. The data (Table I) give an LD_{50} of 670 ± 20 mg./Kg. (2).

At doses below the LD_{50}, the compound caused the mice to show increased spontaneous activity, to become sluggish and depressed, and to fall asleep if left alone. The mice were easily aroused by external stimuli and behaved normally during the period of stimulation. Neither ataxia nor excitement was observed. The induction period was 15 to 45 min.; the duration of action was 2 to 6 hr.

The gross effects of thalidomide, compound IIIa, trimeglamide, and the thiazolothiazole mentioned below were compared following intraperitoneal injection into dogs, rats, mice, and guinea pigs. The effect, induction of normal sleep in the undisturbed animal, was the same for each drug in each species, including the guinea pig.

Mice given doses near and above the LD_{50} exhibited the same general symptoms mentioned above. However, all of the mice which died passed from a depressed to a convulsive state. Marked ataxia and disorientation were observed at these doses. The convulsions did not appear asphyxial, although some depression of respiration was noted. Several mice survived the convulsions which lasted for about 10–20 min.

Three mice, each given 750 mg./Kg. of IIIa and kept in separate cages in a semidarkened environment, exhibited qualitatively the same symptoms as mice given subtoxic doses, *i.e.*, they moved to a darkened corner of the cage and slept. All of these mice survived and none exhibited convulsions. Thus an LD_{50} determined by keeping the treated mice in separate cages would probably be higher than the group LD_{50}.

Anesthetized Dog Experiment—A dog was anesthetized with sodium pentobarbital, 30 mg./Kg. i.v. Carotid blood pressure was measured with a pressure transducer and respiration with a pneumotachygraph in the airway. These functions and the electrocardiogram were recorded on a polygraph. The effects of intravenous injections into the femoral vein of 10 mcg./Kg. of epinephrine, methacholine, and histamine, and the response to vagal stimulation

750	8/10

LD_{50} 670 ± 20 mg./Kg.

were determined during a control period and for 6 hr. after the injection of III*a*. The i.v. injection of 2 mg./Kg. and 8 mg./Kg. did not alter the arterial pressure or electrocardiogram or the response to vagal stimulation or challenge injection of the amines. The slight respiratory depression seen was equal to that produced by the suspending agent alone. Similarly, no changes were seen after the i.m. administration of 40 mg./Kg. of III*a*. These results suggest an absence of autonomic and antihistamine effects.

DISCUSSION

The pattern of effects suggests that this compound is not a sedative-hypnotic since it does not produce anesthesia even in large doses. Nor does it have behavioral or autonomic effects suggestive of a tranquilizer of the phenothiazine type. It appears to be similar in its action to thalidomide and trimeglamide to which it is chemically related and to the chemically unrelated 2,5-bis(1,1-dimethyl-3-cyanopropyl)thiazolothiazole (3).

The specific and tragic toxic effect of thalidomide need not obscure the fact that thalidomide defines a purely somnifacient class of drugs potentially safer than the barbiturates. The experience referred to in this paper suggests that drugs of this new class can be recognized during a routine screening and that the action may reside in structures chemically distant from thalidomide.

Opium Alkaloids IV. Isolation of Isoboldine

By EINAR BROCHMANN-HANSSEN, BENDIK NIELSEN, and KENTARO HIRAI

The aporphine alkaloid isoboldine has been isolated from opium. It has been identified by NMR and mass spectrometry and by comparison of its infrared spectrum with that of synthetic (±)-isoboldine. ORD measurements have shown that the isolated alkaloid has the absolute configuration corresponding to the (*S*)-series. Possible biosynthetic pathways for isoboldine are discussed briefly.

THE APORPHINE alkaloids are widely distributed in nature and, although they occur abundantly in the *Papaveraceae* family, it is only recently that alkaloids of this type have been found in opium. In 1965 Nijland (1) reported the isolation of corytuberine (I) and magnoflorine (*N*-methylcorytuberine). A third member of the aporphine group has now been obtained from opium and identified as isoboldine (II). This alkaloid has previously been isolated from *Nandina domestica* by Tomita *et al.* (2, 3).

All naturally occuring aporphine alkaloids which are known so far are substituted in positions 1 and 2 (III). The amine nitrogen may be secondary, tertiary, or quaternary, and ring D is either unsubstituted or has one or more oxygen functions in positions 8, 9, 10, and 11.

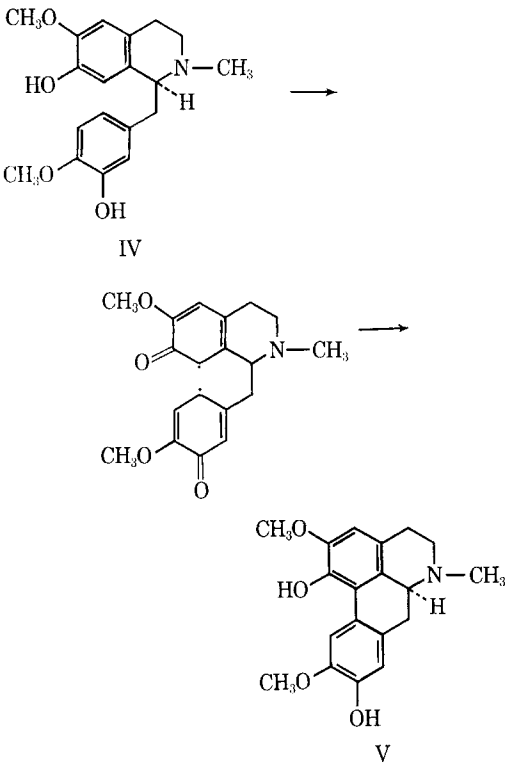
in a vacuum oven at about 30°. The alkalinized material was powdered and extracted with ether in a Soxhlet extractor. The solution in the extraction flask was replaced with fresh ether several times and evaporated to dryness in a rotating vacuum evaporator. The total dry extract obtained in this way weighed 365 Gm. It was dissolved in chloroform and extracted in a separator with McIlvain buffer of pH 6.2. This removed most of the codeine. The chloroform phase was shaken repeatedly with tartaric acid solution (2%), leaving most of the very weak bases (mainly papaverine and narcotine) in the chloroform. When the acid extract was kept in a refrigerator overnight, crystals of thebaine tartrate were formed. These were filtered off and the alkaloids in the filtrate separated into phenolic and nonphenolic bases by extraction with chloroform at pH 13–14. The aqueous layer was adjusted to pH 9–10 with sodium bicarbonate and again extracted with chloroform. After evaporation of the chloroform in a rotating vacuum evaporator, the residue, consisting mainly of diphenolic alkaloids (6.5 Gm.), was subjected to preparative thin-layer chromatography on silica gel (4). Several alkaloid bands could be observed. These were scraped off, the silica gel extracted with warm methanol, and the solutions evaporated under reduced pressure. Two alkaloids obtained in this way were identified as reticuline (2.8 Gm.) and scoulerine (0.5 Gm.) which had previously been isolated from the mother liquors produced during the purification of morphine (5–8). A third alkaloid fraction was crystallized repeatedly from methanol and gave almost colorless crystals (160 mg.) which rapidly became dark when exposed to air, m.p. 125° (micro m.p. K.).

Identification of Isoboldine—The NMR spectrum[1] in deuterochloroform with internal TMS standard revealed three aromatic protons at 2.05, 3.28, and 3.54 τ, two methoxyl groups (singlet, 6.15 τ), an *N*-methyl group at 7.46 τ, and a broad phenolic proton band at 4.3–4.6 τ. Several investigators have studied the nuclear magnetic resonance spectra of aporphine alkaloids and have demonstrated that the NMR spectrum can yield valuable information regarding their substitution pattern (9–11). The low field absorption band (2.05 τ) is characteristic of the aromatic proton at C-11, whereas the bands at 3.28 τ and 3.54 τ are due to the C-8 and C-3 protons, respectively (10). The chemical shift of the methoxyl groups (6.15 τ) indicates that these substituents are located in positions 2, 9, or 10. A methoxyl group at C-1 appears at higher field (6.37–6.58 τ), and a methoxyl group at C-11 has an intermediate chemical shift (6.28–6.35 τ) (9).

When the NMR spectrum of the isolated substance was compared with that of authentic synthetic (±)-isoboldine, the two were found to be identical.

The mass spectrum[2] gave a molecular ion with mass 327. Major fragments appeared in the mass spectrum at *m/e* 326, 312, 296, 284, 269, 253, 165, and 152, corresponding to the favored cleavage of aporphines having an *N*-methyl function (12). The M-31 peak (*m/e* 296) is small, indicating that the alkaloid does not have a methoxyl group in position 1 (12, 13). The M-1 peak (*m/e* 326) is of greater intensity than the peak for the parent ion. This is characteristic of aporphines which are substituted in positions 1,2,9, and 10, while aporphines having a 1,2,10, and 11 substitution pattern exhibit the oppositive relative intensities for these two peaks (14).



Scheme I

The U.V. spectrum[3] in 95% ethanol gave maxima at 303, 280, and 220 mμ typical of 1,2,9,10 substituted aporphines (15–18). The I.R. spectrum[4] in chloroform was identical with that of authentic (±)-isoboldine.

Stereochemistry—Isoboldine isolated from opium gave a specific rotation of $[\alpha]_D^{25}$ + 66° (c = 0.48 in chloroform). [Lit. + 83.2° (2); + 65.3° (3).] ORD measurements[5] gave a large positive Cotton effect at 251 mμ and a small negative Cotton effect at 320 mμ. From the sign of the Cotton effect in the neighborhood of 250 mμ, it is possible to conclude that the absolute configuration of isoboldine corresponds to the *S*-series according to the Cahn-Ingold-Prelog convention or the L-series if based on the amino acids (19). A sample of isoboldine obtained through the courtesy of Professor Tomita exhibited the same ORD curve as the alkaloid isolated from opium.

DISCUSSION

Robinson (20, 21) was the first to propose that aporphine alkaloids might arise in nature by oxidative coupling of a suitably substituted benzyltetrahydroisoquinoline. Barton and Cohen (22) carried this idea one step further when they suggested that

[1] The instrument used was a Varian HA-100 spectrometer.

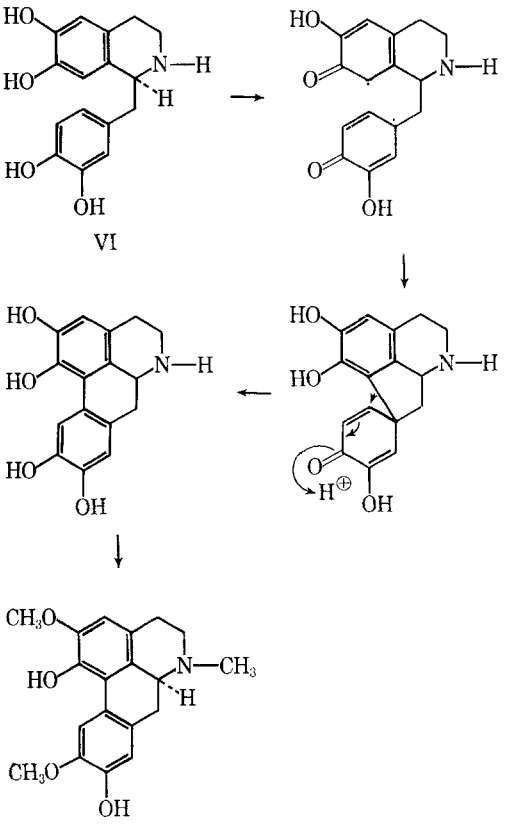
[5] ORD measurements were made in 95% ethanol at 20° on a Jasco ORD/CD-5 instrument.



VI

Scheme II

the oxidative coupling reaction was the result of a phenol oxidation involving *ortho* or *para* coupling *via* an intermediate quinoid biradical. Two possible mechanisms were envisaged, either a direct coupling to give the aporphine structure, or formation of an intermediate dienone which in turn might rearrange to give rise to a great variety of aporphines (22, 23). The first mechanism is illustrated for isoboldine in Scheme I. The logical precursor is (+)-reticuline (IV) which has the same absolute configuration as (+)-isoboldine (V) (7). It occurs in the opium poppy (7, 24) and has been shown to play an important role in the biosynthesis of a large number of opium alkaloids (25, 26).

An *in vitro* synthesis has been carried out in accordance with the oxidative coupling reaction of Scheme I (27, 28).

If the second mechanism (Scheme II) is used to explain the biosynthesis of isoboldine, a reasonable precursor might be (−)-norlaudanosoline (VI) which also has the correct configuration. Although it has not as yet been isolated from opium or the opium poppy, feeding experiments with radioactively labeled (−)-norlaudanosoline have indicated that it is involved in the biosynthesis of opium alkaloids, presumably as a precursor for (+)-reticuline (25). A closely related mechanism has been demonstrated for the biosynthesis of the aporphine alkaloid isothebaine in *P. orientale* (29).

Molecular Weight Determination in Aqueous and Nonaqueous Solvents II. Thermodynamic Properties of Various Solvents

By RICHARD D. JOHNSON* and FRANK M. GOYAN

The change in the resistance of a thermistor from its value when surrounded by a pure solvent is plotted against the concentration of solutions substituted for the solvent. The solutes are chosen for stability and freedom from tendency to associate or dissociate in order to establish a calibration curve for the determination of molecular weights. Within the limit of experimental error, the curves appear to be straight lines in dilute solutions. The slopes of these lines may be used to estimate the approximate thermodynamic properties of solvents by methods analogous to those used in boiling point elevation studies.

THE THERMOELECTRIC vapor-phase osmometer formerly used to study colligative properties of various solutes (1) was improved upon by its developers (2) in a later study of molecular weight determination. This improved instrument has been used to measure changes in the resistance of a thermistor in contact successively with pure solvent and dilute solutions. A matching thermistor in contact with pure solvent during each measurement was used as a reference. The solutes were carefully selected for stability and freedom from tendency to associate or dissociate, and solutions measured ranged in concentration from 0.01 to 0.2 molal. These resistance changes plotted against their respective concentrations give, for each different solvent, a calibration curve that is used for the determination of the molecular weights of solutes. Within the limit of experimental error, these curves appear to be straight lines. The slopes of these lines are shown to be related to thermodynamic properties of certain solvents. The use of equations derived on the assumption of equilibrium show to a very good approximation that these results may be treated like boiling point elevation data at room temperature.

The aforementioned instrument (2) consists of a Wheatstone bridge circuit containing a pair of 100,000 ohm thermistors, a recording potentiometer, and a temperature control system. The measuring thermistor is in series with a decade resistance box which is used to balance the bridge. These thermistors have a high negative temperature coefficient of resistance of about 4% or 4000 ohms/1°C. Instrument sensitivity is such that a change in resistance of less than 1 ohm may be observed. Therefore, a temperature change of approximately 2×10^{-4}° can be observed. Each thermistor is housed in a separate glass cell which is lined with platinum gauze. This gauze, when wet with solvent, provides an atmosphere of solvent vapor inside the cell. Using a ground-glass tipped medicine dropper, drops of solution are placed on the thermistor tip *via* a capillary tube. Following each measurement, the drop of solution is rinsed from the thermistor tip with several successive solvent washings. A lower reservoir and ejection capillary allow for the removal of this waste material.

Both cells are immersed in a constant-temperature bath maintained at 25.00° ± 0.005° by the temperature control system, involving a water bath in a Dewar flask controlled by an Electron-o-therm Sr., model 148, Technical Equipment Co., Walnut Creek, Calif. The entire apparatus is maintained in a constant-temperature controlled atmosphere of a closed cabinet.

One thermistor, wet with a drop of solvent, is always used as a reference resistor. The second holds the various solutions under study including the solvent as the initial calibrating drop. The thermistors measure a slight increase in temperature caused by condensation of the solvent vapor upon the drop of solution, which has a lower vapor pressure. This process in turn changes the resistance of the thermistor in question causing an off-balance condition across the bridge. The recording potentiometer measurement of the off-balance condition is directly related to the change in resistance necessary to return the bridge to balance. The resistance so indicated is added to the decade box in series with the sample thermistor. The difference between this reading and the initial reading of the same box when pure solvent was on the thermistor is the "ΔR" value that is required for the calculations.

EXPERIMENTAL

Five solvents selected for study were water, 95% ethanol, benzene, ethyl ether, and carbon tetrachloride, while sucrose and benzil were the solutes

TABLE I—AVERAGE RESISTANCES AND CONCENTRATIONS FOR SOLUTIONS STUDIED

Substance	No.	Concn., molal	Av. ΔR, ohms
Sucrose (in water)	5	0.01	9
		0.02	18
		0.05	46
		0.10	92
		0.15	138
		0.20	184
Benzil (in 95% ethanol)	4	0.025	63
		0.05	126
		0.10	252
Benzil (in benzene)	3	0.025	138
		0.05	277
		0.10	554
Benzil (in ether)	2	0.01	85
		0.025	205
		0.05	404
Benzil (in carbon tetrachloride)	1	0.01	89
		0.025	227
		0.05	452

employed. The organic solvents were all of reagent quality, the benzene being toluene-free. Ordinary distilled water was used. Sucrose and benzil were also of reagent quality, and purification procedures included recrystallization of the benzil from absolute alcohol and sucrose from water.

Several concentrations of solutions were prepared for each solvent between the range of 0.01–0.2 molal. The solutes were weighed out accurately using an analytical balance, placed in a tared flask, and proper solvent added by weight to give the desired w/w solutions. ΔR readings were obtained as previously described, and a weighted average value was computed for each concentration. These values were plotted against their respective molal concentrations, and the slopes of the curves computed.

RESULTS

Figure 1 and Table I show the results obtained for the various solvents under study. The data for benzene appear in an earlier paper (2), and most of the other data were presented in the doctoral thesis of one of the authors (3). However, the values for 95% ethanol represent later work. The slopes of the curves in Fig. 1 and their reciprocal values have been tabulated in Table II.

DISCUSSION AND RESULTS

From classical thermodynamics the well-known relationship of physical chemistry (4) may be written:

$$\Delta T_b = \frac{RT^2}{l_v \ 1000}\, m \qquad \text{(Eq. 1)}$$

where ΔT_b is the boiling point elevation, l_v is the latent heat of vaporization in calories per gram, m is the molal concentration, R represents the gas constant, and T is the absolute temperature. The linearity of the results shown in Fig. 1 indicate that ΔR is a colligative property proportional to ΔT_b. Therefore,

$$\Delta R = \frac{K}{l_v} \cdot m \qquad \text{(Eq. 2)}$$

TABLE II—SLOPES, RECIPROCAL SLOPES, AND LATENT HEATS OF VAPORIZATION CORRESPONDING TO CURVES IN FIG. 1

Curve No.	Solvent	Slope $\frac{(dR)}{(dm)} = S$	Reciprocal Slope $1/S$	l_v (cal./Gm. at 25°)
1	CCl_4	9060	0.110×10^{-3}	50.2
2	Ether	8050	0.124×10^{-3}	86.1
3	Benzene	5540	0.181×10^{-3}	103
4	95% Ethanol	2520	0.397×10^{-3}	224
5	Water	920	1.087×10^{-3}	584

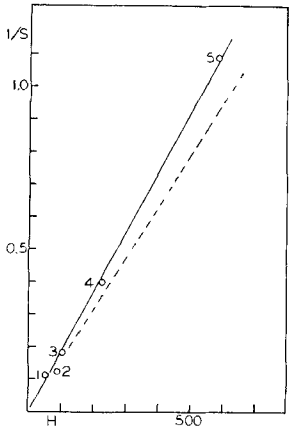

Fig. 2—Reciprocal slopes (× 10³) of curves of Fig. 1 vs. latent heats of vaporization (cal./Gm.). Numbers correspond to those listed for Fig. 1.

where K is a proportionality constant from whence it follows that:

$$l_v = K \cdot \frac{dm}{d\Delta R} \qquad \text{(Eq. 3)}$$

$\frac{dm}{d\Delta R}$ represents the reciprocal slopes listed in Table II. These values plotted against the corresponding latent heats of vaporization should give a straight line. Figure 2 shows this graphically. Latent heats of vaporization displayed in Table II were obtained for 25° by graphical interpolation of established values at various temperatures (5). The value for 95% ethanol was calculated for 25° from the value at the boiling point given by Licht and Denzler (6) by assuming that pure ethanol and the azeotrope required the same correction in going from the boiling point to 25°.

It will be noted from Fig. 2 that all of the points are close to the solid straight line. Ether, which seemed to be the most difficult to work with experimentally, comes closer to the theoretical value shown by the dotted line. This line was established by assuming the relationship:

$$\Delta T_b = \Delta R \cdot f \qquad \text{(Eq. 4)}$$

where ΔT_b and ΔR are taken from Eq. 1, and f represents a conversion factor found to be 2.8×10^{-4}°/ohm by direct measurement with a thermometer. Combining Eqs. 1 and 4 and evaluating all terms gives the slope of the dotted line. By the same reasoning, the solid line gives a value for f of 3.26×10^{-4}°/ohm.

SUMMARY AND CONCLUSION

Calibration curves described above for determining colligative properties in various solvents may be combined in such a way as to reveal expected thermodynamic properties of the solvents. Measurements made on drops of solutions held on the tips of glass rods containing a thermistor show that the vapor exchange is sufficient to minimize the effect of the heat loss which must occur. This situation is no different in principle from the use of a thermometer in a typical boiling point experiment. Although undoubtedly refinements should include the use of instrument constants accounting for heat conduction and other factors, the apparent approximate validity of a classical thermodynamic treatment is a good indication of the effectiveness of this particular instrument.

Absorption and Permeability of a Flavor in Plastic Containers as Determined by Head-Space Gas Chromatography

By SAM J. DONATO

When guarana flavor was used as the flavoring agent in an oral preparation and placed in plastic containers, and when head-space gas–liquid chromatography was applied to the investigation of the stability of this product, the method was found to be rapid and specific. The flavoring constituents of guarana were detected as having been absorbed by the wall of the container and having permeated to the atmosphere surrounding the outside surface of polyethylene bottles. Polyvinyl chloride bottles showed definite absorption of guarana and some change in the appearance of the containers but gave no evidence of permeability.

THE INCREASED importance of plastic containers in the packaging industry has emphasized the need for determining their compatability as a substitute for glass. The object of this work was to develop a rapid method for the study of one phase of this compatability. Much has been accomplished to improve plastics (1) and this achievement has progressed to the point that plastics almost look like glass. Because of its nonfragile nature, lighter weight, and low production cost there is much interest in the pharmaceutical industry for its use as a substitute for glass. A major problem, that of permeability, is associated with plastics and this has led to some reservation as to their total acceptance. In studies thus far reported in the literature, the observations have been arrived at by noting loss in weight and change in appearance, *i.e.*, swelling or collapse of container (2), these being methods which required long standing, careful weighing and handling, and are useful only on a macro scale. Where very small amounts of flavoring are utilized, the aforementioned approach is ineffective and necessitates another analytical technique. In this laboratory such a technique was devised. The author is now able to detect minute traces of flavors as they become absorbed or permeate into new zones within the plastics by using head-space GLC. The procedure is simple, and the graphs obtained are a permanent record of the observations. The use of head-space GLC has been reported in several publications, especially those pertaining to studies in wine and beer flavor (3, 4). These efforts are merely a continuation of these studies. Since glass is very inert and impermeable,

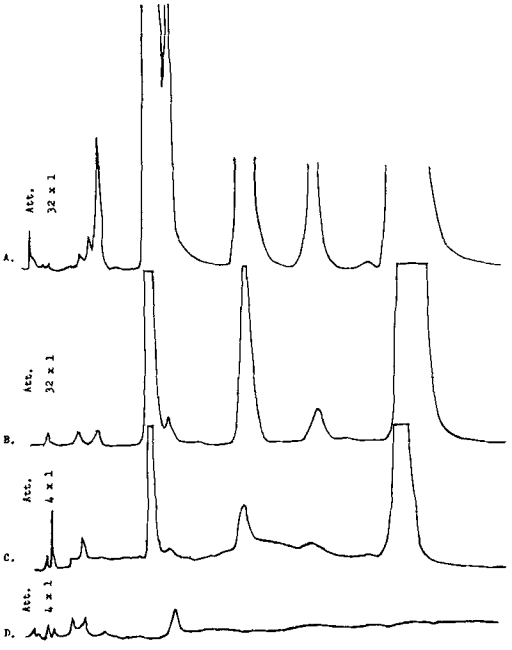

Fig. 1—Head-space gas chromatography of 0.0002% guarana flavor in water. Key: A, *air sample above solution of 0.0002% guarana;* B, *air sample withdrawn from the interior of a washed plastic container that had contained a solution of 0.0002% guarana;* C, *air sample from a closed glass jar containing a polyethylene bottle filled with the guarana flavor;* D, *outside surface air adjacent to glass jar containing the guarana flavor (completely comparable to laboratory air).*

the plastic sample container was allowed to equilibrate in a tightly closed glass receptacle and the enclosed atmosphere was analyzed.

EXPERIMENTAL

Polyethylene, polyvinyl chloride, and glass bottles were each filled with a 0.0002% v/v guarana–water solution, were separately placed in glass jars with aluminum screw caps, and stored at room temperature for at least 24 hr. A 2.0-ml. aliquot of the air space in each case was withdrawn with a Hamilton gas syringe after piercing through the metal cap with a small nail. This air sample was injected into the F & M model 609 flame ionization gas chromatograph. The small opening would always be sealed with silicone grease immediately after withdrawal of the sample. This sealing technique proved very satisfactory. The results are shown in Fig. 1. The analysis was carried out using a column of copper 10 ft. in length, 1/4 in. o.d., packed with 10% Carbowax 20M on 60–80 mesh Diatoport W. The column temperature was kept isothermally at 90° after an overnight equilibration. The injection port was 200° while the detector block temperature was 130°.

Nitrogen was used as the carrier gas with a flow rate of 45 ml./min. Hydrogen and air flow were kept at 45 and 400 ml./min., respectively. The attenuation was as indicated in Fig. 1; the range was ×1 in each case. The recorder speed was set at 15 in./hr. Each determination required approximately 30 min.

DISCUSSION

This method was found to be effective and simple. Some precautions, however, had to be employed. New septums had to be used on each day's run of the GC since the punctures made by the No. 22 gauge needle would, after a day's use, severely damage the septum and create loss in sensitivity. The cap in each sample bottle had to be kept well sealed and care had to be taken when filling the sample bottles so as not to spill any of the solution on the neck or outside surface of the bottles. The bottles were always thoroughly washed.

The column had to be conditioned overnight to give linear base at the range of ×1.

CONCLUSION

At the conclusion of the experiment the plastic containers were removed from the jars, and the containers thoroughly washed. After this washing there was still a strong odor of the guarana flavor in the air inside the plastic containers. This odor was not observed in the glass jars used in the experiment. Samples of air were withdrawn from the interior of the washed plastic containers and injected into the gas chromatograph. At an attenuation of ×32 the characteristic peaks of guarana flavor were present. Figure 1, B, is an indication that there is a considerable amount of guarana constituents still present in the plastic.

The results suggest that the method would be useful with even more dilute solutions, and quantitation is possible.

Alkaloids of the *Papaveraceae* V. Muramine and Berberine from *Argemone squarrosa*

By FRANK R. STERMITZ*

***Argemone squarrosa* Greene (subsp. *squarrosa*) from several locations in central New Mexico was found to contain mainly muramine and berberine, but no allocryptopine. This is in contrast to an earlier literature finding that the same species from southern Colorado contained allocryptopine as the major, if not only, alkaloid. Muramine is now available for the first time in quantities sufficient for pharmacological testing.**

DIVISION of the genus *Argemone* into four tentative alliances based upon chemical and morphological criteria was recently suggested (1). Preliminary chemical studies (2) on *A. polyanthemos* (Fedde) Ownb., *A. corymbosa* Greene (subsp. *arenicola* Ownb.), *A. chisosensis* Ownb., and *A. sanguinea* Greene have indicated that each of these has berberine, protopine, and allocryptopine as major alkaloids. Chemically, these species are thus similar to *A. mexicana* L., *A. ochroleuca* Sweet, *A. aenea* Ownb., and *A. albiflora* Hornem, for all of which some data were already present in the literature. Two of the more tentative alliances were suggested (1) by dividing the above species into two groups based upon morphological criteria (3, 4). The two remaining alliances were based on the presence of pavine-type alkaloids either almost exclusively (*A. hispida* Gray and *A. munita* Dur. and Hilg.) or along with major concentrations of berberine and protopine-type alkaloids (*A. platyceras* L. and O.). Additional preliminary studies (5) have shown that *A. gracilenta* Greene is very similar in alkaloid content to *A. hispida* and that *A. pleiacantha* Greene and *A. platyceras* are closely related. Slavik and Slavikova had earlier suggested (6) somewhat similar alliances, although the number of investigated species was considerably smaller at that time.

Morphologically, *A. squarrosa* Greene was tentatively suggested (4) to be allied to *A. hispida*, but

Preliminary chemical studies (2) on *A. polyanthemos* (Fedde) Ownb., *A. corymbosa* Greene (subsp. *arenicola* Ownb.), *A. chisosensis* Ownb., and *A. sanguinea* Greene have indicated that each of these has berberine, protopine, and allocryptopine as major alkaloids. Chemically, these species are thus similar to *A. mexicana* L., *A. ochroleuca* Sweet, *A. aenea* Ownb., and *A. albiflora* Hornem, for all of which some data were already present in the literature. Two of the more tentative alliances were suggested (1) by dividing the above species into two groups based upon morphological criteria (3, 4). The two remaining alliances were based on the presence of pavine-type alkaloids either almost exclusively (*A. hispida* Gray and *A. munita* Dur. and Hilg.) or along with major concentrations of berberine and protopine-type alkaloids (*A. platyceras* L. and O.). Additional preliminary studies (5) have shown that *A. gracilenta* Greene is very similar in alkaloid content to *A. hispida* and that *A. pleiacantha* Greene and *A. platyceras* are closely related. Slavik and Slavikova had earlier suggested (6) somewhat similar alliances, although the number of investigated species was considerably smaller at that time.

Morphologically, *A. squarrosa* Greene was tentatively suggested (4) to be allied to *A. hispida*, but

the only chemical investigation (7) reported that β-allocryptopine (I*a*) was essentially the only alkaloid present in *A. squarrosa* Greene (subsp. *squarrosa*) collected in southern Colorado. Thus, this species seemed to be one which could not be placed in any of the above alliances with certainty. In the course of a collecting trip in New Mexico it was noted that *A. squarrosa* in most locations had a bright yellow sap, which has been found indicative of considerable concentrations of berberine. It was therefore deemed advisable to chemically investigate the species from this area.

Collections were made at two locations in Lincoln County, where *A. squarrosa* (subsp. *squarrosa*) had previously been collected (4), and one location in Eddy County, where this subspecies had been reported (4) to grow mixed with *A. squarrosa* (subsp. *glabrata*). Each of the three collections was found to contain approximately 0.5% alkaloids, with the Lincoln County plants containing about a 4:1 ratio of muramine (I*b*) to berberine. This ratio was approximately reversed in the Eddy County plants. Only traces of other alkaloids could be detected by thin-layer chromatography of the last mother liquors remaining after removal of muramine and berberine. Because of the similarity of structure and melting point of muramine and β-allocryptopine, an authentic sample of the latter, which had been isolated (7) from the same plant species, was obtained[1] and compared with I*b*. The two were indeed found to be different and the original assignment of structure (7) of the β-allocryptopine was confirmed by additional spectral methods.

On the basis of these results and considering plant morphology, *A. squarrosa* is therefore tentatively assigned to the alliance composed of *A. polyanthemos*, *A. corymbosa*, *etc.* It still remains somewhat distinctive, however, in that all other members of the alliance contain protopine, allocryptopine, and berberine and apparently do not contain muramine.

Muramine has, up to now, only been isolated in trace amounts from *Argemone* (8) and a few *Papaver* species (9) and its synthesis (10) has only recently been accomplished in small yield. The discovery of a good source has now provided sufficient material for pharmacological testing, the results of which will be reported at a later date.

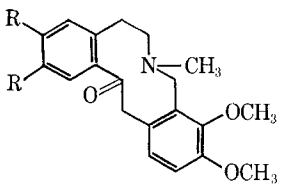
EXPERIMENTAL[2]

Material—The three collections of *A. squarrosa* (subsp. *squarrosa*) used in the present study were made in June 1966 as follows:[3]

(*a*) Lincoln County, N. Mex., 2 mi. east of Capitan on U.S. highway 380; in blossom, but capsules rare. Voucher sample: No. 111162.

(*b*) Lincoln County, N. Mex., east city limits of Lincoln; in blossom, but past peak blossom time. Many capsules. Voucher sample: No. 111156.

(*c*) Eddy County, N. Mex., 4.9 mi. west of Hope on U.S. highway 82; similar growth stage to



I*a*, R, R = —O—CH_2—O—
I*b*, R′ = R = OCH_3

collection (*b*). The presence of *A. squarrosa* (subsp. *glabrata*) as well as intermediates between the two subspecies was noted at this location, but the attempt was made to collect homogeneous subsp. *squarrosa*. Voucher sample: No. 111155.

Isolation and Identification of Alkaloids—The following description [for that of collection (*a*) above] is typical. A total of 521 Gm. of dried, ground whole plant material was extracted for 24 hr. with methanol in a Soxhlet extractor. The methanol was evaporated to a viscous liquid and this was partitioned between 1 *M* sulfuric acid and a 1:1 *n*-butyl alcohol–benzene solution. Some insoluble tar was discarded. After the layers were separated, the organic layer was extracted with further portions of acid. These were combined and washed once with chloroform. The combined aqueous acid solution was made basic with sodium carbonate and extracted three times with equal volumes of chloroform. The chloroform solution was dried with anhydrous sodium sulfate and evaporated *in vacuo* to leave 2.4 Gm. of brown-yellow gum. This was dissolved in 30 ml. of hot methanol and cooled. Brownish transparent prisms (0.38 Gm., m.p. 168–172°) were formed and these were recrystallized once from methanol to yield pure transparent prisms of muramine, m.p. 174–176°. [Lit. (11) m.p. 176–177°.] This was spectroscopically identical to muramine isolated (8) from *A. munita* (subsp. *rotundata*). The methanolic solution from the first muramine crystallization was evaporated to dryness and dissolved in 30 ml. of warm, dilute hydrochloric acid. Cooling the solution yielded yellow-brown microcrystals (0.09 Gm.) of berberine chloride which were spectroscopically identical to a commercial sample. From these results, further work-up of the mother liquors and thin-layer chromatography of residues, the ratio of muramine to berberine in the total alkaloid fraction was estimated at 4:1. Only by heavily loading thin-layer plates with final residues could traces of two other alkaloids be observed. These were not further isolated. Since it was found (7) that ethanol Soxhlet extraction removed only a portion of the allocryptopine from Colorado *A. squarrosa*, the plant residue from the present methanol extraction was submitted to the standard (8) direct butanol–benzene method, but no further alkaloids were obtained.

Collection (*b*) yielded results not differing significantly from those just described. However, when the same procedure was applied to collection (*c*) the first crystallization of the total crude alkaloid fraction yielded berberine, not muramine. Only after redissolving residues in acid and repeating the cycle of extractions and pH adjustment could muramine be isolated. The final results from collection (*c*), again based on isolated amounts plus thin-layer chromatographic estimation of residue

[1] The author is indebted to Professor Soine for this sample.

[2] Melting points were determined on a Mel-Temp apparatus and are uncorrected. Spectral comparisons were made using an Hitachi Perkin-Elmer RMU6-E mass spectrometer and Varian A-60 (NMR), Beckman IR-8 (IR), and Cary 15 (UV) spectrometers. The purchase of the mass spectrometer was made possible through a grant from the National Science Foundation to the Department of Chemistry.

Alkaloids of the *Papaveraceae* VI. Protopine and Allocryptopine from *Arctomecon californica*

By FRANK R. STERMITZ* and V. P. MURALIDHARAN

Protopine and allocryptopine (in approximately equal amounts) make up over 95 per cent of the alkaloidal content of *A. californica*.

THE GENUS *Arctomecon* consists of three species (*A. californica* Torr. et Fremont, *A. humilis* Coville, and *A. merriami* Coville) whose range is restricted to the extreme southwestern corner of Utah, southern Nevada, and the adjoining California desert (1). As part of the continuing investigation of the *Papaveraceae*, it was deemed advisable to investigate this relatively rare genus. Although extensive searches were conducted in 1962–1964 at locations where previous collections of each species had been made, only *A. californica* could be found.[1]

From 700 Gm. of powdered stems and leaves, a total of 2.3 Gm. of crude alkaloid mixture was obtained after treating the powder with 1:1 butanol–benzene, extracting this solution with 1 *M* sulfuric acid, adjusting to pH 9, extracting with chloroform, and evaporating the chloroform layer to dryness. Thin-layer chromatography showed the presence of two alkaloids. A small portion of root material treated in the same fashion showed similar results except with a slightly higher total alkaloid content.

The alkaloid mixture was treated with hot methanol, and protopine was precipitated from the cooled solution. Identification was made by NMR, U.V., and I.R. comparison with a known sample (2). Evaporation of the mother liquor, followed by crystallization of the residue from methanol, was accomplished three times with each crystallization yielding protopine. The fourth crystallization yielded a different alkaloid (m.p. 150°) which, after seven further recrystallizations, had m.p. 156° and was identical in all respects (NMR, I.R., U.V.) to α-allocryptopine, m.p. 160°.[2]

Thin-layer chromatographic analysis of the mother liquors again showed mainly protopine and allocryptopine. An additional two spots could be faintly seen, but sufficient material for further work was not available. Based on the isolated pure alkaloids and thin-layer chromatographic analysis of the mother liquors, protopine and allocryptopine occur in approximately equal amounts in *A. californica* and together represent probably 95% of the total alkaloid content.

General experimental procedures were as previously reported (3).

Effect of the Component Parts of Nicotinamide Adenine Dinucleotide ($NAD^{\oplus}$) as Inhibitors of Lactic Dehydrogenase

By ALBERT J. FORLANO

Kinetic experiments were used to determine the K_m value for $NAD^{\oplus}$ and the K_i values for the component parts of $NAD^{\oplus}$ functioning as inhibitors of the coenzyme. The inhibitory powers of these substances progressively increased as the structure of the inhibitors more closely resembled that of the complete coenzyme. The increasing degree of inhibition appears to be due to more complete binding at the active site of LDH as the structure of the inhibitor approaches the structure of $NAD^{\oplus}$ and effectively prevents the normal binding of the coenzyme.

LACTIC ACID DEHYDROGENASE (LDH), an enzyme found in animal cells, catalyzes the reaction:

$$\text{L(+) lactate} + NAD^{\oplus} \underset{}{\overset{\text{LDH}}{\rightleftharpoons}} \text{pyruvate} + NADH + H^{\oplus} \quad \text{Reaction } 1$$

LDH from rat muscle is specific for L(+)-lactate; however, D(−)-lactate is neither a substrate for LDH nor is it a competitive inhibitor of the normal substrate (1). With reference to the coenzyme portion of LDH one finds that $NAD^{\oplus}$ is approximately 170 times more effective than $NADP^{\oplus}$ for oxidizing lactate (2). Winer and Schwert (3) determined the Michaelis constant (K_m) for $NAD^{\oplus}$ in the reversible reaction *1* over the pH range 5.58 to 10.20. The values ranged from 45.0×10^{-5} moles/L. (pH 5.58) to 5.4×10^{-5} moles/L. (pH 8.59) to 61.0×10^{-5} moles/L. (pH 10.20). The K_m for $NAD^{\oplus}$ in reaction *1* exhibited a minimum at pH 8.7 (3).

The mechanism of LDH inhibition is not well understood. Green and Brosteaux (4) first observed that anions, presumably as competitive inhibitors of lactate binding, decreased the activity of LDH. Kubowitz and Ott (1) showed that high concentrations of pyruvate acted as an inhibitor of LDH. Since pyruvate can act as a competitive inhibitor of reaction *1*, it was decided that the forward reaction would be facilitated if the pyruvate was tied up as soon as it was formed. In the present study semicarbazide hydrochloride was added to the reaction mixture to form the semicarbazone of pyruvic acid and thus ensure maximal forward reaction.

A study of the competitive inhibitors resembling the component parts of $NAD^{\oplus}$ showed that ADP ribose and diadenylic acid are potent enzymatic inhibitors, whereas AMP, ADP, IMP, nicotinamide mononucleotide, nicotinamide, and adenosine were rated as weak inhibitors (5).

The literature appears to have a number of studies involving the inhibitory properties of the component parts of $NAD^{\oplus}$; however, many of these studies were performed by different workers under different experimental conditions. Since there appears to be a correlation between the chemical similarity of $NAD^{\oplus}$ inhibitors and degree of inhibition, it was decided to make a systematic study of the major single components of $NAD^{\oplus}$, followed by combinations of the single components joined together by covalent bonds. The degree of inhibition by these substances in terms of K_i values was determined under the same experimental conditions as the K_m value for $NAD^{\oplus}$.

EXPERIMENTAL

Materials—Lithium lactate (51.1% L-isomer), β-diphosphopyridine nucleotide ($NAD^{\oplus}$), lactic dehydrogenase type I, 70,000 units/mg. protein, all from Sigma Chemical Co.; niacinamide U.S.P.; D(−)-ribose, Eastman Red Label; adenine hemisulfate; 1 H_2O grade B, adenosine-5′-monophosphate morpholidate, grade B; adenosine CFP, the latter three from California Biochemicals; K_2HPO_4, Baker reagent; adenosine-5′-diphosphate sodium salt, ribose-5′-phosphate barium salt, and adenosine-3′-phosphate, the last three from Schwartz Laboratories; Tris, Mann Biochemicals.

KINETIC PROCEDURES

$NAD^{\oplus}$ and the inhibitors were assayed for their effect on LDH in the following manner. The solutions of reagents were added to the spectrophotometer cells in the specified order: 1.0 ml. lithium lactate solution, 0.10 ml. semicarbazide HCl solution, varying amounts of the $NAD^{\oplus}$ solution (as indicated in Table I) to give different concentrations of the $NAD^{\oplus}$ and enough 0.1 *M* Tris buffer (pH 8.8) to make a total volume of 3.10 ml. In the case of the inhibited solutions the specified amount of inhibitor (Table I) was also added and the volume was brought up to 3.10 ml. with 0.1 *M* Tris buffer (pH 8.8). Then 0.03 ml. of the enzyme solution (absorbance 280 mμ = 0.050), which was prepared fresh daily, was added last from a microsyringe. The tubes were rapidly shaken and placed into a Gilford model 2000 multiple sample absorbance recorder equipped with a Beckman DU monochromater. The increases in absorbance at 340 mμ were determined every 20 sec. at 25°. Since the increase in absorbance at 340 mμ is a function of the conversion of $NAD^{\oplus} \rightarrow NADH$ which occurs when the lactate is oxidized, the absorbance increase was used as a means of determining the reaction rate. Inhibitors and combinations of inhibitors were handled in the same fashion. The K_m for $NAD^{\oplus}$ was determined at the different concentrations specified in Table I in the absence of inhibitors and all other conditions remained constant. In the K_i determinations the amount of inhibitor or combinations of inhibitors remained constant and the $NAD^{\oplus}$ concentration was varied as specified in Table I. The final concentrations of the inhibitors in the reaction mixture are given in Table II.

RESULTS

The change in absorbance at 340 mμ *versus* time was followed over a period of 15 min. There was an initial reaction rate that appeared to be maximal which subsequently tapered off. The slope of the initial plot of absorbance *versus* time was utilized in the calculation of the Michaelis constant (K_m) and the inhibitor constants (K_i). The calculation for K_m was based on Eq. 1 from White *et al.* (6) utilizing the

0.100 *M* Adenosine-5′-diphosphate	0.10
0.050 *M* Ribose-5′-phosphate	1.00
0.033 *M* Adenosine	1.00
0.100 *M* Adenosine-3′-phosphate	0.20
0.100 *M* Tris buffer pH 8.8	

[a] All the solutions were prepared in 0.1 *M* Tris buffer. The differences in concentrations were due to differences in solubilities of these reagents. Maximal solubility was desired wherever possible.

Lineweaver-Burk modification of the Michaelis-Menten equation:

$$\frac{1}{v} = \frac{1}{V_{max.}} + \frac{K_m}{V_{max.}} \cdot \frac{1}{[S]} \qquad \text{(Eq. 1)}$$

where $[S]$ = substrate concentration $[NAD^{\oplus}]$, v = reaction velocity at $[S]$, $V_{max.}$ = maximal velocity, and K_m = Michaelis constant for $NAD^{\oplus}$. If a plot of $1/v$ *versus* $1/[S]$ is made, the slope of the line is equal to $K_m/V_{max.}$ and the y intercept equals $1/V_{max.}$; consequently K_m can easily be calculated. The K_m value for $NAD^{\oplus}$ determined in the absence of inhibitors is found in Table II. The calculation of the K_i value utilized Eq. 2 from White *et al.* (6):

$$\frac{1}{v} = \frac{K_m}{V_{max.}}\left(1 + \frac{[I]}{K_i}\right)\frac{1}{[S]} + \frac{1}{V_{max.}} \qquad \text{(Eq. 2)}$$

where $[I]$ represents the concentration of inhibitor, and K_i is the dissociation constant for the enzyme inhibitor complex EI. The K_i is analogous to the K_m value which is equal to the concentration of substrate present at $^1/_2$ the numerical maximal velocity. Consequently, the smaller the value of K_i, the more effective the inhibitor. The reaction velocities obtained in the presence of the inhibitors were used for the calculation of the K_i values. A plot of $1/v$ *versus* $1/[S]$ (S = $[NAD^{\oplus}]$) in the presence of a constant amount of inhibitor was made and the slope of the line was equal to $(K_m/V_{max.})(1 + [I]/K_i)$. Recall that the value of $(K_m/V_{max.})$ is the same as for the uninhibited reaction. The inhibited plots also have the same ordinate value $(1/V_{max.})$ as the uninhibited reaction because these agents function as competitive inhibitors of $NAD^{\oplus}$. The K_i values are presented in Table II.

DISCUSSION

The K_m value of 8.52×10^{-5} *M* determined at pH 8.8 in this study compares favorably with the literature value of Winer and Schwert (3) who found a value of 5.4×10^{-5} *M* at pH 8.59 and 12.0×10^{-5} *M* at pH 8.96. Since the K_i values were determined with the same enzyme preparation, reagents, *etc.*, as the K_m value, there should be a good degree of correlation with each other.

The data in Table II indicate that none of the inhibitors or combination of inhibitors was more firmly bound to LDH than $NAD^{\oplus}$. The high K_i values for ribose and phosphate indicate that these portions individually were weakly bound; however, when they were joined by a covalent bond as in the case of ribose-5′-phosphate, the K_i value dropped sharply indicating much stronger binding than either of the component portions alone. Adenine itself had a moderately high K_i value, however, when it was joined covalently to ribose-5′-phosphate to yield adenosine-5′-phosphate, the K_i of the nucleotide was about $^1/_2$ that of the ribose-5′-phosphate. This is a good indication that adenine is a necessary binding portion of the coenzyme. When an additional phosphate was joined covalently to AMP to yield ADP, the K_i of ADP dropped to $^1/_3$ the value for AMP, indicating the additional attraction afforded by the second covalently bonded phosphate. The increased binding ability contributed by the extra phosphate is understandable because phosphate groups are ionized at this pH and could easily form ionic bonds with some positive group at the active site of LDH. Niacinamide, which is not a potent

Adenosine-5′-$DiPO_4$	1.48×10^{-3}	3.22×10^{-3}	0.17
Adenosine-5′-$DiPO_4$ + niacinamide[a]	5.21×10^{-4}	$3.22 \times 10^{-3} + 0.123$	0.06
Adenosine-5′-$DiPO_4$ + niacinamide + ribose[a]	4.67×10^{-4}	$3.22 \times 10^{-3} + 0.123 + 0.929$	0.06
D(−)-Ribose-5′-PO_4	1.07×10^{-2}	1.61×10^{-2}	1.26
Adenosine	1.56×10^{-2}	1.07×10^{-2}	1.83
Adenosine-3′-PO_4	7.65×10^{-3}	6.45×10^{-3}	0.90

[a] The calculations of these K_i values are based solely upon the molar concentration of the first inhibitor even though the other inhibitors were present.

inhibitor of NAD⊕, potentiated the inhibitory powers of ADP when used in physical combination indicating that another one of the points that NAD⊕ uses for attachment to the LDH had been partially blocked. The same was true for the mixture of ADP with niacinamide and D(−)-ribose.

The K_i for adenosine was fairly high; however, if a phosphate group was joined to the 5′ position covalently to yield the adenosine-5′-PO_4 the K_i decreased to $^1/_3$ of its value. The placement of a covalently bonded phosphate in the 3′ position of adenosine reduced the K_i of adenosine to only $^1/_2$ of its original value. This indicates that the phosphate of a nucleotide is a required portion for bonding to the enzyme; in addition there are steric requirements for maximum binding since both isomers do not have equal K_i values.

Ringold (7) recently theorized that there is an interaction between the quaternary nitrogen of the NAD⊕ and the basic nitrogen of the imidazole ring from histidine at the active site of LDH. With this idea in mind we can see why niacinamide, without a quaternary nitrogen, is not a catalytic species, nor is it very strongly bound to the active site of the enzyme.

One can conclude that the individual components of NAD⊕ are not very strongly bound to LDH, especially in the case of ribose or phosphate alone. However, the amount of inhibition increases as one systematically joins these portions together covalently and the products more closely resemble NAD⊕. This is expected since they become more effective in preventing the complete binding of NAD⊕ to LDH which apparently is a necessary prerequisite for enzymatic activity.

SUMMARY AND CONCLUSIONS

The K_m value for NAD⊕ and the K_i values for the component parts of NAD⊕ as inhibitors of the LDH catalyzed conversion of lactate to pyruvate were determined in 0.1 *M* Tris buffer at pH 8.8.

One finds that the individual component parts of NAD⊕, especially the phosphate and D(−)-ribose, were very poor inhibitors of the coenzyme; however, as the component parts were joined together covalently to make the nucleoside, nucleotide, nucleotide phosphate, *etc.*, their inhibitory powers increased because of greater binding at the active site thus preventing the normal binding of NAD⊕ to LDH.

Alterations in Hyaluronidase Activity and Serum Protein Electrophoretic Patterns After Chronic Heat Stress

By M. M. CLAY* and M. W. ADLER

The effects of a hot environment upon plasma proteins and dermal hyaluronidase spreading activity was studied in rats. Hyaluronidase activity decreased after 1 day of heat, increased after 4 and 16 days, and again decreased after 48 days. Swimming for 1.5 hr. after each period of heat stress resulted in inhibition of hyaluronidase spreading activity with the exception of the 48-day period when activity increased. Swimming caused adrenal gland hypertrophy in unstressed but not in heat stressed rats. The relative concentration of plasma albumin increased during heat stress.

Wittersfors *et al.* (1, 2) have reported hypoalbuminemia with increased extravascular albumin distribution in some patients with gastric carcinoma. The authors suggested increased vascular permeability as a mechanism for loss of circulating albumin. Enhanced as well as diminished dermal connective tissue permeability to colloidal particles has been reported after stress and cortisone administration by this laboratory (3–5). The above work and that of Menkin (6) show a role for glucocorticoid hormones in regulation of vascular as well as connective tissue permeability.

The authors studied the effects of stress upon circulating proteins of rats. They also attempted to determine whether changes in serum proteins accompanied changes in dermal connective tissue permeability. For the first study environmental heat was selected as the stress and intradermally injected India ink and hyaluronidase–India ink were selected as indicators of connective tissue permeability to colloidal particles.

Key:* – – –, *group* A; — · —, *group* B; ····, *group* C; ●, *group* A′; O, *group* C′.

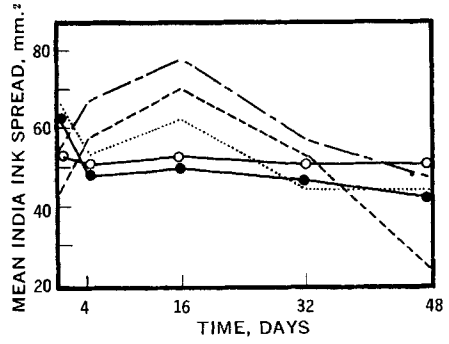

Fig. 2—Effect of stress on the spread of India ink. Group A, *heat stress; group* B, *heat stress, followed by 24 hr. recovery; group* C, *heat stress, recovery, and 1.5 hr. of swimming; group* A′, *nonstressed controls; group* C′, *nonstressed controls, 1.5 hr. of swimming. Key:* – – –, *group* A; — · —, *group* B; ····, *group* C; ●, *group* A′; O, *group* C′.

the rats were gently wiped and kept for 2 hr. in a draft-free cage maintained at 27°. Dermal permeability was then assayed. For each group of 24 treated rats there were 16 control rats of equal initial age and body weight. After 1, 4, 16, 32, or 48 days, dermal permeability was assayed in control rats, group *A′*. The remaining eight control rats, group *C′*, were treated in the same manner as group *C* above.

Assay of Dermal Permeability—Dermal permeability was assayed by the method of Clay and Nelson (7). A volume of 0.05 ml. of each indicator

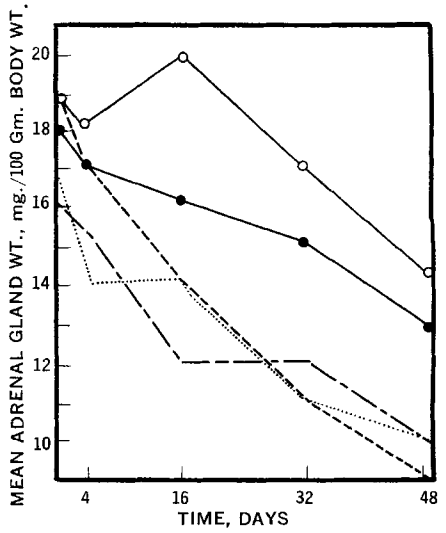

Fig. 3—Effect of stress on adrenal gland weight. Group A, *heat stress; group* B, *heat stress, followed by 24 hr. recovery; group* C, *heat stress, recovery, and 1.5 hr. of swimming; group* A′, *nonstressed controls; group* C′, *nonstressed controls, 1.5 hr. of swimming. solution was injected into the skin of the flank of rats lightly anesthetized with ether. The indicator solution contained 17% by volume of India ink and 0.9% NaCl or the same solution with 150 N.F. units of hyaluronidase[1] added. The area of spread of the India ink in the skin was calculated by substituting the largest and widest dimensions of the ink spot in the formula for an ellipse. Measurements were made 1 hr. after injection under light ether anesthesia. Immediately after measurement of ink spread, the rats were weighed, decapitated, and blood collected. Adrenal glands were removed, dissected free of fat, and weighed on a Christian Becker analytical balance.

Serum Protein Electrophoresis—The blood was permitted to stand for 20 min. The coagulated blood was centrifuged for 10 min. The sera of selected groups were pooled for electrophoretic analysis by means of the Perkin-Elmer model 38 Tiselius electrophoresis apparatus. Pooled sera were diluted 1:3 with barbital buffer of pH 8.6 which was 0.1 *M* with respect to sodium diethyl barbiturate and 0.015 *M* with respect to diethyl barbituric acid, with an ionic strength of 0.1. Each sample was dialyzed in a bag of Visking tubing against the barbiturate buffer for 24 hr. at 1.5°. A volume of 2 ml. of the dialyzed diluted serum was subjected to electrophoretic analysis. The electrophoretic patterns obtained by the scanning method of Longsworth (8) were projected, magnified, traced, and the areas under the peaks measured by means of a planimeter.

RESULTS AND DISCUSSION

TABLE I—SERUM ELECTROPHORESIS DATA

Treatment	% Total Protein				
	Albumin	α1-Globulin	α2-Globulin	β-Globulin	γ-Globulin
4 Days heat stress	40.7	22.7	7.8	18.0	8.7
24 hr. recovery	50.9	16.2	7.2	16.4	6.7
Swimming	53.6	11.7	7.3	21.6	4.4
32 days heat stress	58.3	9.7	6.1	12.0	5.5
24 hr. recovery	51.0	16.2	10.3	16.4	5.2
Swimming	45.0	25.2	5.7	12.9	7.5
48 days heat stress	69.8	[a]	8.5	15.0	4.8
24 hr. recovery	58.6	14.2	7.6	14.0	5.3
Swimming	66.3	[a]	9.8	16.5	7.2
Control	51.2	13.1	6.0	20.5	9.0
Swimming	53.6	11.7	7.3	21.6	4.4

[a] Values included with α2-globulin, as peaks were indistinct. *Note:* totals do not equal 100% due to presence of unidentified components.

cantly during the 48 days of the study (Fig. 1). The acute stress of swimming caused spread to decrease at each time interval ($P = <0.05$, in each case), accompanied by increased adrenal gland weights in the control rats of the C' groups.

Heat stress (group A) resulted in decreased hyaluronidase spreads compared to control levels (group A') at each time interval except 16 days when the spreads were approximately equal. The spreads were decreased as follows: 1 day, (−) 47.6 mm.^{2}; 4 days, (−) 10.7 mm.^{2}; 32 days, (−) 48.1 mm.^{2}; and 48 days, (−) 38.4 mm.^{2}. The differences were significant only at 32 and 48 days ($P = <0.01$). At 32 and 48 days adrenal gland weights decreased from control levels ($P = <0.01$). (Fig. 3.) Clay and Sinai (4) reported that rats maintained at 12° also showed decreased spreads accompanied, however, by increased adrenal gland weights. Hellman *et al.* (9) reported no change in urinary output of 17-hydroxycorticosteroids in human subjects exposed to heat stress. There was, however, an increase in aldosterone secretion.

Figure 1 shows that hyaluronidase–India ink spreads generally increased 24 hr. after removal from the heat (group B) compared to heat stress levels (group A). The differences were, however, not significant. The acute stress of swimming (Group C) caused decreased spreads at the 4, 16, and 32-day intervals compared to the 24-hr. recovery levels ($P = <0.05$ in each case). After 48 days of heat stress, however, swimming resulted in an increase in spread of 40% ($P = <0.05$) and 70% ($P = <0.01$) compared to 24 hr. recovery and heat stress levels, respectively. Swimming caused a similar rebound in spread after only 4, 8, or 16 days of cold stress (4). In this laboratory a single subcutaneous injection of cortisone acetate (5 mg./Kg. body weight) has also caused a rebound in spread in heat and cold stressed rats. In the present study, the changes in spread produced by swimming after 32 and 48 days of heat stress were not accompanied by significant alterations in adrenal gland weight. Fediay and Clay (5) have reported that the combined stress of cold and restriction of movement for 14 days resulted in increased spread, adrenal gland weight, and plasma corticosterone levels.

Spread of the India ink solution not accompanied by hyaluronidase (Fig. 2) failed to show significant differences among the various treatments.

Serum Electrophoresis—In the data presented in Table I, only a single pattern in serum protein composition can be related to dermal permeability changes. Serum albumin rose from 41% after 4 days of stress to 58% and 70% after 32 and 48 days of stress, respectively. Figure 1 shows that hyaluronidase–India ink spread in the skin fell after these time intervals. Decreased connective tissue permeability to colloidal particles might act to restrict movement of albumin out of the vascular system.

The remaining changes in serum protein composition cannot be related to alterations in connective tissue permeability.

Use of a Technique for Measuring Pulmonary Resistance to Airflow for the Pharmacological Evaluation of Bronchodilator Agents

By ROBERT G. FAMILIAR, JOE R. WARDELL, JR., and LEON C. GREENE

A technique for measuring pulmonary resistance to airflow without the interference of compliance changes was used to obtain data on the bronchodilator activity of ephedrine sulfate and methoxyphenamine hydrochloride. The resting pulmonary resistance of cats was increased by injecting histamine (100 mcg., base, i.v.) or 5-hydroxytryptophan creatinine sulfate (25 mcg., base, i.v.) or by electrical stimulation (5 v., 1.5 msec., 15 c.p.s.) of the peripheral ends of both vagus nerves. The average maximum per cent inhibition of the increase in pulmonary resistance induced by the constrictor agents was used to calculate ED_{50}'s of the test drugs. Drugs were administered either intraduodenally or intravenously. The ability to obtain valid quantitative data for the evaluation of potential bronchodilator agents offers a distinct advantage over the methods presently employed.

MEASUREMENTS of lung volume changes with constant pressure inflations or tracheal pressure changes with constant volume inflations have been used to evaluate bronchodilator agents in the intact animal (1–3). At the ventilation frequencies used, these methods are sensitive to changes in lung stiffness and relatively less sensitive to changes in pulmonary resistance to airflow (4). Such measurements are only indirectly related to airway smooth muscle tone and can be influenced by other factors such as pulmonary vascular congestion, edema, or alveolar collapse. It must be appreciated also that no valid quantitative deductions can be made from these methods about airway smooth muscle.

Obviously, a method which measures changes in airway size separate from changes in lung stiffness or lung compliance would be advantageous in the evaluation of bronchodilator agents. With a technique previously described (5), it is possible to separate these parameters and measure pulmonary resistance without the interference of compliance changes. Pulmonary resistance includes both airway resistance and tissue resistance. Tissue resistance represents only a small part of the pulmonary resistance and does not vary markedly even in pathological states (6). Therefore changes in pulmonary resistance are a valid index of changes in airway resistance. This technique has been used in the past to study the action of bronchoconstrictor agents on the airways (7–9), but has not been used for comparative pharmacological evaluation of bronchodilator agents. To demonstrate the application of this technique, two bronchodilators, ephedrine sulfate and methoxyphenamine hydrochloride, have been studied for their ability to inhibit the increase in pulmonary resistance induced by histamine, serotonin, and vagal stimulation.

EXPERIMENTAL

Cats of either sex weighing 1.6–4.0 Kg. are anesthetized with sodium pentobarbital (30 mg./Kg. i.p.), paralyzed with gallamine triethiodide (40 mg. i.v.), and respired through a tracheal cannula at a constant tidal volume (50 ml.) and frequency of 28 breaths per minute. Transpulmonary pressure (P_{tp}) is measured by introducing a No. 12 Malecot catheter through the 5th or 6th intercostal space into the pleural space, and connecting it to one side of a Statham differential pressure transducer (type PM 131 TC). The other side of this transducer is connected to a hole in the side of the tracheal cannula. Airflow is measured with a Fleisch pneumotachograph (type 0.157) in conjunction with a Statham differential pressure transducer (type PM 5 TC). A second Statham differential pressure transducer (type PM 15 TC) is also connected to the pneumotachograph, and a volume signal is obtained by electrical integration of the airflow signal from this transducer. A schematic illustration of the experimental set-up is shown in Fig. 1.

Individual parameters of transpulmonary pressure, airflow, and volume are monitored *via* their respective amplifiers on the upper screen of an Electronics for Medicine recorder (model DR 8). The lower screen of the recorder is used to monitor pulmonary resistance utilizing the subtraction technique of Mead and Whittenberger (5).

Once the resting pulmonary resistance has been established, an increase in resistance is induced either by injecting histamine (100 mcg., base) or serotonin (25 mcg. base) i.v. or by electrically stimulating the peripheral ends of cut vagus nerves. In experiments where vagal stimulation is used, the animal is pretreated 1 hr. before stimulation with 3–5 mg. of neostigmine i.v. to improve the consistency of the response. Control experiments have shown that the responses obtained with any of the constrictor agents are quite consistent over at least a 2-hr. period.

Intraduodenal Administration of Test Drug—To administer a test drug intraduodenally, a midline incision, 4 cm. long, is made in the abdomen and the duodenum is exposed. Two control responses to the constric or agent of choice are made 3 min. apart. The drug is then injected directly into the duodenum, either in suspension (0.5% tragacanth), or solution (distilled water) in a volume of 4 ml. Postdrug responses to the constrictor agent are made at 10, 20, 40, 60, 90, and 120 min.

Intravenous Administration of Test Drug—Two control responses to the constrictor agent of choice are taken 3 min. apart. The test drug is then administered i.v., in saline. Postdrug responses to the constrictor agent are made at 30 sec., 5 min., 15

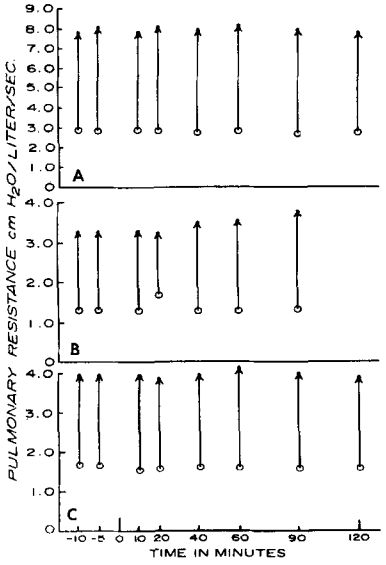

Fig. 2—Average control responses to: A, vagal stimulation (5 v., 1.5 msec., 15 c.p.s.) (two cats); B, histamine (100 mcg., i.v.) (three cats); and C, serotonin (25 mcg., i.v.) (three cats). Open circles represent pulmonary resistance preceding each administration of constrictor stimuli, while the dots on the top of the arrows represent pulmonary resistance 30 sec. after each administration. Distilled water was administered intraduodenally, 4 ml. vol. at zero time.

min., and at various intervals until the response returns to control values.

Evaluation of Data—The per cent inhibition of the increase in pulmonary resistance is calculated by the following formula. The test response is the increase in pulmonary resistance produced by the constrictor stimulus:

$$\% \text{ inhibition} = \frac{\text{av. predrug test response} - \text{postdrug test response}}{\text{av. predrug test response}} \times 100$$

The resting pulmonary resistance during the predrug period serves as the baseline for both the predrug and postdrug test responses. Postdrug test responses which are greater than the predrug value are considered zero per cent inhibition.

A dose-response curve is plotted for any test drug by obtaining a minimum of 3 to 5 individual responses for each dose, and calculating an average maximum per cent inhibition of pulmonary resistance increase. For intraduodenal administration each cat received only one dose of test drug. Several doses of a test drug, the number depending on the duration of individual responses, could be administered for intravenous evaluation. An ED_{50} and 95% Fieller limits are calculated by a method described by Finney (10).

RESULTS

Control Responses to Individual Constrictor Stimuli—The pulmonary resistance increase induced by histamine, serotonin, or vagal stimulation was consistent over time. The average results of the control experiments, in which distilled water (4 ml.) was injected intraduodenally, are shown in Fig. 2.

Intraduodenal Administration of Test Drugs—Ephedrine was shown to inhibit the pulmonary resistance increase induced by histamine, serotonin, and vagal stimulation. ED_{50}'s have been obtained for ephedrine against each of the constrictor agents. The onset of activity was between 20 and 60 min.; the duration was usually greater than 90 min. The dose-response curves are shown in Fig. 3.

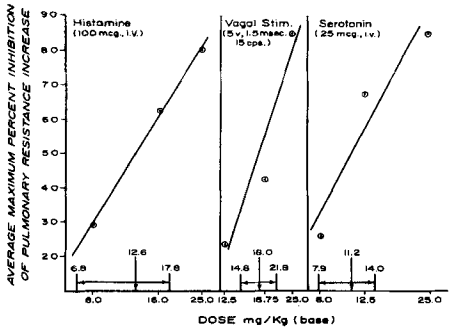

Fig. 3—Effect of intraduodenal ephedrine on the pulmonary resistance increase induced by histamine, serotonin, and vagal stimulation. Each point on the curves represents a minimum of three individual cats. ED_{50} (95% Fieller limits) in each case.

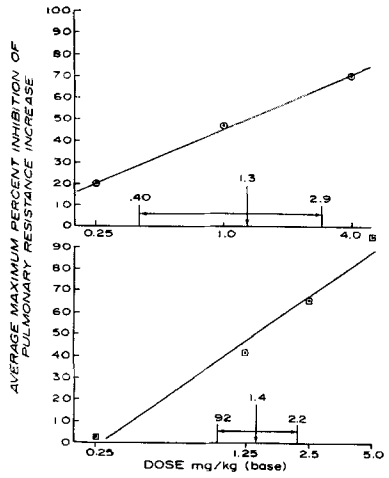

Fig. 4—Effect of intravenous ephedrine (top) and methoxyphenamine (bottom) on the pulmonary resistance increase induced by serotonin (25 mcg. i.v.). Each point on the curves represents a minimum of three responses. ED_{50} (95% Fieller limits) in each case.

Intravenous Administration of Test Drugs—To demonstrate the feasibility of using i.v. administration for drug evaluation, dose-response curves were obtained for ephedrine and methoxyphenamine against serotonin injection (25 mcg., i.v.). Both compounds were shown to inhibit the pulmonary resistance increase induced by this constrictor agent. The results are shown in Fig. 4.

DISCUSSION

The control of airway muscle has been frequently investigated. In the main, the studies fall into two categories. The first includes *in vitro* studies of the action of drugs and chemicals on excised airways or on denervated lung. Such methods are obviously unphysiological, the studies being limited to certain portions of the airways, and correlation with clinical conditions impossible. The second category includes *in vivo* studies involving the assessment of the relationship between inflation pressure and tidal volume during cyclical changes in pressure or volume. These methods measure all three pressures of breathing: elastic, resistive, and accelerative; therefore, changes in either compliance or resistance will affect the measurement. In fact, at the usual frequencies of ventilation, such measurements are relatively insensitive to changes in airway diameter (*i.e.*, resistive and accelerative forces) but are greatly influenced by alterations in lung stiffness (*i.e.*, elastic forces). Although lung compliance may change in the present method, this change is quite obvious (opening of pressure–flow trace) and correction can be made. In other words, the changes measured are due to changes in the size of the airways.

All of the agents used to induce the increase in pulmonary resistance have been implicated in hypersensitivity reactions (11–13). A more meaningful evaluation of potential bronchodilators can be made if they are compared to standard agents for their effect against all three of these constrictor stimuli, rather than any one.

The feasibility of using this method for intraduodenal drug evaluation is demonstrated in Fig. 2. The stable resting pulmonary resistance along with consistent responses to each constrictor stimulus over time makes the method ideal for this purpose. Some drugs may decrease an animal's resting pulmonary resistance in addition to inhibiting the response to a constrictor stimulus. Both effects are reflected in the calculations of drug activity since the predrug resting resistance is used as the baseline for postdrug test responses.

This method of drug evaluation offers a distinct advantage over the other methods since the measurements are not influenced to any great extent by factors such as pulmonary vascular congestion, edema, or alveolar collapse. In addition, as shown, the data can be quantitatively analyzed for a more valid comparison of test agents.

Phytopharmacologic Studies of *Ipomoea muricata* Seeds

By M. L. GUPTA, J. P. TEWARI, S. N. KHANNA*, P. C. GUPTA*, M. C. SRIVASTAVA, and S. S. MISHRA

A glycoside muricatin ($C_{28}H_{52}O_{11}$), isolated from the seeds of *I. muricata*, appears to consist of 4-*O*-L-rhamnopyranocyl-L-rhamnopyranose moiety attached glycosidically to (+)-11 hydroxyhexadecanoic acid. It is cardiac depressant, spasmolytic to the smooth musculature of gut, lowers the blood pressure of the anesthetized dog, and has no action on the respiration, uterus, skeletal muscle, and blood vessels of the frog.

UNDER the research program on systematic phytochemical and pharmacological investigations of the plants belonging to genus *Ipomoea* (5, 6, 9–11), studies on the seeds of *Ipomoea muricata* were undertaken in this department. *I. muricata* (family, Convolvulacae), commonly known as kaladana, is found in the Himalyan region from Kangra to Sikkim and on Dacan hills. Seeds of the plant are bitter, purgative, and used as a substitute for *I. hyderacea* and in powder form as febrifuge (2, 4). Leaves are used in apthous (8). In this communication, characterization and preliminary pharmacodynamic actions of the glycoside muricatin isolated from the seeds of *I. muricata* are reported.

MATERIALS AND METHODS

Chemical—The glycoside muricatin has been isolated from the petroleum ether extract of the authenticated seeds of *I. muricata* by the method of Mishra and Tewari (7).

A chemical examination of the seeds of this plant was also made by Mishra and Tewari (7). They reported an enzyme, a lipoid, an organic acid, a glucoside, $C_{30}H_{54}O_{13}.1^1/_2H_2O$, and a dark brown resinous mass. However, the glycoside muricatin (m.p. 108–109°, $[\alpha]_D^{25} - 44.5°$) isolated in the present study is a white crystalline solid. It was found to be soluble in water, methanol, ethanol, sparingly soluble in acetone, and insoluble in ether, benzene, and chloroform. The elemental analysis of muricatin indicated the empirical formula $C_{28}H_{52}O_{11}$. This water-soluble glycoside was a weak acid with neutralization equivalent 543. Acid hydrolysis yielded 2 moles of L-rhamnose and 1 mole of fatty acid. On the basis of physical and chemical studies, muricatin appears to consist of 4-*O*-L-rhamnopyranocyl-L-rhamnopyranose moiety attached glycosidically to (+)-11-hydroxyhexadecanoic acid.

Pharmacodynamic Studies of Muricatin—The pharmacodynamic actions of this water-soluble glycoside muricatin have been studied on various organ systems. In each case 10 experiments were performed to draw the inference.

To study the effect of muricatin on the frog's heart, perfusion of the frog heart *in situ* and isolated frog's heart was carried out according to the method of Bulbring, as quoted by Burn (1). The ventricular contractions were recorded on a slowly moving drum through a starling heart lever.

The effect of drug was studied on the isolated frog rectus abdominis muscle preparation (set up in a 5-ml. bath), according to the method described by Burn (1). Acetylcholine responses were obtained by offering it in a strength of 1:2,000,000 for 90 sec.

The effect of drug on carotid blood pressure, respiration, carotid occlusion response, and intestine *in situ* was studied on anesthetized mongrel dogs of either sex, weighing between 6 and 10 Kg. Sodium pentobarbital (35 mg./Kg. i.p.) was used as an anesthetic agent. Blood pressure was recorded by introducing an arterial cannula in the left carotid artery and connecting the cannula to a mercury manometer. Respiration was recorded by connecting the trachea with Mary's tambur. All the injections were made through the cannulated femoral vein. Auricular and ventricular contractions were registered in anesthetized dogs by the suspension method of Jackson (3). Intestinal movements in dogs were recorded through Jackson's enterograph.

In the dog the common carotid arteries of both sides were exposed. Gentle pressure by putting bull dog clips on both the carotid arteries for 10 sec., at a point just below the bifurcation of carotid arteries into external and internal carotid arteries, brought about occlusion and rise in blood pressure. In the case of carotid occlusion studies in dogs, the blood pressure was recorded from the femoral artery.

The action of muricatin was also observed on electrically induced contractions (preganglionic stimulation) of the cat's nictitating membrane. Experiments were also performed to study the effect of the drug on blood pressure of the cat, following spinal transection at the C_2 level, using the method of Burn (1).

The effect of the drug was observed on isolated preparations of rabbit's and rat's ileum. The freshly removed segments were suspended in a 10-ml. isolated organ bath, containing Tyrode solution (NaCl, 8.0 Gm.; KCl, 0.2 Gm.; $MgCl_2$, 0.5 Gm.; $NaHCO_3$, 1.0 Gm.; Na_2HPO_4, 0.5 Gm.; distilled water, 1 L.) maintained at 37 ± 1° and freely oxygenated.

The action was also observed on isolated uterus of the gravid and nongravid albino rat, guinea pig, and rabbit. One of the uterine horns was suspended in a 10-ml. bath containing oxygenated modified Locke's solution (NaCl, 9.0 Gm.; KCl, 0.42 Gm.; $CaCl_2$, 0.06 Gm.; glucose, 0.5 Gm.; $NaHCO_3$, 0.5 Gm.; distilled water, 1 L.) at 32°. The effect of a single dose was recorded for 90 sec. and an interval of 5 min. was allowed between the successive doses.

Blood vessels of the frog were perfused with Ringer's solution (NaCl, 0.65%; KCl, 0.014%; $CaCl_2$, 0.012%; $NaHCO_3$, 0.02%; Na_2HPO_4, 0.001%; distilled water, 100 ml.) by introducing a cannula in the innominate artery and counting the drops of perfusate. Injections of the drug were made in the ventral lymph sac.

OBSERVATIONS

Muricatin in graded doses causes a decrease in rate, amplitude, and tone of the frog's heart *in situ* and isolated frog's heart. The repetition of higher doses produced tachyphylaxis. The cardiac depressant

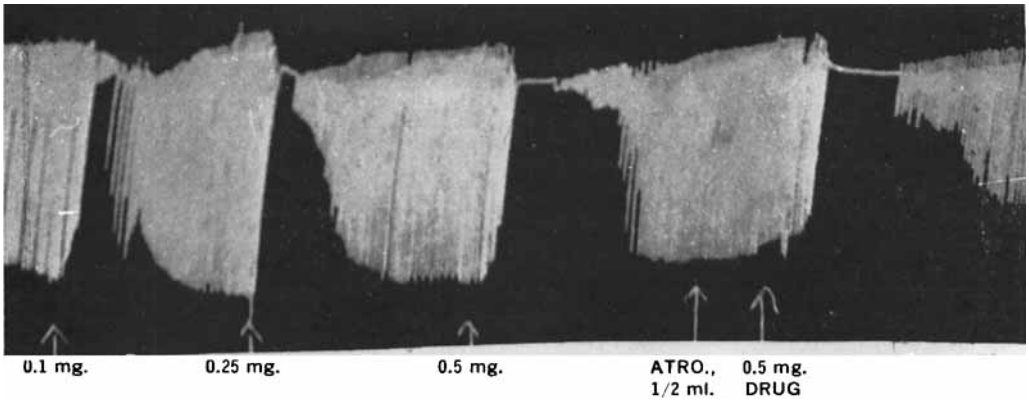

Fig. 1—Effect of muricatin on isolated frog's heart.

effect of the drug could not be blocked by pretreatment with atropine, which, however, blocked the activity of equidepressant doses of acetylcholine (Fig. 1).

Muricatin (1 mg./Kg.) caused a sharp fall in blood pressure (Fig. 2) without having any significant action on respiration of anesthetized dogs. This effect was also noticed in cats. Atropine sulfate (2 mg./Kg.) partially blocked this hypotensive effect of muricatin. But unlike acetylcholine, the drug did not give any pressure response when given after administration of atropine and eserine sulfate (1 mg./Kg.). This hypotensive effect in cats persists to the same degree even after spinal transection at the C_2 level. The hypotensive effect was more marked in experimentally induced hypertension in dogs with norepinephrine infused at the rate of 20 drops/min. at a concentration of 1:1000. Muricatin inhibited both auricles and ventricles *in situ* in dogs. The drug had no significant effect on the dog's carotid occlusion reflex and ileum *in situ* nor on electrically induced contractions of the cat's nictitating membrane.

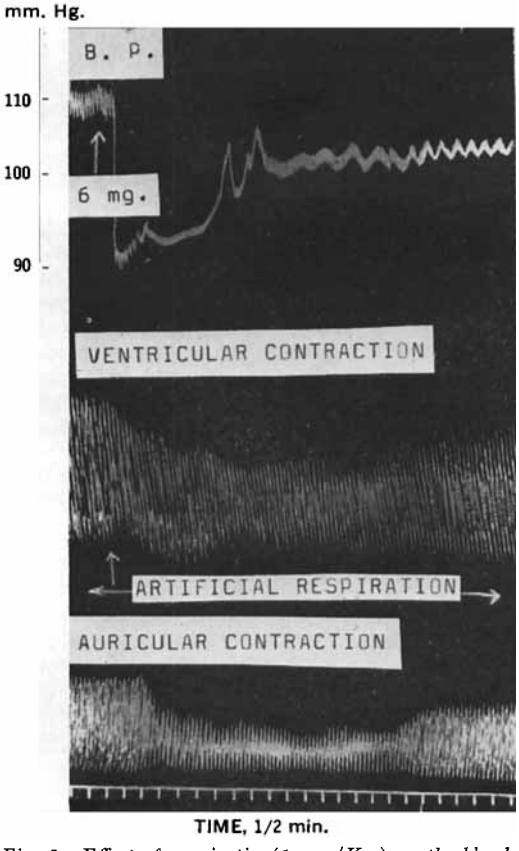

Fig. 2—Effect of muricatin (1 mg./Kg.) on the blood pressure and auriculo ventricular contractions of a female dog (6 Kg.) anesthetized with pentobarbital.

On isolated rabbit and rat ileum, muricatin in all the doses tried exhibited a spasmolytic activity. In these doses this was quite marked in magnitude. The antispasmodic activity of muricatin against spasms induced by posterior pituitary, acetylcholine chloride (0.2 mcg./ml.), histamine diphosphate (0.2 mcg./ml.), barium chloride (0.1 mg./ml.), and 5 HT (0.4 mcg./ml.) in isolated ileum of rabbit and rat has been studied. A 0.5-mg. quantity (in a bath of 10 ml.) of the drug antagonized these spasms (Fig. 3). The spasmolytic activity of papaverine was also of similar pattern, but it was about 4 to 5 times stronger in activity than muricatin in this respect.

The drug failed to have any effect on uterine strips of the various species tried and did not antagonize the spasm of the uterus induced by posterior pituitary. On the frog rectus muscle the drug had no action at any concentration. It did not affect the acetylcholine induced contractions. Muricatin had no effect on the perfused blood vessels of the frog at any concentration.

CONCLUSIONS

Ipomoea provides many plants which are employed in the Ayurvedic system of medicine. A glycoside has been isolated from *I. carnea* (12), but its pharmacological properties have not been reported.

The glycoside muricatin isolated from *I. muricata* in the present communication is water-soluble and thermostable. It shows a characteristic depressant action on the frog's heart. In older work on glycosides this was the principal effect on which attention was focused. In the initial stages fuller contractions in systole occur; various arrhythmias develop later (13).

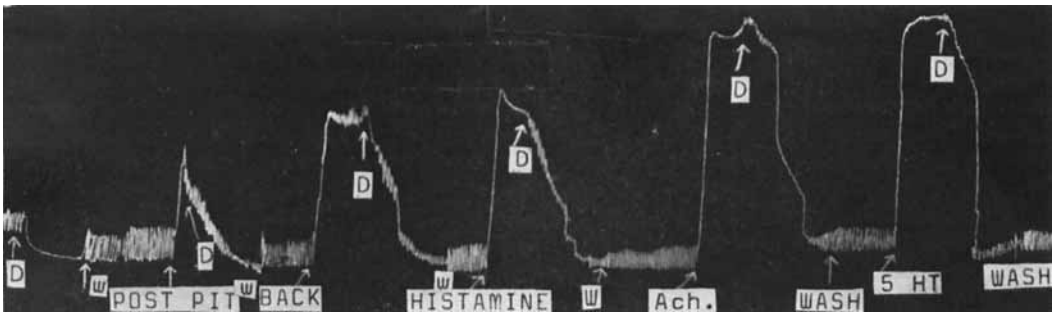

Fig. 3—Effect of muricatin on isolated rabbit ileum. Key: D, *drug (0.5 mg.).*

The blood pressure lowering property of muricatin is a characteristic response, which is partially blocked by atropinization. But this lowering of blood pressure persists even after spinal transection at the C_2 level. Therefore, it can be inferred that the lowering of blood pressure may be due to a myocardial depressant property of muricatin as evidenced by the observations on auricular and ventricular contractions.

The drug shows its benignity toward other organ systems of the body except a direct potent spasmolytic effect on gastrointestinal smooth musculature. In general, the pattern of relaxant and spasmolytic activity of muricatin was similar to that of papaverine. The difference was that the former was a weaker relaxant and spasmolytic compared to the latter. It therefore appears that the mechanism of action of muricatin on ileum is a papaverine-like, direct, nonspecific musculotropic action.

Testing of Tablets with Prolonged Action. Enzyme Activity During the Modified Half-Change Method

By W. A. RITSCHEL and H. ORTH

The enzyme activities of pepsin, pancreatic lipase, trypsin, and amylase were studied. It was found that the activity of the enzymes in freshly prepared artificial gastric fluid and in artificial intestinal fluid decreases during heating from room temperature to 37° and by keeping at 37°. To maintain proper enzyme levels during an 8-hr. interval when testing tablets with prolonged action, a modified half-change method is suggested. A survey of enzyme levels when using this modified method is given.

MANY SUBSTANCES used in tableting as excipients and fillers, such as zein, starch, stearates, and others, are digestible by gastrointestinal enzymes. Therefore, the possible effect of enzymes on disintegration and/or drug dissolution of oral tablets in *in vitro* tests must be taken into consideration, particularly in the case of procedures of several hours' duration applicable to sustained-release medication. In prolonged-release medication forms the drug is often embedded in synthetic fats such as glyceryl monostearate (1), glyceryl myristate (1), glyceryl palmitostearate (2), *etc.* Such glyceryl fatty acid esters are hydrolyzed by pancreatic lipase (3). The enzymatic hydrolysis depends on the length of the carbon chain of the fatty acids (4). The liberation of the active principle embedded in the tablet follows a characteristic inverted curve, because beside diffusion of the drug, digestion of the tablet base material takes place after 3 hr. when optimal pH conditions are reached for the enzyme activity (5). Gelatin, used as a binder in wet granulation as well as in direct compression, is liquified by trypsin (6), while casein (7) and peptides used for coatings (8) are digested. Amylose, suggested as a dry binder for direct compression (9), is digested by amylase. Gelatin, casein, and other peptides are also digested by pepsin (10).

Studying the stability of gastrointestinal enzymes in artificial gastric and intestinal fluid, it was found that the activity of the enzymes was partly destroyed during the time needed to heat the test solutions from room temperature to 37°, and while

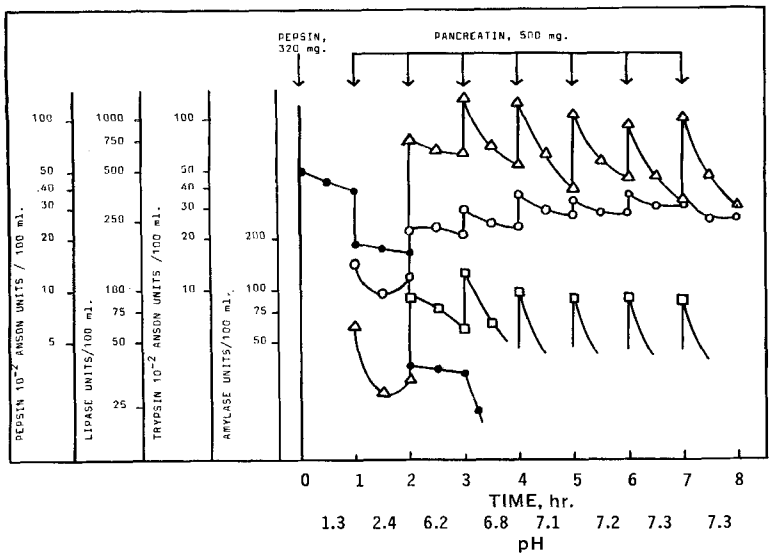

Fig. 1—Semilog plots for the ferment activity of gastrointestinal enzymes during testing with the modified half - change method at 37°. Key: ●, pepsin; △, lipase; ○, trypsin; □, amylase.

keeping artificial gastrointestinal test solutions at 37°. Loss of pepsin activity was 20% within 1 hr.; loss of lipase activity was 68% within 30 min. and 84% within 1 hr.; loss of trypsin activity was 50% within 1 hr.; and loss of amylase activity was more than 50% within 10 min. Based on the results obtained with lipase, it was felt that utilization of the principle of the so-called "half-change method" (11), in order to bring about uniformity of enzymatic activity during the course of the test period, was desirable.

EXPERIMENTAL

Materials—*Artificial Enzyme-Free Gastric Fluid*—Sodium chloride, 0.2%, and 0.7% hydrochloric acid in water. One hundred milliliters of the artificial enzyme-free gastric fluid at 37° was used in each test; 320 mg. of pepsin was added; pepsin activity was determined 30 and 60 min. thereafter.

Artificial Enzyme-Free Intestinal Fluid—Predried sodium phosphate, ($Na_2HPO_4 \cdot 2H_2O$), 0.805%, 0.165% sodium biphosphate ($NaH_2PO_4 \cdot 2H_2O$) in water. Fifty milliliters of the artificial enzyme-free intestinal fluid at 37° was used in each test.

Modified Half-Change Method—After a 60-min. interval, half of the volume of the artificial gastric fluid was withdrawn and substituted with 50 ml. of artificial enzyme-free intestinal fluid at 37°. At hourly intervals thereafter, again half of the fluid was withdrawn and substituted with fresh, prewarmed 50-ml. portions of artificial intestinal fluid. Immediately after each addition, 500 mg. of pancreatin powder was added. The test period was extended for 8 hr.

The activities of enzyme lipase, trypsin, and amylase were tested immediately after addition of each portion of pancreatin to the test solution, 30 min. thereafter, and just before the next addition.

Pepsin and trypsin were analyzed according to Anson (12); lipase activity was determined by the method described by Lazo-Wasem (13). For the estimation of amylase, a method described in the documentation of a manufacturer of pancreatin (14) was used; the method was based on the dextrinication point.

RESULTS AND DISCUSSION

The enzyme levels of the gastrointestinal enzymes during an 8-hr. run of the modified half-change method are shown in Fig. 1. Additions of pepsin and pancreatin are indicated by arrows; the different pH values of the test solution are also indicated in the figure. The change from pH 2.4 to pH 6.2 in the third hour is due to the effectiveness of the buffer substances in the artificial intestinal fluid.

It may be noted from the illustration that the pepsin level falls approximately 20% during the first hour at 37°. On substitution of half of the volume of the artificial gastric fluid by enzyme-free artificial intestinal fluid and addition of 500 mg. pancreatin, the decrease in pepsin activity corresponds to the level of dilution, but after the second substitution of the test solution by enzyme-free artificial intestinal fluid and subsequent addition of pancreatin in the third hour, remaining pepsin activity is negligible. The trypsin levels remain relatively constant during the whole test period, while lipase activity decreases to about 50% of initial between pancreatin additions. The expected amylase level could be found only after the second addition of pancreatin. The hourly additions of pancreatin result in short-lived measurable amylase levels.

Testing with the modified half-change method at a lower temperature to improve enzyme stability is not feasible since optimum enzyme activity depends on temperature and is correspondingly decreased at room or cooler temperatures.

The results obtained indicate that, when testing oral depot tablets, the dissolution or disintegration of which is dependent on gastrointestinal enzymes, it is necessary to use a method such as the "modified half-change method" in order to obtain uniformly effective enzyme levels.

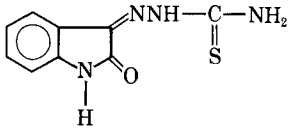
Thiosemicarbazones Derived from Indanedione-1,3

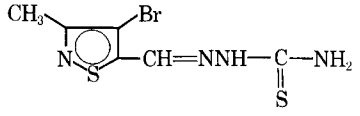
By RAJENDRA S. VARMA and W. LEWIS NOBLES

A series of thiosemicarbazones derived from indanedione-1,3 has been synthesized. Preliminary biological screening data are provided.

ANTIVIRAL (1–7) and tuberculostatic (8–14) activity has been reported for thiosemicarbazones of different carbonyl compounds. Further work on the thiosemicarbazones led to the discovery of the antiviral activity of isatin-3-thiosemicarbazone (I) against the pox group of viruses in human and type 2 polio in ERK cells (15). A number of monocyclic thiosemicarbazones derived from nicotinaldehyde, isonicotinaldehyde, and 2- and 3-thenaldehydes have also exhibited high antiviral activity (5). 4-Bromo-3-methylisothiazole-5-carboxaldehyde thiosemicarbazone (II), when given orally, was found to protect mice infected intracerebrally with neurovaccinia (15). Thiosemicarbazones derived from substituted pyrrolidine-2,3-diones demonstrated protection against experimental influenza infection in mice (15).



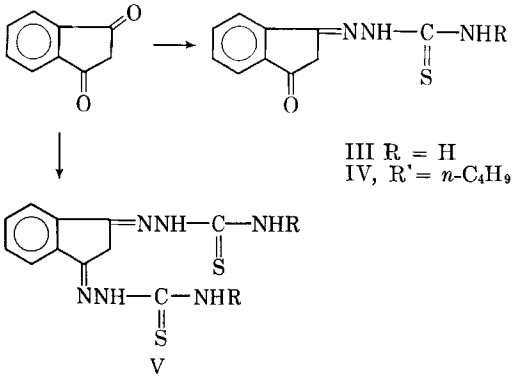
I



II

In view of the antiviral, antituberculous, and antitumor (16, 17) activity demonstrated by certain thiosemicarbazones, the synthesis and biological evaluation of compounds III, IV, and V appeared to be of interest (Scheme I).

Biological Evaluation—Several of the compounds described in this report have been subjected to preliminary antiviral and antibacterial screening procedures. The method with respect to the antiviral screening involved the use of the plastic panel and agar diffusion techniques and, in general, the



III R = H
IV, R' = n-C_4H_9

Scheme I

compounds were screened for possible activity against poliomyelitis type II, *Herpes simplex*, measles, and parainfluenza 3(HA-1) viruses.

In connection with the antibacterial screening, filter paper disks (6.35 mm.) saturated with 2 drops of a suspension of the test compounds (20 mg./ml. in alcohol or water) were tested with various organisms by the use of the agar diffusion method.

Indanedione-1,3-*n*-butylthiosemicarbazone demonstrated activity against the poliomyelitis type II virus as did the indanedione-1,3-methyl dithiosemicarbazone. The other compounds were inactive in this preliminary antiviral screen.

Indanedione-1,3-allyldithiosemicarbazone demonstrated a zone inhibition of 7.5 mm. diameter in the antibacterial screening against *Klebsiella pneumoniae* ATCC 8052; the other compounds reported were inactive against a variety of Gram-positive and Gram-negative organisms utilized in this *in vitro* screening procedure.

EXPERIMENTAL[1]

Indanedione-1,3-thiosemicarbazone (III)—Indanedione-1,3 (0.05 mole) was dissolved in 50 ml. of hot ethanol. To this solution a slurry of thiosemicarbazide (0.05 mole) in 50 ml. of ethanol was added. Instantaneous condensation occurred resulting in the separation of a yellow solid. The reaction mixture was heated for 10 min. and allowed to cool to room temperature. The product was removed by filtration and crystallized from dimethyl-

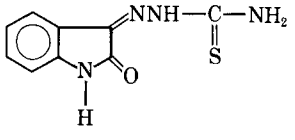
Thiosemicarbazones Derived from Indanedione-1,3

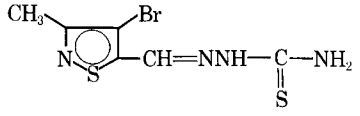
By RAJENDRA S. VARMA and W. LEWIS NOBLES

A series of thiosemicarbazones derived from indanedione-1,3 has been synthesized. Preliminary biological screening data are provided.

ANTIVIRAL (1–7) and tuberculostatic (8–14) activity has been reported for thiosemicarbazones of different carbonyl compounds. Further work on the thiosemicarbazones led to the discovery of the antiviral activity of isatin-3-thiosemicarbazone (I) against the pox group of viruses in human and type 2 polio in ERK cells (15). A number of monocyclic thiosemicarbazones derived from nicotinaldehyde, isonicotinaldehyde, and 2- and 3-thenaldehydes have also exhibited high antiviral activity (5). 4-Bromo-3-methylisothiazole-5-carboxaldehyde thiosemicarbazone (II), when given orally, was found to protect mice infected intracerebrally with neurovaccinia (15). Thiosemicarbazones derived from substituted pyrrolidine-2,3-diones demonstrated protection against experimental influenza infection in mice (15).



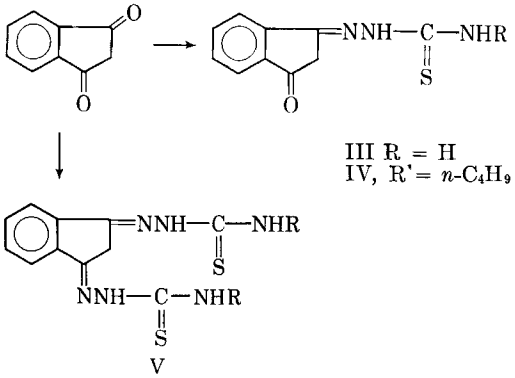
I



II

In view of the antiviral, antituberculous, and antitumor (16, 17) activity demonstrated by certain thiosemicarbazones, the synthesis and biological evaluation of compounds III, IV, and V appeared to be of interest (Scheme I).

Biological Evaluation—Several of the compounds described in this report have been subjected to preliminary antiviral and antibacterial screening procedures. The method with respect to the antiviral screening involved the use of the plastic panel and agar diffusion techniques and, in general, the



III R = H
IV, R' = n-C_4H_9

Scheme I

compounds were screened for possible activity against poliomyelitis type II, *Herpes simplex*, measles, and parainfluenza 3(HA-1) viruses.

In connection with the antibacterial screening, filter paper disks (6.35 mm.) saturated with 2 drops of a suspension of the test compounds (20 mg./ml. in alcohol or water) were tested with various organisms by the use of the agar diffusion method.

Indanedione-1,3-*n*-butylthiosemicarbazone demonstrated activity against the poliomyelitis type II virus as did the indanedione-1,3-methyl dithiosemicarbazone. The other compounds were inactive in this preliminary antiviral screen.

Indanedione-1,3-allyldithiosemicarbazone demonstrated a zone inhibition of 7.5 mm. diameter in the antibacterial screening against *Klebsiella pneumoniae* ATCC 8052; the other compounds reported were inactive against a variety of Gram-positive and Gram-negative organisms utilized in this *in vitro* screening procedure.

formamide–water. Yield 10.5 Gm. (96%), m.p. 230–232° dec. $\nu_{max.}^{KBr}$ 5.85 μ (carbonyl).

Anal.—Calcd. for: $C_{10}H_9N_3OS$: C, 54.79; H, 4.13; N, 19.17. Found: C, 54.82; H, 4.19; N, 19.03.

Indanedione-1,3-n-butylthiosemicarbazone (IV)—To a boiling solution of 4-*n*-butylthiosemicarbazide (0.02 mole) in 25 ml. of ethanol was added indanedione (0.02 mole) dissolved in 25 ml. of ethanol. The resulting reaction mixture was refluxed for 20 min. A solid product separated on cooling; this was suspended in 100 ml. of ethanol–acetone mixture (1:1). The suspension was stirred and filtered. The filtrate, upon refrigeration, yielded a crystalline solid melting in the range of 173–174°. Yield, 5.0 Gm. (91%). $\nu_{max.}^{Nujol}$ 5.88 μ (carbonyl).

Anal.—Calcd. for: $C_{14}H_{17}N_3OS$: C, 61.07; H, 6.22; N, 15.26. Found: C, 61.11; H, 6.14; N, 15.10.

Indanedione-1,3-dithiosemicarbazones—The appropriate thiosemicarbazide (0.15 mole) was dissolved in 50 ml. of ethanol; to this there was added indanedione (0.05 mole). The resulting reaction mixture was refluxed for 4 hr. At the end of this period, the contents were cooled and the product removed by filtration and washed with ethanol. The thiosemicarbazones were recrystallized either from ethyl-acetate or ethanol–dimethylformamide–water. The analyses, melting points, and other pertinent data are recorded in Table I.

Dualistic Thiourea Moiety Taste Response of Methimazole

By GLENN H. HAMOR and AIDA LAFDJIAN

Determination of the taste responses to phenylthiourea, to propylthiouracil, and to 1-methyl-2-mercaptoimidazole (methimazole) using impregnated filter paper strips on a group of 191 individuals showed that methimazole, contrary to its literature description of "almost no taste," is quite bitter to 30 per cent of the population studied, and does possess a dualistic taste similar to the other two compounds tested.

INDIVIDUALS differ in their ability to taste substances containing the thioureylene, —NHCS-NH—, or thiocarbamoyl, —NHC(S)— groups. Phenylthiourea and the cyclic thioureide, propylthiouracil, taste bitter to a considerable portion of the population, and tasteless to the rest; the inability to taste is apparently a recessive, inherited Mendelian characteristic (1–3). Structures of representative compounds, with their taste responses, are given in Figs. 1–3.

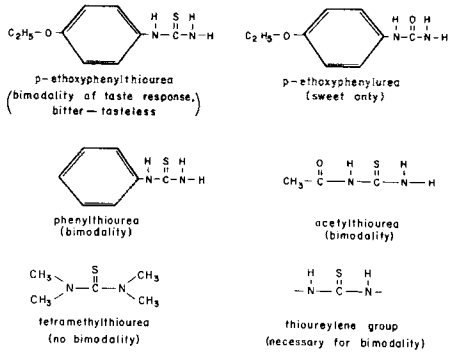

Fig. 1—Thiourea derivatives with taste responses.

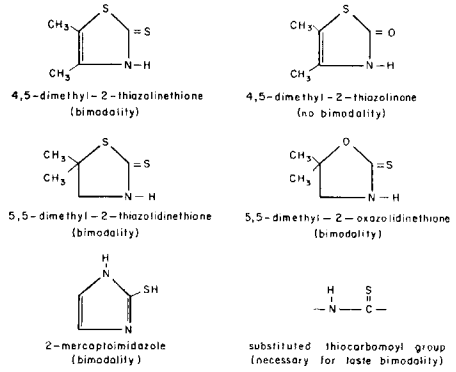

Fig. 2—Thiourea derivatives with taste responses.

The antithyroid substances, L-5-vinyl-2-oxazolidinethione (goitrin) (4, 5), 2-mercaptoimidazole (2), and propylthiouracil (2) possess the dualistic taste response. Harris, Kalmus, and Trotter found that nontasters of phenylthiourea were slightly more prone to develop adenomatous goiter than tasters (6). This finding has been confirmed by Kitchin *et al.*, who also found that toxic diffuse goiter is more prevalent among tasters (7). Shepard and Gartler

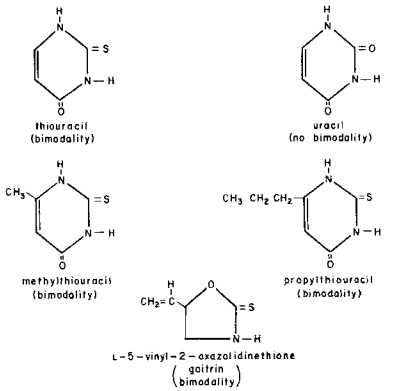

Fig. 3—Thiourea derivatives with taste responses.

reported an increased incidence of nontasters of phenylthiourea among congenital athyreotic cretins (8).

This study extends the determination of the taste response to the antithyroid drug, 1-methyl-2-mercaptoimidazole (methimazole). The propylthiouracil taste response and the phenylthiourea taste threshold were also determined. In order to contribute data to help in possible correlation of taste and thyroid disease, the phenylthiourea taste threshold was also ascertained on a group of thyroid patients. The three compounds in this study are shown in Fig. 4.

EXPERIMENTAL

Serial Dilutions Method—The phenylthiourea taste threshold was determined by the serial dilutions method of Harris and Kalmus (2). A control

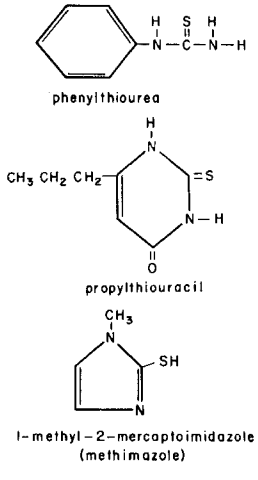

Fig. 4—Structures of compounds studied.

TABLE I—SUMMARY OF TASTE RESPONSES TO MEDICATED PAPER STRIPS

Impregnating Soln. Concn. Gm./100 ml.	Drug	Total	Tasters	Nontasters	Percentage of Nontasters
		Weak			
0.040	Phenylthiourea	191	97	94	49.2
0.040	Propylthiouracil	191	92	99	51.8
0.040	Methimazole	191	56	135	70.6
		Strong			
1.0	Phenylthiourea	279	246	33	11.8
1.0	Propylthiouracil	279	240	39	13.9

group of 171 individuals[1] were tested with 14 concentrations of phenylthiourea. Dilution No. 1 contains 1300 mg./L., and each subsequent number dilution is one-half the strength of the preceding concentration. The threshold is the weakest concentration at which the individual is able to differentiate four cups of distilled water from four cups of the test concentration. The people tested were then divided into two groups; tasters are persons who can distinguish phenylthiourea solutions numbered 5 (81.25 mg./L.) or higher, and nontasters are those who can taste only solutions numbered 4 (162.5 mg./L.) or lower. The phenylthiourea taste threshold was also determined on a group of 148 thyroid patients.[2]

Filter Paper Strip Method—The paper strip method of Parr (9) was used to obtain the relative taste response of persons to phenylthiourea, propylthiouracil, and methimazole,[3] and to establish a correlation between this and the serial dilutions method. Two types of filter paper strips were used for phenylthiourea and propylthiouracil. One type was prepared by soaking the paper strips in a 1% solution of the drug, so that each strip contained approximately 2.5 mg. of compound, which is nearly equal to the 2.6 mg. found in 8 ml. of solution No. 3 in the serial dilutions method. A weaker concentration paper strip was prepared by immersing the strips in a 0.04% solution of the substance in acetone, so that each strip contained about 0.1 mg. of drug, corresponding to the 0.08 mg. present in 8 ml. of the serial dilutions No. 8. Only the more weakly medicated strips of methimazole were prepared.

In the procedure of tasting, the persons were asked to put the weaker of the two strips on the back of the tongue, where sensitivity to bitter taste is pronounced. When a taste sensation was observed, a blank strip was given in order to check the result. If the strip with weak medication did not produce a sensation, the stronger was administered (except in the case of methimazole).

Using the serial dilutions method, the percentage of nontasters found in the white control group of 134 students was 21.6; while that found in 37 Mongolian students was 8.1. Preliminary data obtained by similar performance of the phenylthiourea threshold on a group of 148 thyroid patients indicates a relatively high percentage of nontasters in euthyroid patients and in male thyroid patients, with a low percentage of nontasters in hyperthyroid individuals.

Table I shows that methimazole, like phenylthiourea and propylthiouracil, exhibits the dualistic taste response; and contrary to its literature description of "almost no taste" (10), it is quite bitter to almost 30% of the population. Nontaster percentages found for filter paper strips weakly medicated with phenylthiourea, propylthiouracil, and methimazole were 49.2, 51.8, and 70.6, respectively. Therefore, taste sensitivity to phenylthiourea was the strongest, followed closely by propylthiouracil, whereas sensitivity to methimazole was lower. A similar correlation was observed with strongly medicated phenylthiourea and propylthiouracil paper strips, the percentage of nontasters being, respectively, 11.8 and 13.9.

[1] Consisting mainly of first year students at the School of Pharmacy, University of Southern California, Los Angeles.

Oxidation of Benzyl Alcohol and Benzaldehyde with Xenon Trioxide

By HAROLD J. RHODES, RONALD KLUZA, and MARTIN I. BLAKE

Benzyl alcohol is oxidized by xenon trioxide in acidic or neutral solution to benzaldehyde and benzoic acid. The course of the reaction was followed by gas chromatography. Thin-layer chromatography was used to identify the products of oxidation.

THE OXIDIZING properties of xenon trioxide in aqueous solution have been reported by Williamson and Koch (1) and by Appelman and Malm (2). In acid solution xenon trioxide was shown to be a very powerful oxidizing agent with the advantage that in the reduced form (xenon gas) it is relatively insoluble and does not contaminate the reaction mixture. However, only a few reports have appeared in the literature dealing with the application to the oxidation of organic compounds. Jaselskis and Vas (3) performed a series of qualitative studies on the oxidation of certain *vic*-diols with xenon trioxide. It was presumed that the reactivity of this oxidizing agent was similar to that of periodic acid. Xenon trioxide was found to react readily with ethylene glycol, 2,3-butanediol, and certain primary alcohols in neutral and basic solution. No reaction was noted in acidic solution. In a subsequent paper Jaselskis and Warriner (4) reported a quantitative method for the determination of primary and secondary aliphatic alcohols in aqueous solution. This study was limited to methanol, ethanol, and 2-propanol. It was applicable for both macro and semimicro quantities of alcohol. Jaselskis and Krueger (5) extended the procedure to include a series of mono- and dicarboxylic acids.

In the present paper the xenon trioxide oxidation of benzyl alcohol and benzaldehyde to benzoic acid is reported.

EXPERIMENTAL

Apparatus—A WCLID 1670 gas chromatograph[1] was employed for detection of the products of oxidation and for following the course of the reaction. It was equipped with dual hydrogen flame ionization detectors and stainless steel columns. The 6 ft. × 1/8 in. o.d. columns[2] were packed with 60–80 mesh flux calcined diatomaceous earth coated with 15% diethylene glycol succinate and 13% phosphoric acid.[3] The columns were operated at the following temperatures: 140° for the determination of benzyl alcohol, 120° for benzaldehyde, and 195° for benzoic acid. The injection port was maintained at 200°. A Hamilton syringe (701-N) was employed for injection of samples. Hydrogen gas flow rate was maintained at 5 ml./min., air at 300 ml./min., and nitrogen gas at 50 ml./min.

For the thin-layer chromatography studies, 20 × 5 cm. glass plates, a Desaga variable-gate spreader, and cylindrical development tank were used. A Mineralight ultraviolet lamp,[4] short wave UVS-12, was employed for visualization of colorless zones.

Solutions and Reagents—Benzyl alcohol solution was 0.05 *M* in concentration. For benzoic acid and benzaldehyde, saturated solutions in water were used. Xenon trioxide solution was 0.02 or 0.06 *M* and was prepared by diluting a concentrate (0.2 *M*) with water. The preparation of concentrated xenon oxide solutions is described by Appelman and Malm (2). Since solid xenon trioxide has a tendency to explode, solutions were stored in tightly stoppered flasks at all times. A saturated aqueous solution of potassium iodide was kept at hand to inactivate any spilled or unspent xenon trioxide solution.

Ammoniacal fuchsin reagent (6), 2,4-dinitrophenylhydrazine T.S. (7), and ferric chloride T.S. (6) were used for identification of benzaldehyde and benzoic acid.

Silica Gel HF_{254} (Merck) and Silica Gel G according to Stahl were used for the preparation of the thin-layer chromatographic plates. All chemicals and solvents were reagent grade.

Procedure—*Gas Chromatography*—Exactly 250 μl. of 0.05 *M* benzyl alcohol and 250 μl. of 0.06 *M* xenon trioxide solution were transferred by micropipet to a 2 dr. clear glass screw-top vial. The vial was tightly capped and permitted to stand at room temperature. Corresponding reaction mixtures of benzaldehyde and benzoic acid were prepared in a similar manner. Four controls were prepared containing 250 μl. of the following solutions: benzyl alcohol, benzaldehyde, benzoic acid, and xenon trioxide.

One microliter of each reaction mixture was injected into the gas chromatograph at zero time, after 5 min., and then every 15 min. for 9 hr. The retention times for the oxidation products were determined. The control solutions were injected into the chromatograph and retention times were calculated and used for identification of the oxidation products. The concentrations of the components were calculated by integration of the peak areas and comparison with those obtained from standard solutions of varying concentrations.

Thin-Layer Chromatography—Exactly 250 μl. of 0.05 *M* benzyl alcohol and 500 μl. of 0.02 *M* xenon trioxide solution were transferred by micropipet to a 2 dr. vial. A second reaction mixture was prepared using exactly 250 μl. of 0.025 *M* benzaldehyde solution in place of the benzyl alcohol. The vials were tightly stoppered and permitted to stand at room temperature for 48 hr.

Adsorbent layers, 500 μ in thickness, were prepared by applying aqueous slurries (40 Gm. with 100 ml. water) of Silica Gel HF_{254} or Silica Gel G onto glass plates. Air-drying overnight at room temperature provided adequate activation of the adsorbents. Sample solutions of the reaction mixtures and controls were each spotted portionwise in 5-μl. quantities. Development of the plates was conducted in an ascending manner in tanks pre-

viously equilibrated for 20 min. with the appropriate solvent mixture. Visualization of the plates was carried out either directly or by scanning with an ultraviolet lamp.

For the detection of benzoic acid, a plate layered with Silica Gel HF_{254} was spotted with the reaction mixtures and a control solution of benzoic acid, developed 70 min. to a solvent front migration of 14.7 cm. with chloroform–cyclohexane–acetic acid (80:20:10), and visualized by ultraviolet light scanning.

For the detection of benzaldehyde, aliquots of the benzyl alcohol reaction mixture and a control solution of benzaldehyde were first treated with an excess of 2,4-dinitrophenylhydrazine T.S., before spotting on an adsorbent layer of Silica Gel G. A sample of the 2,4-dinitrophenylhydrazine T.S., as a control, was also spotted on the plate. The chromatogram was developed for 30 min. to a solvent front migration of 17.0 cm. with benzene–ethyl acetate (95:5), air-dried, and examined visually.

RESULTS AND DISCUSSION

In acidic or neutral solution benzyl alcohol is oxidized at room temperature, first to benzaldehyde, and then to benzoic acid. The course of the reaction was followed by vapor phase chromatography. The data are shown in Table I. The retention times for benzyl alcohol, benzaldehyde, and benzoic acid were 65, 54, and 40 sec. The half-time for the oxidation of benzyl alcohol to benzaldehyde was 165 min., and for benzaldehyde it was 285 min. The presence of benzaldehyde and benzoic acid in the reaction mixture was confirmed by comparison of the retention times with those of the control solutions. In addition, the reaction mixture was augmented with samples of known benzaldehyde and benzoic acid. Single peaks were produced for each component and the area under the curve increased by the amount of the component added to the reaction mixture. The presence of benzaldehyde and benzoic acid in the reaction mixture was further confirmed by testing qualitatively with ammoniacal fuchsin and ferric chloride test solutions, respectively.

The reaction mixture was also studied by thin-layer chromatography of Silica Gel HF_{254}, a fluorescent adsorbent. Prior to development, the spotted zones at the origin appeared as dark areas against a brightly fluorescent background when viewed under ultraviolet light. After development of the chromatogram, dark zones were detected at an R_f of 0.65 for the reaction mixtures as well as for the known benzoic acid sample. This test confirmed the presence of benzoic acid in the reaction mixtures. The test proved unsatisfactory for the detection of benzaldehyde because of its loss by volatilization during the drying treatment of the chromatogram. Detection of benzaldehyde, however, was successful through the formation of the 2,4-dinitrophenylhydrazone derivative. The benzaldehyde in the reaction mixture and a known sample of benzaldehyde were converted to the hydrazone derivative which was detected as bright yellow zones on Silica Gel G with an R_f value of 0.75. A corresponding zone was absent for the reagent sample which served as a control. A yellow zone corresponding to 2,4-dinitrophenylhydrazine and having an R_f of 0.50 was apparent for the reaction mixture, the known benzaldehyde solution, and the reagent solution.

Under the conditions of this study the reaction appears to be quantitative. Further studies are now in progress involving the oxidation of other aromatic alcohols, certain organic sulfides, and a variety of amines.

THIS SURVEY of the literature is the fifth compilation to be published in *J. Pharm. Sci.* (1–4). It represents a comprehensive cross-section of the research and development efforts in the various disciplines of the pharmaceutical sciences. Numerous periodicals and selected sections of *Chemical Abstracts* were selectively abstracted. Two changes have been made from the 1965 literature review. The *Pharmacognosy* section has been discontinued and sections on *Sustained Release* and *Cosmetics* have been created. In order to maintain continuity with the previous pharmaceutical sciences reviews of *J. Pharm. Sci.*, their general format was retained.

GENERAL PHARMACY

A series of papers presented an exhaustive review of the problems associated with the production and marketing of new drugs (5, 6). Another survey outlined the application of a broad knowledge of physical and chemical properties of materials in the formulation of new drugs into suitable dosage forms (7). A systematic

approach to the development of a product formula, using the development of a gelled alcoholic formulation as an example, was described (8). The problems involved in the construction, design, and equipment of a new drug plant were reviewed (9). Meyers described in detail the information which might be supplied to obtain approval for marketing a new drug (10). He also commented on good record keeping as essential to maintaining high standards of quality control (11). Another review article, containing 54 references, was concerned with the application of statistical methodology in quality control functions of the pharmaceutical industry (12). The need for good quality control and how it can be achieved was stressed (13). A discussion of the need for good record keeping during the manufacturing and prepackaging of drugs was also published (14).

Excellent review articles on over-the-counter (O-T-C) antacids, O-T-C antiacne aids, O-T-C laxatives, cough depressants, nasal decongestants, antihistamines and other allergy aids, sleep aids and other O-T-C sedatives, and dry skin and chapping aids appeared in *J. Am. Pharm. Assoc.* (15–22). A survey on dimethylsulfoxide also appeared in the literature (23).

Preservatives—Garrett suggested a basic model for the quantification of preservative action which considered the thermodynamic activity of the biologically effective concentration of the preservative in the aqueous phase (24). Instructions and tabulated data, with general rules and exceptions for testing and preservation of medicinals, were published (25). Methods for the evaluation of preservative systems in proprietary products were discussed (26). The factors affecting the binding of phenol derivatives to *Micrococcus lysodeikticus* cells were evaluated (27). Another study was concerned with the stability of chlorobutanol in aqueous solutions (28). Another paper assessed the importance of the lack of moisture to prevent the growth of microorganisms in soap (29). The results of tests on 41 different preservatives in polypeptide containing cosmetic formulations were described (30). In a study designed to examine the effects of preservatives on the aging characteristics of acacia solutions, the unpreserved control solution showed the most pronounced reduction in pH and viscosity (31).

Paruta and Sheth determined the solubilities of methyl, ethyl, propyl, butyl, and benzylparabens in syrup vehicles of varying concentration (32). The effect of surfactants on activity of phenolic-type germicides and preservatives was reviewed (33). The addition of surfactants to 1,3-dichloro-5,5-dimethylhydantoin increased its solubility but did not impair its bactericidal activity as tested on staphylococcus (34). The interaction between methyl *p*-hydroxybenzoate and polysorbate 80[1] has been determined using a molecular sieve technique (35). The use of the Coulter counter to detect the inactivation of preservatives by polysorbate 80 was demonstrated (36). In another study benzoic acid was shown to interact with glycol ethers in water and in aqueous polysorbate 80 solutions (37).

Flavor, Aroma, and Color—Wesley discussed the possibility of using flavor combinations called nondescript flavors instead of individual flavors to get the desired taste for products (38). Several useful tips were presented toward the achievement of good taste and mouthfeel in a vehicle as well as high resistance to cap-locking (39). The solubilization of essential oils by surfactants was the subject of two papers (40, 41). A complete review of sweetening agents was presented (42). One paper showed a direct dependence of relative sweetness on hydrophobic bonding (43). In another paper the use of malic acid in place of citric acid in hard candy was discussed (44). The mechanism of chemical excitation of taste and olfactory receptors was shown to depend upon adsorption of the stimulus molecules to the receptor surfaces (45). The present state of the stereochemical theory of odor was described (46). Some 400 essential oils and pure perfumes were examined for suitability to scent aerosol products (47).

Bhatia, Sokoloski, and Bhatia studied dye–polyethylene glycol 6000 interactions in film-coating solutions and their effect on color uniformity (48). Carotenoids were successfully incorporated into sugar-coated tablets as color agents (49). In another paper the fading of colors was attributed to reduction or oxidation of the dyes; the actual mechanism was not determined (50). In two publications concerned with the influence of ultraviolet absorbers on the color stability of certified dyes, one paper showed the ultraviolet absorbers have little value as color stabilizers for tablet coating, whereas the other publication showed the ultraviolet absorbers can be used to protect certified colors against fading by incorporating the absorbers into the product or into the coating of the package (51, 52). A modified Godlove's equation was adapted to the color changes of various pharmaceutical preparations (53).

Adjuvants—The effect of humidity and temperature on the cohesion of wheat starch,

[1] Marketed as Tween 80 by Atlas Chemical Industries, Inc., Wilmington, Del.

cornstarch, potato starch, acacia, tragacanth, alginic acid, lactose, dextrose, and sucrose powders was determined by Shotton and Harb (54). Anhydrous lactose was found to possess excellent tableting properties and could be run directly on a high-speed tablet machine (55). The montmorillonites were studied for their use as disintegrants, binders, and lubricants in the manufacture of compressed tablets (56). Experimental data indicated that inositol, due to its nonhygroscopic nature, chemical inertness, nontoxicity, physical stability, superior mouthfeel, and texture, could be beneficially employed as the base for the formulation of chewable tablets (57). Other researchers reported on the use of mannitol as the preferred excipient for chewable tablets (58). Microcrystalline cellulose has been recommended as an extremely valuable tableting agent (59). Based on the results of compression effects, physical properties, stability, and drug availability, amylose was shown to have the characteristics desired of the ideal direct compression tablet binder (60). The utilization of sodium carboxymethylcellulose in the preparation of tablets has been proposed (61). Other investigators announced the use of haluasite, a clay mineral of the kaolinite group, as a useful tablet ingredient (62).

The application of silicones to cosmetic and pharmaceutical preparations was the object of publications by Leberl and Dias (63, 64). The relative effects of tortuosity, electrostatic attraction, and increased viscosity of water on the self-diffusion rates of cations in bentonite–water systems were described (65). Karaya gum and ghatti gum were found to be good emulsifying agents at all pH's (66). Corn oil was found to be less stable to oxidation than olive oil in the formulation of topical preparations (67). Malucidin, a protein obtained from brewer's yeast, has been recommended for cosmetic use in the formulation of skin and hair products (68).

Stability—A paper by Parrott discussed the stability of pharmaceuticals, covering parameters such as biological contamination, container, light, age, temperature, moisture, and oxidation (69). Those properties of emulsions, suspensions, and solids which are amenable to measurement and which can be used as parameters for establishing and predicting deterioration of finished consumer products were considered (70, 71). Another report examined seven of the most important chemical reactions taking place during the storage of drugs. Examples of each kind of reaction were given; the kinetics and parameters of these reactions were discussed and counteracting agents were suggested (72). An apparatus for accelerated temperature cycling was disclosed (73). A comparison of short-time storage tests at higher temperatures with the usual commercial storage time period has been made (74). An outline of recommendations regarding methods for accelerated testing of the stability of pharmaceutical preparations has been presented (75). Refractometry was used as a tool to measure the stability of solutions of pharmaceutical preparations (76).

Several investigators studied the hydrolysis of acetylsalicylic acid in the presence of accompanying substances in powder mixtures. Decomposition was shown to be dependent on the pH of the powder mixture (77–79). Brown *et al.* enhanced the stability of pilocarpine hydrochloride solutions by adding methylcellulose (80). The degradation of sodium bisulfite in dextrose solutions was followed (81). Ergotamine injections were stabilized by the addition of ethylenediaminetetraacetic acid and thiourea (82). Heat sterilization (100° for 15 min.) did not affect solutions of lobeline which were acidified to pH 2.8–4.0 by the addition of hydrochloric acid or sodium bisulfite (83).

Doppert and Staverman investigated the kinetics of the retrogradation of amylose in aqueous solutions of pH 4.0, 9.2, and 11.9 (84). In another study the degradation of pectin by γ-radiation under various moisture conditions was reported (85). The autooxidation of fats and oils was shown to be a chain reaction catalyzed by traces of metals or enzymes from bacteria or fungi (86). The results of stability tests of several medium-chain and liquid long-chain triglycerides have been correlated with the results of peroxide number determinations after storage (87). The effect of antioxidants on the stability of hydrated and anhydrous ointment bases was tested (88). Phenylbutazone stability in suppositories was shown to be dependent on the vehicle employed (89). The stability of chloramine-T in acidified aqueous solutions was recorded (90). Matsuoka *et al.* reported that α-chymotrypsin in aqueous solution is stabilized by the addition of glyceryl acetate (91). Standards have been suggested for shipping thermolabile drugs and biologicals (92). The use of tartaric acid as an efficient synergist for antioxidant action in cosmetic products was reported (93).

Stability Kinetics—A detailed analysis was presented on the use of the first-order rate equation with data which only approximates first-order kinetics (94). Pincock and Kiovsky published on the kinetics of reactions in frozen solutions (95). Some of the methods currently

available for studying chemical reactions in the time range 1 to 10^{-10} sec. were considered in another publication (96). A review, with 134 references, covered the subject of acid-catalyzed hydrolysis of glycosides (97).

The rates of hydrolysis of chlorobutanol were found to be reduced by surface-active agents but not by polyethylene glycols (98). Other workers investigated the rates of alkaline hydrolysis of ethyl benzoates in water and in aqueous dimethylsulfoxides (99, 100). The optimum pH for the stability of injection solutions of tetracaine HCl (dicaine), bencaine, and procaine was reported as 3.8, 2.7, 4.4, respectively (101). A difference in rate of degradation of phenobarbital and pentobarbital in alkaline solution was shown (102). The hydroxyl ion-catalyzed hydrolysis of glyceryl esters in aqueous medium in pharmaceutical systems was investigated (103).

Wadke and Guttman showed that the unionized species were much more susceptible to hydrolysis than the ionized form while investigating the hydrolytic behavior of 9-methylisoalloxazine (104, 105). The heats of activation for the reaction of nonionized isoniazid and isoniazid-anion were found to be approximately 11 and 5.6 Kcal./mole, respectively (106). The order of reactions, rate constants, and half-life periods for the hydrolysis of acetylsalicylic acid occurring in aqueous solution in the presence of the salts of phenobarbital,[2] codeine, caffeine, sodium benzoate, magnesium oxide, calcium oxide, calcium carbonate, and calcium gluconate were studied (107). The kinetics of hydrolysis of colchicine and some related tropolone methyl ethers were announced (108). The decomposition of idoxuridine was shown to be first order and maximum stability in solution was obtained at pH's below 7.0 (109). A series of publications on phenothiazine derivatives appeared in the literature (110–114): the rate of photooxidation of propericiazine and its sulfoxide increased with increasing amounts of oxygen and lowering pH; acetylpromazine and its sulfoxide showed less photodegradation than thioproperazine and its sulfoxide; the mechanism of the photodegradation of 10-(2-dialkylaminopropyl)phenothiazines was found to be dependent on the amount of air present; the 10-alkylaminoalkyl side chain was observed to influence photodegradation.

Herd, Eberson, and Higuchi investigated the mechanisms and the relative rates of alkaline hydrolysis of succinanil and methyl-substituted succinanils (115). The anionic forms of polycarboxylic acids, such as succinic and citric acids, were shown to interact reversibly and rapidly with glutaric anhydride in aqueous solution at room temperature to produce species which undergo subsequent hydrolysis (116). The same researchers also studied the irreversible interaction of acetic anhydride with di- and tricarboxylic acids in aqueous solution (117). The kinetics of the reaction of reserpine with nitrous acid were published (118). The acid demineralization kinetics of enamel were reported in an attempt to explore further a recently developed mathematical model in which it was assumed that hydroxyapatite is the thermodynamically governing phase in the mineralization of enamel (119). One paper considered the kinetics and transformations of cycloheximide as a function of pH and temperature (120). The decomposition of meperidine hydrochloride was found to be first order with respect to hydronium-ion concentration and ester concentration (121). Optimum stability for *N,N*-dimethyleneoxide-bis-(pyridinium-4-aldoxime)-dichloride in aqueous solution was reported at pH 3 (122). General equations were derived which related the half-life of tr methylene-bis-(4-formylpyridinium bromide)-dioxime in aqueous solutions to pH and temperature (123).

Antibiotic Stability—Belen'kii *et al.* announced that water, acids, increased temperature, and ultraviolet irradiation inactivate sodium nystatin. They reported that both the photo- and thermoinactivations of nystatin were prevented by the addition of the antioxidant, propyl gallate (124). The kinetics of the stability of oxacillin in aqueous solution were researched over the pH range of 1.44–10.93 (125). Data were collected showing aqueous solutions of methicillin to be most stable at pH 7.44 (126). Streptomycin sulfate, neomycin sulfate, and tetracycline hydrochloride were suspended in a dry mixture of tragacanth and sucrose; after addition of water the suspensions lost 7, 3, and 36%, respectively, of their antibiotic activities when stored for 10 days at room temperature in daylight (127). The stabilization of penicillin G solutions by sodium edetate was demonstrated (128).

Garrett *et al.* quantified and predicted the biological activities of chloramphenicol analogs through the use of microbial kinetics (129). The best viomycin stability in aqueous solution was disclosed to be in the range of pH 3.0 to 4.0 (130). Gramicidin was shown to be hydrolyzed by a *Bacillus subtilis* proteinase at the peptide linkage between L-valine and L-ornithine; the resulting peptide had no antibacterial activity (131). Stability studies of neomycin and penicillin in ointments were presented (132).

[2] Marketed as Luminal by Winthrop Laboratories, New York, N. Y.

Vitamin Stability—The stability of vitamins in pharmaceutical preparations was the subject of several publications. The stability of vitamins A, B, B_2, B_6, ascorbic acid, vitamin D_2, and niacinamide in oral liquid formulations was followed as a function of sucrose, glycerol, and water concentrations (133). The changes of vitamin contents and pH values of liquid medicines during storage in ampuls were also announced (134). Gurevich *et al.* employed Na_2SO_3 to stabilize ascorbic acid in a compound injection solution (135). The effect of liver extract on the stability of vitamins A, B_1, and ascorbic acid when present alone or in multivitamin formulations was determined in a syrup–glycerol–water vehicle (136). Over 100 samples of vitamin preparations were checked for vitamin content after storage for 1–16 years under various climatic conditions (137).

Carstensen *et al.* illustrated moisture stress studies, using vitamin A to exemplify this point (138). The effect of various suppository bases on the stability of a synthetic vitamin A palmitate and of a natural vitamin concentrate was investigated with and without the addition of antioxidants (139). Disodium edetate was found to be the most suitable autooxidation inhibitor for ascorbic acid (140). In comparison with KCNS, edetic acid (Idranal III) was shown to be a more effective inhibitor of oxidation of ascorbic acid in aqueous solutions, at room and at elevated temperatures, as well as in solutions containing copper, iron, or zinc ion (141). All salts studied, except sodium chloride, were shown to have a deleterious effect on the stability of ascorbic acid (142). The stability of dehydroascorbate was observed to be best at a pH of 2.4, the half-life being greater than 1000 min. at 20° (143). Second-order reaction kinetics were shown for the oxidation of ascorbic acid by various quinones using a polarographic technique (144). Stability tests on 12 ascorbic acid formulations at 80°, 60°, and 55° showed the failure of Arrhenius' law in a heterogeneous solid system (145).

Attention continues to be focused on thiamine stability. Two different groups of researchers studied the stability of thiamine solutions in the presence of dipyrone (Sulpyrin) (146–148). Data were presented which showed thiamine nitrate to be more stable than thiamine hydrochloride in a mixture containing vitamin B complex (149). The effects of γ-radiation on vitamin B_6 stability were probed (150). The effects of initial riboflavin concentration, hydrogen-ion concentration, and ionic strength on the light fading of riboflavin solutions were recorded (151).

PHARMACEUTICAL TECHNOLOGY

A discussion of controls on tablets (hardness, disintegration, and drug accuracy), injections (foreign particles and closure), and ointments appeared in the literature (152). Fluidization and its applications in pharmaceutical technology were covered in a two-part review. The first part covered the medical aspects, whereas the second part covered practical applications (153, 154). Ridgway and Segovia elaborated on fluidization and gas suspension techniques in pharmaceutical manufacturing, tablet coating, and granulating (155). Tablet coating by the air suspension technique was commented on by other researchers (156). Punch and die control was the subject of a publication which outlined a program to ensure the protection from defects of punches and dies (157).

Sterility—The use of a biological-chemical indicator for ethylene oxide sterilization of disposable medical and pharmaceutical materials was reported by Brewer and Arnsberger. The indicator system affords an immediate visible indication of gas penetration into the materials during the sterilization cycle and also serves as a biological control (158). Oils, such as liquid petrolatum and castor oil, were safely sterilized by using 0.1% ethylene oxide (159). A review of the properties of ethylene oxide and results of sterilizing tests with filter cartons, membrane filters, and vegetable parchment were summarized (160). Gelatin, when exposed to ionizing radiation, was shown to undergo molecular weight changes through free radical mechanisms involving scission, crosslinking, and weak bond formation (161). A review, with 66 references, was tabulated on the effects of radioactive irradiation on pharmaceutical preparations (162). Sterilization by electrohydraulic treatment was demonstrated by applying this technique to suspensions of *Escherichia coli*, spores of *Bacillus subtilis* var. niger, *Saccharomyces cerevisiae*, and bacteriophage T-2 (163). Methods for the preparation of sterile ophthalmic solutions were discussed in detail (164). Experimental data, collected from various laboratories, were published on the sterility tests of penicillin (165). Membrane filtration procedures for antibiotic sterility testing were offered as an improved approach for determining the sterility of antibiotics (166).

Parenterals—A review of the solubilizing agents used in parenterals appeared in the literature (167). Zoellner and Vastagh demonstrated that *m*-xylidine is a contaminant which causes discoloration of injectable solutions of lidocaine (168). Information on sodium chloride equiv-

alents, cryoscopic properties, and hemolytic effects of certain medicinals in aqueous solution was compiled (169). A discussion on the extemporaneous compounding of intravenous additives was presented (170). A survey of the literature pertaining to problems of incompatibilities and instabilities of parenteral solutions with admixtures was tabulated (171). Mixtures of potassium penicillin G–tetracycline hydrochloride, and potassium penicillin G–chlortetracycline hydrochloride in 5% dextrose were investigated for physicochemical incompatibilities (172). An incompatibility chart of 61 frequently used intravenous additive combinations was published (173).

Tablets and Capsules—Tanaka, Matsushita, and Utsumi ascertained that the disintegration time of calcium *p*-aminosalicylate increased with time due to formation of the hexahydrate which was detected by calorimetric measurements (174). Many manuscripts appeared on the subject of tablet disintegration. In a study on the mechanism of action of starch as a tablet disintegrant, pH was shown to have little effect on swelling, whereas salts were shown to affect swelling (175). In another publication the concentration of water-soluble medicament did not significantly change the disintegration time of tablets (176). Temperature of liquid and tablet compressional force was reported to directly affect the wetting of powder and disintegration time (177). In a study on the mechanism of the action of starch as a disintegrating agent in aspirin tablets, the authors concluded that the primary mechanism appeared to be a swelling action; capillarity *per se* did not appear to have a disintegrating effect (178). Tablets disintegrated 2 to 10 times faster when polysorbate 80 was added to the tablet formulation (179). A comparison was made of the influence of various chemicals on the disintegration time and on the crumbling rate of compressed tablets of acetylsalicylic acid at various stages of storage (180). The disintegration of tablets was studied by changing the ratio of aluminum hydroxide gel and diluent, such as potato starch, lactose, and cornstarch (181). Two methods were developed for testing the swelling capacity of tablet disintegrants (182).

A preliminary report on experiments carried out to find optimum tableting pressures, based on crystallographic consideration for potato starch, lactose, ascorbic acid, phenacetin, phenobarbital, and aminopyrine (amidazophen) appeared in the literature (183). The compression of mixtures of lactose and starch with different binding agents was studied using the dry granulation technique (184). A review of the physical phenomena which occur during the compression of tablets was published (185). An Instron physical testing instrument was adapted to permit its utilization in the evaluation of the compressing characteristics of drug particles and granules (186). In a two-part series, the physical properties of particles prepared by five different granulation methods and factors involved in the sieving of pharmaceutical granules were analyzed (187, 188). A method of measuring the fluidity of semifluid powders was described and used to investigate the role of various silica-type glidants in the direct compression of microcrystalline cellulose and a spray-dried lactose–microcrystalline cellulose blend on two different tablet presses (189). The influence of the addition of lubricants upon the flow rate of granulates was studied by measuring the flow velocity in an apparatus based on the device of Paksy and Sabjan. All lubricants delayed flow, especially polyethylene glycol 4000 and the stearates (190). The rate of flow of varying ratios of four sieve size fractions of rock salt through the hopper of a rotary press was represented by a second degree polynomial equation. No correlation was found between the tangent of the angle of repose and flow rate (191). Gold *et al.* studied the effect of glidants on flow rate and angle of repose (192). An article concerned with the influence of particle size of a glyceryl tri-ester lubricating agent on the physical properties of compressed tablets was presented (193). Tablet binders were evaluated by means of adhesion tension determinations (194). Spray-dried flour was evaluated against spray-dried lactose as a suitable carrying agent for direct compression formulas in tableting (195). Two new physical forms of lactose, spray dried and agglomerated, were used in the direct compression of tableted formulations (196).

Daragan suggested that the rate of dissolution of ethylcellulose films could be increased by including polysorbate 80 or citric acid in the composition of the film (197). A new method of coating tablets, using the revolving coating pan, was published. The coating materials were applied in suspensions or solutions as a spray from a centrifugal disk atomizer (198). A new dosage form, tablets of coated aspirin microspherules, was developed (199). The influence of particle size distribution, particle shape, apparent bulk density, moisture content, additives, and punch shape on the directly compressible characteristics of potassium chloride was investigated (200). Gastric-soluble films were applied to tablets by the dry-pressing method and by the spraying method (201). A three-part series on

medicated candies described the method of manufacture, the problems peculiar to medicated candies with hard sugar bases, stability, and the control aspects (202–204).

Sustained Release—A review dealing with the development and biokinetics of oral sustained-release medications was published (205). A two-part publication discussed the various patents obtained for prolonged-action dosage forms (206, 207). The quantitation of procedures and quantitative studies involving the release of sulfanilamide, caffeine, and potassium acid phthalate from polyethylene matrix disks into aqueous media were presented (208, 209). The mechanism of drug release from tablets made from mixtures of drug and polyvinyl chloride particles was investigated (210). One author pointed out that the development of oral sustained-release dosage forms is predicated on sound physical, chemical, and pharmacological properties of drugs and their bases (211). Another investigation dealt with the result of a mathematical and an analog computer analysis of the kinetic relationships governing the rate of release of drugs from sustained-release dosage forms (212).

A new method of preparing a sustained-action dosage form was developed. This entailed the tableting of film coated granules with subsequent recovery of the intact granules on disintegration of the tablet (213). The formulation and evaluation of a sustained-action compressed tablet with a plastic matrix composed of a vinyl acetate–vinyl chloride copolymer, zein, and gypsum were described (214). A sustained-release tablet preparation containing microcrystalline potassium chloride in a fatty base was developed which was free from any local irritant effect (215). Sucrose distearate, sucrose monostearate, and cellulose acetate phthalate were used for the preparation of prolonged-release granules and pills of sulfisoxazole (216). Draper and Becker observed a direct relationship between *in vitro* drug release rate and average theoretical surface area of sulfaethylthiadiazole–wax[3] particles, but did not observe this relationship for sulfaethylthiadiazole–beeswax particles (217). Spray-dried formulations of sulfaethylthiadiazole for prolonged-release medication were prepared by using shellac, cellulose acetate phthalate, a synthetic wax-like ester,[3] hydrogenated castor oil,[4] aluminum monostearate, and glyceryl monostearate as the dissolution-retarding materials (218). An article appeared which discussed the rationale for sustained-release aspirin (219). Factors affecting the release of a water-soluble drug from a compressed hydrophilic matrix were investigated (220). The influence of the concentration and particle size of the active substance and of polyethylene matrix on the speed of release of the active substance from a delayed-release tablet was published (221).

Suspensions—Nakagaki and Kitamura used an integrating sphere turbidimeter to study particle size distribution of silica suspensions (222). A review on pharmaceutical suspensions was presented which covered types of suspensions, particle size determination, and dependence of stability on factors such as viscosity and agglomeration (223). The effect of ultrasonic vibration on the deformation processes and stability of water dispersions of montmorillonites was investigated (224). The stabilization of clay suspensions during ultrasonic treatment and the effect of electrolytes were presented (225). Ultrasonic waves, at a frequency of 100 Kc., were found to cause a significant reduction in the particle size of polyethylene spheres only if surfactants were present (226). Using an aqueous sulfamerazine suspension, experiments showed good correlation which tested the validity of an accelerated procedure for determining settling volumes, following both centrifugation and storage under ambient conditions (227). A novel method was suggested for accelerating the physical changes in suspensions (228).

Nakanishi published three articles on the viscosity and sedimentation of the dispersed systems of barium sulfate in methylcellulose and carboxymethylcellulose (229–231). The use of high molecular weight compounds such as methylcellulose, sodium carboxymethylcellulose, and polysorbate 60[5] in the production of sulfamethazine (sulfadimezine) and sulfanilamide (streptocide) suspensions was suggested (232). Formulas were given which modified the unpleasant taste of calcium and phosphorus salts (233, 234). The influence of the disperse medium on the stability of an aqueous suspension of propyliodone was studied (235).

Emulsions—A review, with 18 references, on the theory of emulsion stability appeared in the literature (236). Another review covered tests for determining emulsion types, emulsion viscosity, and emulsion stability as influenced by emulsifying agents, particle size, temperature, viscosity, density, and types of emulsion (237). It was pointed out that the key to "leveling" in aqueous emulsion systems is that the product must wet both the substrate and its own drying

[3] Glyco Wax, Glyco Chemicals, Inc., New York, N. Y.
[4] Castorwax, Baker Castor Oil Co., Bayonne, N. J.
[5] Marketed as Tween 60 by Atlas Chemical Industries, Inc., Wilmington, Del.

film (238). Emulsion stability was considered with regard to inversion and HLB balance (239). The electrical conductivity of emulsions was used as a tool for testing and production control of emulsions (240). The effect of the shape of dispersed particles on the dielectric constant of emulsions with a low content of the dispersed phase was studied (241). One manuscript indicated that inversion of emulsions from water-in-oil to oil-in-water is a characteristic of the oil and appears to be most directly related to the viscosity of the oil (242). The relation between the solvent power and the hydrophile–lipophile balance of the emulsifier was determined (243).

In a study dealing with phase interfaces, Ford and Furmidge concluded that a strong interfacial film should be formed which prevents the coalescence of water droplets while permitting the coalescence of oil droplets (244). Flocculation of oil droplets in dilute emulsions was shown to depend upon concentration of oil droplets, the size distribution of the primary droplets, and the amount of salt present (245). The nature and influence of the attractive and repulsive forces which occur during emulsion film formation were discussed (246). Aggregation behavior was observed when an emulsion was diluted in saline containing cetrimide below the micelle concentration (247). The mechanism of emulsion stabilization with reference to yield value and surfactant chain length was outlined (248). New calculations showed that larger amounts of energy are required to overcome the viscous forces and secure emulsification than have been assumed hitherto (249). The effects of aging and surfactant concentration on the rheology and droplet size distribution of a nonaqueous emulsion were presented (250). Interfacial viscosities were studied by means of a viscous traction interfacial viscometer (251). The flocculation and coalescence of emulsion droplets of the normal and inverse types, studied simultaneously, confirmed that the attainment of a stable coalesced emulsion always requires the same amount of any given surfactant, the optimal concentration being independent of the size of the electrostatic energy barrier and the oil medium (252). The factors affecting stability in nonaqueous emulsions were presented (253).

Fox and Shangraw described an automated reciprocating capillary emulsator which duplicates the low-pressure homogenization principle of the interconnected glass syringe method used to prepare repository water/oil emulsions (254). These same authors showed that inorganic electrolytes at concentrations as low as 0.01 *M* increased apparent viscosity, retarded sedimentation, and had a marked stabilizing influence (255). Emulsions made with an ultrasonic emulsifier were reported to be superior to those made with the standard homogenizer (256). New emulsions were developed in which filter and screen light-protective substances were incorporated (257). The relative viscosities of water-in-oil type emulsions were shown to be a function of volume fractions of the dispersoid and also of the sorbitan monostearate[6] concentration (258). Systems having low interfacial viscosities were shown to give relatively stable emulsions (259). A comparison was made of results obtained on a typical pharmaceutical emulsion using optical and electron microscopes, and the Coulter counter for determining emulsion particle size (260). The emulsifying properties of sodium β-boswellate were investigated and shown to be quite good (261).

Ointments and Creams—Whitworth and Becker published on the effects of solubility factors on the diffusion of sulfacetamide and sulfathiazole from ointment bases (262). A "dialysis cell" method was developed for comparatively measuring the release of salicylic acid from various ointment bases (263). The rate of diffusion of procaine from an ointment base and several water-in-oil emulsions was shown to be inversely proportional to the amount of sodium lauryl sulfate present (264). Adsorption was shown to be responsible for a decrease of drug release from ointments (265). The diffusion of sulfanilamide from ointments was less when sulfanilamide was solubilized in the surfactants as compared to when the surfactant was incorporated into the ointment base (266). The diffusion of both salicylic acid and sodium salicylate from hydrophobic bases was shown to be very slow (267). A new apparatus, a rake bladed stirrer which keeps the ointment in constant circulation during an experiment, has been described and used in *in vitro* experiments (268). The rate of chlortetracycline and chloral hydrate release from ointment bases containing bentonic gel was studied (269).

Kutscher *et al.* applied sheets of polyvinyl alcohol coated with gentian violet to oral mucosal tissue and noted dye absorption in 5–55 min. indicating the usefulness of the vehicle as a base for drugs (270). Other investigators used solutions of ethylcellulose and sodium carboxymethylcellulose containing antibiotics as bactericidal film-forming liquids in treating cuts and small skin wounds (271). A rheological investigation of various ointments was described to

[6] Marketed as Span 60 by Atlas Chemical Industries, Inc., Wilmington, Del.

facilitate the selection of the most convenient base for medicinal ointments (272). An easy procedure was developed for the sterilization of ointments (273). Anhydrous ointment vehicles containing palm oil were best stabilized by using butylhydroxytoluene and butylhydroxyanisole, whereas hydrated ointment vehicles containing palm oil were best stabilized by using gallates (274). Polymethylphenylsiloxane liquid has been investigated as a component for ointment bases (275). The hydrophilic capacity of official polyethylene glycol ointment was increased 48% by the addition of 0.5% of dry unneutralized carboxypolymethylene compound (276). Various topical preparations for application to lips to reduce chapping were evaluated (277).

Suppositories—The absorption of streptomycin and chloramphenicol was increased slightly when sodium lauryl sulfate was incorporated in the fatty suppository base (278). Rectal absorption studies of various sulfonamides from aqueous polyethylene solutions in rabbits showed the ionized drugs to be better absorbed than the nonionized drugs, and the sodium salts of sulfonamides to be more effective than their free form (279). The adsorption of a brand of purified siliceous earth[7] in a cocoa butter suppository base was the same as that in a brand name glycol ester suppository base (280). The influence of various commonly used viscosity-inducing modifiers of suppository bases was determined *in vitro* using antipyrine (phenazone) and aminopyrine (aminophenazone) (281). An apparatus was described which can be employed for the control of the physical properties of suppositories made with fatty bases or with water-soluble or water-dispersible bases (282). Upon partial hydrogenation, some liquid vegetable oils assumed consistencies which made it possible to use these reacted oils as vehicles for rectal suppositories (283).

Aerosols—All types of pharmaceutical aerosols were discussed in detail in a review article by Marshall (284). New developments in aqueous foams, and their many interesting applications in cosmetics, were considered (285). In a two-part series, the properties of aqueous alcohol aerosol foams and how they apply to products were discussed, along with the effects of additives and how they may affect the foaming properties of these aerosols (286, 287). The changes in size distribution of an initially homogeneous aerosol were studied as the aerosol coagulated and deposited on the walls of a closed chamber (288). One author demonstrated that molecular complexes formed in aerosol emulsion systems increased emulsion and foam stability and decreased foam drainage (289). The use of the Rotovisco rotational viscometer was described in evaluating the rheological properties of pressurized foams (290). The microbiological testing of aerosol preparations was conducted using *Chaetomium globosum* under conditions that were applicable to the natural growth habits of the organism (291).

The development of water washable spray-on bandages was discussed (292). A new aerosol antiperspirant was considered along with safety data and formulation suggestions (293). A review on germicidal preparations in the form of aerosols along with the qualitative compositions of various air fresheners and surgical antiseptic aerosols was published (294). Chemical specialties foamed with water-dispersed colloidal alumina were studied (295). Hardness, clarity, and gloss retention of leading commercial hair sprays were evaluated to determine formulating goals in preparing aerosol hair sprays (296). Formulation and activity of water-based aerosols containing pyrethrum was the subject of still another manuscript (297).

Cosmetics—deNavarre predicted the development of more treatment cosmetics, some only for prescription sale (298). The physical and chemical properties of branch-chain hydrocarbons, fatty acids, alcohols and esters, both of synthetic and natural origin, which have found increasingly growing application in bases of creams and other cosmetics, were reviewed (299). "Some New Keys to Cosmetic Chemistry 1965" was the title of a review article which contained 278 references (300). One author's experience led to the publication of a manuscript entitled "Cosmetics for Use Under Tropical Conditions" (301). Another review article on cosmetics and toilet preparations contained 47 references (302). A discussion of lipids and their derivatives and other fats and waxes commonly used in cosmetology and dermatology was reported (303).

Rees analyzed the various properties of a good shampoo and also described the numerous types of modern shampoo formulations, including liquid, lotion, cream, powder, and jelly shampoos (304). Appearance, performance during use, and effect on hair after use were the three major criteria for evaluation of shampoos in the opinion of a team of investigators (305). The type of surface-active agents used in modern shampoos was commented on in detail (306). Quaternary ammonium salts were used in hair treatment preparations (307). Another publication presented the various hair dressing formulas for

[7] Trademarked as Aerosil by Degussa, Frankfurt on Main, Germany.

men and the requirements for each type (308). The use of oxidation dyes in hair coloring preparations was surveyed (309). Progress has been made with the formulation of stable, clear, emulsion systems, particularly hairdressing gels (310). The emulsifying, wetting, and foam properties of quaternary ammonium compounds, as applies to their use in hair treatment preparations, were reviewed (311). Protein based detergents were suggested for application in shampoos (312).

Goldrick discussed the need of vitamins for topical application and also gave several typical formulas (313). Water standards were suggested for use in the manufacture of cosmetic preparations (314). Aspects of microbiology, with reference to antimicrobial agents, in cosmetic products were presented (315). The problems relating to the proof of efficacy of antiperspirants and deodorants were examined (316). The significance in the choice of an appropriate vehicle for antiperspirants and deodorants was explored in detail (317). New techniques contributing to the laboratory evaluation of chemical, physical, and chemical/physical combination sunscreen products were presented (318). The nature and type of dermatological testing were discussed with special reference to different categories of cosmetics (319).

Schlossman categorized the types of skin cleaning preparations and gave sample formulations of each (320). The properties of cationic surface-active agents were reviewed and their suitability for use as emusifiers in cosmetics was discussed (321). The various surface-active agents used in bubble bath formulas were disclosed (322). The clear gel system was examined and typical formulas were outlined (323, 324).

Packaging—Lees discussed the use of plastics for packaging (325). A package development checklist was presented along with an explanation on how it is to be used (326). Reports of the committee developing test procedures for the determination of the safety of plastics in pharmaceutical and medinical uses were given (327). A very searching test for the suitability of plastics for cosmetic packaging was suggested (328). Published data were used to establish the superiority of foamed plastics over other pharmaceutical packaging materials. Among the foamed plastics, polystyrene foam was rated best on the basis of its mechanical, heat insulating, water-repellent, and aging properties (329).

The feasibility of using ultrahigh frequency power to accelerate freeze-drying was demonstrated and the facilities were described (330). The engineering aspects of ultrahigh frequency dielectric heating to accelerate freeze-drying was outlined (331). A method for determining the bacterial permeability of plastic films was announced (332). The permeability of plastics was shown to cause problems in the packaging of pharmaceuticals (333). The permeability of various solvents through polyethylene was expressed by an equation (334). The designing of machines for the packaging of sterile pharmaceuticals was described (335).

EQUIPMENT

A recording powder flowmeter consisting of a hopper, a strain gauge, and a recorder presented a new approach to the measurement of powder flow (336). Cohn *et al.* employed an IBM 1620 computer to evaluate data obtained from a compactor optimized to prepare a basic granulation to which other drugs could be added and directly compressed into tablets (337). In another paper the surface areas of powders were determined by flow microcalorimetry (338). A laboratory glass spray drier made from borosilicate glass was described (339). The design, critical components, method, and costs of spray driers were presented (340).

One mixer was described which utilized compressed air to mix solids rapidly, while another was described to blend or agglomerate solids by atomizing liquid into air-suspended solids (341). Nash and Haeger stressed the importance of zeta potential in the development of stable pharmaceutical suspensions (342). Some basic theories about the use of instrumentation in cosmetic color control with emphasis on practical application were reviewed by one author, while another elaborated on an instrument that measured color objectively (343, 344). A new machine for unit dose packaging of tablets and capsules was also described (345). In addition, the automatic packaging of individual ointment-impregnated gauze bandages was a subject for discussion (346).

PHYSICAL PHARMACY

Biles studied the distribution of quaternary ammonium salts between chloroform and water (347). It was also shown that pH affected the distribution of certain medicinal preparations between chloroform and water (348). The kinetics of reactions involved in penicillin allergy revealed that the aminolysis of penicillins by glycine is general base catalyzed (349). A number of antacids were granulated by dry, wet, and spray methods and compared for specific surface area, angle of contact, porosity, and acid-neutralizing capacity (350). An interesting paper concerned with the kinetics of swelling of dextran

gels in water was published (351). The diffusion of water vapor through a hydrophilic polymer film was determined using a multifilm technique (352).

Mark *et al.* studied the oxygen permeability of amylomaize starch films over a wide range of relative humidity (353). The permeation, sorption, and diffusion of water in ethylcellulose were also investigated (354). Freezing point curves were published for the system dimethylsulfoxide–water (355). Phase relationships were presented for a system containing isoelectric gelatin, ethanol, and water (356). A study of membrane characterization by measurement of transient osmotic pressures was reported (357). A review article concerned with the physical aspects of drug action appeared in the literature (358).

Solubility—Bates *et al.* published several papers concerned with the solubilizing properties of bile salt solutions on glutethimide, griseofulvin, and hexestrol as a function of temperature, bile salt concentration, and inorganic electrolyte (359–361). The solubility of 21 steroids in water at 25° was determined and compared to previously reported data (362). The dissolution rates of powdered preparations of sulfonamides and benzoic acid derivatives were studied, and the data were found to be in good agreement with the Noyes-Nernst equation concerning transport controlled dissolutions (363–365). The solubility of sulfonamides in phosphate–citrate buffer systems appeared in the literature (366). Sulfanilamide solubility increased with an increase in concentration and chain length of nonionic solubilizers and temperature (367). Another study presented data giving methods of solubilizing difficultly soluble materials by way of intermediates (368).

Paruta *et al.* investigated the solubility of xanthines, antipyrine, and succinic acid as a function of dielectric constant in several solvent systems (369–372). The dissolution rate and solubility behavior of 3-(1-methyl-2-pyrrolidinyl)-indole as a function of pH have been evaluated (373). In another study data were presented showing the effect of complex formation on dissolution kinetics (374). Benzoic acid was solubilized by polyoxyethylene compounds (375). Another article explored the mechanism of solubilization of water-insoluble substances with sodium benzoate derivatives (376). In addition, spectroscopic examination revealed that benzoic acid was solubilized by nonionic surfactants (377). The rate of crystal growth and dissolution rate of cholesterol crystals in aqueous media were probed (378).

The hydrophilic–lipophilic balance concept was utilized effectively to solubilize a wide variety of perfumery materials (379). Nonionic surfactants have been widely used to effect solution of a number of pharmaceuticals (380, 381). Antibiotics such as erythromycin and chlortetracycline have been the subject of papers in which their solubility and stability have been investigated (382, 383). Goldberg *et al.* presented a series of papers which demonstrated that dissolution rates and gastrointestinal absorption of drugs could be increased by preparing solid solutions and eutectic mixtures (384–386). A new method of solid state dispersion for increasing dissolution rates was described (387). Dissolution rate data appeared for drugs in powder form, granules, and tablets (388).

Slightly soluble acidic drugs were solubilized by using mixtures of alcohol and water (389). It was reported that the rate of rehydration of lyophilized serum globulin can be influenced by temperature, dilution, and the addition of sodium chloride, glucose, or sucrose (390). The solubility of acetanilide and several derivatives was determined in aqueous sucrose solutions (391). Anderson and Morgan showed that the solubilization of hexachlorophene had some effect on its antibacterial activity (392). Another study pointed out that supersaturated micelles form during solubilization (393). Poly-*n*-vinyl-5-methyl-2-oxazolidinone was found to solubilize several barbituric acid derivatives (394).

Complexation—In a study of the interaction of weak organic acids and phenols it was indicated that the drug–plastic interactions were due to hydrogen bonding of the agents to the polyamide, but that secondary valence forces of the Van der Waal's type play a predominate role in the binding mechanism for the more hydrophobic molecules (395). Several papers were concerned with the complexation tendencies of various antibiotics in the presence of metal ions and bovine serum albumin (396–399). Lach and Bornstein reported on solid–solid interactions by diffuse reflectance studies (400, 401). A potential mechanism for aspirin allergy due to an interaction with amines has been mentioned (402). Metal complexes of *d*-glucosamine and its derivatives with copper were found to be stable (403). The interaction of phenothiazine drugs with riboflavine and xanthine dyes was the subject of two papers (404, 405). It was pointed out that pK values, molecular weight, and the number of hydrophilic groups of organic ions are important in dye–drug salt interactions (406). The binding tendencies of cationic dyes to nucleic acids and other biological polyanions were investigated (407); also the nature of bonding in dye aggregates was reported (408).

Connors and Mollica analyzed comparative

studies of complex formation and found that different experimental approaches may not always yield the same numerical result and that comparative studies with several techniques may yield valuable information concerning the natures of the complexes (409). Viscosity measurements were used to study the interaction of benzoic acid derivatives and cationic surfactants (410). It was also reported that imidazole derivatives are useful as chelating agents (411, 412). The general nature of the interaction of phenol and certain macromolecules was investigated utilizing equilibrium dialysis techniques (413, 414).

The solubility product principle and phase rule diagrams were used to demonstrate interactions involving sulfanilamide and sulfathiazole (415). Data were also published which pointed out that β-cyclodextrin and sodium deoxycholate interact with many pharmaceutical agents in aqueous solution (416). Static dialysis techniques were utilized in studying the transfer of drug molecules from the micellar phase (417–419). The mechanism of solubilization of water-insoluble substances in aqueous sodium benzoate solutions has been determined (420, 421). The degree of binding of 8-hydroxyquinoline sulfate to polysorbate 80 was shown to be a function of the concentration of the nonionic surface-active agent (422). The interaction of aqueous polyethylene glycol solutions with iodine was investigated (423). The interaction of several local anesthetic drugs and sodium polyethylenesulfonate was evaluated by membrane dialysis measurements (424). The binding tendencies of methyl orange with proteins were also observed in a similar manner (425). Metal ions were shown to form complexes with ascorbic acid (426); molybdenum-thiol complexes were used as models for molybdenum bound in enzymes (427).

Beckett and Choulis investigated molecular interactions of stereoisomers in the solid state (428). Differential thermal analysis, infrared, and X-ray analysis were employed to evaluate the interactions between ionized surfactants and long chain polar compounds (429). The chelation of sugars and polyols with iron was exhibited most strongly by those compounds that contained a dihydroxyacetone structure in their molecule (430). Hydrophilic gel beads were utilized to form insoluble biologically active compounds (431). The metal chelating tendencies of glyoxylic acid have been investigated (432). The interaction of cationic drugs with polyacrylic acid was studied by phase separation as a function of temperature, polymer, and drug concentration. Separation temperature varied with polymer added, drug concentration, basic structure of drug, and valence of drug cation (433).

Surface Phenomena—A review article, containing 146 references, was concerned with particle–particle interactions (434). Another review commented on the study of the texture of porous solids (435). Micelle formation and other typical phenomena of surface-active substances were the subject of still another review (436). The scope of methods for estimating surface areas of solids from results of adsorption from solution has been described (437). A computer program was set up to reduce the calculations in surface area determinations and to provide an estimate of accuracy and reliability of a set of experimental data (438). The difference between flocculation and coagulation was discussed in detail by Ecanow *et al.* (439). The various methods of determining the surface tension of solids and their shortcomings have been described (440).

The drop volume method was used to study the surface activity of several phenothiazines at the air–solution interface (441). It was also pointed out that the presence of organic cations inhibited surface activity at this interface (442). Solid adsorbents such as kaolin, talc, and activated charcoal were shown to adsorb phenothiazine derivatives (443). Horikoshi and Hata published several papers concerned with a physicochemical study on water contained in solid medicaments (444–446). The neutralization rate, crystal structure, and crystal growth rate of dried aluminum hydroxide gel were shown to be affected by aqueous environment (447, 448). The sedimentation and aggregation of aluminum hydroxide and aluminum oxide particles were explored (449). It was also pointed out that the volume of aluminum hydroxide gels changes when it crystallizes (450).

A new method, comparing the flux magnitudes corresponding to different conditions of gas flow through porous media, has been proposed for the determination of surface areas of powders (451). Adsorption studies were conducted on a number of steroid powders (452). An investigation of the flow rate of loosely packed magnesium hydroxide has shown that the general equation developed by Jones and Pilpel can be applied to single as well as multicomponent mixtures in a wide size range (453). The sorption and desorption data for methylene blue on kaolinite fit the Langmuir equation (454). Brunauer published a review article which discussed the surface behavior of solids (455). Spray-dried clays were evaluated *versus* oven-dried clays and found to vary somewhat in their physical characteristics (456).

The influence of lanolin derivatives on the physical aspects of dispersions was discussed by Conrad *et al.* with particular reference to pigment wetting (457–459). By using the Levich model for the effect of surfactants, a quantitative conclusion was drawn concerning the hydrodynamics of a laminar liquid film in the presence of surfactant, when their distribution on the surface depends on the rate of the adsorption and desorption processes (460). Surface-active agents were shown to have a marked influence on the electrokinetic potential of some sulfonamides in aqueous syrup suspensions (461). In another study the general criteria for the stability of lyophobic sols was established and found valid for any potential of the colloid particles in the critical state (462). From the general criteria of the stability of disperse systems, complete curves were calculated which characterized the coagulating effect of mixtures of various electrolytes for potentials of colloid particles (463). Using a hydrosol of titanium dioxide stabilized by sodium oleate, it was shown that, when the stabilizer content in the dispersion medium is close to the micelle forming concentration, the disperse particles aggregate (464). A quantitative theory was presented which describes the kinetics of coagulation of colloidal systems containing more than one dispersed species (465).

The adsorption of three quaternary ammonium salts has been measured at the oil–water interface (466). In another investigation the electrophoretic mobilities, the rates of agglomeration, and the rates of flow through sedimented particles were studied for a model suspension consisting of spherical particles (467). Nash elaborated on structural vehicles for stabilized suspensions along with physical stability test methods and special factors in producing good parenteral suspensions (468). A detailed study has been made on the destabilization of dilute clay suspensions with a cationic polymer under controlled conditions of pH, ionic strength, initial clay concentration, and intensity and duration of agitation (469). A simple and inexpensive *in vitro* test was utilized to evaluate the defoaming activity of a silicone defoamer in tablet combination with a number of commonly used antacid materials (470). The equilibrium adsorption of kanamycin A by cationic exchange resins was explored (471). The adsorptive mechanism of a palm oil–water emulsion stabilized by a mixture of casein and gelatin was elucidated by combining surface tension studies of the oil–water interface with electrophoresis studies (472). The kinetics of particle adhesion for glass beads in liquid media containing surfactants were investigated (473).

Crystallization—The crystallization of petrolatum waxes was the subject of a review article (474). Morawetz observed that the reactivity of organic crystals is sometimes different from reactions that take place in the liquid state (475). The water solubility of chlortetracycline hydrochloride varied with the change in crystal structure of the compound (476). It was also observed that the biological properties of erythromycin polymorphs were similar, but the melting points and the water of hydration were different (477). The effect of polymorphism on the solubility of pharmaceuticals was shown (478).

Rheology—A visco-coagulograph was developed which records continuously the structure formation in liquids (479). Neuwald and Scheel did a rheological study on new cream bases as a function of temperature, while Boylan presented a rheological study on 13 pharmaceutical semisolids (480–482). A method was described for the continuous monitoring of solutions of stirred reaction media (483). The problems encountered in determining the viscosity of shampoos were discussed (484). The parallel plate plastometer was modified for the measurement of Newtonian and non-Newtonian fluids (485). The rheological behavior of granular material was investigated by another investigator (486). Another paper described the various methods of characterizing the thixotropic properties of an oil-in-water lotion (487). Extrusion type cells have been developed for measuring and recording rheological properties of gels (488).

In another study a modified Brookfield viscometer was used to evaluate dispersions of lipophilic suspending agents (489). Powell *et al.* studied the effects of high shear processing and thermal exposure on the molecular weight and the solution viscosity of selected polymers and found that the viscosity degradation followed a first-order reaction rate with the viscosity half-life for the higher molecular weight grade polymer being considerably less than that of the lower molecular weight grade polymer (490). It was also shown that the limiting shear stress and torque under which a gelatin solution can retain its structure are a function of concentration, time, and temperature (491). The various techniques used for assessing the rheological properties of toiletry and cosmetic products were considered (492). A rheological evaluation of pressurized pharmaceutical foams was presented (493).

PHARMACOCHEMICAL ASPECTS

This section of the review considers many of the papers on polymers, antibiotics, and radio-

isotopes which might be of interest to the pharmaceutical scientist. It is not intended to encompass the vast area of pharmaceutical chemistry concerned with synthesis, structure activity studies, reaction mechanisms, analysis, *etc.* These related disciplines are reviewed annually in other publications and are, therefore, omitted from this report.

Polymers—Carpenter presented a review article, containing 135 references, in which irreversible, reversible, macromolecular, and association colloids were reviewed (494). Recent theory and developments relating to the formation and modification of synthetic polymeric films in relation to the pharmaceutical uses of such films in dosage form development have been discussed (495). Several polymeric materials, currently used in the plastics industry, were evaluated for their use in pharmaceutical film coatings (496). Five commercially available polymers were considered for the preparation of enteric compression coatings utilizing a unique polymer incorporation method which was part of the granulating process (497). In another investigation cellulose acetophthalate was examined as an enteric tablet coating (498). Surfactant polymeric materials have been used to prepare prolonged action insulin preparations (499). Film forming macromolecules have been utilized as protective coatings for skin wounds and for antiseptic sprays and balms (500, 501). The water vapor transmission properties of free polymer films were explored (502). In addition, the water vapor transmission of applied polymer films on tablets was found to be a function of polymer coat formulation, film coat thickness, and nature of the tablet matrix (503).

Antibiotics—Schumacher presented a review, containing 27 references, on the chemistry, microbiology, pharmacology, and the therapeutic application of cephalosporin antibiotics (504). Another paper reviewed both broad spectrum and narrow range antibiotics for activity against Gram-positive or Gram-negative organisms (505). A complete discussion of the newer semisynthetic penicillin derivatives was given (506). The properties of some of the new antibiotics, spinamycin, leucomycin A_1, ericamycin, xanthocidin, and cineromycins A and B were disclosed (507–511). The kinetics and mechanisms of action of chloramphenicol and tetracycline on the generation rates of *E. coli* were investigated (512). Another paper discussed the compatibility of some pharmaceutical preparations with antibiotics (513).

The binding tendencies of sulfonamide drugs to serum protein have been the subject of several papers (514–517). A number of papers appeared in the literature concerning the protein binding of antibiotics, especially the penicillins (518–525). Several papers contained data on blood serum levels of penicillin and some semisynthetic penicillins (526–529). A comparison of tetracycline concentrations, following oral and intravenous administration, indicated that intravenous administration gave superior therapeutic response (530).

Radioisotopes—Wagner and Emmons reviewed the characteristics of an ideal radiopharmaceutical (531). The problems characteristic of radioactive pharmaceuticals have been outlined (532). A biochemical view of radiopharmaceutical developments indicated that to date more attention has been paid to the physical characteristics of the isotopes incorporated into radiopharmaceuticals than to the biochemical aspects of their use (533). Another author pointed out the value of computer analysis of kinetic biological parameters (534).

BIOPHARMACEUTICS

The area of biopharmaceutics considers research efforts directed toward studying the influence of pharmaceutical formulations on the biological activity of drugs. Numerous review articles appear in the literature. An article, containing 67 references, was published on the noncompetitive mechanism governing the action of medicinal drugs (535). Another review discussed pharmaceuticals which modified the activities of gastric enzymes (536). Beckett reviewed the problem of drug distribution and metabolism (537). In addition, another review article discussed the aspects of clinical trials of new drugs and the difficulties of evaluating them for one species from the results obtained in another species (538). Pharmacokinetics were reviewed and discussed (539). The induction of drug-metabolizing enzymes in liver microsomes was the subject of another review article containing 83 references (540). The application of statistics and biometry in the comprehension of drug action was noted (541).

Methods were described which utilize the analog computer as a laboratory aid in the preparation of drug formulations with improved therapeutic efficacy (542). A mathematical and theoretical interpretation of drug distribution and dosage, involving complex pharmacokinetic models and the analog computer, was presented (543). The analog computer was used to help clarify the distribution processes of *d*-tubocurarine in experimental animals (544). Protein binding tendencies of some azo dyes, thyroxine, diphenylhydantoin, and pentaerythritol have

been the subjects of several papers (545–547). The biphasic elimination of noscapine was published (548). Human bioassay techniques have been used for determining the availability of vitamins from preparations resistant to *in vitro* disintegration (549). Data concerned with the modification of drug responses by hydrolytic enzymes were recorded (550).

Effects of Physicochemical Properties—The urinary excretion kinetics of methylamphetamine in man were studied by Beckett and Rowland (551). In a similar study, it was shown that the rate of excretion of methylephedrine and its metabolite, ephedrine, fluctuated with a change in urinary pH (552). Several papers reported data on some basic *in vitro* and *in vivo* studies with six different sulfa drugs (553, 554). The transport of volatile fatty acids across rumen epithelium was altered by concentration gradient, pH, and metabolism (555). It was demonstrated that cholestryamine resin interacted with commonly used, orally administered drugs in both *in vivo* and *in vitro* systems (556). The relation between the physicochemical and pharmacological properties of iron and chromdoitin sulfate colloid for intravenous injection was studied (557).

Effects of Formulation—Lammers reviewed the ways in which a drug can interact with an inactive substance to produce a potentiation or a lessening of the effect of the drug (558). Another review article commented on the effect of drug formulations on the absorption rate (559). Percutaneous absorption of lipid substances and their effect on skin surface was the subject of another review (560). The relationship between the *in vitro* dissolution kinetics and the *in vitro* intestinal absorption characteristics of tablet preparations of coumarin revealed that the composition of the dissolution medium had a significant quantitative and qualitative effect on dissolution kinetics (561). It was also pointed out that the absorption of a number of alcohols and barbiturates was affected by the concentration of nonionic surfactant (562). Static dialysis studies indicated that it was possible to anticipate the amount of drug absorbed in the small intestinal tract containing polysorbate 80 solution (563). Drug release from water-in-oil emulsion systems, containing tensides of a sorbitan[8] series, was investigated (564, 565). Another study further substantiated that drugs are absorbed from micellar solutions (566). It was also shown that a relationship existed between the concentration of polysorbate 80 and the rate of absorption of salicylamide from the small intestine of the rat (567).

A comparative investigation on the rectal absorption of aminophylline and theophylline from various medicated preparations was carried out in man by Neuwald and Ackad (568). The rectal absorption of sulfonamides from oily solutions seemed to take different paths: that of absorption through the rectal membrane after being liberated into the excretion fluid and that of absorption directly from the fatty oil through the rectal membrane (569). Surfactants were found to enhance the release and absorption of barbiturates from suppository bases in most cases; however, binding of the drug was suspected in some bases (570). The rectal absorption of aminopyrine and isopropylantipyrine was carried out in rabbits from an improved hydrophilic ointment base (571). Inert suppository ingredients sometimes have an adverse effect on the rectal absorption coefficient of drugs; this was apparent when antipyrine (phenazone) was evaluated (572).

Several papers were published on the action of proteolytic enzymes on the serum concentrations of the tetracyclines (573–575). Other investigators evaluated the feasibility of using an enzyme–substrate system as a mechanism for controlling the rate of drug release from a dosage form (576, 577). When ethinylestradiol was introduced directly into the small intestine of the rat as an oily solution, it was absorbed more slowly than when administered as an aqueous suspension (578). An antidiarrheal preparation containing attapulgite and citrus pectin was studied for its potential effect on the absorption of promazine from the human gastrointestinal tract (579). The inverted sac technique was used by Aguiar and Fifelski to investigate the effect of pH on the *in vitro* absorption of flufenamic acid. The study revealed that the passage of this drug through the gut membrane was by passive diffusion (580). An evaluation of the blood level duration properties of procaine benzylpenicillin in oil with aluminum monostearate was carried out (581).

Micronized medroxyprogesterone acetate displayed more metabolite in 8 hr. than a nonmicronized preparation, indicating improved absorption with smaller particles (582). Rosen *et al.* reported on the absorption and excretion of radioactively tagged dextroamphetamine sulfate from a sustained-release form. The data suggested that the sustained-release dosage form is a reliable way to administer the drug (583). The absorption, distribution, and excretion of iron following oral administration in the presence

[8] Marketed as the various Spans by Atlas Chemical Industries, Inc., Wilmington, Del.

of various ligands was the subject of another communication (584). Plasma and urinary excretion levels of 5-butyl-1-cyclohexyl-2,4,6-trioxoperhydropyridine were measured after application of various ointments and solutions to the skin of rats or rabbits (585). Flame photometry was used to determine the activity of ointments (586). The topical absorption of various polypeptides in the presence of dimethylsulfoxide has been evaluated (587). Wagner *et al.* pointed out that the rates of absorption of indoxole after oral administration varied with the nature of the dosage form (588). A study evaluating the effect of polyethylene glycol 4000 on the absorption of several barbiturates has also been reported (589).

Absorption Control—A review on the absorption and biochemistry of vitamin B_{12} was published (590). Holt demonstrated that competitive inhibition of intestinal bile salts in the rat was apparent (591). It was also further substantiated that iron was transported across membranes, using a loop of gut with an artificial circulation (592). The release rate characteristics of sulfaethylthiadiazole from various wax formulations were revealed (593).

Absorption Mechanism—Palva discussed the drug-induced malabsorption of vitamin B_{12}, pointing out that *p*-aminosalicylic acid interfered with certain metabolic processes mediated by folic acid (594, 595). An investigation of the prolongation of the therapeutic effect of penicillin by polymeric preparations indicated that the mobility and the rate of elimination of the polymer molecules from the body were responsible for the delayed effect (596). In a similar study polyvinylpyrrolidone was shown to prolong the activity of tetracycline (597). Other authors studied the effect of cations on the transport of sulfonamides through the small intestine of rats and found that absorption of sulfisoxazole was reduced when potassium ion was substituted for sodium ion (598). Ascorbic acid was shown to increase the absorption of iron (599), while allopurinol had no effect on the absorption of iron (600). It was reported that the topical application of dimethylsulfoxide enhanced the topical absorption of phenylbutazone; however, when the dimethylsulfoxide was administered subcutaneously there was no effect (601).

Kinetic Studies—The kinetics of the metabolism, absorption, and decomposition of drugs were reviewed in a paper citing 14 references (602). Another article discussed the pharmacokinetics of various tetracyclines (603). Nelson presented data showing the application of results of pharmacokinetic estimations and their significance (604). A theoretical study of drug action was outlined and the concept was tested with hormones of the neurohypophysis and their analogs (605). Kinetic interpretation was used as a tool to explain pharmacological response (606). A pharmacokinetic model involving first-order processes for drug release, absorption and elimination, for sustained-release preparations, has been described (607). Several papers surveyed the distribution, absorption, and excretion of sulfonamides (608–611).

Gibaldi and Kanig studied the effect of body position and pH on the gastrointestinal absorption of salicylate and creatinine in man (612). The pharmacodynamic behavior of the salicylates has been the subject of several papers (613–617). Tritiated digoxin was used to determine the distribution and excretion of this material in experimental animals (618). Using plasma salicylate levels, the rates of drug absorption and elimination from the blood were determined for salicylic acid and sodium salicylate administered in four different suppository bases (619). In studying protein binding tendencies of sulfonamides it was observed that there was a deviation from first-order kinetics, characterized by a diminishing steepness of the slope of the time–concentration curve (620). The analysis of expired air was shown to offer several advantages over the analysis of blood and urine samples (621).

A kinetic model to explain the elimination of bromsulfophthalein using the Michaelis-Menten expressions has been proposed by Winkler (622). In another study, urinary excretion data were utilized to evaluate some oral prolonged-release forms of dextroamphetamine in man (623). The first apparent demonstration of competitive inhibition of drug metabolism in man was reported (624). The elimination constants and biological half-lives of thiamine were determined for a series of thiamine derivatives (625). Radioactive tracer techniques were used to follow the absorption and excretion of hydroxycyanocobalamin, benzoylthiamine disulfide, and a hypoglycemic metabolite of glycodiazine (626–628). A complete pharmacodynamic evaluation of a sustained-release aspirin product was published (629). The absorption, excretion, and metabolism of nalidixic acid and hydroxynalidixic acid was the subject of two papers (630, 631). The use of kinetic models to study antibiotic absorption, metabolism, and excretion has been proposed (632).

Drug Absorption—Munies described a method for investigating *in vivo* percutaneous absorption based on the determination of methyl ethyl ketone in expired air following topical

application (633). In another paper the absorption, excretion, and elimination of chlorphenesin carbamate in the dog were discussed (634). A large volume liquid scintillation detector was used to determine the rates of excretion, absorption, and intercompartmental clearance in ambulatory dogs (635). A similar study was carried out with cyanocobalamin (636). Radiotracer techniques were used to follow the absorption of furosemide and thimerosal (637, 638). The problems associated with sensitivity and cross sensitivity to drugs were pointed out (639). The absorption, duration of circulation, and elimination of sodium sulfapyridazine by different routes of administration have been evaluated (640). It was reported that the absorption of a vitamin A–casein complex was more efficient than absorption of vitamin A (641).

Levy and Jusko pointed out that the enhanced absorption of riboflavin in the presence of food appeared to be due to the decrease in intestinal transit rate causing the vitamin to remain at absorption sites longer (642). The absorption, distribution, and elimination of a long-acting vitamin B_{12} preparation have been studied (643); and the absorption and excretion of 5-butyl-1-cyclohexyl-2,4,6-trioxoperhydropyridine were determined when it was administered by different routes (644, 645). It has been shown that sulfaphenazole appears in the saliva after intravenous administration (646). Data were presented for the absorption of betamethasone from the gastrointestinal tract in dogs (647). Another publication presented data concerned with the effect of physical activity on the absorption rates of procaine penicillin G implants (648). Another investigator carried out research on the absorption and activity of griseofulvin and some derivatives in rabbits (649). Sweetening agents were also the subject of absorption and excretion studies in humans, rats, and rabbits (650).

A Mechanism for the Hydrolytic Deamination of Cytosine Arabinoside in Aqueous Buffer

By ROBERT E. NOTARI*

The kinetics of hydrolytic deamination of cytosine arabinoside have been studied as a function of pH, temperature, and buffer composition. The reaction components were isolated, identified, and quantified. The sole catalytic buffer species in the phosphate system is $H_2PO_4^-$. The rate of reaction between $NaHSO_3$ and cytosine arabinoside has been studied and the resulting products characterized. A mechanism for the hydrolytic deamination of cytosine nucleosides, catalyzed by hydrogen ion and general acid-base, HB^-, is hypothesized. This mechanism is shown to be consistent with existing literature data as well as the kinetic and $NaHSO_3$ reaction data reported here.

THE ROLE which chemical mutagens play in the deamination of cytosine nucleosides (I) to uracil derivatives (II) has been the subject of several investigations directed toward elucidation of *in vivo* mechanisms of mutagenic activity (1–5). Recently, Shapiro and Klein (5) have proposed two kinetically equivalent mechanisms for the deamination of cytidine (or cytosine) in aqueous buffers of pH 3 to 6. Both mechanisms combine specific hydrogen-ion catalysis with general base catalysis by buffer anion, B^-. However, the catalytic interaction by buffer was not unequivocally defined. It was hypothesized that an anion, B^-, increased deamination rate either by (*a*) removal of a proton from water or (*b*) partial saturation of the 5,6-double bond. Isolation of the components in reaction mixtures revealed only cytidine and uridine (or cytosine and uracil) and did not, therefore, differentiate between the two alternate routes.

The present investigation lends support to the proposed hydrogen-ion catalysis and eliminates the possiblility that proton exchange between anion, B^-, and water is the mechanism for general base catalysis. Evidence presented here demonstrates that general acid-base catalysis results primarily from complete saturation of the 5,6-double bond by a nucleophile, HB^-, and that catalysis by other buffer species such as B^-, B^{2-}, or B^{3-} is either absent or relatively unimportant. The prime criteria for catalysis by a nucleophile such as HB^-, are shown to be (*a*) sufficient nucleophilicity to attack the 6-position following the initial protonation at the 3-position and (*b*) the ability to subsequently donate a proton resulting in the complete saturation of the 5,6-double bond (Scheme I).

Received December 27, 1966, from the College of Pharmacy, Ohio State University, Columbus, OH 43210

Accepted for publication March 7, 1967.

This investigation was conducted while the author served as the 1966 Summer Professor, Product Research and Development, The Upjohn Co., Kalamazoo, Mich.

The author wishes to acknowledge the fine technical assistance of Mr. Carl Zipple, who perfected and performed the analyses. Appreciation for helpful comments on the manuscript is expressed to Drs. W. J. Wechter and R. C. Kelley.

The name for cytosine arabinoside approved by USAN is cytarabine.

* Present address: 1627 Farr St., Scranton, PA 18504

EXPERIMENTAL

Quantitative Analysis of Cytosine Arabinoside and Uracil Arabinoside—Thin-layer plates, 20 × 20 cm., were coated with a 3:1 mixture of Silica Gel G and Silica Gel GF 254. After activating for 1 hr. at 105°, they were scored to form nine 1-cm. channels and washed with benzene–propanol (1:1). Reaction aliquots of 25 μl. were spotted, dried, and then developed with water-saturated butanol–propanol (3:1) for about 2.5 hr. Chromatograms were air-dried for 1 hr. and photographed under 254 mμ ultraviolet light.

The appropriate spot was then scraped from the plate and eluted with five 3-ml. aliquots of 0.01 *M* H_2SO_4 in ethanol. The pooled extract was brought to 50 ml. and its ultraviolet absorbance determined against a similarly prepared blank. A primary standard was run on each plate and the standard absorbance used to calculate the amount of the unknown. Recovery was generally 95% with excellent reproducibility. The wavelength of maximum absorption under these conditions is 285 mμ for cytosine arabinoside and 263 mμ for uracil arabinoside.

Kinetics of Cytosine Arabinoside Loss—Reactions were prepared with "Water for Injection" which had been boiled and cooled under nitrogen. The solutions were filtered under nitrogen through a Millipore filter (0.045) then dispensed into 5-ml. ampuls and sealed. Ampuls were placed in appropriate constant-temperature baths and analyzed as a function of time as described above. (See Tables I and II for experimental conditions.)

Preparation of Cytosine Arabinoside-Bisulfite Reaction Products—An aqueous solution containing 0.2 *M* cytosine arabinoside and 2.0 *M* $NaHSO_3$ was allowed to react for 85 hr. at 70°. The reaction was considered complete when a 254 mμ ultraviolet light no longer revealed a cytosine arabinoside spot on a thin-layer chromatogram. A similar solution was prepared with uracil arabinoside and treated in the same manner.

Characterization of the Components in Reaction Mixtures—Products resulting from the reaction of bisulfite with cytosine arabinoside or from the deamination of cytosine arabinoside were compared to standards on thin-layer chromatograms. The standards were: cytosine arabinoside, uracil arabinoside, cytosine, uracil, and D-arabinose. The following solvents were employed with silica gel support: *A*, butanol–propanol (3:1) saturated with water; *B*, 2-propanol–ammonia–water (7:1:2); *C*, chloroform–propanol (3:1); *D*, ethyl acetate–acetic acid–

ethanol (23:1:1); *E*, butanol–water (86:14). One additional system, *F*, employed aluminum oxide gel and 2-propanol–ammonia–water (7:1:2). Both supports contained phosphors.

RESULTS

Effect of $NaHSO_3$ on Kinetics of Cytosine Arabinoside Loss—The effect of $NaHSO_3$ on the rate of loss of cytosine arabinoside in aqueous phosphate buffer, pH 6.9, 70°, μ = 0.15, is illustrated in Fig. 1. The relative order of the rates was the same at 40°. The 0.01 *M* $NaHSO_3$ solution contained the calculated amount of bisulfite necessary to react with the oxygen content in the headspace of a sealed ampul. Thus, there is an increased rate of cytosine arabinoside loss with increased [$NaHSO_3$] and a pronounced increase in rate when [$NaHSO_3$] exceeds that required for the atmospheric oxygen.

Rate of loss of cytosine arabinoside was found to be first order in the absence of $NaHSO_3$ (Fig. 2). Reactions were not first order in the presence of $NaHSO_3$. The change in order was attributed to $NaHSO_3$ reacting with cytosine arabinoside. (An earlier study demonstrated a loss of $NaHSO_3$ in excess of that consumed by the headspace oxygen.) Assuming a 1:1 reaction permits calculation of the time required for the oxygen and reactant to completely expend the $NaHSO_3$. It can be seen in Fig. 2 that first-order plots become both linear and parallel after the $NaHSO_3$ is depleted.

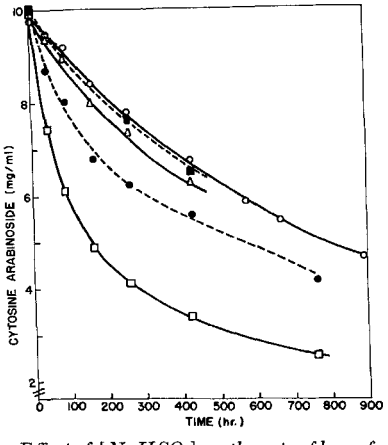

Fig. 1—Effect of [$NaHSO_3$] on the rate of loss of cytosine arabinoside in 0.06 M *phosphate buffer, pH 6.9, 70°, μ = 0.15. Key:* ○, A (*0.000*); ■, B (*0.004*); △, C (*0.010*); ●, D (*0.020*); □, E (*0.040*).

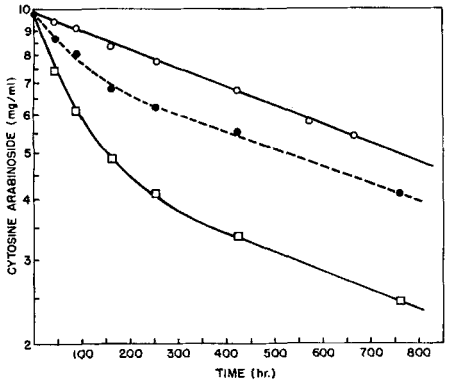

Fig. 2—Effect of [$NaHSO_3$] on the first-order plots for cytosine arabinoside loss in 0.06 M *phosphate buffer, pH 6.9, 70°, μ = 0.15. Key:* ○, A (*0.000*); ●, D (*0.020*); □, E (*0.040*).

A material balance based on the concentration of cytosine arabinoside and uracil arabinoside in several reaction mixtures at 70°, 425 hr., gives further support to the existence of an additional bisulfite reaction product (Table II). It is obvious, from these results, that another reaction product must exist and that its yield increases with increased $NaHSO_3$ concentration. For example, 66% of the initial cytosine arabinoside was converted to the alternate product in the presence of 0.04 *M* $NaHSO_3$ at 70°. In the absence of bisulfite all of the material was accounted for within the limit of experimental error; no other product was formed.

Thin-layer chromatograms, which were viewed under a 254 mμ ultraviolet light, revealed only two spots: cytosine arabinoside and uracil arabinoside (R_f values 0.42 and 0.70 using solvent system *A*). The preservative, benzyl alcohol, appeared as a spot near the solvent front and will be ignored for the purpose of this discussion. Charring with H_2SO_4 and heat revealed a third spot just above the origin. An aqueous solution containing 0.2 *M* cytosine arabinoside and 2.0 *M* $NaHSO_3$ produced no cytosine arabinoside or uracil arabinoside spot after 85 hr. at 70°. Charring with H_2SO_4 and heat again revealed a spot just above the origin.

Bisulfite is known to react with α,β-unsaturated ketones by a 1,4-addition to yield a sulfonate which reverses to starting material upon addition of NaOH (6). Addition of NaOH to the above 85-hr. bisulfite reaction gave the following chromatographic results in the solvents listed: (*a*) no uracil spot, *B,C,D,E;* (*b*) no arabinose spot, *A,B;* (*c*) definite uracil arabinoside spot, *A,B,C,E,F;* and (*d*) definite but minor cytosine arabinoside spot, *A,E,F*. It was assumed that no cytosine was present since the absence of uracil and arabinose was demonstrated.

It was concluded that the major bisulfite reaction product was the sulfonate of uracil arabinoside (III) and the minor reaction product was the sulfonate of cytosine arabinoside (IV). This conclusion is consistent with the following experimental observations: (*a*) the product of the bisulfite reaction has a low R_f value and is not visible under a 254 mμ ultraviolet light; (*b*) the rate of cytosine arabinoside loss is not first order in the presence of $NaHSO_3$; (*c*) there is an increased yield of reaction product other than II with increasing $NaHSO_3$ concentration; (*d*) there is a complete loss of I without formation of II in the presence of a tenfold excess of $NaHSO_3$; and (*e*) treatment of the bisulfite reaction product(s) with NaOH yields primarily II and traces of I.

The reaction between uracil arabinoside and $NaHSO_3$ did not result in an appreciable decrease in the size of the uracil arabinoside spot size during the 85-hr. reaction period. The reaction, thus, appeared to be slower than the corresponding cytosine arabinoside reaction. It seems unlikely, in light of this evidence, that the product III is formed by this route in the cytosine arabinoside reactions.

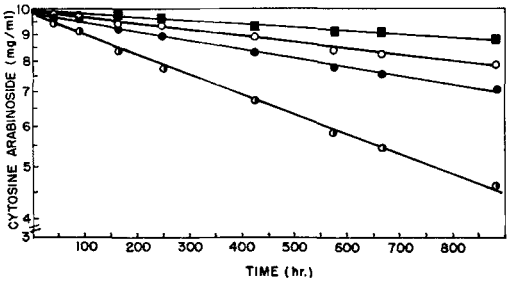

Fig. 3—First-order plots for deamination of cytosine arabinoside in 0.06 M phosphate buffer, pH 6.9, μ = 0.16. Key: ■, 47°; ○, 55°; ●, 60°; ◑, 70°.

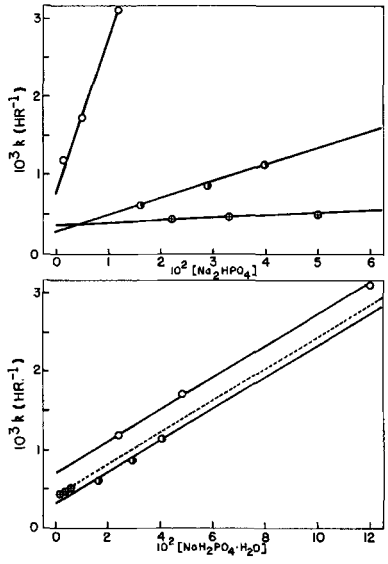

Fig. 4—Apparent first-order rate constants for cytosine arabinoside deamination at 70°, μ = 0.15, as a function of (top) disodium phosphate concentration and (bottom) sodium phosphate concentration. Key: ○, pH 6.2; ◑, pH 6.9; ⊕, pH 7.8.

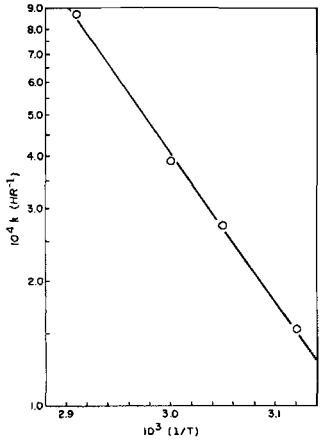

Fig. 5—Arrhenius plot of first-order rate constants for hydrolytic deamination of cytosine arabinoside in 0.06 M phosphate buffer, pH 6.9, μ = 0.15.

Kinetics of Cytosine Arabinoside Deamination in Buffer Solutions—Good first-order plots were obtained for deamination of cytosine arabinoside to uracil arabinoside in aqueous phosphate buffer solutions lacking $NaHSO_3$. Typical examples are shown in Fig. 3. Apparent first-order rate constants, calculated from the slopes of such plots, are tabulated in Table I.

The dependency of the observed first-order rate constants on the concentration of the buffer components is demonstrated in Fig. 4. The parallelism which is present in the plot of *k versus* $NaH_2PO_4 \cdot H_2O$ (Fig. 4, bottom) and absent in the corresponding plot for Na_2HPO_4 (Fig. 4, top) clearly demonstrates that the sole catalytic species in this buffer is $H_2PO_4^-$.

The intercept values, or the rate constants in the absence of buffer, are also reported in Table I. The observed increase in rate in going from pH 6.9 to 6.2 may be interpreted as specific hydrogen-ion catalysis in agreement with that previously reported (5). The failure of HPO_4^{2-} to catalyze the reaction demonstrates that removal of a proton from H_2O by base is not the mechanism by which general base catalysis is occurring. The very small difference between pH 6.9 and 7.8 suggests that specific hydroxyl-ion catalysis does not contribute to an appreciable extent in this pH region.

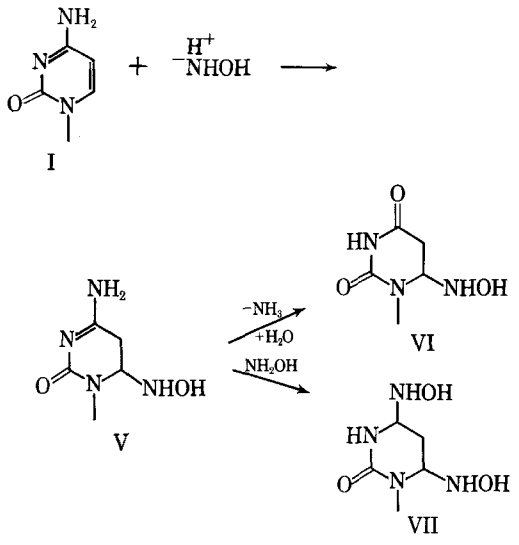
An Arrhenius plot of the apparent first-order rate constants for the deamination of cytosine arabinoside in 0.029 $NaH_2PO_4 \cdot H_2O$, 0.029 Na_2HPO_4, pH 6.9, $\mu = 0.15$ is given in Fig. 5. The value of ΔHa, in the presence of catalytic species, is 16.4 Kcal./mole.

DISCUSSION

Scheme I illustrates the proposed mechanism for either the hydrogen-ion, general acid-base catalysis of cytosine arabinoside (I) deamination or for 1,4-addition by HSO_3^-. The major bisulfite addition product is the sulfonate of uracil arabinoside (III), although some of the cytosine sulfonate (IV) is definitely present. It was concluded from thin-layer chromatographic and material balance data (Table II) that the product resulting from the deamination of cytosine arabinoside in the presence of general acid-base other than HSO_3^- (Scheme I) was uracil arabinoside (II).

There is precedence for both the 1,4-addition by HSO_3^- (6) and also the 5,6-addition to pyrimidine nucleosides. The reaction of NH_2OH with cytosine derivatives has been investigated by several workers (1–3). The reaction pathway involves initial conjugate addition in which NH_2OH saturates the 5,6-double bond to form V which can either deaminate to VI or exchange with a second molecule of NH_2OH at the 4-position (VII). The first addition was illustrated as attack by H^+–$NHOH$ by Schuster (1). (Scheme II.)

The compound V was not isolated since saturation at the 5,6-position results in rapid nucleophilic exchange at C-4 to form VI or VII. This predisposition to deamination which results from saturation of the 5,6-position has been observed on several occasions. The nucleophilic exchange reaction which occurs during hydrolytic deamination has been found to proceed very slowly for cytosine as compared to the corresponding 5,6-dihydro derivatives (3). The deamination of cytidylic acid hydrate was shown to



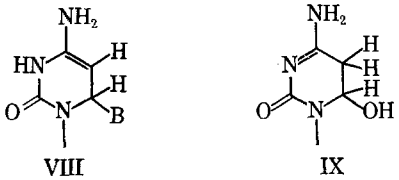
Scheme II

be rapid even at room temperature (4). In addition to this, the rate constants for the deamination of this 5,6-saturated species were independent of both the type and concentration of the buffer. The heat of activation for this deamination is the same as that reported here for the general acid-base catalyzed deamination, 16 Kcal./mole. In the absence of general acid-base species, HB^-, the value for ΔHa is 22 Kcal./mole (7).

An hypothesis explaining the observed increase in deamination rates of the 5,6-saturated cytosines is offered in steps 1–4, Scheme I. Furthermore, it is asserted that this represents the primary mechanism by which specific hydrogen-ion, general acid-base catalysis is occurring. Initial protonation at N-3 followed by saturation of the 5,6-position results in an electron deficiency at C-4 thus facilitating nucleophilic attack by water. Partial saturation to form VIII, as represented by Shapiro and Klein (5), would not result in electron deficiency at C-4.

Accordingly, $H_2PO_4^-$ is an effective catalytic species while HPO_4^{2-}, which will not supply a proton, is not (Fig. 4). This fact also excludes the suggestion that a possible catalytic mechanism is through abstraction of a proton from water by the base (5). If this were the case HPO_4^{2-} would be expected to exhibit a greater catalytic effect than $H_2PO_4^-$.

Catalysis by saturation of the 5,6-double bond is also consistent with the fact that cytidylic acid hydrate (IX) is not subject to buffer effects and has the same ΔHa for deamination as the $H_2PO_4^-$ catalyzed reaction reported here.



There is at present insufficient data available to allow the calculation of catalytic constants for buffer species other than the phosphate system which is defined in this paper. Studies are currently in progress, by the author, to quantitatively evaluate the catalytic effects of other buffers. However, the hypothesis that cytosine deamination is subject to general acid-base catalysis by HB^- can be shown to be consistent with the existing data of several workers. For example, the observed first-order rate constant for cytosine arabinoside deamination in the presence of citrate ion, pH 7.4, 70°, was found to be 3.77×10^{-4}/hr. (7). This agrees with the intercept value of the plot, *k versus* phosphate buffer concentration, pH 7.8, 70°, which is 3.79×10^{-4}/hr. (Fig. 4; Table I). Furthermore, the value of ΔHa for cytosine arabinoside deamination in the presence of $citrate^{3-}$ was shown to be 22 Kcal./mole (7). These data are consistent with the prediction that $citrate^{3-}$ does not meet the criteria for general acid-base catalysis as outlined here.

Table III—Concentrations of Each Buffer Species in 0.5 *M* Solutions at pH 4, the Corresponding First-Order Rate Constants for Cytidine Deamination at 97° ($k_{obsd.}$ in hr.$^{-1}$),[a] and the Portion of $k_{obsd.}$ Attributed to Catalysis by Buffer ($k_{cat.}[cat.]$)[b]

Buffer	HnB	$Hn_{-1}B^-$	$Hn_{-2}B^{2-}$	$10^2 k_{obsd.}$	$10^2 k_{cat.}$ [cat.]
Citrate	0.046	0.385	0.069	3.4	2.1
Oxalate	0.000	0.305	0.195	2.8	1.5
Succinate	0.293	0.202	0.005	2.0	0.7
Formate	0.198	0.306	...	1.4	0.1
Lactate	0.288	0.288	...	1.3	0.0
Acetate	0.432	0.068	...	1.3	0.0

[a] $k_{obsd.}$ = the observed first-order rate constants as reported by Shapiro and Klein (5). [b] These values are calculated from the equation $k_{cat.}[cat.] = k_{obsd.} - 1.26 \times 10^{-2}$ (hr.$^{-1}$), where 1.26×10^{-2} is the value for the intercept of the plot $k_{obsd.}$ *vs.* [H_2 citrate$^-$].

A re-examination of the data of Shapiro and Klein (5) also lends support to the mechanism proposed in Scheme I. Their observed first-order rate constants, $k_{obsd.}$, are listed in Table III. The concentrations of each individual buffer species were calculated and the results are also given. A plot of $[H_{n-1}B^-]$ *versus* $k_{obsd.}$ for the citrate buffer data under good first-order conditions ($[H_2 citrate^-]/[cytidine] \geq 4$) was found to be linear with an intercept value of 1.26×10^{-2} (hr.$^{-1}$). This value for the deamination of cytidine in the absence of buffer effects is comparable to the first-order rate constants reported for the formate, acetate, or lactate buffers under the same experimental conditions (Table III). It was also reported that cytidine deaminated only 2% after 21 hr. of refluxing in either water or 0.5 *M* sodium acetate at pH 7.2. It can be concluded that these buffers do not contain any major catalytic species for cytosine deamination.

Conversely, it is evident from Table III that the citrate buffer system does in fact catalyze cytidine deamination. Since it has been demonstrated that $citrate^{3-}$ is not catalytic, it follows that one of the protonated species must be the catalyst. As a further test of catalysis by HB^-, the derivative of [H_2 citrate$^-$] with respect to [H^+] was set equal to zero and the expression solved for the pH of maximum H_2 citrate$^-$ concentration. Results indicate that the pH of maximum HB^- concentration in a citrate buffer of fixed total concentration would be 3.9. This is consistent with the data which show a rate maximum between 3.5 and 4.0 for this system (5).

Attempts to correlate the catalytic effects of HB^- with that predicted from the Brönsted relation (8) are complicated by the dual nature of the catalyst which is defined here as participating both as an acid and a base. The values for the predicted catalytic constants, k_A (or k_B), in terms of G_A and α(or G_B and β) can be compared for each type of buffer species since the Brönsted relation is well obeyed within a group of similar catalytic species such as H_nB, $H_{n-1}B^-$, B^{2-}, *etc.* The value of the experimental catalytic constant for a potentially catalytic species, X, can also be calculated from $k_X = k_{cat.}$ [cat.]/(concn. X). (See Table III.) The assumption in this latter calculation is that one catalytic species predominates in each buffer as has been demonstrated for the phosphate system. The data were treated in this manner and the results, while not conclusive, are consistent with the present hypothesis. The catalytic constants as calculated from the data were compared to the catalytic constants as calculated from the Brönsted relation using the statistical correction and assigning a value of 0.5 to α or β. The only good correlation evident was that between k_{Hn-1B^-} and the values of k_A (in terms of G_A) for the species $H_{n-1}B^-$. This result is consistent with the choice of HB^- as the primary catalytic species. The fact that the correlation exists for k_A in this comparison and not for k_B implies that the catalytic species requires a donatable proton. The formate, lactate, and acetate ions, which exhibit no significant buffer effect as seen in Table III, also have no value for k_A since the anions cannot act as proton donors.

It can be concluded from the above discussion that the mechanism offered in Scheme I is consistent with the experimental data presented here as well as the related data of the other workers cited above.

SUMMARY

Consideration of the 1,4-addition products formed from the reaction between bisulfite and cytosine arabinoside and consideration of the effects of phosphate, oxalate, succinate, lactate, formate, and acetate buffers has demonstrated that cytosine deamination will be significantly catalyzed by a nucleophile bearing a donatable proton in the presence of hydrogen ions. The primary mechanism of hydrolytic deamination of cytosine nucleosides in aqueous catalytic buffer systems, as illustrated in Scheme I, is as follows: (*a*) protonation of N-3, (*b*) nucleophilic attack at C-6, (*c*) saturation at C-5 by proton addition, and (*d*) nucleophilic displacement at C-4 by H_2O with loss of NH_3.

Effect of Some Nonionic Surfactants on the Rate of Release of Drugs from Suppositories

By J. M. PLAXCO, JR., C. B. FREE, JR.*, and C. R. ROWLAND†

Twenty-eight nonionic surfactants were added to theobroma oil base suppositories. The amount of aminophylline, ephedrine alkaloid, and ephedrine hydrochloride released from these bases was determined by dialyzing the released drug through a cellophane membrane and determining the optical absorbance at the appropriate wavelength. Data obtained indicate that surfactants with HLB values of less than 11 had little effect on the rate of release. Surfactants with HLB values over 11 increased significantly, in most cases, the amount of drug dialyzed. Besides HLB values, other properties of surfactants such as chemical structure, composition, and melting point also affect the rate of release.

THE USE OF suppositories as a form of medication dates back to the time of Hippocrates. Many unsatisfactory agents were tried as bases, but it was not until the discovery and development of theobroma oil as a base in the 18th century that they received much attention. In more recent days much attention has been directed toward modifying and improving bases of theobroma oil, glycerinated gelatin, and polyethylene glycol polymers, and in developing new bases. Until fairly recently, as long as the suppository retained its shape on the shelf, melted or dissolved in the rectum, and showed no visible evidence of incompatibility it was considered satisfactory. Recently it has been recognized

that many factors may affect the action of the drug following administration of the suppository.

From the literature we have a plethora of conflicting reports as to the efficacy of suppository medication. Most clinical work has been done with aminophylline, hence this part of the discussion will be limited mainly to reports concerning aminophylline or theophylline. Segal *et al.* (1) compared the protection against intravenously administered histamine by aminophylline administered by various routes. They found that suppositories gave slightly less relief than intravenous administration but that relief persisted for a longer period of time. Tablets were slower acting and afforded less relief than either of the other two dosage forms. Waxler and Schack (2), on the other hand, found blood levels of aminophylline from suppositories to be much lower than those obtained from intravenous or intramuscular injection, or from uncoated oral tablets. However, blood levels from suppositories were sustained for longer periods of time, except for intramuscular injection. Truitt *et al.* (3) found retention enemas gave highest levels, except for intravenous administration, and that suppositories gave lowest blood levels of all methods tested. Glass *et al.* (4) obtained satisfactory blood levels of theophylline following administration of suppositories of a mannitol or a buffered polyethylene glycol base. Lower blood levels were obtained from other bases.

Drugs may be absorbed from the intestinal tract by three processes: (*a*) active transport, (*b*) passive transport, and (*c*) specialized transport. Passive transport, or diffusion, has been shown to be the method by which most drugs are absorbed. Brodie *et al.* (5) showed that once a drug is in solution in the gastrointestinal tract its passage through the gastrointestinal fluid and across the lipoidal membrane is governed mainly by physical processes and is often predictable, based on the partition coefficient of the undissociated drug moiety and the dissociation constant of the drug. Riegelman and Crowell (6) in their reports on rectal absorption obtained results which agree with the assumption that the limiting factor is the diffusion of the drug to the absorption site. Suppositories, or other dosage forms, which release the drug fastest to the surrounding medium should, theoretically, afford more rapid absorption by the body and higher blood levels of the drug.

The literature contains numerous reports (7–19) of the effects of surfactants on the rate of release of various medicaments from oils, fats, *etc.* This study was to determine the effects of various factors, particularly nonionic surfactants, on the rate of release of drugs from different suppository bases, primarily those composed of theobroma oil.

Since most clinical reports concern aminophylline (theophylline ethylene diamine), it was selected as the primary test drug. For comparative purposes, ephedrine alkaloid and one of its more water-soluble salts, ephedrine hydrochloride, were selected.

Since many of the bases contained surfactants and emulsified when in contact with water, it was necessary to use some means of separating the drug from the emulsified base of theobroma oil. Dialyzing the liberated drug through a cellophane membrane accomplished this separation, permitting determination of the amount of drug, although some ingredients of the base, particularly the surfactants, may have dialyzed also.

EXPERIMENTAL

Materials—Where possible, official products were used. Nonofficial products were of food or drug grade and were used as received from the manufacturer or distributor with no further purification. All theobroma oil was purchased at one time and all dialyzing membrane was from the same manufacturer.

Preparation of Suppositories—After calibration of the mold, 140 mg. of aminophylline, or 700 mg. of ephedrine or ephedrine hydrochloride, sufficient for 14 suppositories, was incorporated by geometric dilution into the just-melted base of theobroma oil and surfactant. After thorough mixing the mass was poured immediately into an unlubricated mold for 12 suppositories. The excess mass was used to prepare the melting point tubes or discarded. Blank suppositories—containing no drug—were prepared of each base to determine the absorbance of each base. The suppositories and melting point tubes were placed in a refrigerator at 5° for 2 days, then stored at room temperature for at least 3 days before testing. All suppositories were satisfactory in appearance and physical stability with no evidence of leakage, blooming, or color change for 3 months. After that time, several batches began to show a mottled appearance but looked satisfactory otherwise.

Procedure for Aminophylline—Dialyzing bags were prepared from dialyzing cellophane tubing, tied with cotton thread, and soaked overnight in distilled water before use. After rinsing the bags twice, 25 ml. of distilled water was placed in each bag which was then placed in a 500-ml. wide-mouth bottle containing 175 ml. of distilled water. The bottle was placed in a constant-temperature water bath at 39° and allowed to reach that temperature. This temperature was selected to ensure being above the clear melting point for all suppositories.

One suppository was placed in each bag which was suspended so that the level of the water inside was even with the level of the water outside the bag. The water in the bottle was stirred by a slowly turning coated magnet and a magnetic stirrer. At intervals a sample was removed from the bottle

and the absorbance at 273 mμ was determined using a Beckman model DB spectrophotometer. The concentration of aminophylline was obtained from a standard curve with corrections made for the absorbance of each suppository base (theobroma oil plus surfactants).

Procedure for Ephedrine and Ephedrine Hydrochloride—Since ephedrine and its salts passed through the dialyzing membrane very rapidly, it was necessary to modify the technique used previously. Instead of using a dialyzing bag, a cellophane membrane, previously soaked overnight and rinsed in distilled water, was stretched firmly over the open end of a thistle tube 38 mm. in diameter and made watertight by a rubber band.

After a suppository had been placed in the tube and the end closed as described, the inverted tube was suspended so that the membrane was just below the surface of 200 ml. of distilled water in a 500-ml. wide-mouth bottle. Water rapidly passed through the membrane and dissolved the drug. The bottle was immersed in a constant-temperature water bath at 39° and stirred by a slowly turning coated magnet and a magnetic stirrer. At intervals a sample was removed from the bottle and the absorbance at 257 mμ determined using a Beckman model DU spectrophotometer. The concentration of ephedrine or ephedrine hydrochloride was determined from the respective standard curve with corrections made for the absorption of the particular suppository base.

RESULTS AND DISCUSSION

Aminophylline—Table I shows the composition and melting range of various types of suppository bases selected to establish variations in rate of release and dialysis of aminophylline. The results of dialyzing the suppositories, shown in Table II, are in general agreement with previously published reports (7–19) on the rate of release of water-soluble substances from suppository bases. The addition of the hydrogenated vegetable oil to stabilize the melting point of theobroma oil greatly reduced the rate of release of aminophylline. The degree of

interference with dialysis suggests that it was more than simply a matter of raised melting point.

Effect of HLB—To determine the effects of some nonionic surfactants in theobroma oil on the rate of release and dialysis, the various surfactants were incorporated as previously described. Table III shows the surfactants, grouped by chemical composition and type, which were added, and the amount of aminophylline dialyzed. Figure 1, with the surfactants arranged in descending order of HLB values, shows the amount of aminophylline dialyzed. In every case more aminophylline was dialyzed from the surfactant-containing base. Relatively uniform and moderate increases were noted from surfactants having an HLB value of less than 11, except for polyoxyethylene oleyl ether and polyoxyethylene lauryl ether.

Maximum drug was dialyzed from bases containing surfactants with HLB values of 11 to 14. Some surfactants with high HLB values (16–18) also released large amounts of drug. This agrees, in general, with other reports (9, 10, 12, 14, 19). Since the required HLB value of theobroma oil for an o/w emulsion is approximately 14 (20), it is to be expected that a surfactant with an HLB of about 14 would be most effective in emulsifying the theobroma oil, greatly increasing the oil–water interface.

Effect of Chemical Composition and Type—A comparison of those surfactants containing the C_{18} saturated moiety (stearic acid ester or stearyl alcohol ether) reveals that the polyoxyethylene fatty acid esters consistently dialyzed more aminophylline than the corresponding polyoxyethylene fatty ethers, sorbitan monostearate, or polysorbate 60, 61, or 65. As a group, the polyoxyethylene fatty acid esters gave best release even though their HLB values were not at 14. Part of the difference in amount dialyzed is undoubtedly due to HLB differences but apparently the ester linkage is superior to the ether linkage. Since stearate is the only radical common to all groups of surfactants, other groupings cannot be compared as completely.

A comparison of laurate or lauryl alcohol ether and oleate or oleyl alcohol ether reveals that the ethers were far superior to the sorbitans or polysorbates (esters or ester-ethers). The presence of sorbitan in the molecule consistently resulted in poor dialysis results. Under the conditions of the test (suppository bases emulsified) it was not possible to determine whether the poor results were due to slow release of the aminophylline from the suppository or whether it was released but not dialyzed. It is probable that the large sorbitan molecule hindered passage of the drug through the membrane.

Examination of the results from the surfactants containing fatty alcohols with equivalent-length polyoxyethylene chains and equivalent HLB values shows that the stearyl alcohol ethers dialyzed the released aminophylline most slowly, followed by cetyl, oleyl, and lauryl alcohol ethers, respectively. The melting range of each suppository base was determined by the U.S.P. XVI method for class II substances (21). All melting ranges were between 32–34°, well below the test temperature, with no consistent pattern due to surfactant. It appears from the results that the more saturated hydrocarbons with higher melting points inhibit the dialysis of aminophylline either by slightly raising the melting point or possibly by complexing with the drug. The former is in general agreement with the finding of Eckert and Muhlemann (15), who reported that at temperatures above the clear melting point of suppositories the rate of release increases enormously for water-soluble drugs, and the rate of diffusion reaches the values of a corresponding aqueous solution.

The increased rate of dialysis of aminophylline from theobroma oil suppositories to which the surfactants were added was probably due to several factors. Apparently the surfactants, acting as solubilizing agents, increased the solubility of aminophylline in water, or they increased the rate of solution by emulsifying the base, thereby increasing the

oil–water interface. It is also possible that they affected the dialyzing membrane, rendering it more permeable to the aminophylline.

It is probable that an intermolecular reaction or binding occurred between the aminophylline and the surfactant or that the drug was trapped within the micelles, especially those containing the sorbitan moiety. The evident difference in amounts dialyzed with those surfactants containing sorbitan indicates a slowdown, which is probably due to the formation of a large, slowly diffusible and dialyzable particle. Recently Kakemi *et al.* (22) have reported reduced absorption of several sulfonamides when nonionic surfactants were added to aqueous solutions of the sulfonamides. They theorized that the sulfonamide was trapped within the micelles of the surfactant and the large molecule passed slowly through the rectal membrane.

Ephedrine and Ephedrine Hydrochloride—Table IV summarizes the milligrams of both ephedrine and ephedrine hydrochloride dialyzed after 30 min. and 1 hr. For ephedrine hydrochloride, equilibrium was approached after 1 hr. For ephedrine, equilibrium was not reached after 24 hr. for all bases. For comparative purposes, the dialysis of the drugs from theobroma oil with no surfactant is shown at the top of the table.

Ephedrine Hydrochloride—Figure 2, with the surfactants arranged in descending order of HLB values, shows the amount of ephedrine hydrochloride dialyzed. The moderate increases noted were much less than the increases reported for aminophylline.

TABLE IV—EPHEDRINE AND EPHEDRINE HYDROCHLORIDE DIALYZED FROM THEOBROMA OIL CONTAINING 5% NONIONIC SURFACTANTS

Surfactant Chemical Type or Compn.[a]	HLB	Time, min. 30 Ephedrine HCl	60 Ephedrine HCl	30 Ephedrine	60 Ephedrine

[a] See footnotes to Table III.

Those surfactants having an HLB value of less than 9 had little effect, some slightly decreased the amount dialyzed. It is possible that the surfactant complexed or reacted with the drug or trapped the drug within the micelles, but the evidence is not conclusive as three of the surfactants, sorbitan monopalmitate and sorbitan monostearate, and POE (2) oleyl ether decreased dialysis and four, sorbitan monooleate and sorbitan trioleate, and POE (2) cetyl ether and POE (2) stearyl ether, had no effect or slightly increased the amount dialyzed. Above an HLB value of 9, the surfactants, with the exception of polysorbate 40, increased slightly the amount dialyzed. The increases were probably due to either an increased solubility of ephedrine hydrochloride or, more probably, to an increased rate of solution of the salt due to the formation of an o/w emulsion, thus increasing the oil–water interface. Below an HLB value of 9, a w/o emulsion formed in which the dissolved or released drug remained inside the oil (external phase).

Ephedrine Alkaloid—Figure 3 shows the amount of ephedrine dialyzed. As expected, due to its more lipid solubility, much less alkaloid was dialyzed than the corresponding hydrochloride salt. Much the same general pattern of dialysis was noted as with ephedrine hydrochloride, with several exceptions. Maximum ephedrine dialyzed from the polysorbate 40-containing base but less ephedrine hydrochloride dialyzed than from theobroma oil alone. With the bases containing polysorbate 60 and POE (4) lauryl ether maximum amounts of ephedrine hydrochloride were dialyzed but essentially no increase was noted with ephedrine. Other minor discrepancies are noted. All surfactant-containing bases with HLB values of less than 9 dialyzed less ephedrine than the base composed only of theobroma oil.

Comparing the dialysis of aminophylline with the dialysis of ephedrine and ephedrine hydrochloride reveals little pattern of consistency. Those bases containing surfactants with HLB values of less than 9 had little effect on the rate of dialysis but surfactants with HLB values of greater than 9 had large increases in the amount dialyzed. This lack of consistency re-emphasizes the necessity for determining the rate of release of each individual drug in each base.

SUMMARY AND CONCLUSIONS

1. The rate of dialysis of aminophylline from various types of suppository bases was determined. Wide variations were found in the amount of aminophylline dialyzed.

2. The effect of the 28 nonionic surfactants added to theobroma oil was variable, although all increased the amount of aminophylline dialyzed. In general, surfactants with low HLB values afforded least increase, and surfactants with HLB values of 11 to 14 showed greatest increase.

3. Those surfactants containing sorbitan in the molecule dialyzed lesser amounts than corresponding surfactants without sorbitan (polyoxyethylene fatty acid esters and polyoxyethylene fatty ethers).

4. It is not clear what effect, if any, the type linkage of the surfactant (*e.g.*, ether, ester, *etc.*) has on the rate of release.

5. It appears that the degree of saturation of the

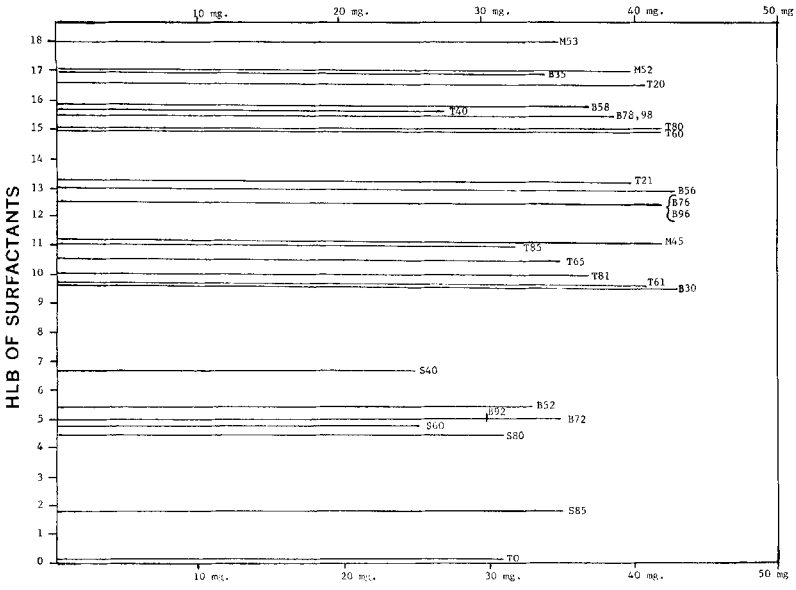

Fig. 2—Milligrams of ephedrine HCl dialyzed after 1 hr. Key same as in Fig. 1.

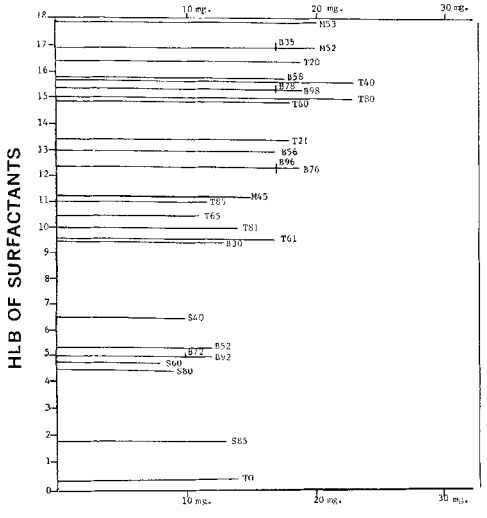

Fig. 3—Milligrams of ephedrine dialyzed after 1 hr. Key same as in Fig. 1.

surfactant, which should affect the melting characteristics of the suppository, has an effect.

6. The rate of dialysis of ephedrine and ephedrine hydrochloride from theobroma oil suppositories containing nonionic surfactants was also determined.

7. For ephedrine hydrochloride no consistent pattern was noted for surfactants having an HLB value of less than 9. Above an HLB value of 9, the surfactants increased moderately the amount of ephedrine hydrochloride dialyzed, but the increases were much less than noted with aminophylline.

8. For ephedrine alkaloid, essentially the same pattern of behavior was noted except that much less drug was liberated and dialyzed in the same period of time. For surfactants with an HLB value of less than 9 there was a decrease in the amount dialyzed.

9. The rate of release of drugs from suppositories containing nonionic surfactants remains unpredictable and should be determined for each drug in each base.

10. This study utilizing a relatively large number of nonionic surfactants points to the possibility of error in using only a small number of surfactants and drawing widespread conclusions.

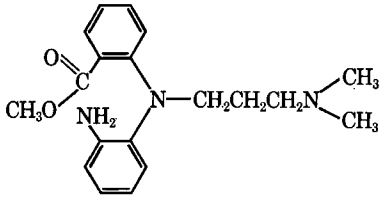
Metabolism and Excretion of Methyl *N*-(*o*-Aminophenyl)-*N*-(3-dimethylaminopropyl) Anthranilate in the Dog and Human

By DAVID L. SMITH, ALBERT L. PULLIAM, and HOWARD KO

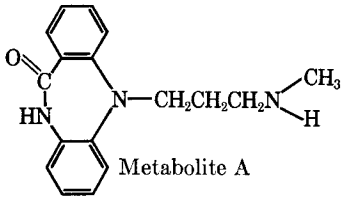
Four urinary metabolites of the title drug, excreted by both the dog and human, have been identified and quantitated. Metabolite A is 5-(3-methylaminopropyl)-5,10-dihydro-11H-dibenzo[*b*,*e*][1,4]diazepin-11-one, metabolite B is the methyl ester of *N*-(*o*-aminophenyl)-*N*-(3-methylaminopropyl)-anthranilic acid, metabolite C is 5-(3-dimethylaminopropyl)-5,10-dihydro-11H-dibenzo[*b*,*e*][1,4]diazepin-11-one, and metabolite D is 5-(3-aminopropyl)-5,10-dihydro-11H-dibenzo[*b*,*e*][1,4]diazepin-11-one. At least 46.3 ± 4.4 per cent (S.E.M.) of the dose was absorbed in the human, 8.6 ± 1.5 per cent was excreted as metabolite A, 30.5 ± 3.4 per cent as metabolite B, 2.4 ± 0.2 per cent as metabolite C, less than 0.2 per cent as metabolite D, and 4.8 ± 0.7 per cent as unchanged drug. The kinetics of excretion of the drug and metabolites indicates that absorption and metabolism take place rapidly. In the human, the average (±S.E.M.) half-lives of excretion of drug and metabolites A, B, and C were 3.0 ± 0.2, 6.5 ± 0.6, 6.2 ± 0.7, and 7.7 ± 1.2 hr., respectively. A comparison of urinary excretion after 10-mg./Kg. oral and intravenous doses of the drug to the same dog indicates efficient absorption of the oral dose. In the dog, the half-lives (±S.D.) for urinary excretion of the drug and metabolites A, B, and C were 5.5 ± 0.8, 6.6 ± 0.5, 4.3 ± 0.5, and 7.2 ± 0.6 hr., respectively. Biliary excretion of the drug and/or metabolites or the presence of undetected metabolites may be indicated from the low recovery after intravenous administration.

THIS STUDY was undertaken to determine the absorption, half-life, and metabolic fate of methyl *N*-(*o*-aminophenyl)-*N*-(3-dimethylaminopropyl) anthranilate (I), an orally active diuretic agent in the rat and dog (1). This report describes the quantitative determination of the drug and its metabolites in dog and human urine samples. Qualitative aspects of the metabolism of this drug in the dog and human have already been reported (2).

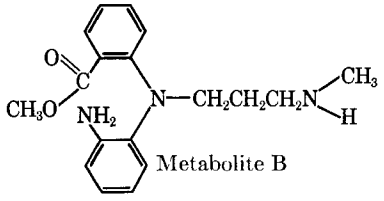


I

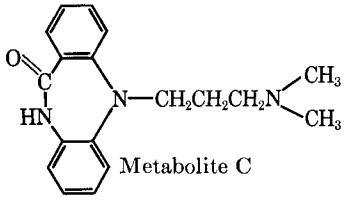
Thin-layer chromatography of chloroform extracts of dog and human urine revealed a zone corresponding to unchanged drug and four other drug-related zones (designated metabolites A, B, C, and D). Thin-layer chromatography in conjunction with the bromcresol purple procedure of Woods *et al.* (3) was used to determine individually the drug and three of its metabolites. Two of these metabolites (A and C) were synthesized to yield samples for analytical calibration purposes. Since standards of metabolites B and D were not available for calibration purposes, the calibration curves for the drug and metabolites A and C were averaged and used for these metabolites.



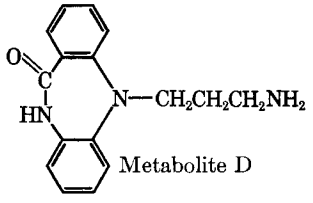
Metabolite A



Metabolite B



Metabolite C



Metabolite D

Received January 19, 1967, from The Upjohn Co., Kalamazoo, MI 49001

Accepted for publication March 14, 1967.

The assistance of Dr. E. M. Schneider and Dr. J. G. Wagner with the design and execution of the human studies, of Dr. G. A. Elliott and Dr. F. S. Eberts with the dog studies, and of Mr. J. I. Northam with the statistical analyses is gratefully acknowledged.

Compd.	System A	System B	System C
Drug	0.61	0.96	0.20
Metabolite A	0.24	0.48	0.02
Metabolite B	0.30	0.79	0.04
Metabolite C	0.49	0.88	0.20
Metabolite D	0.24	0.48	0.45

[a] The zones used for analysis are underlined.

EXPERIMENTAL

Materials—Bromcresol purple (5′,5″-dibromo-*o*-cresolsulfonphthalein indicator) was obtained from Eastman Organic Chemicals. The bromcresol purple reagent was prepared by dissolving 50 mg. of the solid in 100 ml. of analytical reagent grade $CHCl_3$. The synthesis of the drug and metabolite C have been described previously (4). Metabolite A was prepared by Dr. R. S. P. Hsi, The Upjohn Co., using the procedures described by Hanze *et al.* (4).

Thin-Layer Chromatography (TLC)—Silica Gel G plates of 250 μ thickness, impregnated with $ZnSiO_3$ and $(ZnCd)_2S$ phosphors, were employed with the following three solvent systems: system *A*, C_6H_6:CH_3OH:NH_4OH (50:50:1); system *B*, EtOAc:DMF:NH_4OH (50:50:5); system *C*, CH_3OH:$(CH_3)_2C{=}O$:C_6H_6:7 *M* NaOH (50:50:10:1). The zones were located with a mercury lamp (254 mμ). System *A* was used for the isolation of I and metabolite C, system *B* for metabolites A and B, and system *C* for metabolite D. The R_f values are presented in Table I.

Procedure for Determination of Drug and Metabolites—To 5.0 ml. of urine or serum in a 35-ml. centrifuge tube was added 3.0 ml. of pH 10 buffer (20.0 Gm./L. Na_2CO_3 + 12.4 Gm./L. $Na_2B_4O_7$), followed by 25.0 ml. of $CHCl_3$. The mixture was shaken vigorously. After 30 min. of standing at room temperature, the phases were separated by centrifugation (2000 r.p.m. for 10 min.) and the aqueous layer removed by aspiration. A 20.0-ml. aliquot of the $CHCl_3$ was transferred to a 50-ml. open-mouth centrifuge tube and evaporated to dryness under a stream of nitrogen. The tube was washed down successively with 5, 3, and 1 ml. of $CHCl_3$, and evaporated to dryness each time. The residue was dissolved in a few drops of $CHCl_3$, and quantitatively transferred to a thin-layer plate. Standards were spotted and the plate was developed with the appropriate system (Table I). The drug and metabolite zones were individually scraped from the chromatogram and transferred to 15-ml. centrifuge tubes. Five milliliters of pH 10 buffer was added to each tube and, after shaking, the mixtures were centrifuged. Four-milliliter aliquots of the supernates were transferred to another set of 15-ml. centrifuge tubes, 5.0 ml. of $CHCl_3$ added, and the mixtures were shaken vigorously and centrifuged at 2000 r.p.m. for 5 min. The aqueous phases were aspirated and 3.0 ml. of the $CHCl_3$ phases transferred to 10-ml. volumetric flasks containing 0.3 ml. of bromcresol purple reagent. The absorbances were measured at 410 mμ with a Cary spectrophotometer, employing $CHCl_3$ in the reference cell. To correct for background, a zero-hour urine sample was subjected to the same procedure. The concentrations of drug and metabolites were calculated from calibration curves having the following slopes (mcg. drug equivalents/ml./absorbance unit): drug, 32.9; metabolite A, 30.7; metabolite C, 28.1. Since samples of metabolites B and D were not available for calibration, an estimated slope of 30.0 was used.

Dog Studies—To test the extent of absorption of the drug, dog *1* (10.0-Kg. female) was given a 105-mg.[1] oral dose on day 1, no drug on days 2–7, and a 105-mg. intravenous dose on day 8. To test the effect of pretreatment, dog *2* (10.5-Kg. male) was given a 50-mg. oral dose on both days 1 and 2 and dog *3* (9.5-Kg. male) was given a 50-mg. oral dose on day 1, and a 250-mg. oral dose on day 2. In the case of dog *1*, a single 0–24-hr. urine sample was collected and 10 ml. of blood was withdrawn at 0, 0.5, 1, 1.5, 2, 3, 4, 6, 8, 10, 12, and 24 hr. after each dose. In the case of dogs *2* and *3*, urine was collected quantitatively during the intervals 0–1, 1–3, 3–5, 5–8, 8–12, 2–16, 16–24, 24–25, 25–27, 27–32, 32–36, 36–40, 40–49, 49–56, 56–74, and 74–80 hr. after the first dose of drug.

Human Studies—A single dose of 350 mg.[1] of the drug was administered to each of five male volunteer subjects after an overnight fast. Food was allowed 1 hr. after drug administration. Water intake was limited to 8 fl. oz. at the following times relative to the time of dosing: −1, 0, 1.5, 4, 6.5, 10, 14, 23, 24, 25.5, 28, and 30.5 hr. Urine was collected quantitatively during the intervals 0–1, 1–3, 3–5, 5–8, 8–12, 12–16, and 16–32 hr. after drug administration. Blood (10–12 ml.) was withdrawn from each subject at 0, 0.5, 1.5, 4, 6.5, 10, 14, and 24 hr.

RESULTS AND DISCUSSION

Identification of Metabolites—The isolation procedure developed for the drug employed chloroform extraction of pH 10 serum or urine followed by thin-layer chromatography (TLC). When this method was subsequently applied to the determination of the drug in dog and human urine samples, TLC revealed not only a zone corresponding to drug but also at least two other drug-related zones. Two additional TLC solvent systems (Table I) revealed that four metabolites were actually present. The metabolites were isolated from the urine and identified (2) as metabolites A, B, C, and D.

Both the dog and human convert the drug to these metabolites, but, as described below, the relative amounts and rates of excretion of the metabolites differed in the two species.

Quantitation of Drug and Metabolites—The drug and metabolites could be quantitatively extracted from pH 10 serum or urine with 5 vol. of chloroform. The diazotized drug did not react with *N*-1-naphthylethylenediamine, and since its spectral properties were not suitable for direct spectrophotometric determinations at microgram levels in serum or urine, the bromcresol purple procedure of Woods *et al.* (3) was investigated. Both the drug and its metabolites responded in this sensitive procedure. Thin-layer chromatography

[1] In all cases the drug was administered as the dihydrochloride.

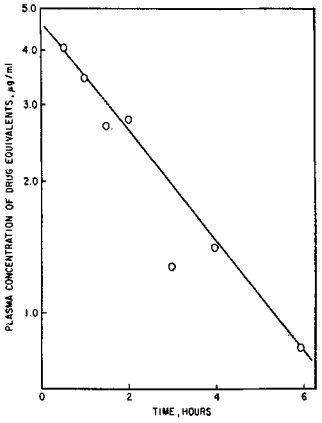

Fig. 1—Plasma levels of drug equivalents after a 10-mg./Kg. intravenous dose to dog 1.

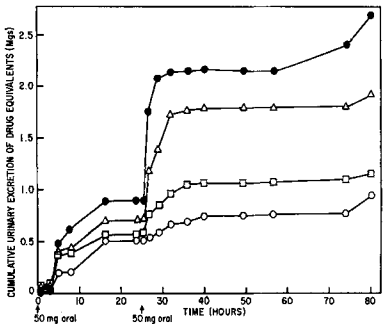

Fig. 2—Cumulative excretion of drug and metabolites after two 50-mg. oral doses to dog 2. *Key: ●, drug; ○, metabolite A; △, metabolite B; □, metabolite C.*

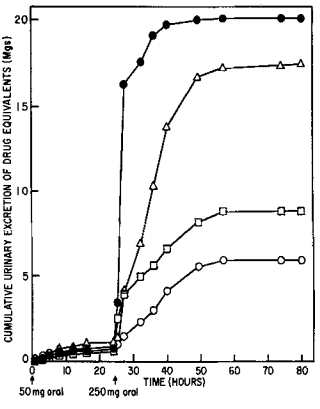

Fig. 3—Cumulative excretion of drug and metabolites after 50- and 250-mg. oral doses to dog 3. *Key the same as Fig. 2.*

was added to the procedure, since the bromcresol purple procedure lacks specificity. The final procedure, therefore, included the following steps. The serum or urine was adjusted to pH 10 and extracted with chloroform. A measured volume of the chloroform extract was evaporated to a smaller volume and quantitatively transferred to a silica gel thin-layer plate. The compounds were eluted from the silica gel support with pH 10 buffer, which was then extracted with chloroform to yield solutions for colorimetric measurement. Three thin-layer systems were required to resolve completely the drug and its four metabolites.

Serum Levels—*Dog Studies*—At a dose of 10 mg./Kg. to the dog, the serum levels after both oral and intravenous administration approached the lower limits of the analytical method; consequently, the half-life for the disappearance of drug-related material from the serum can only be estimated. Because of the extremely low serum concentrations, no attempt was made to quantitate the drug and metabolites individually. After the intravenous dose, the drug-related material disappears from the serum with a half-life of about 3 hr. (Fig. 1). Although the serum concentrations after oral administration were of the same order of magnitude as those after intravenous administration, the points were too scattered to yield a half-life estimate.

Human Studies—The concentrations of the drug and metabolites in the human serum samples were below detectable limits (< 1 mcg./ml.). Since an intravenous dose of 10 mg./Kg. of the drug to the dog had given only barely detectable serum levels, the observation of low serum levels in man was not surprising, and certainly did not prove poor absorption.

Urinary Excretion of Drug and Metabolites—*Dog Studies*—The distribution of drug and metabolites A, B, and C and the per cent of the dose recovered in the urine of each dog are presented in Table II. Since metabolite D was present only in trace amounts, no attempt was made to quantitate it.

The cumulative urinary excretion of drug and metabolites in the dogs which received the drug on 2 successive days is presented in Figs. 2 and 3.

TABLE II—URINARY EXCRETION OF DRUG AND METABOLITES IN THE DOG

Treatment Day	Dog	Rt.	Dose, mg.	% of Dose Excreted: Metabolite A[a]	Metabolite B	Metabolite C	Drug	Total
1	*1*	Oral	105	2.51	5.50	2.94	4.51	15.46
1[b]	*1*	i.v.	105	3.67	6.62	3.51	5.53	19.33

[a] Includes a small amount of metabolite D (<2% of the values given).

The urinary excretion of the first dose seems to be essentially complete prior to the administration of the second one. In the dog which received the two 50-mg. doses, the urinary excretion of drug-related material was greater after the second dose than after the first. Also, in the dog which received the 50-mg. dose on the first day and the 250-mg. dose on the second day, the urinary excretion of drug and metabolites after the second dose—both individually and collectively—was greater than five times the excretion after the first dose. Therefore, in both dogs that received doses on successive days, the percentage of the first dose excreted in the urine was smaller than that of the second. These data illustrate the importance of crossover experiments when comparing different formulations of the same drug.

The intact drug accounts for a greater percentage of the total recovered in the urine on the second day of treatment than on the first, while metabolite A accounts for a much smaller percentage of the total on the second day. These data indicate either a decrease in metabolism or a change in excretion pathways with chronic administration, *e.g.*, the ratio of biliary to urinary excretion of metabolite A may vary with chronic administration in a different manner from that of the intact drug.

The distribution of drug and metabolites in the urine was essentially identical after oral and intravenous administration. An estimate of the oral efficiency can be obtained by comparing the total urinary excretion of drug and metabolites after

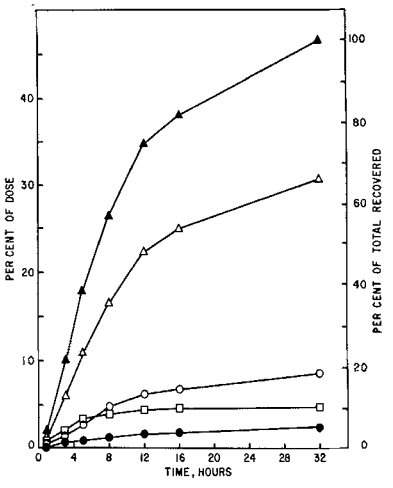

Fig. 4—Average cumulative excretion of drug and metabolites in five humans. Key: ▲, total excretion; ○, metabolite A; △, metabolite B; ●, metabolite C; □, drug.

oral and intravenous administration of the same dose. When the oral and intravenous doses were given on successive weeks to the same dog, the 24-hr. urinary excretion after the oral dose (first week) was 80% of the 24-hr. excretion after the intravenous dose. Assuming the first dose had no effect on the amount excreted after the second dose, the oral efficiency in this dog was about 80%. Actually, it is impossible to determine from these data whether the oral dose had any effect on the amount excreted in the urine after the intravenous dose 1 week later. However, since pretreatment tends to increase the percentage excreted in the urine, the 80% value is very likely a minimum estimate.

Not only does the percentage of the dose excreted in the urine increase with repeated administration, it also increases with increasing dose. The dogs given 50-mg. oral dose excreted an average of 6% of the dose in the urine, while the dog given the 105-mg. oral dose excreted 15.5%. These data support hypotheses such as (*a*) sufficiently high concentrations of the drug or its metabolites may inhibit nonurinary (*e.g.*, biliary) excretion, (*b*) saturation of binding sites of drug and metabolites, or (*c*) stimulation of urinary transport mechanisms.

The low recovery of the drug-related material in the urine after intravenous administration probably results from extensive biliary excretion. Other possibilities, considered to be less likely, include urinary excretion of undetected metabolites or binding of drug and/or metabolites by body constituents.

Human Studies—The cumulative excretion data for the drug and metabolites A, B, and C for each of the five subjects are presented in Table III. The average cumulative excretion is plotted in Fig. 4. Since the cumulative levels of metabolites do not appear to have reached their asymptotic values, excretion may not be complete in 32 hr. The average cumulative urinary excretion of intact drug and metabolites at each time interval, expressed as per cent of dose, is presented in Table IV. The distribution of drug and metabolites in the 0–32 hr. urine of each subject is presented in Table V.

Of the 350-mg. dose, at least 162.0 ± 15.3 mg. (S.E.M.), *i.e.*, 46.3 ± 4.4% (range: 36.5–57.1%), was absorbed. Expressed as drug equivalents, an average (±S.E.M.) of 30.2 ± 5.1 mg. was excreted as metabolite A, 106.7 ± 11.9 mg. as metabolite B, 8.5 ± 0.9 mg. as metabolite C, and 16.7 ± 2.3 mg. as unchanged drug. The percentage of drug-related compounds in each urine collection present as unchanged drug decreases from about 20% in the 0–1-hr. sample to about 3% in the 16–32-hr. sample, whereas beyond 1 hr., the percentage of the total as each metabolite increases only slightly.

Rate of Excretion of Drug and Metabolites—*Dog Studies*—The cumulative excretion data were used to estimate the over-all half-lives for the appearance in the urine of the drug and its metabolites. The half-lives were estimated by plotting the data in first-order fashion (Fig. 5). In the case

TABLE VI—EXCRETION HALF-LIVES OF THE DRUG AND ITS METABOLITE IN EACH HUMAN

Subject	Half-Life, hr. Metabolite A	Metabolite B	Metabolite C	Drug
1	5.3	6.2	6.2	3.0
2	7.8	6.8	7.6	2.9
3	6.0	4.9	6.1	3.1
4	7.9	8.6	12.3	3.8
5	5.3	4.6	6.3	2.4
Mean	6.5	6.2	7.7	3.0
S.E.M.	0.6	0.7	1.2	0.2

of dog *3*, the half-lives (±S.D.) for the appearance in the urine of drug and metabolites A, B, and C after the first dose were 5.5 ± 0.8, 6.6 ± 0.5, 4.3 ± 0.5, and 7.2 ± 0.6 hr., respectively, and, after the second dose, 3.8 ± 0.4, 4.7 ± 0.5, 5.4 ± 0.6, and 4.6 ± 0.6 hr. The half-life for the appearance of total drug-related material was 5.0 ± 0.4 hr. after the first dose, and 5.3 ± 0.4 hr. after the second.

In the case of dog *2*, the scatter of the data does not justify the calculation of the individual half-lives. The appearance of total drug-related material in the urine after both doses also seemed to be consistent with a half-life of about 5 hr. Unlike that found in the human (*vide infra*), the rate constant for the appearance of drug in the urine is not significantly larger than for the metabolites. Therefore, the dog is probably not a satisfactory species for the study of the unusual excretion kinetics observed in the human.

Metabolite C was also administered to the dog. As expected, metabolites A and D were found in the urine. The average half-lives for the appearance of metabolites A, C, and D in the urine, after a single dose of metabolite C, were 4.1, 3.6, and 6.2 hr., respectively. These half-lives for metabolites A and C do not differ significantly from those obtained when I was administered, which indicates that, at least in the dog, the rate of excretion of these compounds is not limited by their rate of manufacture. Like the case of I, when the same dose of metabolite C was administered on 2 successive days to the same

TABLE VII—AVERAGE[a] FITTING PARAMETERS FOR URINARY EXCRETION OF DRUG AND ITS METABOLITES

Compd.	Method of Fitting[b]	Half-Life ($t_{1/2}$), hr.[c]	Total Excreted at t = ∞ hr. U_∞ (mg.)	Lag Time t_0 (hr.)
A	(*1*)	6.5	30.2	0
	(*2*)	9.1	33.7	0
	(*3*)	7.0	31.8	1.04

	(*2*)	7.6	173.5	0
	(*3*)	6.3	167.2	0.73

[a] Average for five human adult males. [b] Methods: (*1*) fit of $U = U_{32}(1 - e^{-Kt})$; (*2*) fit of $U = U_\infty (1 - e^{-Kt})$; (*3*) fit of $U = U_\infty [1 - e^{-K(t-t_0)}]$ for $t > t_0$ hr. [c] $t_{1/2}$ (hr.) = $0.693/K$.

dog, the percentage of the second dose excreted in the urine was much more than twice that of the first dose. This was true even though cumulative urinary excretion plots indicated that excretion of the first dose was essentially complete prior to administration of the second dose.

Human Studies—As a first approximation, in order to estimate the excretion half-lives, the assumption was made that the amount excreted in 32 hr. was equal to the total amount excreted, *i.e.*, $U_{32} = U_\infty$ [method (*1*) of Table VII]. The data for the individual subjects and the average of the five subjects are plotted in first-order fashion in Fig. 6. It is apparent from these plots that first-order excretion kinetics are followed for both intact drug and metabolites. The excretion half-lives over the whole collection period, obtained from the slopes of Fig. 6, are presented in Table VI. The average half-lives (±S.E.M.) for drug and metabolites A, B, and C are 3.0 ± 0.2, 6.5 ± 0.6, 6.2 ± 0.7, and 7.7 ± 1.2 hr., respectively.

The half-lives for the appearance of drug and metabolites in the urine of the humans were also estimated by fitting the data by the method of least squares [methods (*2*) and (*3*) of Table VII] to the following first-order equations:

$$U = U_\infty [1 - e^{-Kt}] \qquad \text{(Eq. 1)}$$

$$U = U_\infty [1 - e^{-K(t-t_0)}] \qquad \text{(Eq. 2)}$$

where U is the milligrams of drug equivalents excreted to time t, U_∞ is the amount excreted at infinite time, K is the observed rate constant for excretion ($t_{1/2} = 0.693/K$), and t_0 in Eq. 2 is a "lag time" which corrects for delays caused by absorption, metabolism, and distribution. Employing these equations, the least squares fit of the data yields estimates of U_∞ as well as the half-life (Table VII). All of the average half-lives obtained from Eq. 2 are within 0.5 hr. of the values obtained from the slopes of the $U_{32} - U$ *versus* t plots of Fig. 6. The average half-lives indicate that the excretion of

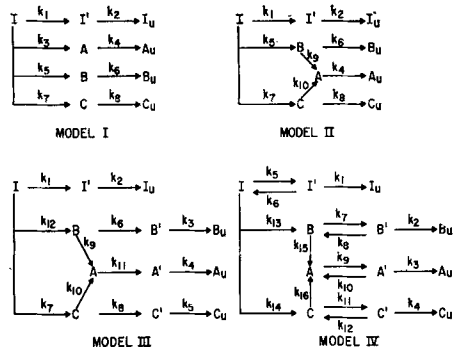

Fig. 7—Schematic models. Drug and metabolites in plasma: I, A, B, C; drug and metabolites in "compartment": I', A', B', C'; drug and metabolites excreted in urine: I_u, A_u, B_u, and C_u.

each of the metabolites is at least 95% complete in 32 hr., thus justifying the original approximation that $U_{32} = U_\infty$.

Rate of Absorption and Metabolism—Since simple first-order excretion appears to be followed for both drug and metabolites (Fig. 6) beginning with the first hour after administration, the drug which is absorbed by the human must be absorbed and metabolized very rapidly. In general, these data indicate that absorption and metabolism are so rapid that excretion of the metabolites is not limited by their rate of formation or by the rate of absorption of the drug.

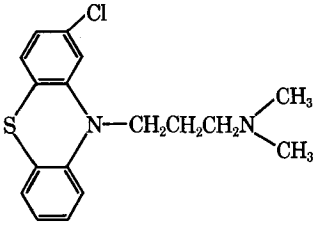
Kinetic Models for Urinary Excretion in the Human—An attempt was made to formulate a mathematical model or models consistent with all the available data. For simplicity, it was assumed that drug absorption had essentially ceased 1 hr. after oral administration and only the data after 1 hr. were considered.

The complexity of kinetic models and equations required to describe the metabolism and excretion of a drug is dependent upon the precision and discrimination of the data. In the present case, measurement by a nonspecific assay of total urinary drug and metabolites yields data which can be approximated by a single exponential function (plus a constant) and which suggest that a single rate constant is involved. However, the added information that three metabolites are formed and excreted at their individual rates requires a more complicated description.

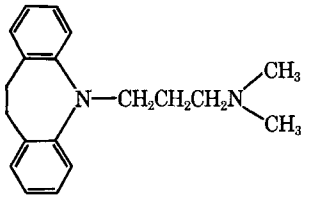
The increasing complexity of mathematical models resulting from increasing discrimination of analytical results is demonstrated by the evolution of models I–IV (Fig. 7). In order to account for the observed urinary excretion, model I postulates that the rate of metabolism of the drug is much faster than the excretion rates of the drug and its metabolites, that each of the metabolites is formed *directly* from the drug (*i.e.*, metabolites B and C are not necessary intermediates in the formation of metabolite A), and that there is a compartment in which the drug is stored and no longer metabolized prior to excretion. Assumption of such a compartment would be consistent with the incomplete metabolism of the drug, even though its excretion rate is postulated to be relatively slow compared to its metabolism.

Once the chemical structures of the metabolites were known, however, model II was constructed to take into account the possibility that metabolites B and C may be chemical intermediates in the formation of metabolite A. In this model, the assumptions are made that the rate of metabolism of the drug is much faster than the excretion rates of the drug or its metabolites (B and C), or the formation rates of the metabolite A, that metabolite A is formed from B and C, and that there is a compartment in which the drug is no longer metabolized prior to excretion.

Since the drug and metabolites have similar chemical structures, it is likely that they enter into the same physiological compartments in which solubility probably plays the main selective role. Hence, in addition to the assumptions of model II, model III postulates a compartment in which the drug *and* its metabolites are no longer metabolized prior to excretion. Model IV is similar to model III except that equilibria are postulated. At present, model IV appears to be the most reasonable description of the chemical and physiological data but none of the models have been completely excluded. A mathematical discussion of these models will be the subject of a future communication.



II



III

Metabolism of Structurally Related Drugs—The investigated drug, although noncyclic, has some structural similarity to the phenothiazine drugs *e.g.*, chlorpromazine (II) and imipramine (III). Both of these compounds are mono- and di-demethylated *in vivo* by several species (5).[2] However, both of these drugs are also ring-hydroxylated and then conjugated with glucuronic acid. Even after hydrolysis with β-glucuronidase, no evidence was found in the present study for ring-hydroxylated or conjugated metabolites. Although Fishman *et al.* (6) have reported the isolation of the *N*-oxides of chlorpromazine (0.7% of the dose) and imipramine (~2% of the dose), no evidence was found for *N*-oxide metabolites in the present study.

Applications of Differential Scanning Calorimetry in Pharmaceutical Analysis

By RENATE REUBKE* and JOSEPH A. MOLLICA, JR.

The application of differential scanning calorimetry to several aspects of pharmaceutical analysis is presented. These include the utilization of this technique in the quantitative estimation of purity, in the relative determination of purity for a control procedure, and in the detection of polymorphism. The purities and heats of fusion of diallylbarbituric acid, naphthalene, glutethimide, dibucaine, and anthraquinone are given. A comparative analysis of several samples of methyl reserpate is presented and the detection of polymorphism in tripelennamine citrate is discussed.

THE AVAILABILITY of commercial instruments capable of performing various types of thermal analysis has led to an increasing number of publications of their application to organic compounds (1–4). One area of application which is of particular interest to a pharmaceutical analyst, and one which has not been extensively investigated, is the quantitative estimation of purity through thermal analysis. Phase solubility analysis is presently one of the most widely used techniques for purity determination (5, 6), since the equilibrium solubility of a pure compound is as characteristic a property as is the melting point. This method, however, suffers from certain disadvantages. Perhaps the most important of these is that the time required for equilibration may be several weeks. It was decided therefore to see if differential scanning calorimetry could overcome some of these disadvantages in determining the "absolute" purity of a compound. This determination is based on the other fundamental property of a compound, its melting point. This method would overcome some of the disadvantages of phase solubility in that the analysis could be completed in 1 day and since one determines the sum of the impurities, it would be possible to estimate purity to within $\pm 0.1\%$ when dealing with samples at the 99%+ level, even if errors of the order to 20% were introduced.

Two other areas of application were also investigated—namely, the utilization of this technique in the determination of relative purity and in the detection of polymorphism. It provides a rapid method for control procedures since one can compare the endotherm of the sample to endotherms of known purity without the necessity of a complete analysis. The presence of polymorphism in several samples of tripelennamine citrate is easily detected by comparing thermograms of different samples and this substantiated evidence that was obtained by spectroscopic methods.

EXPERIMENTAL

A Perkin-Elmer model DSC-1B differential scanning calorimeter was used in this study (7). Aluminum sample pans and pan lids which fit the DSC-1B were used for all samples except the anthraquinone. Anthraquinone samples were sealed in a volatile sample sealer. Care was taken in sample handling and in covering the sample holders with the covers in the same relative position in order to minimize base line drift, which, as pointed out by Rogers and Morris (8), can be caused by differences and variations in thermal emissivity. All samples were run in a nitrogen atmosphere. The materials used were of the quality specified in the text.

A semimicro balance with a sensitivity of 0.01 mg. was used to weigh all samples. Areas were generally determined by planimeter, although in some cases areas were determined by cutting and weighing. In either case, the reproducibility of an area determination was to within 3%.

THEORY

Calorimetric methods for the determination of purity are well known (9, 10); hence, only a brief review of the theory will be given. The equation for the lowering of the freezing point in dilute solution is that developed by Van't Hoff:

$$\frac{dT}{dX_2} = \frac{RT^2}{\Delta H_f}(k/k' - 1) \qquad \text{(Eq. 1)}$$

THEORY

Calorimetric methods for the determination of purity are well known (9, 10); hence, only a brief review of the theory will be given. The equation for the lowering of the freezing point in dilute solution is that developed by Van't Hoff:

$$\frac{dT}{dX_2} = \frac{RT^2}{\Delta H_f}(k/k' - 1) \qquad \text{(Eq. 1)}$$

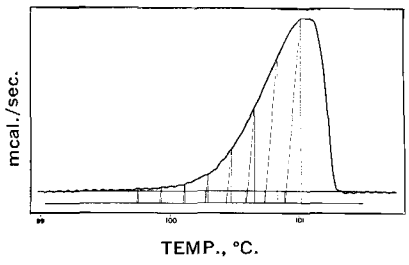

Fig. 1—Thermogram of p-*chlorophenoxyaniline; 1.74 mg.; 1 mcal./sec., full scale; scan rate, 0.625°/min.; chart speed, 4 in./min.*

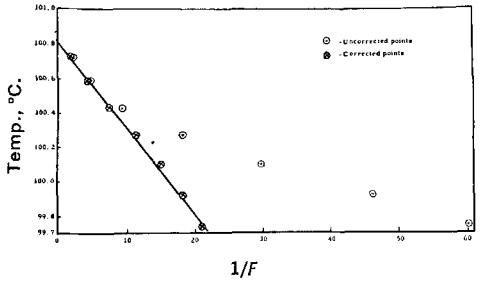

Fig. 2—Plot of T vs. *1/*F *for* p-*chlorophenoxyaniline from thermogram in Fig. 1.*

where T = temperature in °K.,
X_2 = mole fraction of minor component (solute; impurity),
ΔH_f = molar heat of fusion of the major component,
R = gas constant,
k/k' = the distribution of the solute between the solid and liquid phases.

If it is assumed that no solid solutions are formed, *i.e.*, $k/k' = 0$, then upon integration of Eq. 1, one obtains the most commonly used expression for relating mole fraction of impurity to the melting point depression:

$$X_2 = \frac{(T_0 - T_m)\ \Delta H_f}{RT_0^2} \qquad \text{(Eq. 2)}$$

where T_0 = melting point of the pure compound in °K., T_m = melting point of the sample in °K.

If there are no solid solutions formed, then the concentration of impurity in the liquid phase at any temperature during melting is given by:

$$X_2' = X_2/F \qquad \text{(Eq. 3)}$$

where X_2' = mole fraction of impurity in the liquid phase,
X_2 = mole fraction of impurity in the total sample,
F = fraction melted at temperature, T.

Since the melting point depression is directly proportional to the mole fraction of impurity, one obtains:

$$T_0 - T = 1/F\,(T_0 - T_m) \qquad \text{(Eq. 4)}$$

which predicts that a plot of the sample temperature *versus* the reciprocal of the fraction melted at temperature, T, should yield a straight line with a slope equal to $-(T_0 - T_m)$, the melting point depression and the intercept at $1/F = 0$ gives T_0, the melting point of the pure compound.

The value for ΔH_f, the molar heat of fusion, is obtained by determining the area under the melting curve which is proportional to the heat absorbed by the sample during fusion.

These three values, T_0, $T_0 - T_m$, and ΔH_f, may then be introduced into Eq. 2 to calculate the mole fraction of impurity.

RESULTS AND DISCUSSION

Although Eq. 4 predicts a linear relationship in a plot of T *versus* $1/F$, in practice, linear plots were not obtained. Neglecting deviation caused by experimental error, the curvature could result from two sources. [The use of slow scanning rates and small samples of relatively high purity makes errors negligible due to thermal resistance and deviations from "ideality" (11).] If the impurity forms a solid solution with the major component, then the concentration in the liquid phase will be less than that predicted by Eq. 3, and the corresponding equilibrium temperature will be too high; hence, the plot will be concave upward (12). Another factor, which will produce the same type curvature, is the sensitivity limit of the instrument.[1]

With respect to Fig. 1, the melting point depression, $T_0 - T_m$, is equal to 0.048° and T_0 is 100.8° C. If Eq. 4 is rearranged to:

$$F = \frac{T_0 - T_m}{T_0 - T}$$

it is readily seen that at 2° below the melting point, the sample is 2.4% melted, yet the signal at this point is indistinguishable from the base line. If the point at which the signal departs from the base line ($\approx$99.3°) is taken as the starting point for the area measurement, 3–4% of the total area will have been neglected. If the total measured area is designated A, and the partial measured areas are designated a_i, one then has $1/F_i = A/a_i$. The neglected portion could be considered negligible with respect to the total area, but it is significant with respect to the first few partial areas measured as they may be in error by as much as 50–100%. One may compensate for this by adding an adjustable parameter x to linearize the plot, which compensates for the neglected portion which was undetectable due to the sensitivity of the instrument. One then defines:

$$1/F_i = \frac{A + x}{A_i + x}$$

Figure 2 shows a plot of the data before and after correction. The correction in this case amounted to 3.4%. The value x is determined by successive approximation, and if the theory is correct, there should be but one value of x which will yield a linear plot.

However, since no *a priori* knowledge exists as to whether a solid solution is formed, it cannot be stated that the curvature is due entirely to instru-

[1] A complete discussion of the application of the theory to the detailed analysis of a melting curve obtained by a continuously scanning calorimeter was presented by Gray, A. P., in "Determination of Purity by Differential Scanning Calorimetry," presented to Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy, March 1966. He has also treated this subject in the "Thermal Analysis Newsletter," No. 5 and 6, published by the manufacturers of this instrument.

TABLE I—PURITY AND HEAT OF FUSION OF SEVERAL COMPOUNDS DETERMINED BY DIFFERENTIAL SCANNING CALORIMETRY

Sample	Wt., mg.	ΔH, cal./Gm.	T_0, °C.	Purity, mole %
Diallylbarbituric acid[a]	4.04	31.9 ± 1	173.3	99.7_6
	1.14		173.7	99.8_4

mental insensitivity. But, because the corrected value $A + x$ gave good results for heat of fusion in those cases where there was a literature value for comparison and the calculated purities were reasonable, it was assumed that this was the main cause of the curvature.

Samples were selected which would melt without decomposition, and in most cases if there was some independent determination of their purity. The first criterion, that the compound fuse without decomposition, eliminates many compounds of pharmaceutical interest, particularly salts which either melt with decomposition or do not behave ideally.

The anthraquinone samples presented an interesting problem. The attempt was made to distinguish among four samples, all of which were at least 99.5% pure. The calculated purities and the heat of fusion are given in Table I. The results agree with what one would predict semiquantitatively, *i.e.*, the zone-refined material should be the purest and the production sample the least pure. A difficulty encountered with the anthraquinone was that it started to sublime well below its melting point, which led to sloping base lines and endotherms which were not resolvable. This was remedied when the samples were enclosed in the volatile sample sealer. Figure 3 shows two of the endotherms, sample 1 (99.9_9%) and sample 3 (99.9_1%). One can detect a visual difference in these two endotherms, yet they differed in purity by approximately 0.1%.

As a control procedure, methyl reserpate is analyzed by the solubility temperature method. The method involves the determination of the temperature at which the material goes into solution and then a comparison with a standard curve of sample purity *versus* solubility temperature. The sample purity for the working curve is determined by phase solubility. The method is tedious and subject to error. It was decided to investigate whether one could differentiate among these samples by DSC. The purity of the samples listed is that obtained by the solubility temperature method. Figure 4 shows the results of these studies at two different scanning rates. It is seen that even at the relatively fast scanning rate of 10°/min. one can

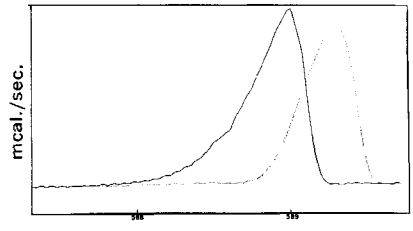

Fig. 3—Thermogram of two samples of anthraquinone; 2 mcal./sec., full scale; scan rate, 0.625°/min.; chart speed, 4 in./min. Key: ·····, zone refined; ———, chromatographically pure.

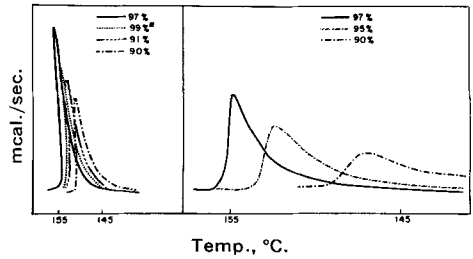

*Fig. 4—Thermograms of several samples of methyl reserpate at scan rates of 10°/min. and 2.5 min.; 8 mcal./sec., full scale; sample sizes were all about 2.5 mg. *Sample which analyzed 99% by temperature solubility method, but was later shown to have a high salt content.*

resolve the sample and is able to estimate the purity to ±1%, although it was found necessary to run at least two compounds of known purity with the unknown in addition to comparing the result to a previously determined working curve in order to compensate for any day-to-day instrumental variation. The method is therefore advantageous in those cases where an existing analytical method is particularly tedious or insensitive. To achieve reproducible results, however, in the authors'

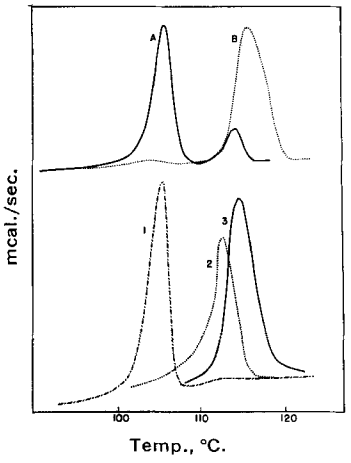

Fig. 5—Thermograms of two samples of tripelennamine citrate (A *and* B). *Curve* 1 *is form* B, *which had been recrystallized and seeded with form* A; *curve* 3 *is form A, which had been recrystallized and seeded with form* B; *curve* 2 *is form* A *after heating. Sample weights were all about 5.3 mg.; scan rate 5°/min.; 8 mcal./sec., full scale.*

opinion, a greater amount of care is necessary than one would have to utilize, for example, in making a spectrophotometric measurement.

During the investigation of various compounds by DSC, it was observed that tripelennamine citrate displayed some anomalous behavior. Two different sources of the material differed in their melting behavior, although chemical analysis showed no significant difference. The thermograms of these two samples are shown in the top half of Fig. 5. It was thought that the tripelennamine citrate existed in two different crystalline forms. The X-ray diffraction patterns and infrared spectra of the two substances also indicated this. If the behavior was caused by different crystalline modifications, then one should be able to transform one into the other. Some preliminary results of these attempts are shown in the lower half of Fig. 5. Form A was carefully recrystallized from acetone and seeded with crystals of form B. Form B was recrystallized from acetone and seeded with crystals of form A. The thermograms of the recrystallized material indicate transformation to forms B and A, respectively. It was also possible to transform A by heating it overnight at a temperature just below its melting point. The data presented above are some preliminary observations. Further investigation on the application of DSC in combination with X-ray analysis on this problem is under way.

SUMMARY

Differential scanning calorimetry provides a rapid and accurate method for purity determination. However, it is limited to those compounds which do not decompose on melting, and unfortunately, therefore, eliminates many compounds of interest. As such, it does not have as wide a range of applicability as does phase solubility analysis. There is also the possibility that the impurity may form a solid solution and thus invalidate the analysis. However, in this respect there are analogous interferences which may invalidate phase solubility analysis (6).

With a reasonable amount of care, the technique can be used to rapidly estimate the purity of a sample by comparison with samples of known purity as evidenced by the differentiation of several samples of methyl reserpate. Also, the technique can be utilized to provide evidence of polymorphic behavior which can complement or supplement spectroscopic analysis.

Differential scanning calorimetry is not the answer to all analytical problems, but it can offer evidence in many areas which is not obtainable by other methods, or it can provide evidence to support that obtained by other techniques.

Experimental Evidence for the Existence of an Adrenochrome–Adrenolutin Complex

By R. W. JANSSEN and C. A. DISCHER

Horizontal linear paper chromatography was utilized to achieve the semiquantitative separation of adrenochrome–adrenolutin mixtures. Data obtained by the spectrophotofluorometric assay of bands eluted from these chromatograms show evidence of the formation of a 1:1 complex of the two components.

As a facet of a continuing study of the photodegradative mechanisms of epinephrine, chromatographic separations of its degradation products were undertaken with a view toward quantitative estimation of the various components present. Heacock and his group used an adsorption method to separate the oxidative degradation products of epinephrine (1). Heacock and Mahon reported the separation of adrenochrome, adrenolutin, and 5,6-dihydroxy-*N*-methylindole on acetylated paper (2).

The accepted mechanism of oxidation and subsequent degradation of epinephrine was first elucidated about 1950 (3–6). An expanded scheme has been published by Harrison (7). Adrenolutin, one of the degradation products, is characterized by an intense apple-green fluorescence. This fluoresence has been utilized as the basis for the assay of epinephrine, adrenochrome, or adrenolutin (8–11).

EXPERIMENTAL

Adrenochrome Preparation—Adrenochrome was prepared by the silver oxide oxidation of epinephrine, using a modification of the method of Somkaite (12), which was derived from that of Sobotka and Austin (13). Oxygen was displaced from the adrenochrome solution during crystallization by placing a small piece of dry ice in the solution. In order to minimize the tendency of moisture from the air to condense in the −40° solution, a cover filled with dry ice was placed over the container holding the crystallizing solution, m.p. 125° dec.[1]

Adrenolutin Preparation—All operations were performed under a carbon dioxide atmosphere using solutions prepared with doubly distilled carbon dioxide saturated water unless otherwise stated. These solutions ranged in concentration from 0.05 to 1.0 mg./ml.

An amount of adrenochrome equivalent to the concentration of adrenolutin desired was placed in a carbon dioxide filled 10-ml. flask. Nitrogen saturated 0.05 *N* tertiary sodium phosphate solution (4.0 ml.) containing ascorbic acid (0.1 mg./ml.) was added. After 2 min., 0.1 *N* phosphoric acid (4.0 ml.) was introduced and the solution brought to volume with buffer (0.1 *M* sodium dihydrogen phosphate adjusted to pH 5.5 with 0.1 *N* sodium hydroxide). The resultant solution was always used immediately. It exhibited the characteristic fluorescence peak of adrenolutin at 518 mμ (corrected) when activated with 412 mμ (corrected) light.

Chromatographic Method—The chromatographic paper[2] (25-cm. strips) was suspended from a glass rod and washed with 2% acetic acid for 18 hr. The strips were next washed with two portions of distilled water and soaked in distilled water for 1 hr. The paper was then dried over silica gel for 6 hr. and stored in a 100% humidity chamber for a minimum of 48 hr. before use.

A modification of the chromatographic apparatus of Hauton (14) was employed. A continuous posterboard strip was placed between the edges of the glass plates to effect a slight separation and to serve as a vapor barrier. The saturation strips described by Hauton were omitted and his procedure of clamping the plates together during runs was found unnecessary.

All chromatographic procedures and elutions were performed in a dry box[3] under a positive carbon dioxide pressure. The running solvent used was normal saline solution saturated with carbon dioxide. Fifty-microliter samples were used in all cases.

Adrenochrome Assay—The sample was applied to the prepared paper as a band 5 cm. from one end. Chromatographic development was allowed to proceed in total darkness until the solvent front was a few centimeters from the terminal end. The section of R_f 0.6–0.9 including the red adrenochrome band at R_f 0.75 was cut from the strip, rolled into a cylinder, and inserted into a micro-filter tube-type funnel and this assembly placed in a 10-ml. flask. The adrenochrome band was eluted by dropwise addition (0.5 ml./min.) of bicarbonate buffer (8.0 ml.) (0.05 *M* sodium bicarbonate adjusted to pH 6.0 with 0.2 *N* hydrochloric acid.) Four per cent ascorbic acid (100 μl.) was added to the eluate and the flask filled to the mark with 10.0 *N* sodium hydroxide, stoppered, and inverted five times. An aliquot of the now pale yellow solution was placed in the spectrophotofluorometer[4] and its fluorescent intensity read at 518 mμ (corrected) exactly 5 min. after the time of addition of the sodium hydroxide. Light at 412 mμ (corrected) was used to activate the solution. The results were given the designa-

tion (A). (All assays throughout this investigation utilized the same activation and emission wavelengths.)

To obtain a time zero fluorescent intensity reading, a 50-μl. sample of each original adrenochrome solution was placed in bicarbonate buffer (8.0 ml.). This solution was treated and read using the same procedure as that for the eluate from the adrenochrome band of the chromatogram. The time zero adrenochrome reading was designated (A_0).

Adrenolutin Assay—Pure adrenolutin solution was analyzed in a manner similar to that for adrenochrome at time zero. A 50-μl. sample was placed in a 10-ml. flask containing bicarbonate buffer (8.0 ml.) and the fluorescent intensity obtained as above; (L_0) was used to designate these results.

Preparation and Analysis of Adrenochrome–Adrenolutin Mixtures—Adrenolutin was prepared as previously described by the addition of 0.05 N tertiary sodium phosphate (4.0 ml.) to an amount of adrenochrome equivalent to the desired quantity of adrenolutin in a 10-ml. flask. The resulting adrenolutin solution was adjusted to a pH below 7 by the addition of 0.1 N phosphoric acid (4.0 ml.). The adrenochrome portion of the mixture was then added, adrenochrome being stable at pH's slightly below 7. The flask was then filled to the mark with pH 5.5 phosphate buffer and the contents mixed by inverting the flask for 1 min. A 50-μl. sample was streaked on the chromatogram and development begun. Upon completion of the chromatographic run, the segment of R_f 0.6–0.9 was cut from the strip and treated according to the procedure outlined for adrenochrome. The value of the fluorescent intensity found was given the designation (F'). (The adrenochrome band was located between R_f 0.70 and 0.80 and the adrenolutin band between R_f 0.40 and 0.50.)

While the chromatogram was being developed, a second 50-μl. sample of the same adrenochrome–adrenolutin mixture was taken and placed in a 10-ml. flask containing bicarbonate buffer (8.0 ml.). Subsequent treatment was identical to that used in the adrenochrome assay. Since this procedure should rearrange all adrenochrome present to adrenolutin and should merely stabilize the adrenolutin already present, the fluorescent intensity found should equal the sum of the values expected from each. This experimentally found total fluorescent intensity at time zero was designated (F_t).

The mixtures of adrenochrome and adrenolutin chromatographed varied in ratio but always totaled 1.5 mg./ml. in solute concentration.

RESULTS AND DISCUSSION

Calibration data are shown in Table I and in graphical form in Fig. 1. The three sets of calibration data gave straight line plots on log-log paper between 0.05 mg./ml. and 1.0 mg./ml. concentration (2.6×10^{-4} to 5.3×10^{-3} M) and were utilized to calculate the amount of each compound present in the mixtures studied.

Adrenochrome concentration in the mixture was found by extending a line from the value of its fluorescent intensity (F') to line (A). Its concentration was then taken as that point on the concentration axis. Adrenolutin concentration was determined by subtracting the fluorescent intensity value on line (A_0) at the above experimental concentration of adrenochrome from the total fluorescent intensity value at time zero (F_t) and extending a line from the fluorescent intensity calculated to line (L_0). The mg./ml. of adrenolutin was then read on the concentration axis directly below the point of intersection.

The results obtained for the adrenochrome–adrenolutin mixtures are represented graphically by Fig. 2. As seen from this figure, when mixtures of adrenochrome and adrenolutin are separated chromatographically, although a qualitative separation is achieved, theoretical recovery of either component was not obtained. The adrenochrome recovery was always above the theoretical line of slope unity, indicating greater than theoretical recovery. Adrenolutin, on the other hand, showed indicated recoveries well below theoretical for all mixtures. Considering the method of analysis used, these experimental results necessitate the conclusion that some adrenolutin or substance giving rise to it was being carried in the adrenochrome band.

The above data can be used to show the existence

TABLE I—FLUORESCENCE-CONCENTRATION CALIBRATION DATA[a]

Concn., mg./ml.	Fluorescence: Adrenochrome-Eluted from Chromatogram (A)	Fluorescence: Adrenochrome at Time Zero (A_0)	Fluorescence: Adrenolutin (L_0)
0.01	1.16	1.16	...
0.05	5.2	6.3	3.58
0.1	9.6	10.5	7.17
0.2	17.9	18.6	14.0
0.5	37.5	42.3	32.6
1.0	64.8	71.5	63.6
2.0	99.8	103.0	...

[a] All fluorescent values were obtained on an Aminco-Bowman spectrophotofluorometer with a No. 3 slit arrangement, a 412 mμ (corrected) activation wavelength, and a 518 mμ (corrected) emission wavelength. All fluorescent values are adjusted to the equivalent of a 0.3 M. multiplier setting. Each value is the average of 4–7 runs.

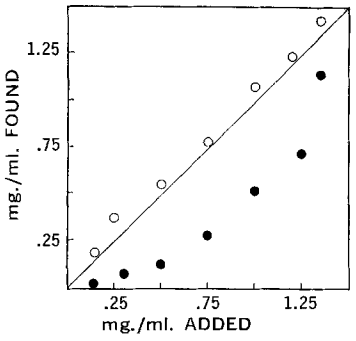

Fig. 2—Analysis results for adrenochrome–adrenolutin mixtures.

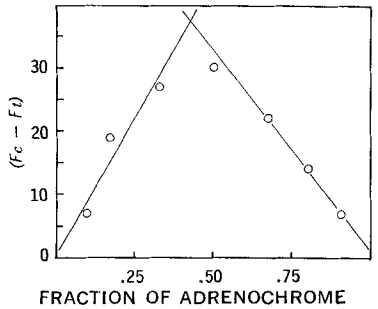

Fig. 3—Modified plot of continuous variation.

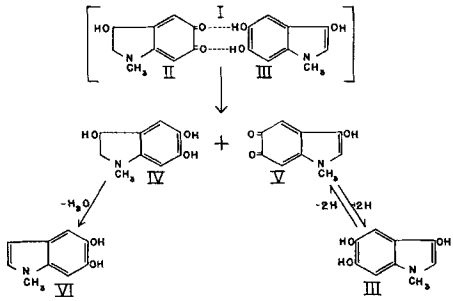
of an adrenochrome–adrenolutin complex in the mixture. By use of a modified method of continuous variation, the difference between the theoretical total fluorescent intensities (F_c) and the actual total fluorescent intensities (F_t) for the various solute ratios studied are plotted against the mole fraction of adrenochrome in the mixtures. Two lines are generated which intersect at approximately 45% adrenochrome (Fig. 3), indicating the greatest decrease in fluorescence near the 1:1 *M* ratio.

It was also observed that when a mixture of adrenochrome and adrenolutin was being separated chromatographically, a nonfluorescent yellow band appeared at the trailing edge of the adrenochrome band. When the chromatogram was sprayed with Ehrlich's reagent [*p*-dimethylaminobenzaldehyde (1 Gm.) dissolved in a mixture of concentrated hydrochloric acid (30 ml.) and ethanol (30 ml.) and the solution diluted to 100 ml. with water], a blue-violet band indicating 5,6-dihydroxy-*N*-methylindole formed at the location of the zone; adrenochrome and adrenolutin did not give the color with this reagent. The nonfluorescent yellow band did not appear when either adrenochrome or adrenolutin were chromatographed separately.

These observations can be explained by assuming a hydrogen bonded 1:1 complex (I) of adrenochrome (II) and adrenolutin (III). As a result of the complexation, the adrenolutin can transfer two hydrogens to the adrenochrome, giving an equimolar mixture of leucoadrenochrome (IV) and adrenolutin-quinone (V) (Scheme I). The latter substance should be stable but the former will dehydrate to 5,6-dihydroxy-*N*-methylindole (VI), in line with the



Adrenochrome–Adrenolutin Complex Degradation Scheme

Scheme I

indicated presence of this substance on the chromatogram. For every molecule of adrenochrome which gains two hydrogens and is transformed to leucoadrenochrome, one molecule of adrenolutin-quinone should also be obtained. When the adrenolutin-quinone is reduced to adrenolutin by the addition of the alkaline ascorbate solution, an amount of fluorescence equivalent to that obtainable from the same number of adrenochrome molecules should result. In addition, the fluorescence due to the now rearranged adrenochrome which originally did not complex is also read. Thus the developed fluorescence of the adrenochrome band should be the sum of the rearranged uncomplexed adrenochrome, adrenolutin carried as the complex, and reduced adrenolutin-quinone formed by degradation of the complex. This sum should be greater than the amount of fluorescence expected from the adrenochrome concentration originally present.

Additional conclusions may be drawn. Since part of the adrenolutin is traveling as a complex in the adrenochrome band, the fluorescent intensity of adrenolutin should be decreased, as observed. Experimental results also show that as expected from these interpretations, the sum (F_t) of the fluorescent intensity related to adrenochrome plus that of adrenolutin is always less than theoretical since part of the original adrenochrome has been converted to the nonfluorescent 5,6-dihydroxy-*N*-methylindole.

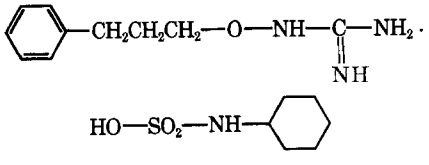
Pharmacologic Studies with 3-(Phenylpropoxy)guanidine Cyclohexanesulfamate

By W. VELDKAMP, H. H. KEASLING, G. A. JOHNSON, W. A. FREYBURGER, and R. J. COLLINS

Some comparisons of the pharmacologic properties of 3-(phenylpropoxy)guanidine cyclohexanesulfamate (U-16,178F) and dextroamphetamine sulfate are reported. While less potent on a milligram basis than dextroamphetamine sulfate, U-16,178F is an effective anorexigenic agent in dogs, rats, and mice at nontoxic doses. In contrast to dextroamphetamine sulfate, U-16,178F, after a single intraperitoneal dose, does not increase motor activity in mice. However, when administered chronically, by admixing it in the diet, U-16,178F causes an increase in motor activity after 24 hr. on diet. U-16,178F, in contrast to amphetamine, causes an initial fall in blood pressure following intravenous administration in the anesthetized dog. It is about one-tenth as potent as dextroamphetamine sulfate in lowering brain catecholamine levels and, unlike dextroamphetamine sulfate, has no tryptamine potentiating activity but protects against maximal electroshock. It has much less antireserpine activity than dextroamphetamine sulfate. U-16,178F also differs from dextroamphetamine sulfate in that changes in ambient temperature have little effect on its acute toxicity.

THE CHEMISTRY and preliminary pharmacology of a series of aralkoxyguanidines was previously reported by Martin *et al.* (1). From these studies 3-(phenylpropoxy)guanidine nitrate was selected as a potential anorexigenic agent. However, the potential hazards involved in preparing and purifying larger quantities of the nitrate salt for further studies prompted the substitution of the cyclohexanesulfamate salt for the nitrate. The cyclohexanesulfamate salt was preferred over the hydrochloride since the latter compound retained a slight odor even after several recrystallizations. Additional pharmacologic studies and comparisons with dextroamphetamine sulfate have been completed and are the subject of this report. U-16,178F has the following chemical structure:



METHODS

A comparison was made of the acute effects of U-16,178F and dextroamphetamine sulfate on food intake in a group of 32 adult mongrel dogs. A crossover design for an 8-point assay was used (2). The dogs were housed in individual cages in a relatively constant-temperature (75° F.) dog room and were fed daily at the same hour. Dog pellets (Purina laboratory chow) were presented for a 30-min. period and the amount eaten was recorded. Drinking water was available at all times. When drugs were tested, they were given orally in a gelatin capsule 1 hr. before presentation of food. The dogs employed had been on this feeding schedule for at least 3 weeks before the assay started. Drug effect was measured as the per cent decrease in food intake for each dog. Control intake was the average of the 5 control days preceding the assay and the 3 control days between the crossover.

To obtain additional information concerning the influence of U-16,178F on food intake and body weight in the dog, it was also administered on a chronic basis. For comparison, dextroamphetamine sulfate was tested under the same conditions, although not simultaneously. Two groups of four mature mongrel dogs were used. These dogs were housed in individual cages in a relatively constant-temperature (75° F.) dog room. Food was available to the dogs from 8:00 a.m. until 3:00 p.m. daily with water available continuously. The dogs used had been on this feeding schedule for at least 1 month. Food consumption was measured daily. Body weight was determined before and after drug treatment. Drugs were administered orally (gelatin capsule) twice daily at 7:00 and 11:00 a.m. for 5 days. Drug effect was assessed as the per cent decrease in food intake for each dog and the decrease in body weight from the beginning to the end of the treatment period. Control food intake was the average of the 5 to 7 control days preceding the treatment period.

Anorexigenic activity was also determined in rats. Upjohn Wistar male rats weighing 190 to 210 Gm. were housed individually and fasted 22 hr. Six rats were used at each dose level. U-16,178F was tested at 3, 10, and 30 mg./Kg. and dextroamphetamine sulfate at 0.3, 1, and 3 mg./Kg. The drugs, dissolved in aqueous methylcellulose (0.25%) so that the dose was contained in a volume of 1 ml./100 Gm. body weight, were administered by oral intubation. Thirty minutes after dosing, a stock ground diet (Upjohn BA) was supplied and the animals were allowed to feed *ad libitum* for a 2-hr. period. The amount of food each rat consumed was recorded and the potency of U-16,178F relative to dextroamphetamine sulfate determined by means of a parallel line assay.

Received February 3, 1967, from the Pharmacology Research Laboratories, The Upjohn Co., Kalamazoo, MI 49001

Accepted for publication March 22, 1967.

TABLE I—EFFECT OF ACUTE SINGLE DOSE ADMINISTRATION 1 hr. BEFORE ON FOOD INTAKE IN DOGS

Compd.	Dose, mg./Kg.	% Inhib.	Compd.	Dose, mg./Kg.	% Inhib.
U-16,178F	1.25	59	Dextroamphetamine sulfate	0.0625	45
U-16,178F	2.5	55	Dextroamphetamine sulfate	0.125	80
U-16,178F	5.0	73	Dextroamphetamine sulfate	0.25	87
U-16,178F	10.0	75	Dextroamphetamine sulfate	0.5	93

The effects of U-16,178F and dextroamphetamine sulfate on food intake, body weight, and motor activity were determined in mice. Groups of eight Carworth Farm male mice (22–24 Gm.) were weighed and then housed together and fed a stock ground diet (Upjohn BA) containing various concentrations of the test compound. The control group received ground diet only. After 24 hr. on this diet, food consumption and body weight changes were determined. Motor activity was measured in actophotometers[1] after the method of Dews (4). After a 10-min. acclimation period in the actophotometers, motor activity of individual mice was recorded for 1 hr. An 8 × 8 Latin square design balanced with respect to treatments, actophotometers, and time of day was used. The mice were left on test diet until they were placed in the actophotometers. The dose of drug ingested by each group of mice was calculated.

Motor activity effects of U-16,178F and dextroamphetamine sulfate were also compared when the compounds were administered intraperitoneally to groups of eight mice. Immediately after injection, the mice were placed in individual actophotometers, allowed to acclimate for a 10-min. period, and then motor activity was recorded for 1 hr. The same 8 × 8 Latin square as described above was used.

To study the effects of U-16,178F and dextroamphetamine sulfate on the overt behavior of cats, groups of eight mature cats were placed together in a small room. Their behavior was evaluated subjectively using a modification of the rating scale devised by Norton (5). This rating system consists of 35 evaluations of cat behavior grouped in six categories: stimulation, sociability, defensive hostility, aggressive hostility, contentment, and a miscellaneous group. The behavior of the cats was scored 7 times at hourly intervals. After the second rating each cat received a dose of one of the drugs, administered orally in a gelatin capsule. Each trial included all dose levels of each drug plus a lactose control. All dose levels of each drug were tested 6 times with the doses randomized among the 16 cats used. No animals were used less than twice or more than 4 times. In all but the first trial, the observer was unaware of the dosing schedule used.

Blood pressure effects of intravenous doses of U-16,178F were determined in 10–14-Kg. mongrel dogs. The dogs were anesthetized with sodium thiopental, 20 mg./Kg. intravenously, followed by sodium barbital, 250 mg./Kg. intravenously. The trachea of each dog was cannulated to ensure an adequate airway, and a femoral artery was cannulated to record blood pressure. Pressure tracings were obtained on a Grass polygraph through a Statham P-23AC transducer. Injections were made into an exposed femoral vein. Responses to epinephrine, acetylcholine, and histamine standards were determined before and after administration of U-16,178F. In two of the four dogs, a 1-min. period of bilateral carotid artery occlusion was added as a test for sympathetic reactivity.

Brain norepinephrine and serotonin levels were determined in the mouse 2 hr. after intraperitoneal administration of U-16,178F and dextroamphetamine sulfate. The method used for extraction of norepinephrine and serotonin from the homogenates was essentially that of Shore and Olin (6) as utilized by Mead and Finger (7). Norepinephrine was determined by the method of Shore and Olin (6) and serotonin was assayed using a modification of the method of Snyder, Axelrod, and Zweig (8).

Tryptamine potentiation, reserpine antagonism, and maximal electroshock protecting activities of U-16,178F and dextroamphetamine sulfate were determined using groups of six Carworth Farm male mice weighing 18–22 Gm. U-16,178F and dextroamphetamine sulfate were administered intraperitoneally in aqueous methylcellulose (25%) at multiple dose levels distributed at 0.3 log intervals. In the tryptamine potentiation test the mice were pretreated with U-16,178F or dextroamphetamine sulfate. Thirty minutes later they were challenged with 25 mg./Kg. of tryptamine hydrochloride intravenously and observed for tryptamine-like symptoms. The 25-mg./Kg. dose of tryptamine hydrochloride does not produce symptoms in control mice while animals treated with an effective dose (*e.g.*, 100 mg./Kg. i.v.) show the following symptoms: hind leg spread, arched back, pawing, head weave, and tremors (9).

In the reserpine antagonism tests one group of mice was treated with 2.5 mg./Kg. of reserpine intraperitoneally and 2 hr. later challenged with the test compound intraperitoneally. Thirty minutes later the degree of ptosis was noted using the 4-point scale of Rubin (10). Another group of mice was treated with the test compound intraperitoneally and after 30 min. challenged with 2.5 mg./Kg. of reserpine intraperitoneally. In each situation control reserpine groups were tested simultaneously. All mice receiving only reserpine had ptosis scores of 4 (complete closure). In the electroshock test mice were treated with the test compounds and 1 hr. later were shocked *via* ear clip electrodes with a 60 c. current for 0.2 sec. at a current intensity of 25 ma. (11).

The influence of ambient temperature on the acute toxicity of U-16,178F and dextroamphetamine sulfate was determined in mice. Groups of six Carworth Farm male mice weighing 18–22 Gm. were injected either intraperitoneally or orally with the compound dissolved in aqueous methylcellulose (0.25%). After injection, the mice were placed in mouse cages[2] that had been divided in half by a plastic wall making compartments 28 × 18 × 14

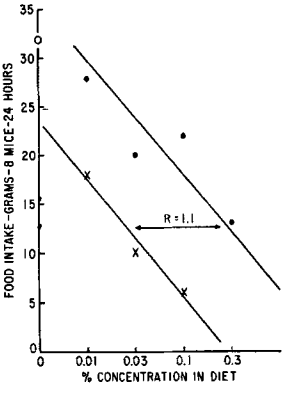

Fig. 2—Parallel bioassay on inhibition of food consumption in mice. U-16,178F (●) vs. dextroamphetamine sulfate (×); control (○).

cm. Standard perforated metal tops were used. Cages with one group of mice at each dose level were placed in a cabinet (120 × 54 × 56 cm.) under the laboratory bench at 22° C., similar groups were placed in a constant-temperature oven (74 × 46 × 46 cm.) at 34° C., and in a refrigerator at 4° C. The two compounds were run in parallel. The high dose used for the oral test with U-16,178F was 400 mg./Kg. and the high dose for the intraperitoneal test for both U-16,178F and dextroamphetamine sulfate was 200 mg./Kg. Decreasing at 0.3 log intervals, the lowest dose of U-16,178F both orally and intraperitoneally was 25 mg./Kg. and the lowest dose of dextroamphetamine sulfate administered was 1.56 mg./Kg. Although the mice were examined at 15-min. intervals for 2 hr., the LD_{50}'s were computed by the method of Spearman and Karber (see *Reference 3*) for the 1 and 2-hr. period.

TABLE III—EFFECT ON MOTOR ACTIVITY OF U-16,178F AND DEXTROAMPHETAMINE SULFATE WHEN ADMIXED WITH DIET

Compd.	Dose Ingested, mg./Kg.	Total Counts 8 Mice for 60 min.
Control	...	4,883
U-16,178F	478	8,437
U-16,178F	251	8,301
U-16,178F	66	7,121
U-16,178F	29	5,975
Dextroamphetamine sulfate	77	11,024
Dextroamphetamine sulfate	36	9,202
Dextroamphetamine sulfate	20	8,681

RESULTS

Acute Effects on Food Intake in Dogs—The results of the comparison of U-16,178F and dextroamphetamine sulfate are shown in Table I. The potency of U-16,178F relative to dextroamphetamine sulfate in this test on a mg./Kg. basis was 0.025 with 95% confidence limits of 0.002–0.078. In this analysis the dog to dog standard deviation for per cent inhibition of food intake was 37%. The dose response slope for U-16,178F was 25%/tenfold increase, while that of dextroamphetamine sulfate was 50%/tenfold increase, but this difference was not statistically significant.

Chronic Effects on Food Intake and Body Weight in Dogs—U-16,178F was tested at 5.0 mg./Kg. b.i.d. and dextroamphetamine sulfate at 0.5 mg./Kg. b.i.d. for 5 days. Body weight loss with the two compounds was about the same, while dextroamphetamine sulfate caused a somewhat greater inhibition of food intake (Table II).

Anorexigenic Activity in Rats—Analysis of the food intake data obtained in rats treated with U-16,178F and dextroamphetamine sulfate showed that on a mg./Kg. basis the potency of U-16,178F relative to dextroamphetamine sulfate was 0.030 with 95% confidence limits of 0.007–0.058.

Effects of Body Weight Change, Food Intake, and Motor Activity in Mice When Admixed with Diet—U-16,178F was tested at 0.01, 0.03, 0.1, and 0.3% concentrations in the diet, while dextroamphetamine sulfate was tested at 0.01, 0.03, and 0.1% concentrations. Effects on body weight change and on food intake are shown in Figs. 1 and 2. On a mg./Kg. basis, U-16,178F was about $^1/_5$ as potent as dextroamphetamine sulfate in causing body weight loss and $^1/_{12}$ as potent in inhibiting food intake in this procedure.

Effects on motor activity after the mice had been on the diet containing the test compound for 24 hr. are shown in Table III. Analysis of variance of motor activity data showed no significant difference between the control and the mice on the diet containing U-16,178F, while the motor activity of the mice on the diet containing dextroamphetamine sulfate was significantly higher than that of the controls. However, when covariance analysis was used to compare motor activity at doses which caused a comparable inhibition of food intake or weight loss, it was found that the motor stimulant effects of U-16,178F were somewhat less than those of dextroamphetamine sulfate, but the difference was not statistically significant.

TABLE IV—EFFECT ON MOTOR ACTIVITY OF U-16,178F AND DEXTROAMPHETAMINE SULFATE WHEN ADMINISTERED 10 min. BEFORE BY INTRAPERITONEAL INJECTION

Compd.	Dose, mg./Kg.	Total Counts 8 Mice for 60 min.
Control	...	6,863
U-16,178F	40	6,616
U-16,178F	20	5,309
U-16,178F	10	6,206
U-16,178F	5	5,763
Dextroamphetamine sulfate	5	18,138
Dextroamphetamine sulfate	2.5	16,690
Dextroamphetamine sulfate	1.2	8,918

Motor Activity in Mice After Intraperitoneal Administration—The effects of U-16,178F and dextroamphetamine sulfate on motor activity in mice after intraperitoneal administration are summarized in Table IV. Analysis of variance of these data showed that while dextroamphetamine sulfate at the 5 and 2.5 mg./Kg. doses caused a statistically significant increase in motor activity compared to controls, U-16,178F had no effect on motor activity at any of the doses tested.

Effect on Overt Behavior in Cats—U-16,178F was administered orally at 1, 3, 10, and 30 mg./Kg. and dextroamphetamine sulfate at 1, 3, and 10 mg./Kg. Both U-16,178F and dextroamphetamine sulfate increased the incidence of head turning, head bob, piloerection, and dilated pupils. However, U-16,178F was only $^1/_{10}$ to $^1/_{30}$ as potent as dextroamphetamine sulfate. Both compounds decreased overt signs interpreted as contentment while sociability was reduced only by dextroamphetamine sulfate. Measures of hostility were not increased by either compound, while spontaneous motor activity was decreased by both. Emesis, diarrhea, hallucinations, and poor contact were not observed in any of the animals, although a slight increase in the incidence of salivation was noted with U-16,178F. A time course evaluation of the data indicated that the maximum activity of both compounds was seen during the first and second hourly observations with a gradual decrease in activities thereafter.

Effects on Blood Pressure, Autonomic Standards, and Carotid Occlusion Response in Anesthetized Dogs—U-16,178F was tested intravenously in four dogs. Doses of 0.5, 1.0, 2.0, 8.0, and 16.0 mg./Kg. were employed in the first pair of animals and 4.0, 8.0, and 16.0 mg./Kg. in the second pair. It produced a brief dose-related fall in arterial pressure reaching −70 mm. Hg for 3 min. at 16 mg./Kg. The hypotensive response to U-16,178F was not blocked by a dose of propranolol (1 mg./Kg.) which completely blocked the depressor action of 10 mcg. of isoproterenol. This would indicate that the hypotensive effect of U-16,178F is not the result of β-adrenergic stimulation. The blood pressure response to carotid occlusion was unchanged at the lower doses of U-16,178F; however, following the 16-mg./Kg. dose, the blood pressure response to carotid occlusion was depressed. Responses to histamine and acetylcholine standards were not changed in any of the four dogs. The pressor responses to epinephrine after all doses of U-16,178F were increased; however, the effect was small (average 11% greater) and was not dose related. The duration of the epinephrine induced pressor response was also somewhat increased (17%–54% longer) and the effect was directly related to the U-16,178F dose.

Catecholamine Depleting Activity—The effects of U-16,178F and dextroamphetamine sulfate on brain catecholamine levels in mice are summarized in Table V. These results show that the norepinephrine values were slightly decreased at each dosage level of U-16,178F with the effect of the 100 mg./Kg. dose approximating the decrease produced by 10 mg./Kg. of dextroamphetamine sulfate. Neither U-16,178F nor dextroamphetamine sulfate altered the serotonin levels.

Effects Against Tryptamine, Resperine, and Electroshock—U16,178F at doses up to 100 mg./Kg. caused no potentiation of tryptamine activity in the mouse while the ED_{50} of dextroamphetamine sulfate for this activity was 18 mg./Kg. U-16,178F

TABLE VI—EFFECTS OF AMBIENT TEMPERATURE ON ACUTE TOXICITY IN MICE

Temp., °C.	LD_{50}, mg./Kg.: Dextroamphetamine Sulfate (i.p.) 1 hr.	Dextroamphetamine Sulfate (i.p.) 2 hr.	U-16,178F (i.p.) 1 hr.	U-16,178F (i.p.) 2 hr.	U-16,178F (p.o.) 1 hr.	U-16,178F (p.o.) 2 hr.
34°	4.5	4.5	79	79	284	224
22°	>12.5	5.6	126	100	400	284
4°	142.0	142.0	142	142	400	356

showed weak antireserpine activity at 100 mg./Kg. On a mg./Kg. basis, U-16,178F was about $^1/_{50}$ as active as dextroamphetamine sulfate when given after reserpine and $^1/_{16}$ as active when given before reserpine. U-16,178F had an ED_{50} of 89 mg./Kg. against maximal electroshock while dextroamphetamine sulfate at doses up to 50 mg./Kg. gave no protection.

Ambient Temperature on Acute Toxicity in Mice—Variations in temperature caused a significant change in the toxicity of dextroamphetamine sulfate but had little influence on the toxicity of U-16,178F. Comparing the LD_{50}'s at 4° and 34° C. there was a thirtyfold change in toxicity with dextroamphetamine sulfate while U-16,178F had less than a twofold change. The results of this experiment are summarized in Table VI.

DISCUSSION

U-16,178F is structurally different from the present marketed anorexigenic agents. As originally pointed out by Modell (12) all of the available anorexigenic agents to date have a phenethylamine moiety in the molecule. This moiety is not present in U-16,178F.

U-16,178F is an effective anorexigenic agent in dogs, rats, and mice. This activity is considered to be due to its central appetite depressant effect and not due to nauseant or anticholinergic activity. No emesis was observed with U-16,178F in dogs or cats at any of the doses tested, and no anticholinergic activity was seen when it was tested against blood pressure effects of intravenous acetylcholine in the anesthetized dog.

When the acute and chronic effects of U-16,178F on anorexigenic activity in the dog are compared, the data suggest that U-16,178F is more effective when given repeatedly than when given in a single dose. This might indicate that U-16,178F has a slower onset of effect than does dextroamphetamine sulfate and/or that there is a less rapid development of tolerance to U-16,178F than to dextroamphetamine sulfate.

A difference between the acute and chronic effects of U-16,178F was demonstrated in the motor activity measurements in mice. An intraperitoneal dose of U-16,178F caused no increase in motor activity when measured for a 1-hr. period 10 min. after administration. However, when administered chronically by admixing it in the diet, it caused an increase in motor activity after 24 hr. on the diet. In contrast, dextroamphetamine sulfate causes an increase in motor activity when given acutely or chronically.

When given intravenously in the anesthetized dogs, U-16,178F produced a brief fall in arterial pressure, followed by a modest rise while the amphetamine is known to cause a definite pressor effect as previously reported (13). The hypotensive effect of U-16,178F was not blocked by propranolol. The secondary rise in pressure seen with U-16,178F coupled with the observation that the blood pressure response to carotid occlusion was depressed following the 16 mg./Kg. dose suggests that U-16,178F has some propensity for releasing norepinephrine and lowering catecholamine stores. This is in agreement with the finding that U-16,178F causes some decrease in brain norepinephrine.

Other qualitative and quantitative differences between U-16,178F and dextroamphetamine sulfate suggest that U-16,178F may be a different type of anorexigenic agent. It is about $^1/_{10}$ as potent as dextroamphetamine sulfate in depleting brain catecholamine levels. Unlike dextroamphetamine sulfate, it had no tryptamine potentiating activity and has much less antireserpine activity. U-16,178F gave protection against maximal electroshock while dextroamphetamine sulfate did not exhibit this activity. The toxicity of U-16,178F was not appreciably increased when the LD_{50} was determined at 30° C. instead of 4° C., while the LD_{50} of dextroamphetaine sulfate increased thirtyfold in this situation.

Identification and Differentiation of Organic Medicinal Agents V

Quaternary Ammonium Compounds

By LESLIE G. CHATTEN, ANN C. NAPPER, and PAMELA JANE BARRY

Identification tests have been presented for 23 compounds containing either one or two quaternary ammonium functional groups. The reactions of these compounds with ammonium reineckate, picric acid, and chloroplatinic acid have been studied and 54 adducts have been isolated and their melting ranges presented. In addition, microcrystal tests showed that many adducts possessed distinctive crystalline morphology. Photomicrographs are presented as a supplemental and additional parameter for characterization purposes.

MEDICINAL AGENTS containing a quaternary ammonium function comprise several pharmacologically heterogeneous groups such as cationic surface-active agents, parasympathomimetics, parasympatholytics, skeletal muscle relaxants, or antagonists of curariform drugs, just to mention a few. Despite the broad scope and importance of these compounds, satisfactory methods for their identification are not available. Although a number of the compounds investigated in this report have official status in either the B.P. (1), the U.S.P. (2), or the N.F. (3), in general, the identification tests employed in these compendia are nonspecific.

It is the purpose of this investigation to develop identification tests of greater specificity, in order to permit differentiation between the various quaternary ammonium compounds.

EXPERIMENTAL

Apparatus—Thomas-Hoover melting point apparatus (calibrated with melting point reference standards); Leitz Laborlux-Pol. microscope equipped with a Zeiss Ikon 35 mm. camera.

Received January 13, 1967, from the Faculty of Pharmacy, University of Alberta, Edmonton, Alberta, Canada.

Accepted for publication March 14, 1967.

Mrs. Napper and Mrs. Barry are indebted to the National Research Council of Canada for financial support during the course of this investigation.

The authors gratefully acknowledge the generous samples of quaternary ammonium compounds from the following drug manufacturers: Abbott Laboratories, Montreal, Quebec, Canada (hexocyclium methylsulfate); Ayerst, McKenna & Harrison, Montreal, Quebec, Canada (valethamate bromide); Ayerst Laboratories, New York (echothiophate iodide); Ciba Company Ltd., Dorval, Quebec, Canada (chlorisondamine chloride, oxyphenonium bromide, and domiphen bromide); Hoffmann-LaRoche Ltd., Montreal, Quebec, Canada (edrophonium chloride, pyridostigmine bromide); Lakeside Laboratories, Milwaukee, Wis. (mepenzolate bromide, pipenzolate bromide); Eli Lilly and Co., Indianapolis, Ind. (dithiazinine iodide); Merck Sharp & Dohme, Montreal, Quebec, Canada, and West Point, Pa. (bethanechol chloride, demecarium bromide); Wm. S. Merrell Co., Cincinnati, Ohio (cetylpyridinium chloride); Parke Davis & Co., Ltd., Brockville, Ontario, Canada (benzethonium chloride); Searle & Co., Chicago, Ill. (methantheline bromide, propantheline bromide); Smith Kline & French, Inter-American Corp., Montreal, Quebec, Canada (isopropamide iodide); Sterling-Winthrop Research Institute, Rensselaer, N. Y. (ambenonium chloride, penthienate bromide); Warner-Chilcott Co. Ltd., Toronto, Ontario, Canada (hexamethonium chloride); John Wyeth and Brother, Walkerville, Ontario, Canada (trimethidinium chloride); Wyeth Laboratories Inc., Philadelphia, Pa. (pentolinium tartrate).

Quaternary Ammonium Compounds—Drugs investigated are listed in Table I.

Reagents and Solutions—All reagents used were A.C.S. grade, or reagent grade if the former was not commercially available. Ammonium reineckate 1% aqueous solution; picric acid saturated ethanolic solution; chloroplatinic acid 10% in diluted HCl; solutions of quaternary ammonium compounds, ammonium reineckate, picric acid, and chloroplatinic acid for microcrystallography are listed in Table II.

Formation of Derivatives

All derivatives were dried *in vacuo* over phosphorus pentoxide for 24 hr. prior to determining their respective melting points on a Thomas-Hoover melting point apparatus. All melting points were corrected by reference to a calibration curve.

Reineckates—The reineckates were prepared according to the following modified procedure of Chatten and Levi (4). With the exception of isopropamide iodide, mepenzolate bromide, and dithiazinine iodide, 1 mmole of quaternary ammonium salt was dissolved in a minimum amount of water. While stirring vigorously, 1 mmole of ammonium reineckate in aqueous solution was added for each quaternary ammonium functional group present in the parent compound. Isopropamide iodide and mepenzolate bromide were dissolved in a minimum of ethanol, while acetone was selected as the most satisfactory solvent for dithiazinine iodide.

After cooling for 2 hr. or until precipitation was complete, the reineckate crystals were filtered, dried, and then recrystallized by dissolving in a minimum of acetone and adding water to the cloud point. The solution was cooled until recrystallization was complete. For certain reineckates, *i.e.*, those of cetylpyridinium, pyridostigmine, edrophonium, propantheline, methantheline, chlorisondamine, demecarium, and domiphen, compounds of high purity could only be obtained by washing them with ethanol prior to drying.

Elemental analyses (C, H, N) confirmed the purity and identity of the reineckates.

Picrates—To 1 mmole of the quaternary ammonium salt, dissolved in water, 1 mmole of picric acid in 10 ml. of ethanol was added for each quaternary ammonium functional group. The mixture was allowed to stand in the refrigerator for 30 min. and the crystals were removed by suction filtration. Recrystallization was accomplished by dissolving the

TABLE I—MELTING POINTS OF DERIVATIVES OF QUATERNARY AMMONIUM COMPOUNDS

[a] Concentrations of solutions are expressed in percentages. Time when picture was taken: 1–5 min. [b] Ethanol (95%) solution.

derivative in a minimum of ethanol or acetone and adding water slowly until the cloud point was reached. The mixture was set aside in the refrigerator to recrystallize. Elemental analyses (C, H, N) verified the purity and identity of the picrates. For the three quaternary ammonium parent compounds which are insoluble in water, solvents utilized are outlined under *Reineckates*.

Chloroplatinates—To 1 mmole of the quaternary ammonium salt, dissolved in a minimum of water, 1 mmole of chloroplatinic acid in dilute HCl was added for each quaternary ammonium functional group in the molecule. The resulting mixture was cooled in an ice bath for 20 min. or overnight in the refrigerator. The fine precipitate was filtered off, washed with cold water, and recrystallized from

boiling ethanol. If the adduct was insoluble in hot ethanol, it was washed well with cold methanol. In those three instances where the quaternary ammonium parent compound was not soluble in water, they were dissolved in ethanol and the chloroplatinic acid was added as an aqueous methanolic solution.

Elemental analyses (C, H, N) confirmed the purity and identity of the chloroplatinates.

Photomicrographs

To 1 drop of an aqueous or alcoholic solution of each quaternary ammonium salt placed on a microscope slide, 1 drop of reagent solution (ammonium reineckate, picric acid, or chloroplatinic acid) was added. The solutions were mixed well and covered with a cover glass. One to five minutes was allowed for the formation of crystals, and the pictures were taken at a magnification of approximately 100×.

RESULTS AND DISCUSSION

Examination of the official compendia (1-3) reveals that 13 of the 23 quaternary ammonium compounds are official in one or more compendia. In only three monographs are derivatives used as a means of identification. Two are picrates and one a reineckate. Monographs of the other compounds rely, to a large extent, upon identification by a series of relatively nonspecific color and precipitation tests. All adducts prepared in this investigation are presented in Table I, together with their melting ranges and previously reported literature values.

Reineckates—In general, ammonium reineckate proved to be a very useful reagent for the preparation of derivatives, although products of satisfactory purity could not be obtained for either dithiazinine or edrophonium. For cetylpyridinium, chlorisondamine, demecarium, methantheline, propantheline, and pyridostigmine repeated crystallization failed to yield products which gave acceptable elemental analysis. However, adducts of high purity were obtained after these materials were well washed with ethanol prior to drying. According to the official compendia (1, 2) pyridostigmine reineckate melts at 153–156°. The results of this investigation revealed that only that derivative which melted at 140–143° gave satisfactory elemental analysis.

Examination of Table I reveals that a certain amount of overlap of melting points exists between several derivatives. Therefore, reineckates cannot be used as the sole criterion for identification purposes.

Picrates—Sixteen of the 23 quaternary ammonium compounds gave adducts of high purity with picric acid. For each of the remaining seven compounds, a viscous oil was obtained which failed to crystallize. Examination of Table I reveals that the picrates are highly satisfactory derivatives in that a minimum of overlapping of melting ranges occurs between compounds.

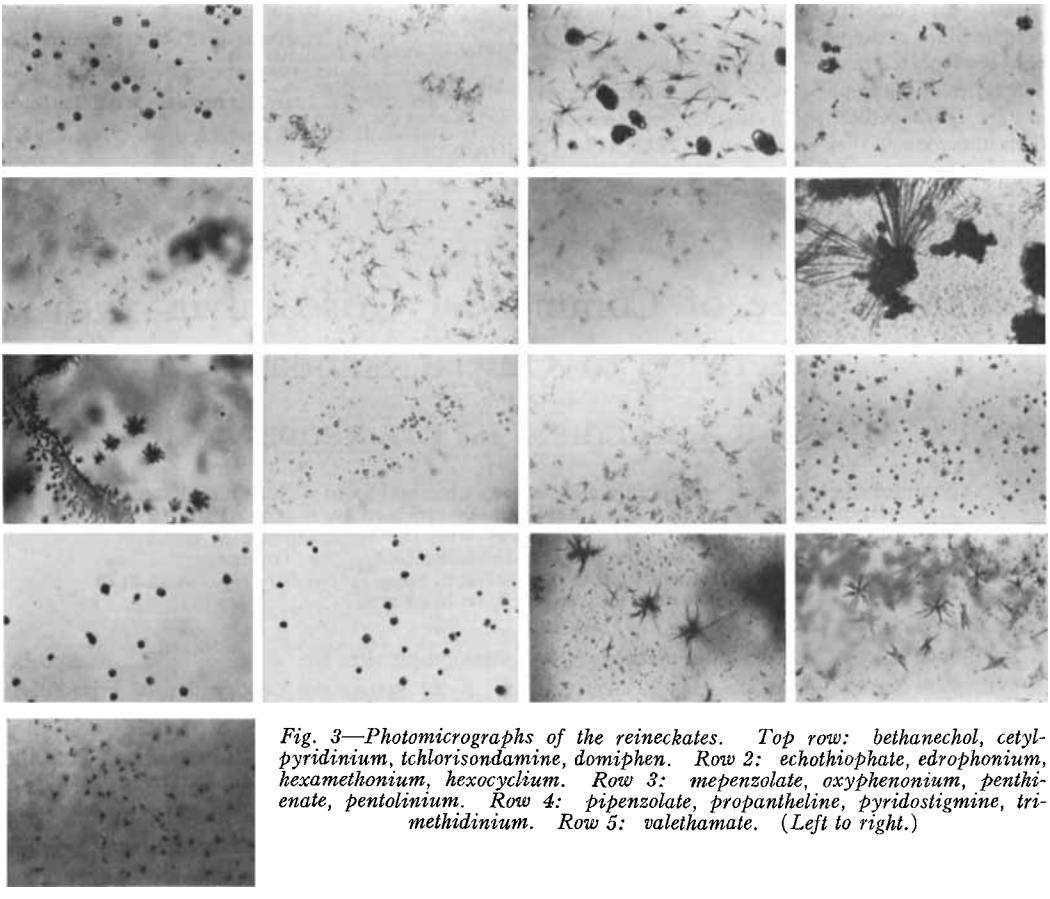

Fig. 3—Photomicrographs of the reineckates. Top row: bethanechol, cetylpyridinium, tchlorisondamine, domiphen. Row 2: echothiophate, edrophonium, hexamethonium, hexocyclium. Row 3: mepenzolate, oxyphenonium, penthienate, pentolinium. Row 4: pipenzolate, propantheline, pyridostigmine, trimethidinium. Row 5: valethamate. (Left to right.)

Chloroplatinates—Although some overlapping of melting ranges occurs in a few instances, the 17 derivatives that resulted with this reagent are valuable aids in the identification of the corresponding parent compound.

Attempted preparation of the chloroplatinate from isopropamide iodide and echothiophate iodide resulted immediately in a black decomposed mass from which no satisfactory product could be isolated. Demecarium bromide and dithiazinine iodide gave impure products which could not be purified by recrystallization. Chlorisondamine and mepenzolate chloroplatinates were crystalline compounds in which the carbon analysis did not correspond with theoretical values, even after repeated crystallizations.

Photomicrography

The three reagents employed in the preparation of the derivatives were utilized in the characterization studies by microcrystallography. Table II, a compilation of the experimental results, shows the percentage concentration of quaternary ammonium compound to that of reagent when crystals occurred. Other results such as oil globules or amorphous mass are recorded in the appropriate columns. In some instances, each of the three reagents produced crystals with a particular quaternary ammonium compound. Generally, success was noted with at least one of the reagents employed. However, exceptions to this were benzethonium chloride, demecarium iodide, isopropamide iodide, methantheline bromide, oxyphenonium bromide, and dithiazinine iodide. With the last named material, crystals of the parent compound appeared repeatedly.

Figure 1 shows the photomicrographs of those compounds which gave crystalline picrates, while Fig. 2 illustrates the chloroplatinates. While each of these reagents was useful in only a limited number of instances, the crystalline morphology of the derivatives depicted is remarkable. Figure 3 presents the photomicrographs of the 17 reineckates and most of these offer unique crystalline habits. Thus the photomicrographs of these three figures would be of high utility in differentiating the parent compounds. Like other physicochemical criteria, however, one should not rely upon one single criterion such as crystalline morphology for identification. It is an aid to identification just as color tests or derivatives are.

It is interesting to note the crystals of ambenonium reineckate and isopropamide reineckate were obtained once, but since neither could be repeated, their photographs were not included in Fig. 3.

SUMMARY

A series of physical chemical criteria, by which 23 quaternary ammonium compounds can be identified and differentiated, has been presented.

Fifty-four derivatives of these drugs have been prepared in a systematic manner, of which 52 have not been reported to date in the literature.

A series of photomicrographs have been included in Figs. 1–3, together with a summary of the conditions under which they were formed (Table II).

Particle Size of Commercial Griseofulvin with Reference to Official Standards

By B. A. MATTHEWS and C. T. RHODES

Samples of commercial griseofulvin have been obtained from various manufacturers and their particle size distribution has been determined by means of the Coulter counter. These results have been compared with the requirements of the monographs in the B.P., U.S.P., and the proposed specification of the "International Pharmacopoeia" and, in the light of this comparison, suggestions for improvement of these specifications have been made.

GRISEOFULVIN (7-chloro-4,6-dimethoxycoumaran - 3 - one - 2 - spiro - 1′ - [2′ - methoxy-6′-methylcyclohex-2′-en-4′-one]) has gained widespread acceptance in the oral treatment of fungal infections in man (1). It is the subject of monographs in a number of pharmacopeias (2–6). Early work on serum and tissue levels of the drug in rats, by Bedford *et al.* (7), and in humans, by McNall (8), suggested that the drug is poorly absorbed from the gastrointestinal tract. Further confirmation of this was published by Sharpe and Tomich (9), who were unable to determine the lethal dose of orally administered griseofulvin in rats and mice and by Gonzales-Ochoa *et al.* (10), who attempted to treat dermatophytoses in man.

All drugs, whether readily or sparingly soluble, dissolve more rapidly when finely divided, and Nelson (11, 12) showed that for theophylline salts and tetracycline, the rate of appearance of the drug in the blood stream following oral administration was determined by the solution rate. Griseofulvin is almost insoluble in water (13) and several attempts have been made to determine the effect of particle size on blood levels in animals (14) and man (15–17). Kraml *et al.* (17) found that a 0.5-Gm. dose of micronized griseofulvin produced serum levels indistinguishable from those produced by a 1.0-Gm. dose of nonmicronized griseofulvin. The monograph in the "British Pharmacopoeia" 1963 (2) recognizes two grades of griseofulvin called, respectively, "coarse particle" and "fine particle," whereas the "United States Pharmacopeia" (4) specifies one called "microsize," which corresponds approximately to the "fine particle" of the "British Pharmacopoeia." In each case some particle size requirements are given. The Food and Drug Administration monograph on microsize griseofulvin specifies additional particle size requirements based on specific surface area measurements by an air permeability technique. The limits are 1.3 to 1.6 sq. M./Gm. The proposed monograph for griseofulvin in the Volume of Specifications of the second edition of the "International Pharmacopoeia," to be published later this year, has a particle size specification based on a sieve technique. A limit of 5% by weight is allowed to be retained on a 300-mesh sieve (aperture size 53 μ).

The authors have obtained samples of commercial griseofulvin from several sources and by means of the Coulter counter (18, 19) have examined these to determine their particle size distribution. They have also utilized microscopy and specific surface area measurements to check results and have compared these with the particle size requirements of the pharmacopeias.

EXPERIMENTAL

Apparatus—A Coulter counter model B[1] with 50-μ and 140-μ orifices was used to determine the particle size. The electrolyte was 1% sodium

chloride and polysorbate 80[2] was used as a dispersing agent, in conjunction with ultrasonic vibration.[3] The 50-μ orifice was calibrated with 1.305-μ diameter polystyrene-latex[4] and also by 4.6-μ diameter puff-ball spores. Good agreement was achieved between the respective calibration constants. The 140-μ orifice tube, which was used for the coarse material, was calibrated with 13.6-μ paper mulberry pollen. The electrolyte was filtered through a 0.45-μ Millipore[5] filter, and background counts at all settings of the Coulter were always well below the recommended limits.

Materials—Samples of fine and coarse griseofulvin were requested from two manufacturers in the United Kingdom, three in the United States, and one in France, West Germany, and Italy. The results of the inquiries are given in Table I. The authors subsequently obtained several samples of different batches of griseofulvin from manufacturers *A*, *B*, and *E* and submitted these to analyses on the Coulter counter.

Method—For each measurement a concentrated suspension was prepared in electrolyte, which had been previously saturated with griseofulvin, and this was subjected to ultrasonic dispersion. Dilutions were made in saturated electrolyte to a suitable working strength and counts were taken at the lowest settings at the beginning and end of the determination to ensure that flocculation did not occur.

Mounts were prepared for microscopy by using ultrasonic dispersion to prepare a concentrated suspension of discrete particles and this was mounted in glycerin containing polysorbate 80. Photographs were taken as a check on particle size. Specific surface area measurements were made on the Fisher sub-sieve sizer[6] which is based on the work of Gooden and Smith (20).

The data from Kek Ltd. was supplied in the form of tables of mean particle diameter against porosity. Since the mean particle diameters reached a minimum at a porosity of 0.425 in each case, it was considered justifiable to make comparisons of specific surface at this value using the formula given by Pendleton (21).

[6] The authors are grateful to Mr. P. D. Hines, Kek Ltd., Manchester, England, for specific surface area measurements.

RESULTS AND DISCUSSION

Fine Particle Griseofulvin—Three determinations were performed on separate samples of batch 1 of fine particle griseofulvin from manufacturer *B*, to determine the reproducibility of repeated measurements. The results of this experiment are given in Table II. Since the count was still increasing at the lowest settings of the instrument, the 100% level was determined by extrapolating the curve of log $\Sigma(\Delta n)\ \bar{v}$ against diameter d for the last six points as recommended in the Coulter instruction manual (22).

These results show good agreement especially at the middle and fine end of the particle size distribution. There is more variation at the coarse end, where only a few particles are counted at each size, and consequently sampling errors tend to be greater. Counts were then performed on three separate batches from manufacturer *A*, three from manufacturer *B*, and one from manufacturer *E*. These are shown in Table III. Extrapolation was performed on the data from all the batches from manufacturer *B* and for that from *E* for the reasons given above. The size distribution of the material obtained from

manufacturer *A* appeared to cut off at around 1 μ, which corresponded to the lowest setting on the instrument, and extrapolation was not considered necessary in this case. The size distribution of the three batches from manufacturers *A* and *B* appears to fall into a definite and distinctive pattern with little between-batch variation, suggesting that good control is achieved by each manufacturer.

Histograms of representative batches of material from manufacturers *A* and *B* and of the sample from manufacturer *E* are given in Figs. 1–3. In addition, plots of cumulative weight per cent above stated size against size using the mean of the values for the three batches from manufacturers *A* and *B* are given in Fig. 4. The "British Pharmacopoeia" monograph on griseofulvin (2) states that for the fine particle material "the particles are mostly less than 4 μ in diameter with only occasional particles exceeding 5 μ." The "United States Pharmacopeia" (4) states that "particles of the order of 4 μ pre-

dominate." It is not entirely clear from these statements whether the specifications refer to a number distribution or a weight distribution. For powdered drugs the latter is obviously more important since a very few particles at the upper end of the distribution can affect the weight per cent distribution considerably.

When the results in Figs. 1–3 are compared with the above requirements, it is seen that the peak of the size distribution curve is at about 2.5 μ for the material from manufacturer *B*, 3.5 μ for that from *A*, and 5 μ with that from *E*. It was found that almost 60% by weight of the sample from this latter manufacturer was above the 4 μ limit. The B.P. requirement that only an occasional particle should be above 5 μ may be true on a number basis, but the results show that the samples from manufacturers *A* and *B* showed about 20% by weight above 5 μ and that from *E* almost 50%.

Shape Factor—Since the diameter obtained with the Coulter counter is a mean spherical diameter and the authors knew that many of the particles in fine particle griseofulvin were acicular, photographs of several samples of this material were taken. A drawing of a typical field taken from a photograph is shown in Fig. 5. From this it may be observed that the average length/breadth ratio of the needles is about 3. No mention of shape is made in the size requirements of the pharmacopeias and one dimension of the particle may be much larger than the Coulter diameter. For example a sphere of 4 μ diameter would have approximately the same volume as a cylinder of diameter 2.5 μ and length 7.5 μ. Allowing for this the results of microscopic measurements were in good agreement with the Coulter data. The length of the acicular particles is small compared with the dimensions of the sensitive volume of the orifice, and we have been informed (23) that despite the shape factor the pulse height will be a true measure of the particle volume.

Specific Surface Area Measurements—The papers (15–17) which have related the absorption of griseofulvin to its particle size have used the parameter, specific surface area. This was therefore determined for a sample of griseofulvin from each manufacturer. The results are given in Table IV.

The shape of the histograms in Figs. 1–3 are reflected in the results of these specific surface area measurements. The lower value of the modal particle size of the material from manufacturer *B* is to some extent counterbalanced by the existence of another peak between 10 and 20 μ, and so the difference in specific surface area between samples *A* and *B* is not as would otherwise have been expected. The coarsest sample *E* had a specific surface area of 80% of that of the finest *B*. Atkinson *et al.* (15) have shown a close correlation between specific surface area of griseofulvin and absorbability, but it is not possible to say whether the differences found in the samples above would be clinically significant.

Coarse Particle Griseofulvin—Owing to the relative economy of treatment with fine particle griseofulvin, both manufacturers *A* and *B* have ceased to market the coarse particle material. The authors have, however, obtained samples from each and the results of size distribution analyses with the Coulter counter are given in Table V and Fig. 6.

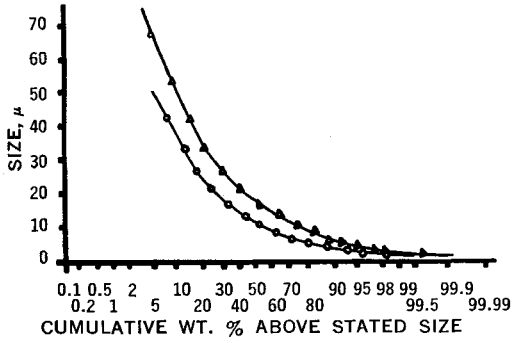

Fig. 6—Plot of cumulative weight per cent above stated size against size for coarse particle griseofulvin. Key: O, manufacturer A; △, manufacturer B.

TABLE VI—SPECIFIC SURFACE AREA OF COARSE PARTICLE GRISEOFULVIN

	Mfr. *A*	Mfr. *B*
Specific surface area, sq. M./Gm.	0.38	0.48

No specification is given in the U.S.P. for this material, but the B.P. states that the particles are "mostly about 30 μ in diameter with occasional particles up to 60 μ." The proposed monograph for the 2nd "International Pharmacopoeia" (24) does not specify whether the type of material referred to is coarse or fine. From the particle size test which allows 5% by weight to be retained by a sieve with a mesh size of 53 μ, it appears that the material is similar to coarse particle griseofulvin of the B.P.

The sample from manufacturer *A* has no particles with an equivalent spherical diameter greater than the maximum permitted value but the peak of the size distribution is around 15 μ. The sample from manufacturer *B* has a few particles coarser than the permitted maximum but its size distribution peak is also around 15 μ. The greater percentage of coarse material in this sample is reflected in the specific surface area measurements given in Table VI.

The sample from manufacturer *A* has no particles with a Coulter diameter greater than the 53-μ mesh diameter specified in the "International Pharmacopoeia," whereas that from manufacturer *B* had 8.9% above this limit. However, as mentioned earlier, the particles are often acicular and consequently such particles with an equivalent spherical diameter greater than 53 μ could pass through a sieve of this mesh size.

SUMMARY

Samples of griseofulvin available commercially from different sources exhibit considerable differences in particle size distribution. Because of the imprecise nature of the official standards in the pharmacopeias, a wide range of size distributions can be considered as meeting their requirements. The authors have shown that the Coulter counter can be used to determine the particle size distribution of this drug and because of the shape factor feel that the methods used should be specified by the pharmacopeias. Because of the relationship between blood levels and particle size, it is felt that more stringent specifications should be given. It is suggested that a modal diameter of the distribution expressed as a weight percentage with upper and lower limits controlling the amount outside them would be more effective in controlling the particle size of this material. Because of the relationship between specific surface and blood levels, it is felt that all pharmacopeias should also include some limits of this parameter.

Effect of Complex Formation on Drug Absorption IV

Role of Intragastric Diffusion in the Absorption of Free and Caffeine-Complexed Salicylic Acid from the Rat Stomach

By RICHARD H. REUNING* and GERHARD LEVY†

The effect of complex formation on salicylic acid absorption from the rat stomach has been determined under conditions where the drug solution in the stomach was either stirred by means of a microstirrer or left unstirred. Complexation of part of the salicylic acid with caffeine resulted in a significant decrease in the over-all salicylic acid absorption rate under both conditions. Stirring had no significant effect on the absorption rate of salicylic acid, nor did it affect the absorption rate of salicylic acid in the presence of caffeine. This indicates that diffusion of salicylic acid and/or of the salicylic acid–caffeine complex to the absorbing membranes is not the rate-limiting step in the gastric absorption of salicylic acid under the experimental conditions. It appears, therefore, that the decreased absorption rate of salicylic acid in the presence of caffeine is due to the decreased thermodynamic activity of salicylic acid resulting from complex formation, with the complex being either unabsorbed or more slowly absorbed than free salicylic acid.

IN A RECENT publication in this series (1) it has been reported that the absorption rate of salicylic acid from the *in situ* ligated rat stomach is decreased significantly in the presence of the complexing agent caffeine. It was suggested that this decrease may be due to the following mechanism(s): (*a*) a difference in the partition coefficients of salicylic acid and the salicylic acid–caffeine complex between the aqueous gastric fluids and the lipoid phase of the mucosal barrier, causing the salicylic acid–caffeine complex to be either unabsorbed or more slowly absorbed than free salicylic acid, and/or (*b*) a decreased diffusion rate of the complex through the gastric fluids to the gastric mucosa. The first mechanism was suggested by the relative values of the apparent *in vitro* partition coefficients of the different species (salicylic acid > salicylic acid–caffeine complex > caffeine), while the second mechanism derives support from the quantitative agreement between the results of the absorption experiments and the calculated effect of caffeine on the over-all[1] diffusion rate of salicylic acid in the system (1). The possibility that diffusion to the absorbing membranes is rate-limiting in the absorption of rapidly absorbed weak acids from the ligated rat stomach was suggested originally by Schanker *et al.* (2).

Two experimental approaches were utilized in an attempt to distinguish between these two different mechanisms which could account for the effect of caffeine on salicylic acid absorption. One of these approaches was to reverse the conditions of the original experiment and to determine the effect of salicylic acid on caffeine absorption. If the first mechanism (*i.e.*, modification of the apparent *in vivo* partition coefficient) were operative, one would expect salicylic acid to enhance the over-all absorption rate of caffeine since the apparent partition coefficient of the caffeine–salicylic acid complex is appreciably higher than that of caffeine alone. This approach was tried, but had to be abandoned due to the limited solubility of salicylic acid (which precluded extensive complexation of caffeine) and due to its damaging effect on the gastric mucosa when nearly saturated solutions of the drug were used. The second experimental approach, which is the subject of this report, was to stir the gastric contents by means of a specially designed microstirrer so that diffusion to the absorbing membranes would definitely not be rate-limiting in the absorption process. Thus, if diffusion to the gastric mucosal membrane is a rate-limiting step in the absorption of salicylic acid under unstirred conditions, one would expect the absorption rate of free salicylic acid (*i.e.*, in the absence of caffeine) to increase when the gastric content is stirred. One would also expect that the magnitude of the effect of caffeine on salicylic acid absorption would be changed when the gastric content is stirred because a step other than diffusion to the membranes will then become absorption rate-limiting. On the other hand, if diffusion to the absorbing membrane is not rate-limiting, one would expect that stirring would

[1] In the context used in this paper, "over-all" refers to the combined effect or behavior of free and complexed drug.

have no effect on the absorption rate of salicylic acid in the absence of caffeine, and that the decrease in salicylic acid absorption rate caused by complexation with caffeine will be of equal magnitude under stirred and unstirred conditions.

EXPERIMENTAL

Absorption Rate Measurements—Female Wistar rats weighing 210 to 295 Gm. were used. Food was withheld for 18–24 hr. prior to the experiment. The rats were anesthetized with urethan (1.25 Gm./Kg. i.p.) and remained under anesthesia throughout the absorption experiment. Three different experimental procedures were used; these will be referred to as "unstirred," "static stirrer," and "rotating stirrer." In each experiment 6 ml. of one of the following solutions was introduced into the stomach: (*a*) ethanol 2%, (*b*) salicylic acid 0.1%, ethanol 2.0%, or (*c*) salicylic acid 0.1%, ethanol 2.0%, caffeine 2.75%. All concentrations refer to per cent weight in volume. One-tenth *N* HCl was used as the solvent for each solution.

In the experiments utilizing the "unstirred" procedure a midline incision was made in the abdominal region of the rat and the stomach was exposed. The esophagus was then ligated tightly immediately adjacent to the cardiac sphincter, care being taken not to occlude major blood vessels. A transverse incision was made in the intestine extending about half-way across the lumen diameter and located approximately 0.8 cm. from the pyloric sphincter.[2] The stomach was rinsed once with about 5 ml. of 0.9% sodium chloride solution (37°) by inserting a 16-gauge ball-tipped needle attached to a 5-ml. syringe into the stomach through the incision in the intestine. Six milliliters of the drug solution, initially at 37°, was then injected into the stomach *via* the intestinal incision by means of a 10-ml. syringe fitted with a 23-gauge silver lacrimal cannula.[3] A ligature was placed around the pyloric sphincter and needle prior to the injection in order to prevent leakage. This ligature was tightened further as the cannula was withdrawn. After completion of the above procedure the midline incision was closed with wound clips. One hour after injection the entire stomach was excised and homogenized.[4] The homogenate was then assayed for unabsorbed salicylic acid and ethanol.

The methodology used in the "static stirrer" experiments was similar to that described above, except for the following modifications. A ligature was not initially placed around the esophagus. After rinsing the stomach as previously described, a specially designed microstirrer,[5] shown in Fig. 1, was inserted through the intestinal incision into the stomach. The microstirrer was then secured by tying a ligature around the small intestine at the pyloric sphincter, since this was located directly over

Insert: cross-section of the Teflon tip.*

a groove in the stirrer shaft (Fig. 1, B). The drug solution was then introduced by the technique previously described, except that the lacrimal cannula was inserted into the stomach through a small incision in the esophagus about 0.5 cm. cephalad to the cardiac sphincter. The midline incision through the skin and body wall of the rat was then closed with suture except for an opening through which the stirrer protruded, as shown in Fig. 2. In these "static-stirrer" experiments the microstirrer was not rotated during the absorption period. At the end of this period the stomach with the remaining drug solution and the microstirrer was excised, the stirrer was detached, the stomach and its contents were homogenized, and the homogenate was assayed for unabsorbed salicylic acid and ethanol.

The "rotating stirrer" experiments were performed in the same manner as the "static stirrer" experiments except that after completion of the surgical procedure, the externally located Teflon sleeve of the microstirrer was secured by a clamp, the flexible shaft was attached to a precision laboratory motor,[6] and the stirrer was revolved at 290 ± 10 r.p.m. Stirring was initiated 5 to 7 min. after injection of the solution into the stomach and was continued over the remainder of the 1-hr. absorption period. Observation (through the somewhat transparent gastric wall) of the movement of the small air bubbles within the stomach indicated that adequate mixing of the gastric contents was achieved.

Analytical Methods—Salicylic acid in the gastric homogenate was assayed as described previously (1). Assays were done in duplicate using two 20-ml. portions of the 50 ml. of homogenate. The average recovery of known quantities of drug added to homogenized stomach tissue was 95%. Ethanol was determined by the method of Hoult and Pawan (3). Two aliquots of each homogenate were diluted and assayed, with duplicate determinations being carried out on each diluted aliquot. Standard curves were prepared simultaneously with each set of assays. The average recovery of ethanol from homogenized stomach tissue was 98%.

Statistical Analysis[7]—The salicylic acid and

[2] This incision was needed only for the insertion of the microstirrer in the other two procedures. The same methodology was used when the microstirrer was not inserted in order to obtain a proper control.

ethanol absorption data (Table I) were analyzed separately using a 3 × 2 analysis of variance (three experimental conditions, absence and presence of caffeine) with subsequent *F*-tests (4, 5) on the six categories in which both ethanol and salicylic acid were present in the drug solution. The Student *t* test was used to compare the category in which ethanol alone was present with the category in which ethanol and salicylic acid were employed (unstirred condition).

Exclusion of Data—Experiments with the microstirrer occasionally caused pronounced gastric damage. The results of these experiments were not included in the tabulated data. The basis for the exclusion of data was the magnitude of ethanol absorption observed in the "ethanol alone-unstirred" category. All experiments in which ethanol absorption was less than the lowest individual value observed in this category (26%) were excluded.

RESULTS

The results of this study are summarized in Table I. The over-all absorption rate of salicylic acid was decreased by caffeine under all experimental conditions (unstirred, static stirrer, and rotating stirrer). The effect of caffeine was highly significant ($p < 0.01$) in each instance. The absorption rate of ethanol, which was included in the drug solutions as a noncomplexed marker, was not significantly affected by the presence of caffeine under any of the three experimental conditions ($p > 0.05$). Stirring itself had no significant effect on the absorption rate of free salicylic acid, salicylic acid complexed with caffeine, or ethanol (all static stirrer *versus* rotating stirrer experiments, $p > 0.1$). Thus, the decrease in the over-all absorption rate of salicylic acid caused by caffeine was of similar magnitude under both static stirrer and rotating stirrer conditions. Salicylic acid apparently increased the absorption rate of ethanol slightly. This effect was barely significant ($p \sim 0.05$ by *t* test of ethanol-unstirred *versus* salicylic acid, ethanol-unstirred data). It could also be concluded that the presence of the stirrer (whether rotating or not) in the stomach resulted in a significant decrease in the absorption rate of both ethanol and salicylic acid ($p < 0.01$).

Experiments with the microstirrer occasionally caused gastric damage (opaque appearance of the mucosa and/or bleeding). This resulted in a pronounced decrease in the absorption rates of ethanol and salicylic acid. Based on the criterion described under *Experimental*, the following data were excluded: salicylic acid–ethanol, static stirrer, 1; salicylic acid–ethanol–caffeine, static stirrer, 1; salicylic acid–ethanol, rotating stirrer, 7; salicylic acid–ethanol–caffeine, rotating stirrer, 2. It is apparent that the highest incidence of gastric mucosal damage occurred with salicylic acid–ethanol under rotating stirrer conditions. This is probably due to the well known mucosal damaging effect of salicylic acid which may have been enhanced by the mechanical effect of stirring. Some of the instances of mucosal damage may have been due to accidental contact of the rotating part of the stirrer with the gastric mucosa. The average absorption rate of ethanol in the discarded experiments was 19.5 (4.6)%[8] while that in the control experiments was 34.6 (6.7)%.[8] The effect of caffeine on salicylic acid absorption was evident even in the experiments which were discarded because of gastric damage; the difference between the absorption rates of salicylic acid in the absence and presence of caffeine was statistically significant (*t* test, $p < 0.01$) even when none of the collected data were excluded from the analysis.

TABLE I—EFFECT OF STIRRING ON THE ABSORPTION RATE OF SALICYLIC ACID WITH OR WITHOUT CAFFEINE

Initial Compn. of Soln.,[a] %		Condition	% Absorbed[b] in 1 hr. Salicylic Acid	Ethanol
Salicylic acid	0.100	Unstirred	58.1 (6.7)[c]	43.6 (9.3)[c]

DISCUSSION

The decrease in the gastric absorption rate of salicylic acid caused by caffeine was of similar magnitude to that observed in a previous study from this laboratory (1).[9] Also, as in the previous study, caffeine had no significant effect on the absorption rate of ethanol. Ethanol, which is not complexed by caffeine, was included in all drug solutions as a marker to detect any possible changes in the gastric

[8] Standard deviation in parentheses.

[9] It should be noted that the volume of solution introduced into the rat stomach in this study was 6 ml., while the volume used in the previous study was 5 ml. The body weight of the rats used in the previous study was 100–150 Gm. Larger animals had to be used in the present study in order to accommodate the microstirrer.

mucosa and/or its blood supply which might affect the absorption rate of the drugs. Since caffeine did not affect the absorption rate of ethanol but reduced the over-all absorption rate of salicylic acid, it may be concluded that the observed effect is due to an interaction of caffeine with salicylic acid and not to a direct effect of caffeine on the permeability of the gastric mucosa. The complex formation between salicylic acid and caffeine is well known (6) and it has been estimated that about 84% of the salicylic acid in the salicylic acid–caffeine solutions used in this study is complexed with caffeine (1).

Stirring had no significant effect on the absorption rate of ethanol nor on the absorption rate of salicylic acid, with or without caffeine. It appears, therefore, that diffusion of drug through gastric fluids to the membrane is not the rate-limiting step in the absorption of a rapidly absorbed drug such as salicylic acid or a somewhat more slowly absorbed drug, such as ethanol. This conclusion is in agreement with the theoretical considerations outlined by Laidler (7) and Danielli (8), who assumed that when a molecule is diffusing through a nonporous membrane separating two aqueous phases, diffusion through the aqueous phases ordinarily is sufficiently rapid relative to diffusion through the membrane that the former can usually be neglected in the kinetic analysis. Our results indicate that fluid mixing due to body movement of the breathing, although anesthetized, animal is sufficient so that gastric absorption, even without artificial stirring, will not be rate limited ordinarily by intragastric diffusion. Since the magnitude of the caffeine effect on the absorption rate of salicylic acid was similar under "static stirrer" and "rotating stirrer" conditions, it may also be concluded that the absorption of salicylic acid existing in complexed form is not rate limited by the rate of diffusion of the salicylic acid–caffeine complex through the gastric fluids to the absorbing membranes. It should be mentioned, however, that movement of drug to the gastric membranes can be the absorption rate-limiting step if the viscosity of the drug solution is increased considerably (9).

These results are of further interest since they may shed some light on an important aspect of the gastrointestinal absorption of drugs by passive diffusion. Schanker *et al.* (2) have observed an "upper limit" in the relative absorption rate (*i.e.*, per cent per hour) of rapidly absorbed drugs such as salicylic acid, benzoic acid, and *p*-hydroxypropiophenone from the rat stomach. These investigators have suggested that this "upper limit" may be the result of drug diffusion through gastric fluids to the biologic membrane (rather than diffusion through the membrane itself) becoming the rate-limiting step in the gastric absorption of sufficiently rapidly absorbed drugs. They were able to show that gastric blood flow was not a limiting factor in the absorption process. The results of the present investigation, which involved experimental conditions similar to those of the study by Schanker *et al.* (2), show that the rate of movement of drug molecules through the gastric fluids is not rate limiting and cannot account for the upper limit in the gastric absorption of drugs as observed by Schanker and co-workers. A review of the available evidence leads to the conclusion that the rate of transfer of drug from aqueous gastric fluids into the lipoid barrier (real or hypothetical) of the gastric membranes will no longer be absorption rate limiting when the *in vivo* partition coefficient of the drug exceeds a certain value. The quantitative similarity in the maximum relative absorption rate (or, more exactly, the absorption rate constant) of diverse passively absorbed drugs suggests that the rate-limiting step is one of diffusion; the results of the present study indicate that the locus of the rate-limiting diffusion is somewhere within the gastric membrane barrier or possibly in the mucous layer immediately adjacent to the gastric epithelium (particularly in the gastric pits), rather than the gastric fluids. From a practical point of view, it appears that increasing the lipoid–water partition coefficient of drugs by molecular modification may be of limited value in increasing absorption rate when the drug itself already has a relatively high partition coefficient. It must be realized, of course, that when a drug is given in solid form rather than in solution, it is dissolution, rather than membrane permeation, which will usually be rate limiting in the absorption process.

The reason for the effect of salicylic acid on ethanol absorption is not readily apparent. This relatively small effect, which was only of borderline statistical significance, was not observed in a previous study (1) and also was not apparent in the "static stirrer" and "rotating stirrer" experiments of the present study. It is likely to have been due to chance, particularly since ethanol absorption appears to have been more variable than salicylic acid absorption.

The decrease in the absorption of salicylic acid and ethanol in the presence of the stirrer may have been due to the manipulation involved while inserting the stirrer into the stomach. It does not appear to be due to the extra distention of the stomach by the added volume of the stirrer ($\sim$0.75 cm.^{3}) and a resulting decrease in blood flow through capillaries in the gastric mucosa, since Schanker *et al.* (2) found that aniline clearance from blood to stomach was essentially constant over a range of gastric volumes encompassing the volume used in the present study.

Certain theoretical calculations outlined previously (1) suggest that the salicylic acid–caffeine complex may be absorbed as such and at a rate intermediate between that of free salicylic acid and free caffeine. These calculations had to be based on assumptions which, unfortunately, are rather speculative. The possible presence of other than 1:1 complexes of salicylic acid and caffeine, the possible existence of caffeine dimers and larger aggregates, the possibility of competitive binding of one or both components of the complex by membrane constituents, and the likelihood of partial dissociation of the complex at the surface of the biologic membranes (10) make it impossible to reach a definitive conclusion with respect to the absorption of the salicylic acid–caffeine complex as such. A relatively conclusive experiment, namely the determination of the effect of complexation with salicylic acid on the absorption rate of caffeine, could not be carried out because of the technical difficulties outlined in the introductory discussion. Studies are now in progress with systems which, it is hoped, do not involve these difficulties.

Effect of Polymorphism on the Absorption of Chloramphenicol from Chloramphenicol Palmitate

By ARMANDO J. AGUIAR, JOHN KRC, JR., ARLYN W. KINKEL, and JOSEPH C. SAMYN

The effect of polymorphism on the availability of chloramphenicol from chloramphenicol palmitate was studied. *In vivo* absorption studies in humans, following single oral doses of the ester, indicate that the polymorphic state of chloramphenicol palmitate influences significantly the blood levels obtained. The use of enzymatic hydrolysis as an *in vitro* method for predicting blood levels is evaluated. The utility of X-ray diffractometry, melting point determinations, and infrared spectroscopy in qualitative and quantitative analysis of the polymorphic forms is discussed. In addition to the two previously reported polymorphs of this drug designated as polymorphs A and B, a third polymorph, form C, is described.

PHYSICAL PROPERTIES such as particle size, solubility, rates of solution, aggregation of primary particles, and wettability have been shown by various workers (1–7) to influence the absorption and therapeutic efficacy of relatively insoluble drugs. The polymorphic state of a drug can also be an important factor (8) since differences in the free energy of polymorphs influence some of these properties. Higuchi (9) has suggested that these differences may appreciably affect their physiological activity.

The present study is concerned with an evaluation of the effect of polymorphic state on the absorption of chloramphenicol from chloramphenicol palmitate. The study was also designed to determine the usefulness and limitations of commonly applied analytical techniques such as X-ray diffractometry, infrared spectroscopy, and melting point techniques in identifying and characterizing the polymorphs of chloramphenicol palmitate. Furthermore, the utility of enzymatic hydrolysis as an *in vitro* criterion for predicting *in vivo* blood levels is examined.

This report deals with the properties and absorption characteristics of polymorphs A and B of chloramphenicol palmitate. Data on the third polymorph (form C) will be presented in a subsequent publication.

Chloramphenicol palmitate was synthesized by Edgerton (10) as a tasteless derivative of chloramphenicol. Glazko *et al.* (11) showed that the intact esters are poorly absorbed from the intestinal tract and must first be hydrolyzed by the esterases in the small intestine before any significant absorption can take place. The rate of hydrolysis of the ester is governed by the rate of solution which, in turn, is dependent on factors such as primary particle size, state of aggregation of primary particles, but most important, as this study shows, on the polymorphic form.

PAST WORK ON THE POLYMORPHISM OF CHLORAMPHENICOL ESTERS

Milosovich (12), studying the physical stability of chloramphenicol palmitate suspensions, suggested the existence of two polymorphs of this drug. Subsequently, Tamura and Kuwano (13) and Maruyama *et al.* (14) reported their work on the two polymorphs and an additional amorphous glassy phase.

Almirante and his co-workers (15) showed that chloramphenicol stearate also exists in two forms, one of which gave good blood levels regardless of particle size. These authors also showed that the presence or absence of a wetting agent had no appreciable effect on the blood levels obtained.

Recently Menachemoff (16) reported that the hydrolysis time of chloramphenicol palmitate is the

essential factor for the rate of absorption, and the amount of hydrolysis is related to the crystalline structure of the palmitate.

ANALYTICAL METHODS

The analytical methods commonly applied to confirm the existence of polymorphic states are X-ray diffractometry, optical crystallography, infrared spectroscopy, and fusion behavior (17–20). When polymorphs can be prepared separately and their physical characteristics established, distinguishing features can be accurately chosen for their identification and analysis in mixtures. In these laboratories, X-ray diffractometry provided a dependable method for initial identification and for quantitative analysis of polymorphs of chloramphenicol palmitate.

Once the characteristic diffraction criteria for the polymorphic forms were established by X-ray diffraction, it was found that other methods, such as infrared spectroscopy, could be conveniently used for routine determinations of the quantity of polymorph A present in any samples containing mixtures of the polymorphic forms.

X-Ray Diffractometry—The X-ray diffraction patterns for polymorphs A, B, and C of chloramphenicol palmitate are summarized in Fig. 1. It is evident that these patterns differ.

X-Ray diffractometry was used successfully to measure the quantities of polymorphs A and B present in chloramphenicol palmitate suspensions over the whole range of composition. The relative intensities of two diffraction lines—one at 19.8° (2θ, CuKα) associated with form B, and the other at 20.3° (2θ), associated with form A—were used. A working curve, in which composition was plotted against the ratio of intensities, $I_{20.3°}/I_{19.8°}$ (Fig. 2) was prepared by reading intensities of known mixtures of forms A and B.

It should be noted that an analysis of this type is based on the assumption of a binary system of A and B polymorphs. The presence of form C or amorphous material in the sample can cause errors. The interference of form C was obviated by applying a suitable correction to the intensity at 20.3° (2θ), determined on the basis of the intensity of form C at 9.2° (2θ). Amorphous chloramphenicol palmi-

tate did not affect the analysis of A and B with regard to proportion, but only with regard to the absolute amount of each.

X-Ray Diffraction Instrumentation and Procedure—A Norelco diffractometer was used. The instrument was equipped with a flat specimen spinner, which rotated the packed powder in the plane of its surface. The sample was packed into an aluminum planchet having a depression 1.5 mm. deep and 22 mm. in diameter. The flat side of a spatula was used to pack the powder and smooth it so that a uniform level surface was presented to the X-ray beam. Coarse or lumpy powder was first ground in a mortar or mechanical blender.

The instrumental variables of the diffractometer were set as follows: (*a*) 1° divergence and scatter slits, and 0.006 in. receiving slits; (*b*) CuKα radiation, 35 Kv., 20 ma., Ni filtered; (*c*) detector: scintillation counter with pulse height discrimination. Intensities were measured by recording the time necessary to count a fixed number of pulses, usually 25,600.

Infrared Spectroscopy—The method used for the infrared determination of chloramphenicol palmitate polymorphs followed closely that of Maruyama *et al.* (14) using a Beckman IR-4 spectrophotometer.

Thus far, two infrared spectra of solid chloramphenicol palmitate have been encountered, one of which is specific for polymorph A, while the other shows minor variations for any of the "non-A" phases. The infrared spectra for polymorphs A, B, and C are shown in Fig. 3. It is readily apparent that while the spectrum for form A is characteristic, the spectra for forms B and C are indistinguishable.

The infrared procedure can therefore be used to determine quantitatively the concentration of polymorph A present in a sample of chloramphenicol palmitate. However, it cannot be used to either distinguish or estimate the quantity of polymorph B in the presence of C or other "non-A" phases.

To compare the accuracy of X-ray diffractometry and infrared spectroscopy in estimating quantities of polymorph A in chloramphenicol palmitate powders, known mixtures of polymorphs A and B were prepared and analyzed by these methods. The results are given in Table I. The values obtained are close and it is obvious that these methods can be used interchangeably for estimating the quantity of polymorph A.

Melting Point—The use of melting point determinations is of limited value for identification of polymorphic forms of chloramphenicol palmitate or as a dependable criterion of their purity. It was found that regardless of the techniques used for determining the melting point, form C was transformed into form B, and the melting point observed (about 86°) was that of form B. Similar transformations also occurred when attempts were made to determine the melting point of the amorphous phase.

The presence of impurities also affected the melting point. Analytical difficulties precluded the quantitative determination of homologous impurities in chloramphenicol palmitate. However, it was found that the extent and nature of such impurities had a marked and varying effect on the melting point.

ABSORPTION STUDIES

The absorption studies were carried out to: (*a*) evaluate and compare the blood levels obtained with suspensions of form B of chloramphenicol palmitate in the presence and absence of a surface-active agent, (*b*) determine the absorption properties of suspensions containing varying concentrations of polymorphs A and B, (*c*) ascertain the type of blood levels obtained from suspensions containing 100% polymorph B with a larger (25 μ) particle size.

Experimental—For the purpose of the absorption studies, experimental suspensions of chloramphenicol palmitate were prepared in an aqueous vehicle containing sweetening agents, gums, a preservative, and flavoring agents. For convenience of identification, these suspensions were labeled K, L, M, N, O, P, and Q.

Suspension K was prepared by suspending polymorph B with a uniform particle size of about 1 μ. The drug was well dispersed by adding polysorbate 60 to the vehicle. This preparation was used as a "reference standard" with which the absorption patterns of the other suspensions were compared.

Suspension L contained 100% polymorph B. No surface-active agent was added to the vehicle. The drug was highly aggregated. The average particle size, determined microscopically, was approximately 5 μ.

Suspension M was made from 100% form A chloramphenicol palmitate powder. The powder was prepared by dissolving the drug in hot xylene and allowing to cool overnight. The suspension was highly aggregated. The average particle size was about 5 μ. No surface-active agent was added to the vehicle.

[1] Marketed as Tween 60 by Atlas Powder Co., Wilmington, Del.

Suspension N, containing 75% of form A and 25% of form B, was prepared by mixing suspensions M and L in these proportions.

Suspension O was prepared by mixing equal quantities of suspensions L and M to obtain a mixture of 50% form A and 50% form B.

Suspension P, containing 25% of form A and 75% form B, was prepared by mixing 75 parts of L with 25 parts of M.

Suspension Q contained 100% form B with an average particle size of 25 μ. The drug was crystallized from ethanol. No surface-active agent was used, and the drug was highly aggregated in suspension.

The properties of the suspensions used in the absorption studies are summarized in Table II.

Methodology—To ascertain the effect of polysorbate 60 on the absorption of chloramphenicol from suspensions of chloramphenicol palmitate containing 100% polymorph B, a double-blind crossover type of study was used.

Six normal adult male human volunteers were used. These ranged in weight from 134 to 199 lb. with an average weight of 154 lb. Three of the subjects were given oral doses of suspension K, equivalent to 1.5 Gm. chloramphenicol, and three other subjects received the same dose of suspension L. After 1 week, each subject received the opposite suspension.

Blood specimens were taken at 0, 1, 2, 4, 8, 12, and 24 hr. after dosage. Urine collections were made for 24 hr. before medication, and at 0–2, 2–4, 4–6, 6–8, 8–12, and 12–24 hr. after dosage. Total urine volumes were measured for each collection period and a sample of each specimen was retained for analysis.

All samples were assayed for total nitro compounds, using Glazko's (21) colorimetric procedure. All values are reported in terms of chloramphenicol equivalents and are the average of the value obtained for six individuals in each instance.

Thirty normal male volunteers were used to study the absorption of chloramphenicol from suspensions containing varying quantities of polymorphs A and B (suspensions L, M, N, O, and P). Their weights ranged from 150 to 170 lb. Their average weight was 160 lb.

The volunteers were divided into groups of six individuals, and each group was given one of the suspensions. Each individual in the group received oral doses of the suspension equivalent to 1.5 Gm. of chloramphenicol. The procedure and intervals of time used to collect the blood and urine samples were the same as those described for the first study. The samples were also assayed in the same manner.

The absorption characteristics of chloramphenicol palmitate suspension Q were determined in five normal male volunteers. Their weights ranged from 143 to 220 lb. and their average weight was 182 lb. The dose, urine and blood collection periods, and assay procedure were identical to the ones described previously for the other suspensions.

RESULTS AND DISCUSSION

Results of blood levels obtained in the first study, designed to evaluate the absorption characteristics of polymorph B with and without polysorbate 60 (suspensions K and L), are shown in Fig. 4. This

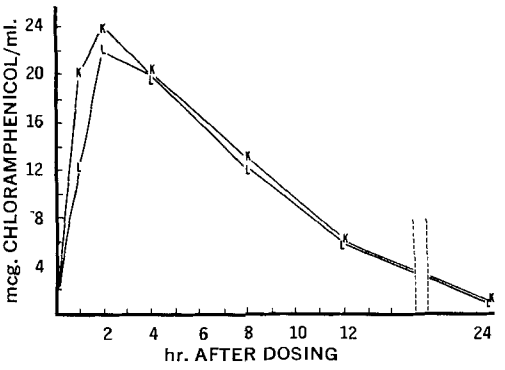

Fig. 4—Comparison of mean blood serum levels in normal humans, obtained with suspensions of 100% form B chloramphenicol palmitate. (K, with polysorbate 60; L, no surface-active agent.) Single oral dose equivalent to 1.5 Gm. chloramphenicol.

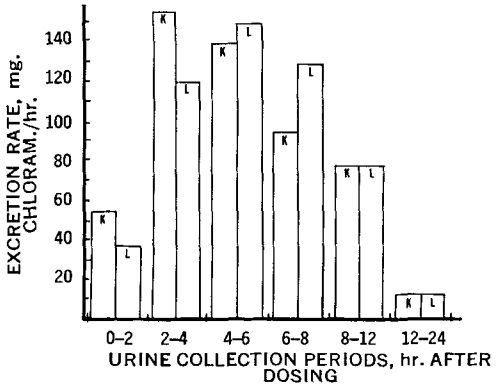

Fig. 5—Urinary excretion rate of total nitro compound (chloramphenicol equivalent) following single oral dose of 100% form B chloramphenicol palmitate suspension. (K with and L without polysorbate 60.)

plot of mean blood levels *versus* time shows that the suspension L without the surfactant appears to give comparable blood levels to suspension K with polysorbate 60.

The absorption from suspension L is, however, slightly slower initially as indicated by the lower plasma levels 1 hr. after dosage. However, no apparent differences occur at later time periods. The slower absorption is indicated also by the urinary excretion data shown in Fig. 5. The maximum excretion rate with suspension K was found in the 2–4-hr. collection period after the drug was administered, while the highest excretion rate with suspension L was found to be 4 to 6 hr. after dosage.

The delay in the absorption of suspension L can perhaps be ascribed to the slightly larger primary particle size (than that of suspension K), but it seems more likely that it is due to the highly aggregated state of the primary particles in the suspension. It is reasonable to assume that the presence of aggregates in the suspension in the initial stages will decrease the surface area presented for dissolution and hydrolysis of the ester. At later times, when the drug is dispersed in the gastric media, there is no

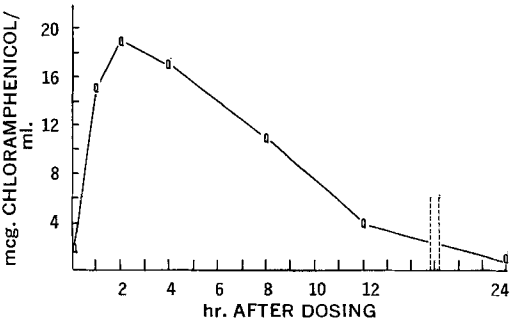

Fig. 9—Mean blood serum levels obtained with suspensions of chloramphenicol palmitate prepared from 100% polymorph B with average particle size of 25 μ.

longer any difference in the absorption patterns of the two suspensions.

The first study agrees with the observation of Almirante (15), who showed that good blood levels of chloramphenicol stearate could be obtained without polysorbate and the levels depend primarily upon the crystal form present.

Mean blood levels obtained in the second study intended to determine the absorption properties of chloramphenicol palmitate suspensions containing varying ratios of polymorphs A and B (suspensions L, M, N, O, P) are shown in Fig. 6. Urinary excretion data are given in Fig. 7.

In these single dose studies the highest mean blood levels were obtained with the suspensions containing only form B. The blood levels decreased proportionately as the concentration of form A increased. These results demonstrate that the levels are influenced by the type and concentration of the crystal polymorph present.

The differences in the absorption are even more evident from Fig. 8 where the absorption at 2 hr. ("peak" blood levels) is plotted *versus* per cent form B present in the suspension. A linear relationship apparently exists between the "peak" levels and concentration of polymorph B, the levels increasing in a direct relationship to the increase of polymorph B.

The results of the third study, shown in Fig. 9, indicate that good blood levels can be obtained with polymorph B having a larger particle size. Although the average primary particle size of the drug in suspension Q was approximately 25 μ, the absorption pattern is not significantly different from that observed with suspension L containing smaller particle size polymorph B.

It appears from these absorption studies that the polymorphic form is of much greater significance than the particle size. The greater availability of the metastable polymorph of chloramphenicol palmitate is apparently related to its greater thermodynamic activity.

Some measure of the difference in the free energy content between polymorphs A and B is obtained from solubility measurements carried out at different temperatures. From these measurements it was found that the heat of solution for polymorph A was 21.8 Kcal./mole, while that for polymorph B

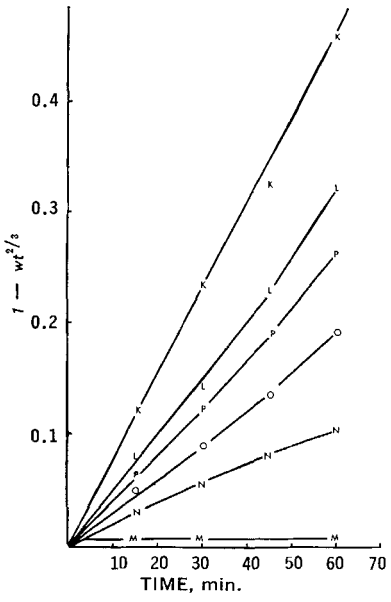

Fig. 10—Enzymatic hydrolysis rates of chloramphenicol palmitate suspensions plotted in accordance with Eq. 5. (K, 100% polymorph B with polysorbate 60) (L, 100%; P, 75%; O, 50%; N, 25%; M, 0%, polymorph B).

was 15.4 Kcal./mole. The details and results of these experiments are being presented in another publication.

USE OF ENZYMATIC HYDROLYSIS TO PREDICT BLOOD LEVELS

Glazko *et al.* (22) showed that chloramphenicol palmitate can be hydrolyzed *in vitro* at 37° by pancreatin at pH 4.5. They also indicated that the *in vitro* hydrolysis rate could be used to predict the development of blood levels in humans.

If proper conditions are selected for the experimental determinations of the hydrolysis rate, it can be shown that the rate of dissolution of the chloramphenicol palmitate particles in the suspension is a diffusion controlled process. Following Higuchi's work (23) on the dissolution rates of finely divided drug powders, one can then write Eq. 1 to describe the dissolution rate for a single particle as a function of time:

$$\frac{dw}{dt} = -\frac{4\pi D w^{1/3}}{\left(\frac{4}{3}\pi\rho\right)^{1/3}}\Delta c \qquad \text{(Eq. 1)}$$

where

Δc = concentration gradient from surface of particle to boundary of diffusion layer,
D = diffusion constant,
w = weight of single particle of chloramphenicol palmitate,
ρ = density.

For n particles in a uniform suspension of spheres, one then has:

$$\frac{dw_t}{dt} = \left(\frac{dw_1}{dt} + \frac{dw_2}{dt} + + + + \frac{dw_n}{dt}\right)$$

$$= -\frac{4\pi D\Delta c}{\left(\frac{4}{3}\pi\rho\right)^{1/3}}\left(w_1^{1/3} + w_2^{1/3} + + + + w_n^{1/3}\right) \qquad \text{(Eq. 2)}$$

Integrating Eq. 2, between the limits w_0 (total weight of particles at time zero) and w_t (total weight of particles at time t) one obtains:

$$-\int_{w_0}^{w_t}\frac{dw_t}{w_t^{1/3}} = \frac{4\pi D\Delta c n^{2/3}}{(4/3\pi\rho)^{1/3}}\int_{t=0}^{t=t} dt \qquad \text{(Eq. 3)}$$

which resolves to:

$$\frac{3}{2}\left(w_0^{2/3} - w_t^{2/3}\right) = \frac{4\pi D\Delta c n^{2/3}}{\left(\frac{4}{3}\pi\rho\right)^{1/3}}t \qquad \text{(Eq. 4)}$$

Now $w_0 = \frac{4}{3}\pi r_0^3\, nd$, where n = number of particles per 1 ml., and r_0 = initial radius of particles.

Equation 4 can be divided by the initial weight of chloramphenicol palmitate raised to the two-thirds power ($w_0^{2/3}$) and simplified to obtain Eq. 5.

$$\frac{w_0^{2/3} - w_t^{2/3}}{w_0^{2/3}} = \frac{2D\Delta c}{\rho r_0^2}t = Kt$$

or

$$1 - fw_t^{2/3} = Kt \qquad \text{(Eq. 5)}$$

where $K = \frac{2D\Delta c}{\rho r_0^2}$ and $fw_t^{2/3}$ = fraction total weight raised to the two-thirds power.

Therefore, a plot of $1 - fw_t^{2/3}$ *versus* t should give a straight line with a positive slope which is directly proportional to the solubility of chloramphenicol palmitate in the vehicle, and inversely proportional to the initial surface area of a single particle for a suspension containing one of the polymorphic forms.

In Fig. 10 representative data plotted according to Eq. 5 are shown. It is apparent from this plot that when dealing with suspensions containing either polymorph A or polymorph B (suspensions K, L, and M) the data appear to fit well with the theoretical concepts presented. The value of K can then be determined from the slope of these lines. When dealing with suspensions containing mixtures of polymorphs (suspensions P, O, and N) the lines initially appear to follow approximately Eq. 5. However, the authors have not been able to derive equations to deal quantitatively with suspensions containing such mixtures.

The experimental conditions can be selected to ensure that the determining factor in the initial rate of hydrolysis of chloramphenicol palmitate is the rate of solution or the drug. The factors which control rate of solution of chloramphenicol palmitate in suspensions are solubility of the different polymorphic forms and specific surface area.

Suspension K with 100% polymorph B well dispersed, having a particle size of about 1 μ, is used as a control. This control preparation is arbitrarily assigned as having a 100% hydrolysis rate. The values obtained with other suspensions are then compared with the control preparation and the results are tabulated as per cent relative hydrolysis rate with reference to the control preparation.

The rate of hydrolysis test values has paralleled blood level values with the exception of suspensions containing 100% polymorph B which are in a highly aggregated state. These suspensions gave lower hydrolysis rates but satisfactory blood levels.

Examples of the per cent relative hydrolysis rate values obtained with different suspensions are given in Table III together with the "peak" blood levels and the per cent mean urinary excretion 24 hr. after administration of the suspension.

From the data given in Table III it is apparent that the suspensions can be effectively deaggregated by the *in vivo* mechanisms of the gastrointestinal tract, thus increasing the surface area available for hydrolysis, which is not evident from the *in vitro* method.

It appears that although the *in vitro* enzymatic hydrolysis test could predict blood levels satisfactorily in most cases, certain refinements still have to be made in the technique to study the effect of aggregation, *etc.*, on the hydrolysis rates.

TABLE III—COMPARISON OF "PEAK" BLOOD LEVELS WITH THE PER CENT RELATIVE HYDROLYSIS RATE DETERMINED BY ENZYMATIC HYDROLYSIS TESTS

CONCLUSIONS AND SUMMARY

In using analytical methods for identifying polymorphs, careful consideration, as shown in this study, should be given to their usefulness and limitations. For identification and analysis of chloramphenicol palmitate polymorphs, X-ray diffractometry was found to be the most accurate method. The infrared spectra are useful in distinguishing form A from the "non-A" phases. Melting point *per se* is of limited value in identifying the polymorphs of chloramphenicol palmitate.

These studies demonstrate the influence of polymorphic state of chloramphenicol palmitate on its physiological availability. The suspension containing only form B gives higher blood levels following single oral doses than suspensions containing only form A. The blood levels decrease proportionately as the concentration of polymorph B decreased in the suspension.

Addition of a surface-active agent to the suspension has a very limited influence on the availability of chloramphenicol palmitate, and high blood levels are obtained in its absence.

It is also shown that increasing the particle size of chloramphenicol palmitate to 25 μ had little effect on the blood levels. The enzymatic hydrolysis test can be used for predicting blood levels from chloramphenicol palmitate suspensions if the particles are not highly aggregated.

This study emphasizes the effect of polymorphic form on the availability of chloramphenicol palmitate. In view of these findings, it would appear that other slightly soluble drugs should be carefully examined both for the existence and effect of polymorphs.

Biosynthesis of Tropic Acid in *Datura innoxia*

By C. A. GIBSON* and H. W. YOUNGKEN, JR.†

Phenylalanine-UL-^{14}C, phenylalanine-1,3-^{14}C, and shikimic acid-UL-^{14}C were fed to mature *Datura innoxia* Mill. plants, and the radioactive hyoscyamine and scopolamine were extracted and degraded to determine the position of the radioactive carbon of the tropic acid moiety. The results indicated that all the carbons of tropic acid are derived from the carbons of phenylalanine and the carboxyl carbon of tropic acid is derived from the carboxyl carbon of phenylalanine by way of some intramolecular shift mechanism.

IN THE PAST, several compounds have been studied as possible precursors of the branched chain aromatic acid, tropic acid. Among these phenylalanine, sodium acetate, phenylacetic acid, propionic acid, and tryptophan were employed. Although phenylacetic acid (1) and tryptophan (2) can be incorporated into tropic acid, more significant results have been obtained with phenylalanine as the labeled precursor (3–7).

When phenylalanine-3-^{14}C was fed to mature *Datura stramonium* plants, the hyoscyamine and scopolamine were labeled in carbon 2 of the tropic acid moiety (1, 3, 7). The hydroxymethyl group (carbon 3) was labeled when phenylalanine-2-^{14}C (4) or phenylacetic acid-1-^{14}C (1) was the radioactive precursor. The above labeling patterns have led to the formulation of a proposed pathway of biosynthesis in which an active 1-C unit serves as the precursor of the carboxyl group of tropic acid (1). Since ^{14}C-labeled carbonate, formate, formaldehyde, methionine, and serine do not significantly label the carboxyl carbon of tropic acid (1, 6), considerable interest has been focused upon the origin of this carbon atom.

Louden and Leete (5, 6) reported that tropic acid was labeled in the carboxyl carbon after *D. stramonium* plants were fed with L-phenylalanine-1-^{14}C. These results indicate the involvement of the carboxyl carbon of phenylalanine as a precursor of the carboxyl group of tropic acid. These workers have proposed a pathway of biosynthesis involving the equivalent of an intramolecular shift of the carboxyl carbon of phenylalanine to the position occupied in the tropic acid molecule. The work reported here was accomplished in order to add to the evidence in support of the latter pathway.

If a phenylpropanoid molecule, such as phenylalanine or phenylpyruvic acid, is actually involved in the biosynthesis of tropic acid, then labeled shikimic acid should label only the aromatic ring portion of this acid. Also, generally labeled phenylalanine should label tropic acid in such a way that benzoic acid, obtained by oxidation of tropic acid, would contain 7/9 the specific activity of its parent tropic acid. A third precursor, phenylalanine-1,3-^{14}C in which the ratio of the specific activities of the two radioactive carbon atoms is known, should label the carbons 1 and 2 tropic acid in the same ratio of specific activities as that of the parent compound if the "carboxyl shift" pathway is functioning.

EXPERIMENTAL

Growth and Processing of Plant Material—*D. innoxia* Mill. plants were grown from seeds selected from plants previously grown in the Drug Plant Garden, University of Rhode Island. The seedlings were potted in sandy loam and were grown in a Hotpack environment control room, model 1288-13, using the following conditions: light period, 16 hr. at a temperature of 32° ± 1° and a relative humidity of 40% ± 5%; dark period, 8 hr. at a temperature of 23° ± 1° and a relative humidity of 60% ± 5%.

The plants were maintained under the above conditions exposed to approximately 1800 f.-c. of light during the "light" period until the plants were 3 months old. The radioactive compounds were administered to the 3-month-old plants by means of cotton wicks pulled through their stems according to a modification of the procedure given by Comar (8). Details of the amount of tracer fed and the activities of the alkaloids are shown in Table I. The alkaloids were diluted prior to degradation.

Extraction and Separation of the Alkaloids—The plants were harvested 14 days after the administration of the ^{14}C-labeled compounds and the alkaloids extracted according to the procedure reported by Leete (9). Further purification of the total alkaloid extract was accomplished by immiscible solvent extraction in a separator. The hyoscyamine and scopolamine were separated by way of the column chromatography method reported by Leete (10) using diatomaceous earth[1] as the stationary phase. Final purification of the individual alkaloids was carried out by means of thin-layer chromatography. Glass thin-layer chromatography plates

[a] Obtained by mixing known quantities of DL-phenylalanine-1-^{14}C and DL-phenylalanine-3-^{14}C. [b] Biosynthesized by Dr. B. A. Bohm, College of Pharmacy, University of Rhode Island. [c] Total alkaloids calculated as hyoscyamine. [d] Calculated by difference.

(20 cm. × 20 cm.) were prepared with a spreader[2] using Silica Gel G[2] as the adsorbent (25 Gm. Silica Gel G in 50 ml. water). The alkaloids were applied streakwise to the plates and chromatographed in sealed glass chambers using dimethylformamide–diethylamine–ethanol–ethyl acetate (1:1:6:12) as the solvent (11). The thin-layer chromatograms were air dried and kept in a vacuum desiccator for 24 hr. in order to remove the volatile solvents, particularly diethylamine and dimethylformamide. Dragendorff spray reagent, as modified by Munier and Macheboeuf (12), was used to locate the alkaloid zones by spraying a small strip across the plate perpendicular to the solvent front. Since dimethylformamide interferes with the Dragendorff color reaction (13), the strip had to be sprayed first with a 0.25% solution of sodium nitrate in 0.5% hydrochloric acid and dried before spraying with the Dragendorff reagent.

The zones of the thin-layer chromatograms containing the respective alkaloids were carefully scraped from the plates, and the alkaloids were eluted with absolute ethanol and rechromatographed repeating the above procedure. Each alkaloid, hyoscyamine and scopolamine, purified by this procedure, showed only a single spot on thin-layer chromatograms using either the system given above or with chloroform–diethylamine (9:1) as the solvent. The amount of the purified alkaloid was determined by colorimetric assay (14).

Hydrolysis of Alkaloids—Sufficient nonradioactive alkaloid was added to the purified alkaloids to provide a sample of known weight between 125 and 150 mg. Complete hydrolysis was accomplished by dissolving the alkaloid in 35 ml. of warm water and adding 10 ml. of 2 N sodium hydroxide. The mixture was evaporated on a water bath to 10 to 15 ml. The aminoalcohol, tropine or scopine, was extracted with five 25-ml. portions of chloroform, each chloroform portion being washed with 10 ml. of water. No further purification of the aminoalcohol was attempted.

Following acidification with dilute hydrochloric acid, the aqueous hydrolysate was extracted with several portions of isopropanol–chloroform (1:3). Crude tropic acid was obtained by evaporation of the isopropanol–chloroform solvent. Purification of the tropic acid was accomplished by repeated recrystallization from a mixture of hot benzene and petroleum ether yielding glistening white plates, m.p. 116.5–118°.

Degradation of Tropic Acid—Several workers (1, 3, 7) have shown that phenylalanine-3-^{14}C yields tropic acid labeled only in the carbon adjacent to the ring, and Leete (4, 6) has shown that L-phenylalanine-1-^{14}C labels only the carboxyl carbon of tropic acid. In no case has it been reported that either phenylalanine-3-^{14}C or phenylalanine-1-^{14}C can label the hydroxymethyl carbon of tropic acid. It was therefore determined that the specific radioactivity of tropic acid, along with that of the benzoic acid obtained from tropic acid, would yield the relative specific radioactivities of the two labeled carbons of tropic acid.

Tropic acid (40 to 50 mg.) was refluxed with 250 mg. of potassium permanganate in 5 ml. of water for 2 hr. The hot solution was filtered and, after cooling, acidified with hydrochloric acid. The acidic solution was then extracted with ether for 10 hr. using continuous liquid–liquid extraction. Removal of the ether yielded a light brown residue which, upon sublimation at 100–105° for 1 hr., yielded 10–12 mg. of colorless needles of benzoic acid, m.p. 121–122°.

Preparation of ^{14}C Samples and Determination of Radioactivity—Radioactive samples were assayed by combustion of the material to carbon dioxide and collecting the evolved gas in an ion chamber. The radioactivity of the gas was then determined on the Dynacon[3] model 6000 vibrating capacitor elec-

[2] Thin-layer chromatography kit, supplied by Research Specialties Co., Richmond, Calif.

[3] Nuclear Chicago Corp., Des Plaines Ill.

trometer using the rate of charge method of determining radioactivity.

The apparatus used for combustion of the organic material was the van Slyke wet combustion apparatus designed for use with the Dynacon model 6000. The reagents were prepared according to van Slyke *et al.* (15).

RESULTS

While all the alkaloid samples obtained after feeding with the three radioactive compounds were radioactive, the samples obtained from shikimic acid-fed plants were not sufficiently active to permit separation of the hyoscyamine and scopolamine. The low activity was due to the relatively very low specific activity of the shikimic acid sample. The alkaloids obtained from the plants fed L-phenylalanine-UL-^{14}C and DL-phenylalanine-1,3-^{14}C, respectively, were separated and the hyoscyamine and scopolamine purified before degradation.

If all the carbon atoms of L-phenylalanine-UL-^{14}C are incorporated in tropic acid, then the tropic acid should possess 1.28 times the activity present in the benzoic acid derived from it by oxidation. The results reported here support this theory since the tropic acid/benzoic acid specific activity ratios were 1.22 and 1.21, respectively (Table I). Shikimic acid-UL-^{14}C labels only the aromatic ring of tropic acid, as evidenced by the fact that almost all (91%) of the specific activity of the tropic acid obtained from the total alkaloid fraction was recovered in the benzoic acid obtained by oxidation.

When DL-phenylalanine-1,3-^{14}C, prepared by mixing known quantities of DL-phenylalanine-1-^{14}C and DL-phenylalanine-3-^{14}C, was fed and the values were determined by the following formula:

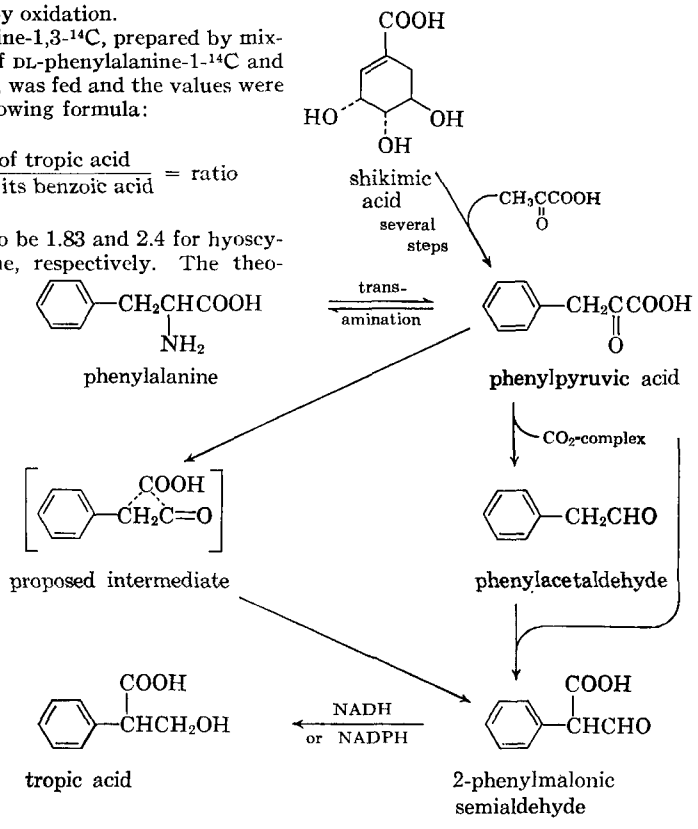
$$\frac{\text{specific activity of tropic acid}}{\text{specific activity of its benzoic acid}} = \text{ratio}$$

the ratios were found to be 1.83 and 2.4 for hyoscyamine and scopolamine, respectively. The theoretical value based upon the DL-phenylalanine-1,3-^{14}C is 1.74. The value found for hyoscyamine is a little higher than expected, but this may be explained by a more rapid hyoscyamine turnover or by losses incurred due to chemical manipulation. However, the ratio value for scopolamine (2.4) is significantly high and cannot be reasonably explained without further study.

DISCUSSION

Two general pathways have been proposed for the biosynthesis of tropic acid in *Datura*. Briefly, these may be stated as follows: (*a*) phenylalanine, after transamination to phenylpyruvic acid, undergoes decarboxylation to phenylacetic acid (or possibly its coenzyme A derivative); recarboxylation at the α-carbon of this acid followed by reduction of the original carbonyl group yields tropic acid; (*b*) phenylalanine, after transamination to phenylpyruvic acid, undergoes an intramolecular shift of the carboxyl group to the carbon adjacent to the ring; reduction at the carbonyl carbon yields tropic acid. The results of this research support the second pathway.

The total number of carbon atoms present in the molecule is the same for both phenylalanine and tropic acid. Several experiments (1, 3–7) have shown that phenylalanine can serve as the precursor of at least carbons 2 and 3 of tropic acid, *i. e.*, DL-



Proposed Biosynthetic Pathway for Tropic Acid

Scheme I

phenylalanine-3-^{14}C labels carbon 2 of tropic acid whereas DL-phenylalanine-2-^{14}C labels carbon 3 of this acid. One experiment (6) has indicated that L-phenylalanine-1-^{14}C can label the carboxyl carbon (carbon 1) of this aromatic branched-chain acid. Since no variations in this labeling pattern have been observed, the incorporation of phenylalanine-1,-3-^{14}C into tropic acid, wherein the ratio of the specific activity of carbons 1 and 2 of tropic acid equals that of carbons 1 and 3 of the phenylalanine precursor, strongly supports the hypothesis that the carboxyl carbon of phenylalanine is a precursor of the carboxyl carbon of tropic acid.

Since benzoic acid, which was obtained by oxidation of the tropic acid from *D. innoxia* plants that were fed phenylalanine-UL-^{14}C, possesses a specific activity equal to 80% of that of its parent tropic acid, phenylalanine appears to be a precursor of all the carbon atoms of the tropic acid. The incorporation of shikimic acid-UL-^{14}C in only the aromatic ring structure of tropic acid further supports the involvement of a C_6-C_3 compound. Phenylalanine is a C_6-C_3 compound biosynthesized by way of the so-called shikimic acid pathway (16). The incorporation of shikimic acid into tropic acid does not directly implicate phenylalanine in the biosynthesis of tropic acid, but it does implicate the involvement of the shikimic acid pathway by which phenylalanine is formed.

Scheme I shows a biosynthetic pathway for tropic acid [essentially the pathway proposed by Leete (6)] based upon the results given above and previous reports in the literature. It may best be described in the following three major steps.

Synthesis of Phenylalanine—This compound is formed by transamination of phenylpyruvic acid (16) which is formed by way of the shikimic acid pathway. [An excellent review on shikimic acid has been published by Bohm (17).] In the plant, tropic acid may well be formed from phenylpyruvic acid without the actual conversion of this acid to phenylalanine. However, the ease with which these two compounds undergo interconversion makes this point very difficult to confirm.

Formation of 2-Phenylmalonic Semialdehyde—The carboxyl group of this compound is derived from the carboxyl group of phenylpyruvic acid (phenylalanine). This transfer or shift of the carboxyl group may occur *via* an intramolecular shift, analogous to the methyl malonyl coenzyme A to succinyl coenzyme A isomerization (18). A second possible route by which this shift may occur is *via* an enzyme-bound decarboxylation–recarboxylation sequence. These two possible pathways for the carboxyl shift have also been suggested by Leete (6). Since no attempts have been made to determine the form in which the 2-phenylmalonic aldehyde occurs, *i. e.*, coenzyme A derivative, phosphate derivative, *etc.*, no suggestions are proposed for this pathway.

Formation of Tropic Acid—Reduction of the aldehyde group of 2-phenylmalonic semialdehyde would yield tropic acid. This reaction could be accomplished by NADH or NADPH mediated by an enzyme analogous to alcohol dehydrogenase.

The results of this work support the pathway given in Scheme I for the following reasons.

(*a*) The incorporation of shikimic acid into the ring-carbons of phenylalanine is in agreement with the known pathway of phenylalanine biosynthesis (16). (*b*) The results are in agreement with the results of other experiments (1, 3, 7) with respect to the incorporation of carbon-1 of the amino acid. (*c*) The ratio of the radioactivity of carbons 1 and 2 of tropic acid equals that of carbons 1 and 3 of phenylalanine as shown by degradation of the tropic acids obtained from plants fed DL-phenylalanine-1,3-^{14}C, as well as those fed L-phenyalanine-UL-^{14}C.

These results do not necessarily contradict the entire pathway proposed by Underhill and Youngken (1), but do contradict a sequence of decarboxylation of phenylpyruvic acid (from phenylalanine) followed by a separate recarboxylation step. However, a similar sequence during which all the reactants remain enzyme-bound so that the carbon dioxide removed in the first step is utilized in the recarboxylation step cannot be ruled out.

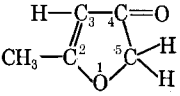
5-Methyl-3(2H)-furanone from Acid-Catalyzed Solvolysis of 2-Deoxy-D-ribose

By JOACHIM K. SEYDEL, EDWARD R. GARRETT*, WERNER DILLER, and KLAUS-JÜRGEN SCHAPER

5-Methyl-3(2H)-furanone (VIII) is produced from 2-deoxy-D-ribose (I) under defined conditions of acid, temperature, and time. Its production is a direct function of sugar concentration and its ultraviolet absorbance serves as a sensitive assay for the sugar. The compound VIII was identified by spectral data (NMR, U.V., I.R.), thin-layer chromatography R_f values in three different solvent systems, and chemical reactivities. The compound VIII obtained from deoxyribose and synthesized by a different route was the same. A mechanism dependent on the direction of water elimination after cyclization, dehydration, and rehydration can explain the formation of VIII and the previously obtained levulinic acid whose production from furfuryl alcohol (III) was explained by a similar mechanism. The spectrally observed kinetic intermediate with a $\lambda_{max.}$ at 225 mμ is consistent with the proposed mechanism.

THE THERMAL degradation of 2-deoxy-D-ribose in acid solution under specifically defined conditions produces an ultraviolet chromophore and the absorbance at $\lambda_{max.}$ 261 mμ is directly proportional to the sugar concentration (1, 2). The chromophore is extractable by chloroform and can easily be destroyed by treatment with mild alkali at room temperature. A direct sensitive spectrophotometric assay method for 2-deoxy-D-ribose in the presence of other sugars and other stable chromophores was developed on the basis of these properties (1). This method was used subsequently by Byvoet (3) for the determination of the deoxyribose content of deoxyribonucleic acid (DNA).

The isolation and identification of the compound which produces the chromophore as a 5-methyl-3(2H)-furanone [2-methyl-Δ^2-furenidone-(4)] (VIII) and its mechanism of formation are described in this paper.



VIII

EXPERIMENTAL

Apparatus—A Cary model 14 recording ultraspectrophotometer, a Varian HA 100 high resolution spectrometer with electronic counter, a Leitz infrared recording spectrometer with accessories for micro-techniques, and an Atlas mass spectrometer were used in these studies.

Materials—2-Deoxy-D-ribose (Carl Roth OHG, Karlsruhe, Germany) and diacetylethylacetate (Theodor Schuchardt G.m.b.H., Munchen, Germany), furfuryl alcohol (Eastman Organic Chemicals, Rochester, N. Y.), and ribitol (Nutritional Biochemical Corp., Cleveland, Ohio). All other chemicals were of analytical reagent grade.

Procedure for the Production, Isolation, and Purification of 5 - Methyl - 3(2H) - furanone [2 - Methyl - Δ^2 - furenidone - (4)] from Acid-Degraded 2 - Deoxy - D - ribose—2 - Deoxy-D-ribose (670 mg.) was dissolved in 1 L. of 1.0 *N* HCl and heated in a thermostated bath at 80.0° for 10 hr. The acid-degraded products were extracted with small portions of chloroform until no absorbance at 261 mμ was observed. The combined chloroform extracts were dried over anhydrous sodium sulfate and concentrated to about 10 ml. The concentrated mixture was purified by thin-layer chromatography.

The plates for thin-layer chromatography were prepared with 0.4-mm. or 1.0-mm. (preparative) layers of Silica Gel GF_{254} (E. Merck AG, Darmstadt). The mixture was spotted, or applied as a line with a syringe in the preparative case, at the origin of the plates. Chromatograms were developed for 12 cm. using as solvent systems: (*a*) chloroform–methanol, 80:15; (*b*) benzene–methanol, 9:1; (*c*) benzene–ether, 9:1. After development and drying, the spots were viewed under short wavelength ultraviolet light (254 mμ) or sprayed with 2,4-dinitrophenylhydrazine. Purification was effected by means of 1-mm. preparative thin-layer plates.

The compounds were scraped after development and extracted with chloroform. The silica gel was separated by centrifugation and filtration. When necessary for refining, the procedure was repeated. The R_f values of 5-methyl-3(2H)-furanone for the respective solvent systems were: (*a*) 0.72, (*b*) 0.37, and (*c*) 0.14. The purified substance was used to obtain the various spectrophotometric data.

Spectrophotometric Data—U.V.: $\lambda_{max.}$ 258 mμ, ϵ = 14,100, chloroform; $\lambda_{max.}$ 258 mμ, ϵ = 12,400, ethanol; $\lambda_{max.}$ 261 mμ, HCl; $\lambda_{max.}$ 295 mμ, NaOH.

Received February 17, 1967, from the Chemische Abteilung des Forschungsinstituts Borstel, Institut fur Experimentelle Biologie und Medizin, Borstel, Germany, and the *College of Pharmacy, University of Florida, Gainesville, FL 32601

Accepted for publication April 24, 1967.

The excellent technical assistance of Miss S. Bockelmann is gratefully acknowledged. The authors are indebted to the Department of Organic Chemistry, Kiel University, Kiel, Germany, for mass spectrum analysis.

I.R. (film): 2930, 2870, 2720, 1750, 1710, 1608, and 1150 cm.$^{-1}$. NMR: chemical shift δ-values are given in parts per million (p.p.m.) from an internal tetramethylsilane standard; coupling constants are in Hz; spectra were run at room temperature in $CDCl_3$ as solvent. NMR data were H-(3), 5.48 (Q), J_{3,CH_3} 0.8; H-(5), 4.50 (Q), J_{5,CH_3} 0.9; =C—CH_3, 2.24 (D), J 0.8.

Synthesis of 5-Methyl-3(2H)-furanone (VIII)—The compound was synthesized in a four-step reaction sequence in accordance with the methods of Becker (4) and Rosenkranz *et al.* (5).

Diacetylethylacetate, b.p. 103°, n_D 1.4663, was prepared from acetylacetate. γ,γ'-Dibromo-diacetyl-ethylacetate, m.p. 49–50° corrected, yield 88%, was prepared from diacetylethylacetate. [Lit. values: 38%, m.p. 54–55°, 52–54° (4).] 4-Carbethoxy-5-methyl-3(2H)-furanone was prepared subsequently by a method used by Becker (4), yield 37%, and purified by vacuum sublimation, m.p. 72–73°. (Lit. values: 55%, m.p. 74–76°.) The I.R., U.V., and NMR data were identical with those reported by Rosenkranz *et al.* (5) and are consistent with their structure assignments. The data do not support the structure assigned by Becker (4).

5-Methyl-3(2H)-furanone, b.p. about 60° (12 mm.), was prepared from 4-carbethoxy-5-methyl-3(2H)-furanone in accordance with the literature (5, 6). The final compound was purified by preparative thin-layer chromatography [plate 1.0 mm. Silica Gel GF_{254} (E. Merck AG), solvent: benzene–methanol 9:1] R_f: 0.37. The NMR data were H-(3), 548 [5, 41] (Q), J_{3,CH_3}0.8 [about 1]; H-(5), 4.50 [4.60] (Q), J_{5,CH_3}0.9 [0.9]; =C—CH_3, 2.24 [2.24] (D), J 0.8. Figures in brackets are the data reported by Hofmann *et al.* (6).

Degradation of Furfuryl Alcohol and Ribitol—Furfuryl alcohol and ribitol, 1×10^{-4} M, in 1.00 N HCl were maintained at 80.0° and aliquots analyzed on the Cary recording ultraviolet spectrophotometer as a function of time.

RESULTS AND DISCUSSION

When an aqueous solution of 2-deoxy-D-ribose is heated, a chromophore appears with a U.V. absorption at 261 mμ. The rate of appearance of this chromophore is not strictly first order as shown by preliminary kinetic studies (1). It is similar to an autocatalytic reaction with an initial lag before the first-order decay in the appearance of the chromophore. It is probable that the 261 mμ chromophore is associated with a final product of a sequential series of reactions. Prior to the 261 mμ chromophore a band, $\lambda_{max.}$ 225 mμ, appears by an apparent first-order rate process, which is proportional to hydrogen ion activity at a constant temperature. It is possible that this 225 mμ chromophore is a precursor to the compound responsible for the 261 mμ chromophore. The rate of appearance of the 261 mμ chromophore is proportional to the hydrogen ion activity at a constant temperature. At 80° and in 1 N HCl the final absorbance at 261 mμ is reached after 5 hr. and remains constant for at least 24 hr. The 261 mμ absorbance was found to be directly proportional to the deoxyribose concentration and serves as an assay method for deoxyribose (1, 3).

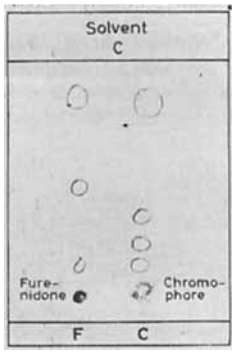

Fig. 1—Typical thin-layer chromatograms of a crude reaction mixture of synthesized 5-methyl-3(2H)-furanone, F, *and a chloroform extract of the acid-degraded 2-deoxy-*D*-ribose,* C. *The solvent system was benzene–ether, 9:1.*

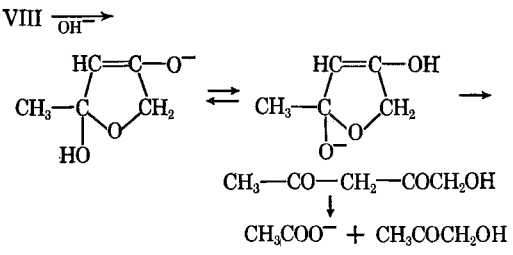


Scheme I

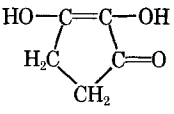
The chromophore-containing compound is extractable from acid solutions with chloroform and is unstable in alkaline solutions (1). The half-life at 28° in NaOH ($8.5 \times 10^{-4}M$) is 61 min. The compound reduces Fehling's solution and changes the color of a $FeCl_3$ solution to a red-brown. The oily colorless compound yellows and resinifies on standing in air.

Only a small fraction of the deoxyribose degrades to form the 261 mμ chromophoric compound. On the assumption that this compound is VIII, a maximum yield of 15% can be calculated from ultraviolet absorbance. Since many other compounds are present, isolation and purification were difficult. A characteristic thin-layer chromatogram of the chloroform extract of degraded 2-deoxy-D-ribose as compared with VIII is shown in Fig. 1. The spots were observed by spraying with 2,4-dinitrophenylhydrazine. The spots closest to the origin are VIII and the chromophoric compound, respectively. The hydrazones of both were red in color, indicative of compounds with unsaturated ketones.

The infrared spectrum of the purified isolates of degraded deoxyribose containing the ultraviolet chromophore had strong absorption bands at 1740, 1710, and 1608 cm.$^{-1}$. No hydroxyl group was indicated. Although the hydroxyl group absence and the presence of a conjugated ketone with a five carbon skeleton derived from a pentose would be consistent with an "angelica-type" lactone [X, XI (Scheme II)], the infrared spectra of X denied the hypothesis of such 4-hydroxy pentenic acid lactones which are formed on heating levulinic acid (7).

Several other substances are known to be products of the acid degradation of sugars. Reichstein and Oppenauer (8) reported the isolation of reductic acid (XIII) from strenuous acid treatment of pen-

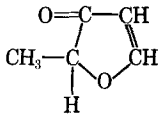
toses. The presence of hydroxyl groups in this compound denies this structure as our compound. The known products of sugar degradation such as levulinic acid (XII) (9) and ω-oxylevulinic aldehyde (10) are denied from their recorded ultraviolet absorption spectra.



XIII

The consideration of α-pyrone and furfural (12) as possible degradation products can be excluded by the wavelengths of their ultraviolet absorption and by the results of NMR and mass spectra.

The possible structures from the considered information are VIII and its structural isomer, XIV.



XIV

The three signals observed in the NMR are at 5.48, 4.50, and 2.24 p.p.m. and the intensities are in the ratio of 1:2:3 protons (Fig. 3). These signals can be assigned to a methyl group attached to a double bond, a methylene group attached to an ether oxygen, and a vinyl proton. They are inconsistent with XI and exclude XIV. The mass spectrum showed a peak consistent with a molecular weight of 98.

The 5-methyl-3(2H)-furanone (VIII) has been described in the literature (5, 6) and the NMR data were consistent. The comparison of I.R. (Fig. 2), U.V., NMR (Fig. 3), and thin-layer chromatograms in three different solvent systems (Fig. 4) demonstrated that VIII synthesized for comparative purposes and the isolated and characterized compound which gives rise to a 261 mμ chromophore from the thermal acid degradation of deoxyribose were identical. The chemical properties of structure VIII (5, 6) are the same as those of the acid degradation product of deoxyribose. Both compounds reduced Fehling's solution, gave a red-brown color with $FeCl_3$, formed phenylhydrazones, were stable in acidic solutions, and unstable in alkali with a shift of the 261 mμ chromophore to 295 mμ. The probable structures of compound VIII in alkali and its subsequent breakdown in analogy with the literature (5) are as shown in Scheme I.

Mechanism—Supportive evidence of the mechanism for the formation of VIII from deoxyribose through the pathway I–VIII (Scheme II) is available from the literature.

Birkofer and Beckmann (13) have demonstrated

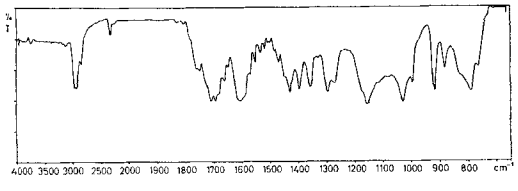


Fig. 2—Infrared spectrum of the isolated 261 mμ chromophoric compound obtained from the acid degradation of 2-deoxy-D-ribose which is the same as the spectrum of synthesized 5-methyl-3(2H)-furanone (film with microtechnique accessories).

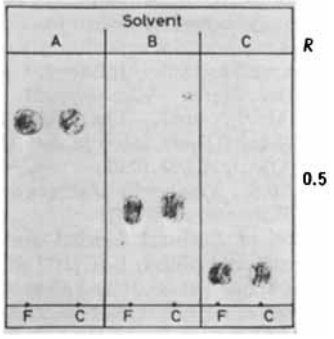

Fig. 4—Typical thin-layer chromatograms of synthesized 5-methyl-3(2H)-furanone, F, and the purified isolated 261 mμ chromophoric compound from degraded 2-deoxy-D-ribose, C, in several solvent systems. Key: A, chloroform–methanol, 80:15; B, benzene–methanol, 9:1; C, benzene–ether, 9:1.

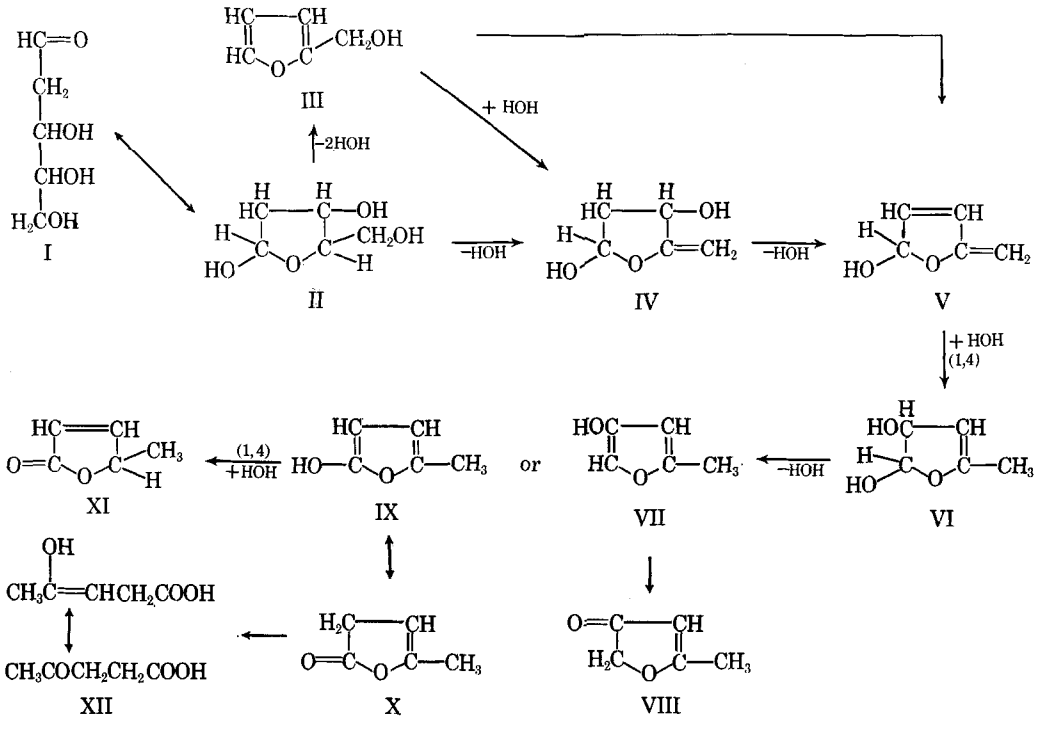

Scheme II

that levulinic acid (XII) is a product of acid treatment of furfuryl alcohol (III) and passes through the isolated intermediate, 4,5-dihydroxy-4,5-dihydrosilvan (VI). They postulated the formation of this intermediate (VI) from 1,4-hydration of the precursor (V) which was produced from acid catalyzed rearrangement of furfuryl alcohol (III). This could occur just as readily from dehydration and rehydration of furfuryl alcohol (III) to form the postulated product (IV) of deoxyribose dehydration. This product (IV) can also form V by a subsequent dehydration.

On further dehydration, the 4,5-dihydroxy-4,5-dihydrosilvan (VI) will produce either the enolic form of the lactone of levulinic acid (XII) or VIII. Since the yield favors levulinic acid (XII) [about 50% (13)] rather than VIII [about 15% (1)], removal of the hydroxyl from the 3 position from VI is favored over the removal of the hydroxyl from the 2 position.

Recently, Anet (14) has shown that the methyl ether of the furanose form of aldoses produces a 5-substituted -3(2H)-furanone, on treatment with 0.1 *N* HCl at 70° in 30 min. These are conditions approximately equivalent to those used in the formation of VIII from deoxyribose. It was also reported that VIII rapidly polymerized in nonaqueous solvents containing traces of acid (5, 14) consistent with our observed resinification of chloroform-extracted VIII from deoxyribose degradation. This polymerization may be the explanation of the slow decrease in absorbance of the developed 261 mμ chromophore of degraded deoxyribose when held in acidic solution for long periods of time (1). The reported shifting (13) of the $\lambda_{max.}$ 261 mμ (acid solution) to 296 mμ in 0.01 *N* NaOH is the same as reported for the compound from degraded deoxyribose.

The sequence of reactions from deoxyribose through the pathway I–VI to the products VIII and levulinic acid (XII) is a plausible one consistent with all available information and identifications. It is also consistent with the observed kinetics of the formation of VIII by acid treatment of deoxyribose (1). The S-shaped curve for the formation of VIII implies that the reaction proceeds through a relatively stable intermediate or intermediates. It is possible that the 225 mμ absorbance which precedes the 261 mμ absorbance assigned to VIII represents an intermediate. In Scheme II, a plausible assignment of the 225 mμ $\lambda_{max.}$ by Woodward's rules is structure V, calculated $\lambda_{max.}$ 224 mμ (15).

The degradation of furfuryl alcohol (III) in 1.00 *N* HCl at 80.0° initially produced a 225 mμ absorbance that disappeared in 1 hr. while a 261 mμ absorbance appeared. The 261 mμ absorbance reached its maximum value, 0.62, after 5 hr. and was constant for 24 hr. Addition of alkali at room temperature shifted the $\lambda_{max.}$ to 293 mμ and a rapid loss of this new chromophore was observed. As predicted by Scheme II, furfuryl alcohol showed degradative properties similar to deoxyribose and produced the same chromophore with the same properties under the same conditions which were consistent with VIII. When ribitol was treated in the same manner, no significant chromophore was observed.

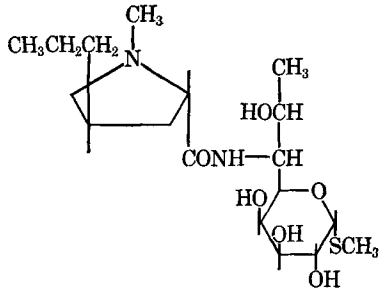
Preparation of Tritium-Labeled Compounds III

Lincomycin by Exposure to Tritium Gas and Partial Determination of Intramolecular Distribution of Tritium

By RICHARD C. THOMAS, GEORGE J. IKEDA, and HARRY HARPOOTLIAN

Lincomycin was tritiated more satisfactorily by its exposure to tritium in the presence of platinum black catalyst than by its exposure alone under conventional Wilzbach conditions. Incorporation of tritium and radiochemical purity, prior to purification, of the catalytically exposed lincomycin were far greater than those of the material exposed without catalyst. The intramolecular distribution of tritium was influenced by the exposure conditions. Catalytically exposed lincomycin contained virtually all its tritium in the propylhygric acid moiety, whereas the noncatalytically exposed sample contained approximately two-thirds of its tritium in this portion of the molecule; the remainder was in the methyl thiolincosaminide moiety.

LINCOMYCIN[1] (I) is a new antibiotic whose discovery and biological properties (1), isolation and characterization (2), and structure (3–7) have been reported.



I

Clinical use has shown it to be an effective agent for treatment of infections in man (8). This paper is concerned with preparation of radioactive lincomycin by two tritium-gas-exposure methods and a comparative determination of the resulting intramolecular distributions of tritium.

Radioactive lincomycin was required for metabolism studies in animals and man. Tritium labeling by the gas-exposure method of Wilzbach (9) was undertaken as the most attractive route to radioactive lincomycin. Incorporation of tritium, however, was poor and radiation-induced degradation was extensive; so, even though a usable product was obtained, attention was shifted to modifications of Wilzbach's method. The use of an electric discharge, as well as other sources of radiation, to promote ionization and excitation of the tritium gas was not particularly attractive since the authors had previously observed increased radiation-induced decomposition in applying this method to sulfonylurea compounds (10). Meshi and Takahashi (11), however, reported a modification of the Wilzbach method in which the compound, intimately mixed with platinum black catalyst, is exposed to tritium gas. Although this technique appears to have been little used since its introduction, it is reported to give better tritium incorporation than the conventional Wilzbach method. This was indeed found to be the case when the catalytic technique was applied to lincomycin.

Meshi and Sato (12) have shown that, in the cases of several compounds, the catalytic modification gives a different intramolecular distribution of tritium than does the Wilzbach method. A partial determination of the intramolecular distribution of tritium in lincomycin, labeled by

the two methods, was therefore made. Virtually all the tritium was accounted for in the propylhygric acid moiety of the catalytically tritiated sample whereas only two-thirds was in this moiety in the sample tritiated without catalyst.

EXPERIMENTAL

Determination of Radioactivity—All counting was performed with a Tri-Carb[2] model 314X or 314-EX2A liquid scintillation spectrometer at −8° under conditions suitable for measuring tritium. Appropriate aliquots of samples were dissolved in 15 ml. of diotol scintillator (13) [toluene–dioxane–methanol (350:350:210 by volume) containing 73 Gm. naphthalene, 4.6 Gm. 2,5-diphenyloxazole, and 0.08 Gm. 1,4-bis-2-(5-phenyl-oxazolyl) benzene per liter]. The absolute counting efficiency for each sample was determined by recounting following addition of an internal standard of tritium-labeled toluene and results then expressed as microcuries (μc.).

Paper chromatograms were scanned for radioactivity with a Vanguard[3] model 880 radiochromatogram scanner. Thin-layer chromatograms were scanned for radioactivity by scraping sequential 1-cm. sections of the silica gel support into individual vials and counting in the usual manner with a liquid scintillation spectrometer.

Paper and Thin-Layer Chromatography—Paper chromatograms were developed by the descending method using Whatman No. 2 paper in the following systems: (*a*) 1-butanol–water (84:16 by volume), (*b*) 1-butanol–acetic acid–water (2:1:1 by volume), (*c*) 5% citric acid in water made to pH 7.0–7.5 with ammonia, and (*d*) 2-propanol–2 *N* HCl (65:35 by volume). Thin-layer chromatography was carried out on 250-μ films of Silica Gel GF[4] using the following systems: (*a*) methanol and (*b*) methyl ethyl ketone–acetone–water (15:5:5 by volume). Chemical detection was accomplished by spraying the developed paper sheets or thin-layer plates with a mixture of four parts 2% aqueous $NaIO_4$ and one part 1% $KMnO_4$ in 2% aqueous Na_2CO_3. Yellow spots appear on a purple background.

Column Chromatography—A 2.8-cm. diameter column was packed to a height of 55 cm. with 200–400 mesh acidic cationic exchange resin.[5] The column was washed consecutively with 4 *N* HCl, saturated NaCl solution, 4 *N* NaOH solution, 1 *N* HCl, and 0.1 *N* HCl prior to each use. The lincomycin sample to be purified was added to the column in 25 ml. of 0.1 *N* HCl. The column was then washed with 1 L. of 0.1 *N* HCl followed by 1 L. of water. Lincomycin was eluted by passing 1.5 L. of 2 *N* NH_4OH through the column at a flow rate of approximately 100 ml./hr. while collecting 20-ml. fractions.

Exposure of Lincomycin to Tritium Gas—(*a*) A 1.0-Gm. sample of finely pulverized lincomycin base was exposed to 4 c. of carrier-free tritium gas at room temperature in the dark for 8 days under approximately 0.2 Atm. tritium pressure. Following removal of the tritium gas, the crude sample was dissolved in 20 ml. of water and the resulting solution was lyophilized. Labile tritium was completely removed by repeating this procedure three times. The crude sample had a specific activity of approximately 11 μc./mg. and was grossly impure, radiochemically, as shown by the previously mentioned paper and thin-layer chromatography systems.

(*b*) Another 1.0-Gm. sample of finely pulverized lincomycin base was thoroughly mixed with 1.0 Gm. of platinum black[6] and exposed to 4 c. of carrier-free tritium gas under the conditions mentioned previously. In this case, however, the tritium gas was entirely adsorbed on the catalyst so the pressure was approximately 10^{-5} mm. At the end of the 8-day exposure period, the mixture was added to 20 ml. of water and the catalyst was removed by filtration through diatomaceous earth.[7] The filtrate, containing the lincomycin, was lyophilized and labile tritium was completely removed as previously described. The crude sample had a specific activity of approximately 15 μc./mg. Its radiochemical purity was approximately 80% as determined by paper and thin-layer chromatography.

Purification of Tritiated Lincomycin—In each case the crude lincomycin was taken up in 25 ml. of 0.1 *N* HCl and subjected to ion-exchange chromatography as previously described. Fractions containing lincomycin (as determined by counting individual column fractions and subjecting selected ones to paper chromatography and scanning for radioactivity) were combined and lyophilized to a residue *in vacuo*. The residue was recrystallized as the hydrochloride salt by taking it up in 3 ml. of water, adding 30 ml. of acetone, and adjusting the pH to 2 with 12 *N* HCl. This procedure was repeated until constant specific activity was attained.

In the case of lincomycin subjected to conventional Wilzbach tritiation, a constant specific activity of 0.60 μc./mg. was attained in three crystallizations with a yield of 0.317 Gm. (as the hydrochloride salt). A constant specific activity of 10.5 μc./mg. with a yield of 0.629 Gm. was obtained for the catalytically exposed material after two crystallizations. Both samples were shown to be radiochemically pure by paper and thin-layer chromatography, followed by scanning for radioactivity, in the previously mentioned systems. In each case the radioactive zone corresponded to the colored zone, produced by the spray reagent, which in turn corresponded to the migration of authentic lincomycin hydrochloride.

Both tritiated samples had infrared spectra corresponding to that of authentic lincomycin hydrochloride.

Anal.[8]—Calcd. for $C_{18}H_{34}N_2O_6S \cdot HCl \cdot H_2O$: C, 46.90; H, 7.87; Cl, 7.69; N, 6.08; S, 6.96; eq. wt., 461. Found (noncatalytically tritiated sample): C, 46.86; H, 8.11; Cl, 7.89; N, 6.10; S, 7.09; eq. wt., 458. [7] Marketed as Celite by the Johns-Manville Corp., New York, N. Y.
[8] Another and larger sample of tritiated lincomycin hydrochloride, purified, recrystallized, and dried by the methods described, contained 1 mole of water as determined by Karl Fischer titration.

TABLE I—INTRAMOLECULAR DISTRIBUTION OF TRITIUM IN TRITIATED LINCOMYCIN

Component Counted	from Noncatalytically Tritiated Lincomycin		from Catalytically Tritiated Lincomycin	
	μc./m*M*	%	μc./m*M*	%
Lincomycin·HCl[a]	2.48	100	12.5	100
Propylhygric acid·HCl	1.53	62	11.9	95
Methyl thiolincosaminide	0.83	33.4	0.23	1.85
HCl distillate[b]	0.01	0.40	0.10	0.99
Methyl mercaptan[b]	0.08	3.22	0	0
Hydrazine distillate[b]	0.34	13.7	3.06	24.5

[a] The lincomycin hydrochloride was diluted with nonradioactive carrier for degradation. (See *Footnote 9.*) [b] Based on total lincomycin hydrochloride subjected to HCl hydrolysis or hydrazinolysis.

A solution of 1.252 Gm. of noncatalytically tritiated lincomycin hydrochloride[9] in 15 ml. of 1 *N* HCl was refluxed for 20 hr. while passing the evolved gases through a trap containing 10 *N* NaOH to trap methyl mercaptan liberated during hydrolysis. The reaction mixture was evaporated to dryness *in vacuo* and the distillate was collected for radioactivity determination. The residue was leached with boiling acetonitrile and the resulting solution was treated with charcoal[10] and evaporated to a small volume. The propylhygric acid hydrochloride was allowed to crystallize in the refrigerator overnight, filtered, and dried at room temperature *in vacuo*. Yield, 0.163 Gm.; m.p. 184–185° (capillary, uncorrected). The infrared spectrum was identical to that of anhydrous authentic propylhygric acid hydrochloride.

Anal.—Calcd. for $C_9H_{17}NO_3 \cdot HCl$: C, 52.05; H, 8.74. Found: C, 51.82; H, 8.90.

The radioactivities of the lincomycin hydrochloride, the contents of the NaOH trap, the distillate, and the propylhygric acid hydrochloride were determined and are listed in Table I.

(*b*) A 1.268-Gm. sample of catalytically tritiated lincomycin hydrochloride[9] was hydrolyzed as described above to yield 0.030 Gm. of propylhygric acid hydrochloride after three recrystallizations, m. p. 188–189° (capillary, uncorrected). The infrared spectrum of the sample corresponded to that of anhydrous authentic propylhygric acid hydrochloride.

Anal.—Calcd. for $C_9H_{17}NO_2 \cdot HCl$: C, 52.05; H, 8.74. Found: C, 51.74; H, 8.88.

The radioactivities of the various fractions are presented in Table I.

Hydrazinolysis of Tritiated Lincomycin (5)—(*a*) A solution of 0.400 Gm. of noncatalytically tritiated lincomycin hydrochloride[9] in 2 ml. of hydrazine hydrate was refluxed for 70 hr. The reaction mixture was evaporated to dryness *in vacuo* and the distillate was collected for radioactivity determination. The residue was triturated with hot acetonitrile, cooled, and filtered. The crystalline material (0.214 Gm.) was recrystallized from dimethylformamide, filtered, washed with cold methanol, and dried at room temperature *in vacuo* to yield 0.092 mg. of methyl thiolincosaminide, m.p. 222–223° (capillary, uncorrected). Its infrared and mass spectra corresponded to those of the authentic compound.

The radioactivities of the distillate and the methyl thiolincosaminide are presented in Table I.

[9] The tritiated lincomycin hydrochloride samples were diluted with nonradioactive carrier lincomycin hydrochloride by recrystallization from water–acetone prior to degradation.

[10] Darco G60.

(*b*) A 1.27-Gm. sample of catalytically tritiated lincomycin hydrochloride[9] was subjected to hydrazinolysis as described above. The crystalline residue (0.734 Gm.) from trituration was recrystallized to yield 0.296 Gm. of methyl thiolincosaminide, m.p. 223–224° (capillary, uncorrected). Its infrared and mass spectra corresponded to those of the authentic compound.

The radioactivities of the distillate and the methyl thiolincosaminide are presented in Table I.

RESULTS AND DISCUSSION

The radiochemical purity of the crude, catalytically tritiated lincomycin was far greater than that of lincomycin tritiated by the conventional Wilzbach method; 80% and 6%, respectively. It appears that either less radiation decomposition occurred under the catalytic conditions or that if high specific activity impurities were formed they were largely adsorbed on the platinum-black catalyst and not removed in the washing operation. In either event, the catalytic sample was easier to purify and radiochemically pure product was obtained in greater yield.

The incorporation of stably bound tritium in lincomycin by the catalytic method was 17 times that obtained by the conventional method. This effect of platinum black catalyst was found and reported by Meshi and Takahashi (11) in the cases of salicylic acid, valine, prednisolone, benzoic acid, inositol, and thiamine and by Meshi and Sato (12) in the cases of benzene, naphthalene, dinitrobenzene, phthalic anhydride, and benzoyl valine. They ascribe this increased incorporation to catalytic exchange of hydrogen rather than to increased absorption of decay energy by the system.

The intramolecular distributions of tritium in lincomycin prepared by the two methods were quite different. As shown in Table I, the noncatalytic sample contained 62% of its tritium in the propylhygric acid moiety and 33.4% in the methyl thiolincosaminide portion. Corresponding values for the catalytic sample were 95% and 1.84%, respectively. The origin of the small amount of tritium lost to the solvent during HCl hydrolysis is uncertain. The methyl mercaptan, cleaved from methyl thiolincosaminide during acid hydrolysis, contained 3.22% of the molecular tritium in the case of the noncatalytic sample and no tritium in the case of the catalytic sample. The rather large amount of tritium lost to the solvent during hydrazinolysis had to originate predominantly in the propylhygric acid moiety in the case of the catalytic sample and most likely did in the case of the noncatalytic sample. It has been shown (6) that during

hydrazinolysis the number 2 position of propylhygric acid is completely racemized. It, therefore, is likely that the tritium lost to the hydrazine solvent originated in this position of the lincomycin. Thus, 13.7% and 24.5% of the molecular tritium can be assigned to the number 2 position of the propylhygric acid moiety in the cases of the noncatalytic and catalytic samples, respectively.

In regard to ease of purification, yield of product, and incorporation of stable tritium, the catalytic method was superior to the conventional Wilzbach method for tritiating lincomycin. On the other hand, the noncatalytically tritiated lincomycin had a more uniform distribution of tritium making it more suitable for drug metabolism studies. If metabolism resulted in hydrolysis of lincomycin at the amide linkage, the methyl thiolincosaminide moiety could not be traced in the case of the catalytic sample because of its lack of tritium.

Synthesis of Tetrose Nucleosides I

Adenine Nucleosides of Erythrose and Threose

By DANIEL H. MURRAY and JOHN PROKOP

D- and L-Erythrose and D- and L-threose were individually converted to their triacetates which were condensed with chloromercuri-6-benzamidopurine in the presence of titanium tetrachloride. After deacylation, the four crude mixtures of anomeric nucleosides were each resolved on a strong anion exchange resin, leading to the isolation of all eight possible 9-tetrafuranosyladenines. The anomeric configurational assignments were made by consideration of the mechanism of nucleoside condensation (Baker's *trans* rule) and by Hudson's rules of isorotation. Preliminary results of tests for biological activity with *Streptococcus faecalis* 8043 and with adenosine deaminase are reported.

In recent years substantial attention has been directed toward the synthesis of potential inhibitors of nucleic acid metabolism. This has led to the preparation of a wide variety of 5- and 6-carbon sugar nucleosides, of which several of the compounds containing pentose sugar moieties have exhibited antibacterial and/or antitumor activity, for example, cordycepin, xylofuranosyladenine, and spongoadenosine. The majority of such nucleosides have been shown to act as nucleotides *via* phosphorylation at the 5′-position. On the other hand, some compounds have been shown to act in their nucleoside form, for example, decoyinine (1) and 5′-deoxyxylofuranosyladenine (2). In these, lack of a hydroxyl group at a terminal position removes the possibility of nucleotide formation. The 9-tetrofuranosyladenines are further examples of this class of nucleosides. Only the 9-β-D-erythrofuranosyladenine (III) has been prepared previously (3). It has been of interest in the present study to prepare all eight of the possible 9-tetrosyladenines. The biological activity of these is reported in a separate communication (2).

Accepted for publication April 24 1967.

DISCUSSION

The general method of synthesis involved coupling of an acetylated sugar with chloromercuri-6-benzamidopurine (II) (Scheme I) in the presence of titanium tetrachloride. Previous experience with this method (4, 5) has indicated that higher yields of nucleoside are frequently obtained as compared with the more usual procedure of condensation in which the acylated sugar is first converted to the corresponding halide. Furthermore, it has been reported that the use of titanium tetrachloride has led to the formation of significant quantities of the *cis* nucleoside[1] (6, 7). It was anticipated that at least one of the *cis* nucleosides in the present series, 9-β-D-threofuranosyladenine (X), might have significant biological activity. Hence, the authors

[1] The terminology *cis* or *trans* nucleoside refers to the configuration of substituents on carbons 1 and 2 of the sugar moiety.

hydrazinolysis the number 2 position of propylhygric acid is completely racemized. It, therefore, is likely that the tritium lost to the hydrazine solvent originated in this position of the lincomycin. Thus, 13.7% and 24.5% of the molecular tritium can be assigned to the number 2 position of the propylhygric acid moiety in the cases of the noncatalytic and catalytic samples, respectively.

In regard to ease of purification, yield of product, and incorporation of stable tritium, the catalytic method was superior to the conventional Wilzbach method for tritiating lincomycin. On the other hand, the noncatalytically tritiated lincomycin had a more uniform distribution of tritium making it more suitable for drug metabolism studies. If metabolism resulted in hydrolysis of lincomycin at the amide linkage, the methyl thiolincosaminide moiety could not be traced in the case of the catalytic sample because of its lack of tritium.

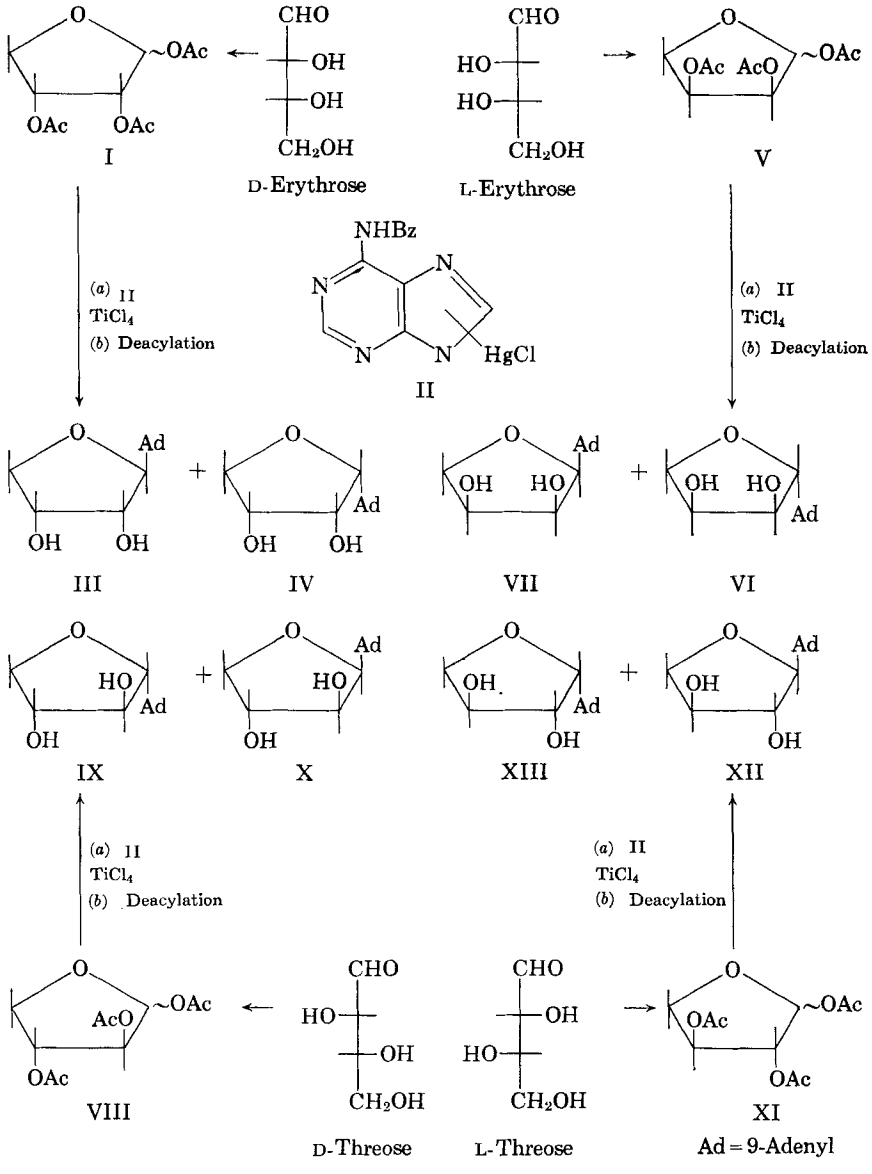
DISCUSSION

The general method of synthesis involved coupling of an acetylated sugar with chloromercuri-6-benzamidopurine (II) (Scheme I) in the presence of titanium tetrachloride. Previous experience with this method (4, 5) has indicated that higher yields of nucleoside are frequently obtained as compared with the more usual procedure of condensation in which the acylated sugar is first converted to the corresponding halide. Furthermore, it has been reported that the use of titanium tetrachloride has led to the formation of significant quantities of the *cis* nucleoside[1] (6, 7). It was anticipated that at least one of the *cis* nucleosides in the present series, 9-β-D-threofuranosyladenine (X), might have significant biological activity. Hence, the authors

[1] The terminology *cis* or *trans* nucleoside refers to the configuration of substituents on carbons 1 and 2 of the sugar moiety.



Scheme I

have sought a procedure which would yield sufficient of a desired *cis* nucleoside for limited biological testing. The titanium tetrachloride coupling step was a desirable element in the procedure.

A second desirable element was a routine method for separating the anomeric pairs of nucleosides. Although such anomeric mixtures of nucleosides, particularly those resulting from condensation of 2-deoxysugars, have been resolved satisfactorily through fractional crystallization procedures, this method is tedious and becomes of more limited use when one of the anomers in the mixture is present in only a relatively small proportion. Chromatographic separations involving adsorption techniques are also limited because of their inability to handle practical amounts of compounds, and, in some instances, because of poor resolution necessitating rechromatography. A recent method, which is reported to give good resolution and has large capacity, involves chromatography on a strong anion exchange resin, and utilizes the differences in pKa's of the sugar hydroxyl groups at high pH (8). Application of this procedure to the mixtures of nucleosides obtained by the condensation of acetylated tetroses led to the isolation of all eight possible 9-tetrafuranosyladenines.

The four tetroses required for these syntheses were obtained through established routes. D-Erythrose was prepared by periodate cleavage of 4,6-*O*-ethylidene-D-glucose followed by acid hydrolysis (9). The resulting syrupy sugar was acetylated using acetic anhydride in pyridine to give the syrupy acetate (I) which was probably an anomeric mixture. Condensation of I with chloromercuri-6-benzamidopurine (II) in the presence of titanium tetrachloride, deacylation with methanolic ammonia,

TABLE I—MELTING POINTS AND SPECIFIC ROTATION FOR THE NUCLEOSIDES

Nucleoside	M. p.	$[\alpha]_D^{20}$
III	239–240° dec.	−114°
VI	238.5–239.5° dec.	+112°
IV	217–218°	+45°
VII	216.5–218°	−44°
IX	214.5–215°	+66°
XII	214.5–215°	−66°
X	239.5–240.5° dec.	−5°
XIII	240–241° dec.	+5°

and chromatography on anion exchange resin of the quaternary ammonium type[2] led to the isolation of crystalline 9-β-D-erythrofuranosyladenine (III) and 9-α-D-erythrofuranosyladenine (IV) in yields of 31 and 13%, respectively. Sixty per cent aqueous methanol[3] was used as eluent throughout these separations.

L-Erythrose was obtained by the procedure starting from rhamnose (10). The sugar was acetylated as before to give the syrupy triacetate (V) in 81% yield. Similar condensation with II and deacylation with methanolic sodium methoxide, followed by chromatographic separation on the anion exchange resin gave the crystalline β- and α-anomers (VI and VII) in yields of 36 and 7.4%, respectively, based on the crude triacetate (V). That these nucleosides (VI and VII) were the enantiomers of III and IV can be seen by comparison of their melting points and specific rotations as shown in Table I. In addition, the infrared spectra of these mirror-image pairs were superimposable.

D- and L-Threose were obtained by periodate oxidation of 1,3-*O*-benzylidene-D- and -L- arabitol, respectively, followed by acid hydrolysis (11). These sugars were readily converted to their triacetates using acetic anhydride in pyridine. The product in each case consisted of both a crystalline isomer and a noncrystallizing syrup obtained from the liquors, and were probably the anomeric forms (12). Either of these products could be converted to the desired nucleosides. Crystalline D-threose triacetate (VIII) was converted to the anomeric adenine nucleosides as described above for D- and L-erythrose. Chromatography of the crude product on the anion exchange resin gave only two ultraviolet absorbing peaks which proved to be 9-α-D-threofuranosyladenine (IX) and 9-β-D-threofuranosyladenine (X) in yields of 55 and 10%, respectively, based on the triacetate. When the crude, syrupy triacetate (VIII), obtained from the mother liquors, was condensed and chromatographed, additional α- (IX) and β- (X) nucleosides resulted in yields of 31 and 3.1%, respectively, along with several minor ultraviolet absorbing peaks which were not characterized.

Crystalline L-threose triacetate (XI) was similarly converted to 9-α-L-threofuranosyladenine (XII) and 9-β-L-threofuranosyladenine (XIII) in yields of 57% and 12%, respectively. When the syrupy triacetate (XI) was employed, the respective yields of α- and β-anomers were 34 and 4.3%. That the α-nucleosides (IX and XII) and the β-nucleosides (X and XIII) represented enantiomeric pairs can be seen by comparison of the constants shown in Table I. The infrared spectra of these pairs were superimposable.

Periodate consumption studies established the furanoside structure of these nucleosides. In addition, the D-erythrosides (III and IV) oxidized rapidly with 1 *M* equivalent of periodate being consumed within 5 min. In contrast, oxidation of the L-threosides (XII and XIII) was considerably slower with 1 *M* equivalent of periodate being consumed only after 5 days. These results are consistent with those reported earlier for the periodate consumption of 2′,3′-*cis* and -*trans* hydroxyl groups in nucleosides containing furanosyl sugars (13).

The anomeric configurations of these nucleosides could be implied by their relative yields. So far as is known, the *trans* nucleoside predominates in all nucleoside condensations including those involving the titanium tetrachloride procedure (6, 7, 14). Application of Hudson's rules of isorotation (Table I) supports these assignments.

Biological Activity—The effect of these nucleosides on growth was examined in *Streptococcus faecalis* 8043. Only compounds X and XII were inhibitory, preventing 50% of growth at 2×10^{-5} *M*. All the others were negative. Compounds X, XII, and VII were significantly inhibitory in an adenosine deaminase system. These results are discussed in detail elsewhere (2).

EXPERIMENTAL[4]

D-Erythrose Triacetate (I)—To a stirred solution of 7.09 Gm. (54.8 mmoles) of D-erythrose syrup (9) in 50 ml. of reagent pyridine was added 23.5 ml. (250 mmoles) of acetic anhydride dropwise below 20°. The flask was stoppered and the reaction was allowed to remain at room temperature overnight. The dark amber reaction was then poured into 200 ml. of an ice water mixture with stirring and, after 30 min., the mixture was extracted with chloroform (3 × 100 ml.). These extracts were combined and washed with aqueous saturated sodium bicarbonate (3 × 100 ml.) and water (100 ml.). After drying over magnesium sulfate, the extract was treated with activated charcoal[5] and filtered through diatomaceous earth[6] giving a pale yellow filtrate which was evaporated to dryness *in vacuo* (60°). The last traces of pyridine were removed by evaporative distillation *in vacuo* with 25 ml. of toluene yielding 12.0 Gm. (89%) of a light amber syrup which was sufficiently pure for condensation. For analysis, a sample was distilled in a sublimation tube and a clear, colorless liquid was collected at 105–110°/0.06 mm.; $[\alpha]_D^{28}$ −66.2° (c 4.8, $CHCl_3$); $\nu_{max.}^{film}$ (cm.$^{-1}$) 1750 (acetate C=O), 1375 (methyl), 1220 (acetate C—O—C).

Anal.—Calcd. for $C_{10}H_{14}O_7$: C, 48.78; H, 5.73. Found: C, 48.55; H, 5.81.

[2] Marketed as Bio-Rad AG1×8(OH) by Bio-Rad Laboratories, Richmond, Calif.

[3] Practical grade methanol was entirely satisfactory for this purpose.

[4] Melting points were obtained using a Mel-Temp instrument and are uncorrected. The infrared and ultraviolet spectra were determined on Perkin-Elmer models 337 and 202, respectively, and optical rotations were obtained using a Perkin–Elmer 141 polarimeter. The column chromatograms were monitored with an ISCO model UA analyzer. Galbraith Laboratories, Inc., Knoxville, Tenn., performed the elemental analyses.

[6] Marketed as Celite by Johns-Manville, New York, N. Y.

9-α- and β-D-Erythrofuranosyladenine (IV and III, Respectively)—A mixture of 9.27 Gm. (38 mmoles) of crude erythrose triacetate (I), 17.9 Gm. (38 mmoles) of chloromercuri-6-benzamidopurine (II) (4, 5), 18 Gm. of diatomaceous earth, and 650 ml. of ethylene dichloride was distilled until 80 ml. of distillate had been collected. After cooling to room temperature, a solution of 4.13 ml. (38 mmoles) of titanium tetrachloride in 45 ml. of ethylene dichloride was added dropwise and the mixture was then heated under reflux overnight while protected from moisture. The mixture was cooled to room temperature and 40 ml. of aqueous saturated sodium bicarbonate was added while stirring vigorously. Additional solid sodium bicarbonate was added until a neutral reaction was obtained. The mixture was filtered through diatomaceous earth and the cake was washed with additional ethylene dichloride (3 × 35 ml.). After combining the filtrate and washings and removal of the solvent *in vacuo*, the residue was redissolved in 300 ml. of chloroform, filtered free of some insolubles, and washed with 300 ml. of 30% aqueous potassium iodide and 300 ml. of water. The organic solution was dried over magnesium sulfate, treated with activated charcoal, and filtered, and the filtrate was evaporated to dryness *in vacuo* (60°) leaving crude 2',3'-di-*O*-acetyl-9-α- and β-D-erythrofuranosyl-6-benzamidopurine as an amber glass; yield, 11.3 Gm. (71%); $\bar{\nu}_{max.}^{KBr}$ (cm.$^{-1}$) 1750 (acetate C=O), 1700 (amide C=O), 1375 (methyl), 1220 (acetate C—O—C), 710 (monosubstituted benzene).

A solution of 11.2 Gm. of the above blocked nucleosides in 360 ml. of anhydrous methanol was saturated with ammonia gas while maintaining the temperature at about 5°. After standing in a stoppered flask at 5° overnight, the ammonia and solvent were removed *in vacuo* and the residue partitioned between 300 ml. of water and 100 ml. of chloroform. The organic phase was separated and the aqueous phase was washed further with chloroform (2 × 100 ml.). The organic phases were combined and back-washed with 100 ml. of water which was then added to the original aqueous phase. A small amount of insolubles was removed by filtration and the aqueous phase was then concentrated *in vacuo* to about 100 ml. After addition of 120 ml. of methanol, the nucleoside-containing solution was transferred to the top of a column (8.0 × 50 cm.), packed with the anion exchange resin, which was previously equilibrated with 60% aqueous methanol. The nucleosides were eluted with the same solvent at a rate of approximately 475 ml./hr. with the fractions collected at 1-hr. intervals. Fractions 23–28 were combined and evaporated to dryness giving the α-anomer (IV) as needles; yield, 1.15 Gm. (13%), m.p. 212–217°. Two recrystallizations from 95% ethanol gave the analytical sample, m.p. 217–218°; $[\alpha]_D^{20}$ + 45° (c 0.67, H_2O); $\lambda_{max.}^{pH\ 1}$ (mμ) 257.5 (ε 14,500); $\lambda_{max.\ 259.5}^{pH\ 7\ and\ 13}$ (ε 15,000); $\nu_{max.}^{KBr}$ (cm.$^{-1}$) 3400–3100 (broad OH and NH), 1605, and 1575 (C=C and C=N). Periodate consumption (moles of periodate/mole of compound) (13, 17, 18): 1.00 (5 min. and constant).

Anal.—Calcd. for $C_9H_{11}N_5O_3$: C, 45.57; H, 4.67; N, 29.52. Found: C, 45.54; H, 4.60; N, 29.70.

The β-anomer (III) was obtained by combining fractions 42–58 and removing the solvent *in vacuo* to give a nearly white, crystalline solid; yield, 2.74 Gm. (31%), m.p. 224.5–225.5° dec. The analytical sample was obtained by recrystallizing twice from 50% aqueous ethanol, m.p. 239–240° dec.; $[\alpha]_D^{20}$ −114° (c 0.40, H_2O); $\lambda_{max.}^{pH\ 1}$ (mμ) 257.5 (ε 14,000); $\lambda_{max.}^{pH\ 7\ and\ 13}$ 260 (ε 14,500); $\bar{\nu}_{max.}^{KBr}$ (cm.$^{-1}$) 3355, 3130 (OH and NH), 1605, 1575 (C=C and C=N). Periodate consumption (moles of periodate/mole of compound) (13, 17, 18): 0.95 (5 min.), 0.99 (1 hr.), 1.00 (48 hr.).

Anal.—Calcd. for $C_9H_{11}N_5O_3$: C, 45.57; H, 4.67; N, 29.52. Found: C, 45.69; H, 4.78; N, 29.54.

L-Erythrose Triacetate (V)—To a stirred solution of 3.64 Gm. (30 mmoles) of syrupy L-erythrose (10) in 30 ml. of reagent pyridine was added 12.9 ml. (136 mmoles) of acetic anhydride dropwise while maintaining the temperature below 20°. The reaction was allowed to remain at room temperature in a stoppered flask overnight, then poured into 100 ml. of an ice water mixture and worked up as described above for the D-isomer; yield of light amber syrup was 6.05 Gm. (81%) and was sufficiently pure for condensation. For analysis, a sample was distilled in a sublimation tube and a clear, colorless liquid was collected at 105°/0.06 mm.; $[\alpha]_D^{28}$ +63.7° (c 3.6, $CHCl_3$); $\bar{\nu}_{max.}^{film}$ (cm.$^{-1}$) 1750 (acetate C=O), 1375 (methyl), 1220 (acetate C—O—C).

Anal.—Calcd. for $C_{10}H_{14}O_7$: C, 48.78; H, 5.73. Found: C, 49.29; H, 6.04.

9-α- and β-L-Erythrofuranosyladenine (VII and VI, Respectively)—A mixture of 5.59 Gm. (23 mmoles) of crude L-erythrose triacetate (V), 10.8 Gm. (23 mmoles) of chloromercuri-6-benzamidopurine, 11 Gm. of diatomaceous earth, and 400 ml. of ethylene dichloride was distilled until 60 ml. of distillate had been collected. The reaction was cooled to room temperature and a solution of 2.5 ml. (23 mmoles) of titanium tetrachloride in 25 ml. of ethylene dichloride was added dropwise. The reaction was then heated under reflux for 18 hr. while protected from moisture. After cooling the mixture to room temperature, 25 ml of aqueous saturated sodium bicarbonate was added followed by additional solid sodium bicarbonate while stirring vigorously until a neutral reaction was obtained. The mixture was then processed as described for the D-isomers leaving crude 2',3'-di-*O*-acetyl-9-α- and β-L-erythrofuranosyl-6-benzamidopurine as a light amber glass; yield, 7.05 Gm. (73%); $\bar{\nu}_{max.}^{KBr}$ (cm.$^{-1}$) 1750 (acetate C=O), 1700 (amide C=O), 1375 (methyl), 1220 (acetate C—O—C), 710 (monosubstituted benzene).

A solution of 6.82 Gm. of the crude, blocked nucleosides in 160 ml. of 0.1 *N* methanolic sodium methoxide was allowed to stand at room temperature in a stoppered flask for 24 hr. After neutralizing the reaction with glacial acetic acid and removal of the solvent *in vacuo*, the residue was partitioned between 100 ml. of water and 100 ml. of chloroform. The organic phase was separated and the aqueous phase washed further with chloroform (2 × 50 ml.), filtered free of insolubles, and evaporated to near dryness *in vacuo*. The residue was redissolved in 100 ml. of 50% aqueous methanol and transferred to the top of a column (3.8 × 50 cm.) packed with the anion exchange resin. The nucleosides were eluted using 60% aqueous methanol (to which the column had been equilibrated originally) at a rate of approximately 80 ml./fraction. Fractions were

collected at 1-hr. intervals. The α-anomer (VII) was obtained by combining fractions 31–38. These fractions also contained a small amount of a contaminating substance which immediately preceded the desired peak from which it was incompletely separated. Subsequent rechromatography of these combined fractions did allow complete removal of the interfering substance. Removal of the solvent *in vacuo* left the desired nucleoside (VII) as a crystalline solid; yield 385 mg. (7.4% from L-erythrose triacetate), m.p. 207–211°. Three recrystallizations from 95% ethanol gave the analytical sample, m.p. 216.5–218°; $[\alpha]_D^{20}$ −44° (c 0.61, H_2O); $\lambda_{max.}^{pH\ 1}$ (mμ) 257.5 (ε 14,200), $\lambda_{max.}^{pH\ 7\ and\ 13}$ 259.5 (ε 14,800). The infrared spectrum of this substance was superimposable with that of the D-isomer (IV). Mixed melting point with IV was depressed.

Anal.—Calcd. for $C_9H_{11}N_5O_3$: C, 45.57; H, 4.67; N, 29.52. Found: C, 45.81; H, 4.75; N, 29.74.

Combination of fractions 55–74 and removal of the solvent *in vacuo* gave the β-anomer (VI) as a crystalline solid; yield, 1.88 Gm. (36% from L-erythrose triacetate), m.p. 229–233°. For analysis, a sample was recrystallized twice from 50% aqueous ethanol, m.p. 238.5–239.5° dec.; $[\alpha]_D^{20}$ +112° (c 0.42, H_2O); $\lambda_{max.}^{pH\ 1}$ (mμ) 257.5 (ε 14,000), $\lambda_{max.\ 260}^{pH\ 7\ and\ 13}$ (ε 14,300). The infrared spectrum was superimposable with that of the D-isomer (III). Mixed melting point with III was depressed.

Anal.—Calcd. for $C_9H_{11}N_5O_3$: C, 45.57; H, 4.67; N, 29.52. Found: C, 45.62; H, 4.80; N, 29.71.

D-Threose Triacetate (VIII)—To a stirred solution of 3.52 Gm. (29 mmoles) of syrupy D-threose (11) in 30 ml. of reagent pyridine was added dropwise 20 ml. of acetic anhydride below room temperature. The reaction was allowed to remain at room temperature in a stoppered flask overnight, then poured into 100 ml. of an ice water mixture to decompose the remaining anhydride. The mixture was extracted with chloroform (3 × 50 ml.) and the combined extracts were washed with aqueous saturated sodium bicarbonate (4 × 50 ml.) and water (50 ml.). The extract was dried over magnesium sulfate, treated with activated charcoal, and filtered, and the filtrate evaporated to dryness *in vacuo* (50°). The last traces of pyridine were removed by repeated distillations *in vacuo* of toluene (3 × 25 ml.) yielding 6.79 Gm. (94%) of a partially crystalline syrup. After trituration with 30 ml. of absolute ethanol, the crystalline portion was collected on a filter, washed with absolute ethanol, and dried; yield, 1.43 Gm. (20%), m.p. 115.5–117°. One recrystallization from absolute ethanol gave m.p. 117–118.5°; $[\alpha]_D^{28}$ +35.3° (c, 4.1, $CHCl_3$). [Lit. (12) m.p. 117–118°, [α] +35.55 (c 4, $CHCl_3$).]

The above filtrate was evaporated to dryness *in vacuo* (50°) yielding 5.31 Gm. (74%) of the noncrystalline anomer of D-threose triacetate. This material was also suitable for condensation.

9-α- and β-D-Threofuranosyladenine (IX and X, Respectively)—A mixture of 1.23 Gm. (5 mmoles) of crystalline D-threose triacetate, 2.37 Gm. (5 mmoles) of chloromercuri-6-benzamidopurine (II), 3 Gm. of diatomaceous earth, and 100 ml. of ethylene dichloride was distilled until 25 ml. of distillate had been collected. The reaction was cooled to room temperature and a solution of 0.55 ml. (5 mmoles) of titanium tetrachloride in 6 ml. of ethylene dichloride was added dropwise. The mixture was then heated under reflux overnight while protected from moisture. To the cooled mixture was added 16 ml. of aqueous saturated sodium bicarbonate with vigorous stirring, followed by additional solid sodium bicarbonate until a neutral reaction was obtained. After filtration through diatomaceous earth, the cake was washed with 35 ml. of ethylene dichloride, the washing combined with the filtrate, and the solvent removed *in vacuo*. A solution of the residue in 50 ml. of chloroform was filtered free of some insolubles, then washed with 50 ml. of 30% aqueous potassium iodide and 50 ml. of water. The chloroform solution was dried over magnesium sulfate, treated with activated charcoal and filtered through diatomaceous earth, and the filtrate evaporated to dryness *in vacuo* (50°) leaving crude 2′, 3′-di-*O*-acetyl-9-α and β-D-threofuranosyl-6-benzamidopurine as an amber glass; yield 1.77 Gm. (83%); $\bar{\nu}_{max}^{KBr}$ ($cm.^{-1}$) 1750 (acetate C=O), 1700 (amide C=O), 1375 (methyl), 1220 (acetate C—O—C), 710 (monosubstituted benzene).

A solution of 1.75 Gm. of the above blocked nucleosides in 40 ml. of 0.1 *N* methanolic sodium methoxide was allowed to stand at room temperature in a stoppered flask for 24 hr. Without further processing, the solution was transferred to the top of a column (3.8 × 50 cm.) containing the anion exchange resin which had previously been equilibrated with 60% aqueous methanol. The nucleosides were eluted using 60% aqueous methanol at a rate of approximately 80 ml./hr. Fractions were collected at 1-hr. intervals. The β-isomer (X) was isolated by evaporation of fractions 60–70 which yielded 121 mg. (10.4% from D-threose triacetate) of a crystalline solid, m.p. 234–236° dec. Two recrystallizations from 95% ethanol gave the analytical sample, m.p. 239.5–240.5° dec.; $[\alpha]_D^{20}$ −5° (c 0.40, H_2O); $\lambda_{max.}^{pH\ 1}$ (mμ) 257.5 (ε 14,000), $\lambda_{max.\ 260}^{pH\ 7\ and\ 13}$ (ε 14,600); $\bar{\nu}_{max.}^{KBr}$ ($cm.^{-1}$) 3400–3100 (broad OH and NH), 1605, 1575 (C=C and C=N).

Anal.—Calcd. for $C_9H_{11}N_5O_3$: C, 45.57; H, 4.67; N, 29.52. Found: C, 45.66; H, 4.71; N, 29.66.

The α-isomer (IX) was isolated from fractions 74–91 as a crystalline solid; yield, 641 mg. (54.6% from D-threose triacetate), m.p. 213–215°. A pure sample was obtained by recrystallizing twice from 95% ethanol and thorough drying at 100°, m.p. 214.5–215°; $[\alpha]_D^{20}$ + 66° (c 0.58, H_2O); $\lambda_{max.}^{pH\ 1}$ (mμ) 258 (ε 14,000), $\lambda_{max.\ 260}^{pH\ 7\ and\ 13}$ (ε 14,500); $\bar{\nu}_{max.}^{KBr}$ ($cm.^{-1}$ 3500–3150 (broad OH and NH), 1605, 1575 (C=C and C=N).

Anal.—Calcd. for $C_9H_{11}N_5O_3$: C, 45.57; H, 4.67; N, 29.52. Found: C, 45.84; H, 4.82; N, 29.72.

When the crude, noncrystallizing portion of D-threose triacetate (above) was condensed, deacylated, and chromatographed in a similar manner, additional nucleosides were obtained amounting to 31% of the α- and 3.1% of the β-isomer.

L-Threose Triacetate (XI)—To a stirred solution of 3.75 Gm. (31 mmoles) of syrupy L-threose (15) in 35 ml. of reagent pyridine was added 24 ml. (255 mmoles) of acetic anhydride dropwise below 30°. After standing overnight at room temperature in a stoppered flask, the solvents were removed *in vacuo* (50°). The remaining traces of pyridine and acetic acid were removed by repeated distillation *in vacuo*

of toluene (3 × 30 ml.). A solution of the residue in 200 ml. of chloroform was treated with activated charcoal, filtered through diatomaceous earth, and the filtrate evaporated to dryness *in vacuo* (60°) leaving a partially crystalline, amber syrup; yield, 7.18 Gm. (93%). The crystalline anomer was obtained by triturating the residue with 10 ml. of absolute ethanol and collecting the product on a filter; yield 2.22 Gm. (29%), m.p. 114–117°. One recrystallization from 10 ml. of absolute ethanol gave 2.17 Gm. of the pure compound, m.p. 117–118°; $[\alpha]_D^{28}$ −35.5° (c 4.2, $CHCl_3$). [Lit. (12) m.p. 117–118°, $[\alpha]_D$ +35.55° (c 4, $CHCl_3$) for the D-isomer.]

Evaporation of the filtrate to dryness gave 4.95 Gm. (64%) of the crude, noncrystalline anomer of L-threose triacetate which was also suitable for condensation.

9-α- and β-L-Threofuranosyladenine (XII and XIII, Respectively)—Crystalline L-threose triacetate (XI), 1.23 Gm. (5 mmoles), was condensed with chloromercuri-6-benzamidopurine (II) in exactly the same manner as described for the D-isomer. This resulted in the isolation of 1.70 Gm. (80%) of crude 2′,3′-di-*O*-acetyl-9-α- and β-L-threofuranosyl-6-benzamidopurine as a yellow glass; $\bar{\nu}_{max.}^{KBr}$ (cm.$^{-1}$) 1750 (acetate C=O), 1700 (amide C=O), 1375 (methyl), 1220 (acetate C—O—C), 710 (monosubstituted benzene).

A solution of 1.03 Gm. of the crude, blocked nucleosides in 25 ml. of 0.1 *N* methanolic sodium methoxide was allowed to remain at room temperature for 24 hr. in a stoppered flask. Without further processing, the solution was transferred to the top of a column (3.8 × 50 cm.) of the anion exchange resin previously equilibrated with 60% aqueous methanol. The elution procedure was identical to that described for the D-isomers except that the rate was somewhat slower, approximately 70 ml./hr. Fractions 68–81 were combined and evaporated to dryness *in vacuo* to give 84 mg. (11.7% from L-threose triacetate) of crystalline β-anomer (XIII), m.p. 236.5–238° dec. The analytically pure compound was obtained after two recrystallizations from 95% ethanol, m.p. 240–241° dec.; $[\alpha]_D^{20}$ +5° (c 0.49, H_2O); $\lambda_{max.}^{pH\ 1}$ (mμ) 258 (ε 14,100), $\lambda_{max.\ 260}^{pH\ 7\ and\ 13}$ (ε 14,500). The infrared spectrum was superimposable with that obtained for the β-D-isomer (X). Mixed melting point with the D-isomer (X) showed a depression. Periodate consumption (moles of periodate/mole of compound) (13, 17, 18): 0.05 (5 min.), 0.12 (1 hr.), 0.60 (24 hr.), 0.83 (72 hr.), 0.91 (96 hr.), 0.98 (120 hr.).

Anal.—Calcd. for $C_9H_{11}N_5O_3$: C, 45.57; H, 4.67; N, 29.52. Found: C, 45.61; H, 4.70; N, 29.46.

The crystalline α-isomer (XII) was obtained by combining fractions 85–107 and evaporating to dryness *in vacuo;* yield, 409 mg. (57.0% from L-threose triacetate), m.p. 211.5–213°. Two recrystallizations from 95% ethanol and thorough drying *in vacuo* at 100° for at least 24 hr. gave the pure compound, m.p. 214.5–215°; $[\alpha]_D^{20}$ −66° (c 0.60, H_2O); $\lambda_{max.}^{pH\ 1}$ (mμ) 258 (ε 13,800); $\lambda_{max.}^{pH\ 13}$ 260 (ε 14,200), $\lambda_{max.}^{H_2O}$ 260 (ε 14,200). The infrared spectrum was superimposable with that obtained for the α-D-isomer (IX). Mixed melting point with IX was depressed. Periodate consumption (moles of periodate/mole of compound) (13, 17, 18): 0.02 (5 min.), 0.08 (1 hr.), 0.59 (24 hr.), 0.80 (48 hr.), 0.89 (72 hr.), 0.94 (96 hr.), 0.98 (120 hr.).

Anal.—Calcd. for $C_9H_{11}N_5O_3$: C, 45.57; H, 4.67; N, 29.52. Found: C, 45.43; H, 4.58; N, 29.72.

Condensation of crude, noncrystalline L-threose triacetate (above), deacylation, and chromatography as described above gave the α-anomer (XII) in 34% yield and the β-anomer (XIII) in 4.3% yield.

Irreversible Enzyme Inhibitors LXXXVII

Hydrophobic Bonding to Dihydrofolic Reductase IX. Mode of Binding of *m*-Aryloxyalkyl Groups on 4,6-Diamino-1,2-dihydro-2,2-dimethyl-1-phenyl-*s*-triazine

By B. R. BAKER and GERHARDUS J. LOURENS

The relative binding to dihydrofolic reductase by 16 *m*-substituted 4,6-diamino-1,2-dihydro-2,2-dimethyl-1-phenyl-*s*-triazines—nine of which are newly synthesized—has been measured. Strong evidence is presented to indicate that the increased binding by terminal phenyl groups on a *m*-substituent is due to complexing to a relatively hydrophilic area since terminal benzyl and terminal phenoxy groups give nearly the same increments in binding. The possible conversion of such compounds to candidate active-site-directed irreversible inhibitors of dihydrofolic reductase is discussed.

A HYDROPHOBIC BONDING area on an enzyme can have considerable utility in the design of potent and selective inhibitors, particularly if this area is adjacent to the active site (1). Since a hydrophobic bonding area on an enzyme that uses a polar substrate, such as dihydrofolic reductase, is probably nonfunctional with respect to binding of the substrate (1), large differences in the hydrophobic bonding area of this enzyme from different species would be expected to occur by evolution (2); such differences in the hydrophobic bonding area between pigeon liver and *E. coli* B dihydrofolic reductases (3), or between T_2-phage induced and *E. coli* B dihydrofolic reductases (4), or in other species (5) have been detected. In the case of dihydrofolic reductase, binding to the hydrophobic region can lead to complications; for example, if hydrophobic bonding is sufficiently strong, different rotomers of pyrimidine-type inhibitors may be bound where the hydrophobic group on the inhibitor is determinate for the rotomer (6).

The evidence for rotomers was initially based on differences in reversible binding with a variety of inhibitors (6, 7), then further verified with candidate irreversible inhibitors (8, 9). It was noted in the 2-amino-5-phenylbutyl-4-pyrimidinol series (I) that the reversible binding varied considerably with the R-substituent at the 6-position (6); the 6-methyl derivative (I*a*) was about 30 times more effective than the 6-propyl derivative (I*b*) (6), and the 6-phenylethyl derivative (I*d*) was in between in effectiveness (10). In contrast, in the 2,4-diamino series (II), the binding was independent of the 6-R-group; R = CH_3 (II*a*) (11), R = *n*-propyl (II*b*) (6), and R = the phenethyl derivative (II*d*) (8). All showed nearly identical reversible inhibition of the dihydrofolic reductase from pigeon liver. These results were rationalized on the basis that (*a*) the hydrophobic region is not between the pyrimidyl and phenyl moieties of dihydrofolate (III) (12, 13), but is near where the 4-position (or 8-position) of III resides on the enzyme (6)—as indicated by rotomer I; (*b*) the 4-pyrimidinols projected the 6-R group back toward the active site as indicated in rotomer I; and (*c*) the 2,4-diaminopyrimidines projected the 6-R group away from the active site (6) with the R-group probably not even in contact with the enzyme. That the alkylating function of I*d* and II*d* was not positioned the same way within their complexes with dihydrofolic reductase was indicated by the facts that the 4-pyrimidinol (I*d*) was an effective irreversible inhibitor of the enzyme (10), but the

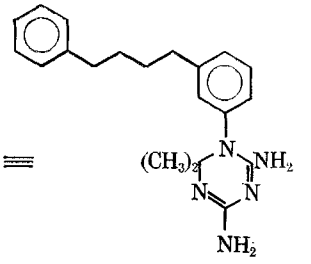
IV*A*



IV*B*

corresponding 2,4-diaminopyrimidine (II*a*) was not (8); although this result with II*d* was not unanticipated, it did create a serious problem in the design of irreversible inhibitors effective at low physiological concentration (8).

The effectiveness of an active-site-directed irreversible enzyme inhibitor is dependent upon two major factors: (*a*) the rate of inactivation is dependent upon the concentration of reversible enzyme–inhibitor complex which is in turn dependent upon the concentration of the inhibitor and the binding constant of the inhibitor, and (*b*) the rate of reaction of the neighboring group reaction between the leaving group on the inhibitor juxtaposed to a nucleophilic site on the enzyme (14, 15). Thus, in order to have an irreversible inhibitor effective at a physiological concentration of 10^{-8} *M*, it would be necessary that the inhibitor have a reversible binding constant of 10^{-7} *M* or less (8, 15). The 2-amino-4-pyrimidinol (I*d*) meets one of the two criteria for an effective irreversible inhibitor: I*d* rapidly alkylates a nucleophilic site on the enzyme with a half-life of about 12 min. at a concentration sufficient to convert 50% of the enzyme to a complex, but this concentration (4×10^{-5} *M*) is much too high for *in vivo* use. The 2,4-diaminopyrimidine (II*d*) also meets only one of the two criteria for an effective irreversible inhibitor since at 4×10^{-9} *M* it can complex 50% of the enzyme, but unfortunately does not inactivate the enzyme in a rotomeric conformation believed to be II. One possible solution to this enigma has been previously explored (16); the exploration of another possible solution is the subject of this paper.

DISCUSSION

The 4,6-diamino-1-phenyl-*s*-triazines are believed to complex to dihydrofolic reductase in a rotomeric configuration similar to the 2,4-diamino-5-phenylbutylpyrimidines (II). It was recently observed that additional binding to the enzyme can occur with aralkyl groups that are substituted on the *m*- or *p*-position of the 1-phenyl moiety (17) (see Table I). Since the 1-phenyl group does not have a restricted rotation and must be nearly coplanar with the triazine ring when complexed to the dihydrofolic reductase from most species (5, 7, 18–21), a substituent such as the phenylbutyl group of IV can be pointed to the left (IV*B*) away from the active site or pointed to the right (IV*A*) toward the enzyme active site when complexed to the enzyme. Since the area on the right approaches the area that binds the polar dihydrofolate (III) it should be more polar than the hydrophobic region and be more apt to have polar nucleophilic groups present, which could be subject to attack by active-site-directed irreversible inhibitors; therefore, the mode of binding of the *m*-phenylalkyl substituents were investigated, and the results are listed in Table I.

Two series of side chains were investigated with terminal aryl or aryloxy groups—namely, (*a*) *m*-alkyl substituents and (*b*) *m*-alkoxy substituents. The latter class has the advantage that there is a greater variety of ground-state conformations for the bridge between the two phenyl rings; this is of considerable importance in the ability of a leaving group of the inhibitor to bridge to a nucleophilic site on the enzyme within the enzyme–inhibitor reversible complex.

Introduction of an ether linkage such as methoxy (VIII) on the 1-phenyl moiety leads to a fivefold loss in binding (Table I); such a loss could be

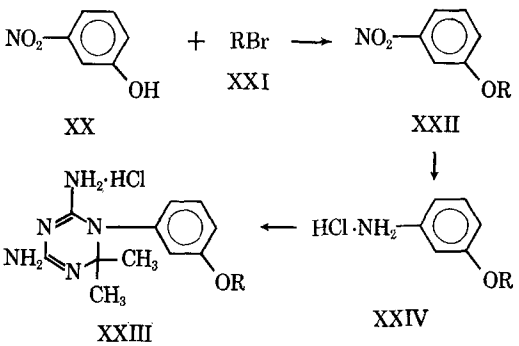
[a] All compounds were prepared by method *E* and had infrared and ultraviolet spectra in agreement with their assigned structures. [b] Recrystallized from ethanol. [c] Recrystallized from ethanol–ether. [d] Recrystallized from ethanol–petroleum ether (b.p. 40–60°).

anticipated since introduction of other polar groups on the 1-phenyl moiety led to decreased binding, presumably due to repulsion from the hydrophobic region on the enzyme (22). Surprisingly, another threefold loss occurred in binding when the chain was extended to *n*-propoxy (VI). Of more importance was the fact that introduction of a terminal phenyl on the *n*-propoxy group, as in XIV, gave a seventeenfold increase in binding; this result compares favorably with the elevenfold increase in binding when a terminal phenyl group is introduced on the *n*-butyl group as in IV (17). Similar increments in terminal phenyl binding were observed in IX *versus* X and XII *versus* XIII.

It was previously observed that the binding of a 5-phenylbutyl group on the pyrimidine (I*a*) was thirtyfold better than the 5-phenoxypropyl group (23); this result has been attributed to the increased hydrophobic bonding of a terminal benzyl group compared to a terminal phenoxy group plus some possible repulsion of the ether oxygen from the hydrophobic region (7). A similar repulsion of the ether group of VIII has just been discussed. Therefore, the replacement of a methylene group by an ether oxygen can be used as a test for the relative hydrophobic character of a binding region. Note that exchange of benzyl in XIV for phenoxy in XV gave no appreciable change in binding; similar comparisons are XVI *versus* XVII and XVIII *versus* XIX. Therefore, the nearly identical binding by phenoxy and benzyl indicates that the terminal phenyl moiety may well be complexed to a relatively hydrophilic region on the enzyme surface, as suggested earlier for the conformation of IV*B*. If indeed these terminal phenyl groups of molecules such as IV and XV are complexed in a relatively polar region of the enzyme, then introduction of a bromoacetamido group on the terminal phenyl group should make logical candidate active-site-directed irreversible inhibitors of dihydrofolic reductase that could be operational in the 10^{-7}–10^{-8} *M* region; such studies are being vigorously pursued.

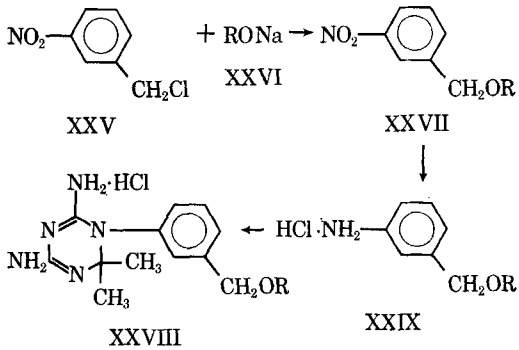
CHEMISTRY

The 1,2-dihydro-1-phenyl-*s*-triazines in Tables I and III were made from the appropriate aryl amine hydrochloride and cyanoguanidine in acetone—the three-component method of Modest (20). The synthetic methods for the required amines could be divided into three classes. The first class contained an ether linkage to the 1-phenyl moiety of type XXIII. *m*-Nitrophenol (XX) was converted to the sodium salt with sodium hydride then alkylated with the appropriate bromide (XXI), except for XXIIe where 4-phenylbutyl chloride was employed. The nitro groups were reduced catalytically with a palladium-charcoal catalyst in ethanol in the presence of a slight excess of hydrochloric acid; the amine hydrochlorides (XXIV) were isolated in good yield. Condensation of XXIV with cyanoguanidine in acetone afforded the triazines (XXIII); of course, commercial XXIV*a* base was employed. (Scheme I.)



Series *a*, R = CH_3
b, R = $C_6H_5(CH_2)_2$—
c, R = $C_6H_5(CH_2)_3$—
d, R = $C_6H_5O(CH_2)_2$—
e, R = $C_6H_5(CH_2)_4$—
f, R = $C_6H_5O(CH_2)_3$—

Scheme I



Series *a*, R = CH_3
b, R = C_6H_5

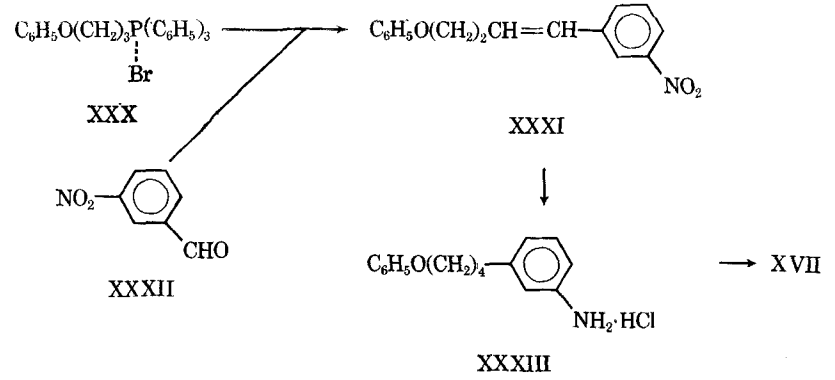
Scheme II

The second series contained the oxymethylene bridge as in XXVIII; these were prepared *via* *m*-nitrobenzyl chloride (XXV). Reaction of XXV with phenol in acetone in the presence of potassium carbonate afforded XXVII*b*. The methyl ether (XXVII*a*) was prepared from XXV with sodium methoxide. The remainder of the sequence for XXVIII was the same as for XXIII. (Scheme II.)

The third type is represented by XVII (Table III). Condensation of the Wittig reagent (XXX) from phenoxypropyl bromide (24) with *m*-nitrobenzaldehyde (XXXII) in tetrahydrofuran in the presence of potassium *tert*-butoxide afforded XXXI as an oil. Hydrogenation with platinum oxide catalyst gave crystalline XXXIII in 40% over-all yield from XXXII. Condensation with cyanoguanidine afforded the desired dihydro-*s*-triazine (XVII). (Scheme III.)

Methods—Melting points were determined in capillary tubes with a Mel-Temp block and those below 230° are corrected. Infrared spectra were determined in KBr pellet, unless otherwise indicated, with a Perkin-Elmer 137B spectrophotometer. Ultraviolet spectra were determined in water with a Perkin-Elmer 202 spectrophotometer. Thin-layer chromatograms (TLC) were run on Brinkmann Silica Gel GF and spots were detected by iodine vapor or by visual examination under ultraviolet light.

m-Nitrophenyl γ-Phenylpropyl Ether (XXIIc)—*Method A*—A solution of 3.83 Gm. (27.5 mmoles) of *m*-nitrophenol in 10 ml. of dimethylsulfoxide was added dropwise over a period of about 10 min. to a magnetically stirred mixture of 10 ml. of dimethylsulfoxide and 1.27 Gm. (26 mmoles) of a 53.5% dispersion of sodium hydride in mineral oil, protected from moisture. The red solution was warmed to 80°, then 4.98 Gm. (25 mmoles) of 3-



Scheme III

phenylpropyl bromide was added; the temperature rose to 95°. After being stirred in a bath at 80–85° for 90 min., the mixture was cooled, diluted with 75 ml. of benzene, and washed successively with 100 ml. of water, 25 ml. of water, 5% aqueous sodium hydroxide (3 × 15 ml.), and finally water (2 × 25 ml.). The benzene solution, dried with magnesium sulfate, was evaporated *in vacuo*. Crystallization from *n*-propanol gave 4.02 Gm. (62%) of product, m.p. 27–28°. $\nu_{max.}$ (film): 1610, 1580 (C=C); 1530, 1345 (NO_2); 1245, 1030 (C—O—C); 810, 795 (*m*-C_6H_4); 735, 698 cm.$^{-1}$ (C_6H_5). (See Table II for analytical data and for other compounds prepared by Method *A*.)

m-Nitrophenyl Phenoxyethyl Ether (XXIId)—*Method B*—To a solution of 1.41 Gm. (26 mmoles) of sodium methoxide in 10 ml. of reagent methanol was added 3.83 Gm. (27.5 mmoles) of *m*-nitrophenol (XX), followed by 5.03 Gm. (25 moles) of β-bromophenetole. After being refluxed with magnetic stirring for 18–22 hr., the mixture was spin-evaporated *in vacuo*. The residue was partitioned between 50 ml. of ether and 30 ml. of water. The separated ether layer was washed with 5% aqueous sodium hydroxide (2 × 10 ml.), then water (3 × 10 ml.). Dried with magnesium sulfate, the solution was evaporated *in vacuo*. Recrystallization of the residue from isopropyl alcohol gave 4.13 Gm. (64%) of product, m.p. 94–95°. $\nu_{max.}$ 1605, 1600, 1580, 1500 (C=C); 1520, 1350 (NO_2); 1250, 1060 (C—O—C); 805, 800 (*m*-C_6H_4); 762, 742, 700 cm.$^{-1}$ (C_6H_5). (See Table II for analytical data and for other compounds prepared by this method.)

m-Aminophenyl β-Phenethyl Ether Hydrochloride (XXIVb)—*Method C*—A solution of 1.83 Gm. (7.5 mmoles) of XXII*b* in 100 ml. of ethanol containing 0.75 ml. of 12 *N* aqueous hydrochloric acid (9 mmoles) was shaken with hydrogen at 2–3 Atm. in the presence of 0.15 Gm. of 5% palladium-charcoal; reduction was complete in about 20 min. The filtered solution was evaporated *in vacuo*. Recrystallization of the residue from isopropyl alcohol–petroleum ether (b.p. 40–60°) gave 1.05 Gm. (56%) of white crystals, m.p. 126–128°. $\nu_{max.}$ 2870 (broad, NH); 2600, 1950 (NH_3^+); 1620, 1600, 1530, 1498 (NH, C=C); 1275, 1028 (C—O—C); 795, 785 (*m*-C_6H_5); 755, 702, 690 cm.$^{-1}$ (C_6H_5). (See Table II for analytical data for other compounds prepared by this method.)

4-(m-Aminophenyl)butyl Phenyl Ether Hydrochloride (XXXIII)—*Method D*—To a magnetically stirred mixture of 1.51 Gm. (10 mmoles) of *m*-nitrobenzaldehyde, 5.25 Gm. (11 mmoles) of XXX (24), and 15 ml. of reagent tetrahydrofuran, cooled in an ice bath and protected from moisture, was added 1.12 Gm. (10 mmoles) of potassium *tert*-butoxide. After being stirred in an ice bath for 1 hr. and at ambient temperature for 18 hr., the mixture was filtered and the insolubles washed with tetrahydrofuran. The combined filtrate and washings were evaporated *in vacuo*. The residual oil was dissolved in benzene and passed through a 3-cm. diameter column containing 64 Gm. of silica gel to remove triphenylphosphine oxide. The first fraction of yellow colored solution was collected and evaporated *in vacuo;* yield, 1.83 Gm. (68%) of XXXI as a yellow oil. $\nu_{max.}$ (film) 1600, 1595, 1500 (C=C); 1525, 1350 (NO_2); 1245, 1040 (C—O—C); 800 (*m*-C_6H_4); 735, 690 cm.$^{-1}$ (C_6H_5).

A solution of 1.83 Gm. of XXXI in 100 ml. of ethanol containing 0.75 ml. of 12 *N* aqueous hydrochloric acid was shaken with hydrogen at 2–3 Atm. in the presence of 100 mg. of platinum oxide catalyst; reduction was complete in 15 min. The reaction mixture was processed as described under *Method C;* yield, 1.10 Gm. (69%), m.p. 147–149°. A second recrystallization from isopropyl alcohol–petroleum ether (b.p. 40–60°) gave the analytical sample as white crystals, m.p. 150–152°. $\nu_{max.}$ 2850, 2600, 1950 (NH, NH_3^+); 1600, 1570, 1510, 1490 (NH, C=C); 1255, 1035 (C—O—C); 790 (*m*-C_6H_4); 758, 690 cm.$^{-1}$ (C_6H_5). (See Table II for analytical data.)

4,6-Diamino-1,2-dihydro-2,2-dimethyl-1-[m-(2-phenoxyethoxy)phenyl]-s-triazine Hydrochloride (XV)—*Method E*—A mixture of 664 mg. (2.5 mmoles) of XXIV*d*, 217 mg. (2.7 mmoles) of cyanoguanidine, and 4 ml. of reagent acetone was refluxed for 20 hr. with magnetic stirring. The cooled mixture was filtered and the product washed with acetone; yield, 631 mg. (65%), m.p. 168–170°. Recrystallization from ethanol–petroleum ether (b.p. 40–60°) gave 559 mg. (57%) of white crystals, m.p. 173–174°. $\lambda_{max.}$ 246, 268–280 (plateau) mμ; $\nu_{max.}$ 3300, 3150 (broad, NH); 1660 (C=NH^+); 1630, 1600, 1545, 1520 (NH, C=C, C=N); 1250, 1070 (C—O—C); 800, 785 (*m*-C_6H_4); 750, 705, 690 cm.$^{-1}$ (C_6H_5). (See Table III for analytical data and additional compounds made by this method).

Action of Angiotensin II Upon Renal Vascular Resistance

By WILLIAM E. HAGEMAN* and JOSEPH P. BUCKLEY

The effects of angiotensin II, vasopressin, *l*-norepinephrine, and elevated perfusion pressure were investigated on the peripheral resistance of the vascular beds in isolated rabbit kidneys in which the rate of flow was controlled by a Sigmamotor pump. Angiotensin II produced marked rhythmic fluctuations in perfusion pressure, having a mean amplitude of 52 mm. H_2O (n = 124); and when flow was decreased so that perfusion pressure was equal to control levels, the mean amplitude of rhythmic fluctuations was still 40 mm. H_2O. This effect of angiotensin II appeared to be affected by both age and sex with peak activity occurring at 2 to 4 months of age and the kidneys from female rabbits being significantly more responsive than those of male rabbits. Vasopressin also significantly increased the amplitude of the rhythmic fluctuations in perfusion pressure but to a much lesser degree than angiotensin II. The effect of *l*-norepinephrine was not significantly different from that induced by simple elevation of perfusion pressure. These data suggest that angiotensin II may exert a direct effect upon renal vascular smooth muscle of the "single-unit" type by increasing the number of spontaneous, local depolarizations through an increased influx of Ca^{2+} into the muscle cells. Such an action might also involve angiotensin II in the autoregulation of renal blood flow.

THE INVOLVEMENT of the kidney as a possible cause of, or contributor to, arterial hypertension was suspected in the latter part of the 19th century. Tigerstedt and Bergman (1) demonstrated that crude saline kidney extracts produced a pressor response when injected into anesthetized rabbits. The active principle(s) of the extract was postulated to have a direct vasoconstrictor action; and although it was impure and unidentified, they called it renin. This work lay dormant for over a quarter of a century before interest was renewed when Goldblatt *et al.* (2) demonstrated a reproducible hypertension of renal origin in dogs by the production of renal ischemia, and Volhard (3) introduced his theory of "pale hypertension" and its relationship to nephrosclerosis.

Since Goldblatt's discovery, the vasoactive principles, renin and angiotensin II, have been isolated, identified, and extensively investigated. These findings have stimulated profuse pharmacological research in the area of renal hypertension. However, the true physiological mechanism of the hypertensive state and the relationship of the kidney, angiotensin, and renin in arterial hypertension are not yet clearly defined. Considerable controversy and conflicting experimental evidence exist, and angiotensin is a focal point of these controversies.

Studies involving the role of the kidney in cardiovascular changes or disorders must take into consideration all of the factors involved in the complex relationships of the renal and cardiovascular systems. One such factor is the kidney's remarkable capacity to rapidly readjust in the wake of changing systemic arterial pressure so that renal blood flow remains fairly constant as the arterial pressure is altered. Waugh (4) reported that, within a normal range of arterial blood pressure, a 50% elevation of arterial pressure resulted in only a 5% increase in renal blood flow. Investigators have been cognizant of this phenomenon for many years, and the mechanisms of such "autoregulation" have been the subject of extensive research. However, there is still much discussion over the role of autoregulation and the factors involved in its mechanisms.

Regardless of investigators' disagreement on the mechanisms involved in the initiation of this phenomenon, it is almost universally accepted that vascular components play a major role in autoregulatory processes. In light of this fact, it might well be pertinent to ask what happens in a pathological state such as that produced by hypertension. The classic experiments of Goldblatt *et al.* (2) indicated that pathological changes of the renal arterial vasculature in dogs can produce a sustained arterial hypertension which is hemodynamically similar to essential hypertension in man. Byrom (5) reported uniform constriction interrupted by sharply localized dilatations in intestinal and cerebral arteries of renal hypertensive rats. Giese (6) infused synthetic angiotensin into nephrectomized rats to produce acute hypertensive vascular disease. He was able to not only demonstrate a very characteristic pattern of "alternating constrictions and dilatations" along the course of intestinal arteries, but,

TABLE I—EFFECT OF PRESSURE AND ANGIOTENSIN INFUSION UPON THE PERFUSION PRESSURE OF ISOLATED PERFUSED[a] KIDNEYS OF RABBITS

Conditions	N	Mean Perfusion Pressure, mm. Hg ± S.E.[b]	Rhythmic Activity Amplitude, mm. H_2O ± S.E.[b]	Rhythmic Activity Rate/min. ± S.E.[b]
Pre-Angiotensin II Infusion				
Perfusion pressure	151	75.31 ± 1.76	9.74 ± 0.89	2.79 ± 0.16
Elevated perfusion pressure[c]	144	108.80 ± 2.05	19.60 ± 1.46	3.68 ± 1.25
Angiotensin II Infusion				
Perfusion pressure	124	109.43 ± 2.32	52.42 ± 3.60	3.27 ± 0.11
Decreased perfusion pressure[d]	44	64.23 ± 6.38	40.14 ± 3.99	2.58 ± 0.22
Post-Angiotensin II Infusion				
Perfusion pressure	123	76.87 ± 2.40	14.41 ± 1.18	2.89 ± 0.20
Elevated perfusion pressure[c]	89	111.24 ± 2.94	29.72 ± 3.07	3.49 ± 0.15

[a] Perfused with Tyrode's solution. [b] S.E. = $\sqrt{\frac{\Sigma(x - \bar{x})^2}{n(n-1)}}$. [c] Perfusion pressure increased by adjusting Sigmamotor pump to approximate pressure induced by angiotensin II. [d] Perfusion pressure decreased by adjusting Sigmamotor pump.

using vascular labeling with colloidal carbon particles, he was able to show increased vascular permeability which was restricted to the dilated segments of the vessels.

Several investigators have reported similar changes in vascular elements subsequent to the infusion of angiotensin. Benelli *et al.* (7) reported a spontaneous rhythmic motility of the parenchymal as well as the vascular smooth muscle apparatus of the isolated cat spleen during perfusion with an angiotensin solution. Buckley (8) reported an induced rhythmicity in isolated rabbit kidneys upon perfusion with angiotensin, which seemed to be diminished with the increasing age of the animal.

Spontaneous rhythmic changes in renal vascular resistance have also been noted. Waugh (9) perfused isolated kidneys of dogs with PVP-Locke solution and observed "an unusually high degree of brief rhythmic changes in renal flow and prevenous resistance," concomitant with autoregulation of flow and subsequent to elevation of perfusion pressure, which were not affected by procaine anesthetization of intrarenal neural elements, but which were abolished by higher doses of procaine which were sufficient to depress the reactivity of the renal vascular elements to barium chloride or epinephrine injections. In view of these aforementioned results, the intent of the present investigation was to investigate further the nature of the rhythmic alterations in the renal vasculature and to determine its relation to angiotensin and other factors.

METHODS

Effect of Angiotensin II Upon Isolated Perfused Rabbit Kidneys and the Production of Rhythmic Alterations in Perfusion Pressure—New Zealand albino rabbits were selected at random and anesthetized with 30 mg./Kg. of sodium pentobarbital *via* a marginal ear vein. Each kidney was carefully isolated, the renal artery and vein were distally ligated, and the renal artery cannulated. A polyethylene cannula, made by building polyethylene tubing up to a $^3/_{16}$-in. bore starting with size PE 60 tubing, was used. Each layer of tubing was treated with epoxy cement to assure a tight, leak-proof seal. The ureter and renal vein were severed and the kidney removed from the animal and quickly suspended in a perfusion system which maintained the temperature of the internal and external environment of the kidney at 37°. The cannula was connected to one orifice of a small T tube which was also connected to a transducer, recording the perfusion pressure onto a Grass polygraph calibrated at two different sensitivities to allow the perfusion pressure to be monitored in both mm. Hg and mm. H_2O.

The kidney was perfused with Tyrode's solution mol. wt. 73,000, containing 1% dextran[1] (Pharmachem Corp., Bethlehem, Pa.) in such a manner the perfusion pressure ranged approximately between 75–100 mm. Hg and the flow between 12 and 20 ml./min. A Sigmamotor pump was used to maintain a constant flow from two 32-oz. reservoir bottles, one containing Tyrode's solution and the other containing Tyrode's solution plus angiotensin II, 0.01 mcg./ml. The reservoirs were kept in a constant-temperature bath at 37° and aerated with 95% oxygen and 5% carbon dioxide *via* fritted-glass gas dispersion tubes in order to assure adequate and balanced aeration of the solutions. The right kidney was prepared first, followed immediately by the left; and both were suspended in similar perfusion systems. Approximately 15–30 min. were allowed for the venous flow to stabilize to between 12–20 ml./min., after which time each kidney was treated according to the following procedure.

(*a*) The perfusion pressure was increased by adjusting the flow of the Sigmamotor pump to a level of pressure similar to that expected to be achieved by the infusion of angiotensin II, as

[1] Stock solution *1:* NaCl, 200 Gm.; KCl, 5 Gm.; $CaCl_2$ (anhydrous), 5 Gm.; $MgCl_2 \cdot H_2O$, 5 Gm.; glass-distilled water *q.s. ad.* 1000 ml. Stock solution *2:* $NaHCO_3$, 50 Gm.; $NaH_2PO_4 \cdot H_2O$, 2.5 Gm.; glass-distilled water *q.s. ad.* 1000 ml. Stock solution *3:* Dextran (mol. wt. 73,000), 100 Gm.; dextrose (anhydrous), 25 Gm.; glass-distilled water *q.s. ad.* 1000 ml. Mix 80 ml. of stock solution *1*, 40 ml. of stock solution *2*, add 200 ml. of stock solution *3*, and make up to a total volume of 2 L. with glass-distilled water.

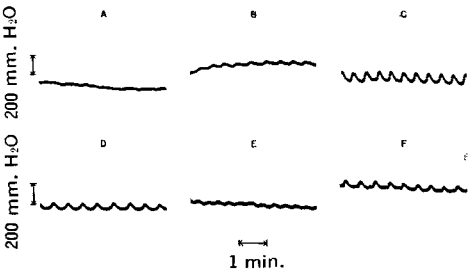

Fig. 1—Typical responses due to angiotensin II infusion and perfusion pressure changes in isolated perfused rabbit kidney. Key: A, *pre-angiotensin II infusion at normal perfusion pressure;* B, *pre-angiotensin II infusion at elevated perfusion pressure;* C, *angiotensin II infusion;* D, *angiotensin II infusion at decreased perfusion pressure level;* E, *post-angiotensin II infusion at normal perfusion pressure;* F, *post-angiotensin II infusion at elevated perfusion pressure.*

determined from preliminary experiments. (*b*) The perfusion pressure was returned to original levels and allowed to stabilize for 5–10 min. (*c*) Angiotensin II was infused until the maximum effect was obtained. If rhythmic fluctuations in perfusion pressure occurred, the perfusion pressure was readjusted to pre-angiotensin II infusion pressure levels by reducing flow *via* the Sigmamotor pump. (*d*) Flow was returned to control levels *via* the Sigmamotor pump, and angiotensin II infusion stopped. (*e*) Steps (*a*), (*b*), and (*c*) were repeated several times until maximal rhythmic alterations were observed. (*f*) Perfusion pressure levels were monitored in mm. Hg, and amplitude changes of the rhythmic alterations were measured in mm. of water. Records were made at a chart speed of 0.25 mm./sec.

Effect of Other Vasopressor Agents on the Rhythmic Fluctuations in the Perfusion Pressure of Isolated Perfused Rabbit Kidneys—The procedure described above was followed utilizing either *l*-norepinephrine,[2] 0.25 mcg./ml., or vasopressin,[3] 0.01 units/ml., in place of angiotensin II in one of the perfusion reservoirs.

Effect of Age and Sex upon the Rhythmic Alterations in Perfusion Pressure Induced by Angiotensin II Infusion into Isolated Perfused Rabbit Kidneys—New Zealand albino rabbits of both sexes were obtained at certain selected ages. Females were used at ages of 1, 2, 4, 8, and 12 months; and males were used up to the age of 8 months since 12-month-old male rabbits were not available during the course of the experiment. The previously described procedure for isolation, removal, perfusion, and treatment was followed.

Analysis of Data—All data were punched onto IBM cards and analyzed by either the BMD 02V, BMD 05V, or BMD 07V analysis of variance programs on the IBM 7090 computer.

RESULTS

Effect of Angiotensin II Infusion Upon Rhythmic Fluctuations in Perfusion Pressure of Isolated Perfused Rabbit Kidneys—The data obtained in these experiments are summarized in Table I. Angiotensin II,[4] when infused at a concentration of 0.01 mcg./ml. and at a rate of 12–20 ml./min., produced rhythmic alterations in perfusion pressure up to 250 mm. H_2O (Fig. 1) with a mean amplitude of 52.4 ± 3.6 mm. H_2O. Even when the perfusion pressure was decreased to pre-angiotensin II levels by decreasing the rate of perfusion, there was only a 15–20% decrease in the amplitude of rhythmic fluctuations to 40.1 ± 4 mm. H_2O. Although simply increasing the perfusion pressure did produce rhythmic pressure alterations, the response to angiotensin II was over 2.5 times that achieved by pressure alone. These data indicated that pressure *per se* cannot fully account for the rhythmic changes in perfusion pressure produced by the infusion of minute doses of angiotensin II, and that this polypeptide plays a direct role in inducing these rhythmic alterations in perfusion pressure. Although the rhythmicity produced by angiotensin II is significantly greater ($p = <0.01$) than that present either prior to or following the infusion of angiotensin II, the post-angiotensin II responsiveness is also significantly greater both at normal and increased perfusion pressure ($p = <0.01$). Angiotensin II did not significantly alter the rate of the rhythmic changes.

Effect of Other Vasopressor Agents on the Rhythmic Fluctuations in the Perfusion Pressure of Isolated Perfused Rabbit Kidneys—The data obtained in these experiments are summarized in Tables II and III. *l*-Norepinephrine at a concentration of 0.25 mcg./ml. and at a rate of 12–20 ml./min. produced rhythmic activity approximately equivalent to that induced by the elevation of perfusion pressure alone. When compared with the effects of angiotensin II infusion, *l*-norepinephrine produced approximately 1/4 the increase in amplitude of rhythmic activity induced by angiotensin II ($p = <0.01$), the mean amplitude of the rhythmic alterations in perfusion pressure induced by *l*-norepinephrine being 12.1 ± 2.9 mm. H_2O compared to a mean amplitude of 52.4 ± 3.6 mm. H_2O produced by angiotensin II infusion.

Vasopressin, 0.01 units/ml., 12–20 ml./min., significantly greater rhythmic fluctuations in perfusion pressure than that produced by simple elevation of perfusion pressure ($p = < 0.05$). However, the 24.6 ± 1.5 mm. H_2O amplitude of rhythmic alterations in perfusion pressure produced by vasopressin was less than 50% of that produced by angiotensin II infusion. Vasopressin did not seem to produce a sensitization as did angiotensin II since there was no significant difference between the pre- and post-infusion period responses at either normal or elevated perfusion pressure. The effect of vasopressin upon the amplitude of the perfusion pressure alterations was 133% of the effect produced by simple elevation of perfusion pressure, but the response to vasopressin infusion was over 200% greater than the response to *l*-norepinephrine infusion ($p = <0.05$).

Effect of Sex Upon Rhythmic Alterations in Perfusion Pressure of Isolated Perfused Rabbit Kidneys—In order to analyze these data for the over-all effect of sex, the kidneys from female rabbits were grouped together, ignoring age, and compared with the kidneys from male rabbits at

[a] Perfused with Tyrode's solution. [b] S.E. = $\sqrt{\frac{\Sigma(x - \bar{x})^2}{n(n-1)}}$. [c] Perfusion pressure elevated by adjusting Sigmamotor pump to approximate pressure induced by *l*-norepinephrine. [d] Perfusion pressure decreased by adjusting Sigmamotor pump.

each of the five parameters studied: pre-angiotensin II infusion at both normal and elevated perfusion pressures, during angiotensin II infusion, and post-angiotensin II infusion at normal and elevated perfusion pressures.

The kidneys from female rabbits were statistically more responsive to angiotensin II than those kidneys obtained from male rabbits ($p = <0.05$), the mean amplitude of rhythmic fluctuations of perfusion pressure of kidneys from females being 56.9 ± 5.4 mm. H_2O compared to a mean amplitude of 42.2 ± 4.1 mm. H_2O in the males' kidneys.

Effect of Age Upon Rhythmic Alterations in Perfusion Pressure of Isolated Perfused Rabbit Kidneys—The contribution of age to the induction of rhythmic changes in perfusion pressure is graphically presented in Figs. 2 and 3. The amplitude of the rhythmic alterations in perfusion pressure was compared at different age levels in kidneys from male and female rabbits separately. The amplitude of the rhythmic changes in perfusion pressure in kidneys from female rabbits was significantly affected by age at all five parameters studied ($p = <0.05$). In kidneys from male rabbits, there was only a significant effect of age during perfusion at normal perfusion pressures prior to and after angiotensin II infusion ($p = <0.05$). The rhythmic fluctuations were greatest between the ages of 1 to 4 months in all five parameters studied in both male and female rabbits' kidneys. In both sexes at normal perfusion pressure prior to angiotensin II infusion, the most sensitive age was 1 month. Under all other parameters the peak response was at 4 months in both sexes except during angiotensin II infusion, where the peak sensitivity was at 2 months of age in kidneys from female rabbits where the mean amplitude of rhythmic changes was 77.5 ± 8.2 mm. H_2O. The peak response produced by angiotensin II in the kidneys of male rabbits was at 4 months of age where the mean amplitude was 53.3 ± 11.2 mm. H_2O.

There was a marked decrease in the amplitude of rhythmic alterations in perfusion pressure in kidneys of 8-month-old rabbits of both sexes, the mean amplitude in the kidneys of females being 45.0 ± 11.3 mm. H_2O and that of kidneys from males being 29.5 ± 6.11 mm. H_2O. Angiotensin II produced rhythmic alterations in perfusion pressure having a mean of 36.3 ± 12.8 mm. H_2O in the kidneys of 12-month-old female rabbits.

DISCUSSION

The relatively slight changes in renal blood flow from normal levels under various physiological conditions have become a well accepted fact. Sympathetic vasoconstrictor control of the renal vessel under normal conditions has been ruled out

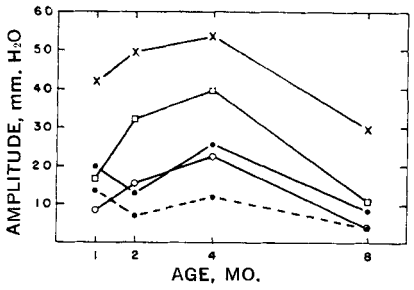

Fig. 2—The effect of age on rhythmic fluctuations in perfusion pressure of isolated kidneys from male rabbits. because surgical and pharmacological denervation do not elevate the renal blood flow. Such changes in renal resistance to blood flow as a consequence of changes in blood pressure have inherited the term autoregulation of renal blood flow, because no extrarenal, nervous, or humoral factors are believed to be involved. There is experimental evidence that an elevated tension in the arteriolar wall stimulates the vascular smooth muscle to contract. Little doubt exists that during normal kidney function, resistance changes are caused by smooth muscle reactions. There does exist, however, a basic question of whether smooth muscle contraction during autoregulation is initiated only by the tension change in the arteriolar wall or whether it is a muscle response to either a change in renal metabolism or an intrinsic humoral factor, both of which might be related to arterial perfusion pressure.

There has been a considerable amount of evidence supporting the proponents of the myogenic theory for autoregulation by vascular smooth muscle. Many conclusions have been drawn based upon the electrophysiological studies performed by Bozler (10) and Bulbring (11) on other types of smooth muscles. Funaki (12) confirmed this work on vascular smooth muscle. Evidence from these experiments indicated that there are two types of smooth muscle cells, some with a higher, more stable membrane potential (multi-unit) and some with lower, less stable membrane potentials (single-unit). The multi-unit type smooth muscle is dominant in the larger vessels, and the single-unit type dominates in the smaller vessels. A slight continuous distension of the wall of a blood vessel due to elevated blood pressure might then affect the smooth muscle cell by increasing the rate of the spontaneously generated local depolarizations in proportion to the extent of distension which, in turn, initiates depolarization followed by excitation–contraction.

There is also experimental evidence in dogs suggesting that renin release occurs subsequent to pressure changes within the kidney (13). Anatomically, the individual nephron is ideally arranged so that changes in the dynamic or chemical pattern of the intratubular fluid can be sensed by the vasa afferens at the initial portion of the distal convoluted tubule, the area in which the juxtaglomerular apparatus is located. It has been suggested that the juxtaglomerular apparatus is involved in a mechanism to prevent a further increase in renal blood flow, glomerular filtration rate (GFR), and intrarenal pressure when the renal arterial blood pressure increases above 90 mm. Hg (14). Such a mechanism would narrow autoregulation down to a problem of adjusting the physical factors, which are responsible for the tubular load, to the tubular reabsorption capacity, which has to handle the filtered load. Both physical and metabolic factors are involved in the formation of urine; and since the physical factors occur at the initial phase of urine formation, the most likely candidate for achieving a glomerular–tubular balance might be maintenance of a stable physical component (effective filtration pressure). Also it is possible to regulate the effective filtration pressure by a single mechanism, *i.e.*, tonus of afferent glomerular vessels, whereas regulation of tubular activity would be far more difficult and complex. The possibility then exists that the renin–angiotensin system, which seems to have its origin at the juxtaglomerular apparatus, being sensitive to both changes in electrolytes (15) and effective in altering the vascular resistance in the kidney, may be involved in renal autoregulation of blood flow as a result of the maintenance of glomerular tubular balance. A sudden elevation of renal arterial blood pressure initially increases renal blood flow and thereby increases GFR which causes increased tubular load and urine flow velocity. Such changes could change the dynamics of flow of the tubular fluid and increase the osmolarity at the macula densa within seconds. The increased osmolarity could then stimulate the juxtaglomerular apparatus to release a vasoactive substance which would thereby decrease the GFR *via* afferent vasoconstriction.

The results of the present study indicate that angiotensin II may have an effect upon the vasculature of the kidney other than that of direct vasoconstriction. This effect expressed itself as a rhythmic fluctuation in the perfusion pressure of the isolated perfused rabbit kidney. Pressure elevation was also capable of inducing a similar type of fluctuation, as would be expected according to the myogenic theory; but angiotensin II was significantly more effective in inducing such alterations. Such a reaction could possibly be interpreted on an electrophysiological basis using the results of

Funaki's experiments as guide lines. It is possible that angiotensin II exerts its effect upon vascular smooth muscle, at least in part by decreasing the resting membrane potential by increasing the influx of Ca^{2+} ions. This theory is supported by recent evidence that isolated renal arteries constrict in response to angiotensin II only in the presence of the calcium ion (16). Tobian and Chesley (17) have also demonstrated that small arteries and arterioles from renal hypertensive rats have a significantly greater Ca^{2+} content than those of normotensive control animals. The decreased membrane potential increases the number of spontaneous local depolarizations, thereby reaching more muscle fibers and exaggerating the vasomotion of the small vessels. The frequency of firing, however, did not seem to be influenced in that there was no significant difference in the rate of occurrence of the rhythmic fluctuations between control conditions and during angiotensin II infusion. In other words, the effect of elevated pressure initiates rhythmic fluctuations probably by the myogenic mechanism described by Funaki (12); however, the influence of a hormone closely related to the kidney may be capable of greatly accentuating the effect of pressure upon the activity of vascular smooth muscle and might possibly be the direct-acting intrinsic hormonal factor concerned with renal autoregulation of blood flow.

The effect of angiotensin II in producing the rhythmic changes in perfusion pressure cannot be fully explained by the myogenic theory as described by Bayliss (18), since the rhythmic fluctuations were only slightly decreased when the perfusion pressure was reduced to control levels during angiotensin II infusion. Also, the effect of angiotensin II is significantly greater than the effects produced by elevation of perfusion pressure or the effect produced by the two other vasoconstrictor agents, *l*-norepinephrine and vasopressin. The effect of *l*-norepinephrine was only slightly greater than that of pressure elevation alone, whereas vasopressin, another polypeptide, did have some effect other than the influence of pressure; but it was not nearly so pronounced as that of angiotensin II.

This study also indicated that these effects of angiotensin II upon the vasculature of the kidney are both age and sex dependent. The pattern which is seen when the age of the animal is varied is interesting in that there seemed to be an increasing reactivity up to the age of 4 months, and then a drastic decline in responsiveness of the rabbit kidney occurred. It might be speculated that when the animal is very young, the kidney's vasculature is not completely developed; and the majority of the vessels are still relatively small. It is also possible that during this time these small vessels are dominated by the single-unit type of muscle cell described by Bozler and therefore possess an inherently lower resting membrane potential, thereby being less stable and more prone to depolarization. As the animal matures, the vessels become larger; and the dominance shifts to that of the multi-unit muscle cell which possesses a more stable membrane potential and lacks automaticity. The occurrence of such events seems logical in the light of Funaki's report that the vasculature of the larger vessels is dominated by multi-unit smooth muscle cells and the smaller vessels by single-unit smooth muscle cells, even though both types of cells can be found in both large and small vessels. This is by no means a suggestion that an older animal has lost the ability of autoregulation. The mature animal still possesses an adequate supply of small preglomerular arterioles which are dominated by the single-unit type of muscle cells, but the major vessels are almost completely composed of the multi-unit smooth muscle cells. It would perhaps be more correct to say that the young animal is better able to regulate renal blood flow in the face of changing cardiovascular patterns, so that during its young formative period the rabbit is better able to assure the constancy of its internal environment.

There is also the question of the effects of sex upon the responsiveness of the renal vasculature, since the female rabbit's kidneys were more responsive at almost every age tested. The explanation for this phenomenon probably lies in the difference in the hormonal nature of internal environment of the two sexes; and perhaps the female endocrine system, particularly estrogens, potentiates the responsiveness of the vascular smooth muscle.

Laboratory Studies with Nitrofurantoin

Relationship Between Crystal Size, Urinary Excretion in the Rat and Man, and Emesis in Dogs

By HENRY E. PAUL, KENYON J. HAYES, MARY F. PAUL, and A. RUSSELL BORGMANN

Studies were conducted relating the effect of varying the crystal size of orally administered nitrofurantoin on absorption and urinary excretion in the rat and man and emesis in dogs. It was discovered that there is an optimal average crystal size of about 150 mesh, or its equivalent surface area falling between 80 to 200 mesh limits, which reduces emesis while still permitting ample urinary excretion for efficacy.

THE USE OF nitrofurantoin[1] as a urinary tract antibacterial agent has become firmly established since initial reports of the first laboratory (1, 2) and clinical studies (3–5). During the years of successful use of this drug a limited number of patients have exhibited nausea or emesis to the extent that they were deprived of an effective medication. Little or no success attended attempts to overcome this defect by combining other substances with nitrofurantoin, although experience indicates administration of the drug with meals or with milk is helpful (6). A recent review article (7) provides general information on nitrofurantoin.

Since obvious means of controlling or reducing nausea and/or emesis associated with drug administration have not proved completely satisfactory in the case of nitrofurantoin, a thorough examination of the problem was undertaken. While studies in these laboratories have not clearly delineated the mechanism of nitrofurantoin-induced nausea or emesis, there is some evidence to indicate this undesirable side effect may be of neural origin. Rate of drug absorption could possibly be a factor. Accordingly, modification of the absorption pattern of individual nitrofurantoin doses by controlling release into the gastrointestinal tract might reduce this undesirable side effect.

Although there are several means whereby the absorption pattern of a drug may be modified or controlled (8, 9), one effective way with compounds having limited water solubility is the control of the surface area available for solution in the gut by varying the crystal size. Numerous reports (10–13) demonstrate the fact that the rate and amount of absorption of slightly soluble drugs can be markedly increased by reducing crystal size thereby providing increased surface area for a given dosage. Unfortunately, increased toxicity often accompanies this change (14, 15). Conversely, the use of larger crystals of drug having less surface area per dose, toxicity (as evidenced by nausea and vomiting) might be eliminated or greatly reduced. Such an approach, however, is beset with the likelihood of diminution of efficacy. Since nitrofurantoin has a water solubility of only about 200 to 400 mg./L. at 37° at the physiological pH values expected in application, larger crystals having considerably less surface area for a fixed dosage would dissolve much more slowly, thereby slowing the rate of absorption.

EXPERIMENTAL

Nitrofurantoin of different crystal sizes was made by recrystallization from nitromethane. These crystals of rhombic anhydrous nitrofurantoin were sieved into appropriate size ranges and some micronized in a Sturdevant mill for finest material. To explore emetic effect, very coarse (50–60 mesh) crystals, fine crystals (200–325 mesh), and micronized material (<10 μ) were orally administered in gelatin capsules to 20 fasted dogs in two independent comparative studies in single doses ranging from 10 to 20 mg./Kg. in the first and at a higher 25 mg./Kg. level in the second trial. An ample clearance time of 3 days between doses was established. Data from these studies are summarized in Table I. At these dosages emesis occurred in 40 to 75% of the dogs receiving either the fine 200–325 mesh or finer (micronized) material, but only in 5% of those receiving the coarse 50–60 mesh crystals—a great improvement. The crystal size ranges studied here actually measure from less than 10 μ up to about 300 μ in diameter, presenting almost a *thirtyfold* difference in available surface area for the *same weight* of drug.

While this control of emesis might be a result of the slower absorption rate produced by the decreased surface area of the larger crystals, it could

Received November 4, 1966, from the Research Laboratories, The Norwich Pharmacal Co., Norwich, NY 13815

Accepted for publication April 4, 1967.

This study was a cooperative effort between the Research Divisions of Biology, Chemistry, and Pharmacy.

Appreciation is especially due to Donald T. Humphrey and Esther G. Nohle for numerous nitrofurantoin assays, to Paul H. Seehausen for extending and refining crystal preparation methods, and to Dr. Julian G. Michels for establishing crystal size control procedures. The authors wish particularly to thank Dr. Paul V. Newland for arranging and supervising the human volunteer studies and Dr. William B. Stillman for over-all direction.

TABLE I—EFFECT OF NITROFURANTOIN CRYSTAL SIZE ON EMESIS IN DOGS

Study and Single Dosage	Crystal Size *vs.* No. of Dogs Vomiting Out of 20: 50–60 Mesh	200–325 Mesh	Micronized
First Study			
150 mg./dog (10–20 mg./Kg.)	1	8	9
Second Study			
25 mg./Kg./dog	1	14	15

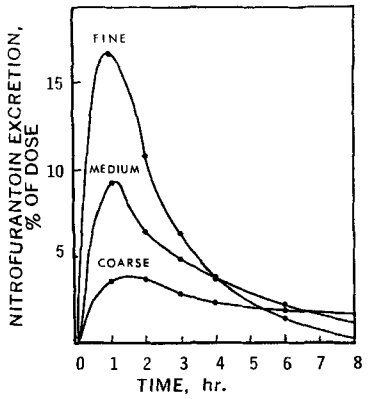

Fig. 1—Effect of crystal size of orally administered nitrofurantoin on urinary recovery rate in the rat. Key: coarse, 50–80 mesh (300–180 μ); medium, 80–200 mesh (180–75 μ); fine, 200 mesh to micronized (75–10 μ or less).

also have been the result of reduced total absorption, a possibility that must be considered when too large a crystal size of a slightly soluble drug is employed (16, 17). Since the effectiveness of nitrofurantoin is associated with its urinary concentration (18, 19), a reduction in toxicity (emesis) would have no medical practicality if excretion were also *proportionately* reduced.

Quantitative urinary excretion studies were initiated in rats, a physiologically suitable animal, to determine the effect of crystal size on both rate and total excretion of orally administered nitrofurantoin. This information would also provide an indication of the rate and amount of nitrofurantoin absorbed from the gut (13, 17, 20). Good correlation exists in the urinary excretion of nitrofurantoin by the rat, dog, and man (7).

In studying the effect of variation of nitrofurantoin crystal size on absorption, as measured by both urinary excretion rate and total excretion, several exploratory studies were conducted to establish size of oral dose, collection periods, crystal size ranges to study, *etc.* Urines were assayed by a spectrophotometric method (21). The nitrofurantoin crystals of selected size were administered as an aqueous suspension by gavage to adult rats—usually a group of four for each crystal size test. Following single dosage at the 10 mg./Kg. level, collection periods were established at 0–1, 1–2, 2–3, 3–4, 4–8, and 8–24 hr. to supply the required information. Of particular interest would be a substantial reduction of the absorption rate immediately following dosage. That this can be accomplished is clearly shown in the excretion curves covering the 0 to 8 hr. period as presented in Fig. 1. Each curve is based on data from 8 to 12 rats (2 or 3 groups of 4 animals each) receiving, respectively, relatively coarse (50–80 mesh), medium (80–200 mesh), and fine (200 mesh to micronized material). It is apparent that the particle size of nitrofurantoin alone can greatly influence the rate of intestinal absorption which is reflected in the measured urinary excretion (20). The rapidity with which urinary concentration rises and falls following administration of the finer crystal range shows that solution and absorption must have been rapid indeed. In fact, it has been shown that for micronized (<10 μ) material absorption can be so rapid that half of the total amount excreted can be recovered in the urine by the end of the first hour! Conversely, it will be noted that in the case of the medium and coarser crystals appreciable nitrofurantoin was still being excreted at 8 hr. In this study the 0 to 24 hr. total recovery of the dose given was 45% and 42% for the fine and medium crystals, but this had dropped to 33% for the coarser crystals. Not shown in this figure is an important further finding: in the last 8–24 hr. collection period the remaining portion excreted related to the total amount excreted (not to the total dose) was 3% for the fine, 20% for the medium, and 40% for the coarser material. The coarsest material alone resulted in prolonged excretion coupled with appreciably reduced total excretion.

Further studies with rats were conducted with particular emphasis on the relation of crystal size to total urinary excretion or drug recovery. Some variation in total recoveries was encountered between studies, but the over-all crystal size relationship to rate and total urinary excretion remained clear. It was found that sodium carboxymethylcellulose should not be used without proper precaution as a thickener for an aqueous suspension of nitrofurantoin. Unless this suspension is used *immediately*, needle-like nitrofurantoin hydrate crystals form on prolonged mixing or standing which appreciably affect nitrofurantoin-crystal size relationship studies. Methylcellulose or some other inert thickening agent could be used.

More refined and extensive comparative tests were conducted with humans and dogs to study the relationship of crystal size to total urinary excretion in humans and nitrofurantoin-induced emesis in dogs. In these tests 32 purebred beagles and a population of 15 humans were used. Wherever possible, each test animal or human received every crystal size for comparison. A previously established sensitive dose of 10 mg./Kg./dog was used. Humans were standardized at 100 mg./subject. Ample clearance time was allowed—3 days for dogs and 7 days for humans. Crystals were admixed with lactose and administered in capsules. To demonstrate the relationship between crystal size, drug excretion, and emesis, data from representative studies are plotted in Fig. 2. Contrary to expectation there is a crystal size range in which there is a marked reduction of nausea and minimal reduction of total nitrofurantoin excretion.

A crystal size of about 150 mesh nitrofurantoin (about 100 μ), or its surface area equivalent, was selected as an optimal desired size from a potentially

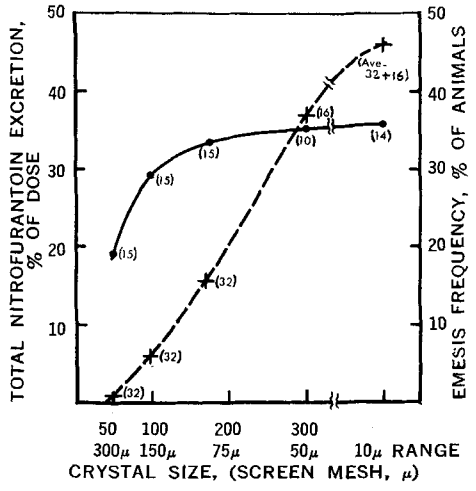

Fig. 2—Relation between total urinary recovery in humans and emesis frequency in dogs following oral administration of nitrofurantoin of different crystal sizes. Values in parentheses are numbers of subjects used. Points are plotted essentially at median values for nonoverlapping crystal size ranges used. Key: ●, urinary excretion (humans); ×, emesis (dogs).

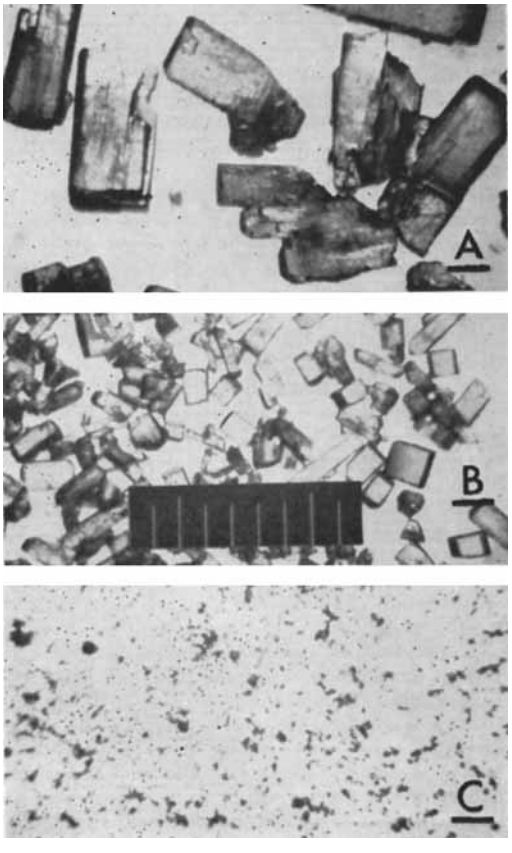

Fig. 3—Nitrofurantoin crystals. Key. A, coarse, 50 to 80 mesh or 300 to 180 μ; B, medium, 80 to 200 mesh or 180 to 75 μ; reference scale 100 μ/division; C, fine, micronized crystals. 25× magnification.

useful range of 50 to 400 mesh. For practical reasons a narrower working range was chosen of 80–200 mesh (180–75 μ size), or its surface area equivalent of about 200–500 cm.²/Gm. Figure 3 illustrates crystals of this median size range compared to coarse (50–60 mesh) and fine material (micronized or marketed tablet—as providing crystals in the 10 μ range, equivalent to a theoretical 1500 mesh).

These findings were amplified by conducting appropriate studies in humans to obtain information on the effect of crystal size (surface area) on the urinary excretion rate, urinary concentration, and total excretion of nitrofurantoin following single oral doses to couple maintenance of efficacy with reduced nausea potential. Fifteen volunteer subjects were used in comparative studies, each serving as his own control. Subjects ate a standard breakfast immediately prior to administration of a selected crystal size in a single test dose of 100 mg. nitrofurantoin in a capsule. Marketed tablets[2] (100 mg.) were included in the study for comparison. Fluid intake was controlled and caffeine and alcohol were prohibited. Total urine collections were made at specified time intervals and nitrofurantoin concentrations determined on each collection from each subject by a recently developed method (22) or modification of an earlier one (23).

Table II presents a summary of the results. From the five columns it will be noted that: (*a*) the maximum per cent of nitrofurantoin excreted in *any* 2-hr. collection period decreased as the crystal size was increased, being definitely reduced in the case of the coarsest material, demonstrating decreased absorption rate with larger crystal sizes. (*b*) The average time at which maximum percentage excretion occurred increased with particle size. (*c*) The maximum urinary concentration attained was lower with the larger crystals, partially a result of the extended excretion period. (*d*) The average time at which maximum urinary concentration was reached was later for larger crystals, again reflecting slower absorption. (*e*) The total amount of nitrofurantoin excreted (*i.e.*, per cent of the dose given) in the urine decreases with increased particle size, but only in a degree to cause serious concern in crystal sizes larger than 50 mesh.

DISCUSSION

It appears that these human studies basically agree with those conducted in rats. From a potentially useful range of 50 to 400 mesh a more practical range of nitrofurantoin crystals of the 80–200 mesh size has been selected as providing ample urinary concentration with satisfactory total urinary excretion. Accordingly, such nitrofurantoin crystals, termed "macrocrystals," have now been introduced into clinical trial for critical testing of efficacy and emetic action in patients having urinary tract infections who, in addition, suffer nausea and emesis from commercial nitrofurantoin tablets. In the crossover studies planned, each patient will serve as his own control, making such tests more meaningful with reasonable numbers, rather than to test the macrocrystals on all patients using nitrofurantoin for urinary tract infections where nausea and emesis percentages are relatively low.

TABLE II—SUMMARY OF CRITERIA MEASURED IN HUMAN VOLUNTEERS RECEIVING VARIOUS SIZES OF NITROFURANTOIN CRYSTALS[a]

Crystal Size[b] of Nitrofurantoin	(1) Max. % Excreted in Any 2-hr. Period	(2) Av. Time of Max. % Excretion, hr.	(3) Max. Urinary Concn. Attained, mg./L.	(4) Av. Time Max. Urinary Concn. Attained, hr.	(5) Total % of Initial Dose Excreted
50–60 mesh	8.3	4.9	83	5.5	19.6
80–120 mesh	12.9	4.6	124	5.0	29.8
140–200 mesh	16.6	3.8	159	4.1	32.3
200–400 mesh	17.8	3.6	156	3.4	35.4
Marketed nitrofurantoin tablets (Provide fine crystals in the 10 μ range)	20.0	3.6	151	3.0	36.1

[a] Each value based on 15 complete individual studies—no pooling of samples. Exceptions: 10 individuals only were available from same population for 200–400 mesh and 14 for tablets. [b] Size checked by microscopic measurement.

SUMMARY

A study of the effect of crystal size of orally administered nitrofurantoin on its urinary excretion in the rat and man demonstrates a slower rate of absorption from larger crystal size than from fine crystals with ample total urinary excretion from a suitably selected size or size range.

Studies with dogs reveal that the larger crystals are much less provocative of emesis than the smaller crystal size.

Based on quite favorable relationships between nitrofurantoin crystal size, total urinary excretion, and reduction of emesis established by these studies, nitrofurantoin crystals ranging from 80 to 200 mesh and of about 150 mesh average size, or its equivalent in surface area as determined by solubility rate, have been selected for clinical study.

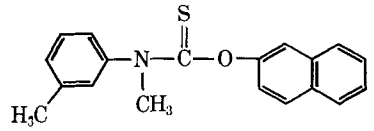
Qualitative and Quantitative Tests for Tolnaftate

By EDWARD F. SALIM* and WILBUR S. FELKER†

Provisional, unofficial monographs are developed by the Drug Standards Laboratory, in cooperation with the manufacturers of the drug concerned, for publication in the *Journal of Pharmaceutical Sciences*. The ready availability of this information affords discriminating medical and pharmaceutical practitioners with an added basis for confidence in the quality of new drug products generally, and of those covered by the monographs particularly. Such monographs will appear on drugs representing new chemical entities for which suitable identity tests and assay procedures are not available in the published literature. The purity and assay limits reported for the drugs and their dosage forms are based on observations made on samples representative of commercial production and are considered to be reasonable within expected analytical and manufacturing variation.

2-NAPHTHYL-N-METHYL-N-(3-TOLYL)THIONOCARBAMATE; $C_{19}H_{17}NOS$; mol. wt. 307.42. The structural formula of tolnaftate may be represented as:



Physical Properties—Tolnaftate occurs as a white to creamy white fine powder, m.p. 110–113° (U.S.P., class I). It is freely soluble in chloroform and in acetone, slightly soluble in alcohol, sparingly soluble in ether, and practically insoluble in water.

Identity Tests—A 1 in 100,000 solution of tolnaftate in methanol exhibits an ultraviolet absorbance maximum at about 257 mμ [absorptivity (*a*) about 71] and a minimum at about 243 mμ. The spectrum is shown in Fig. 1.

The infrared spectrum of a 0.5% dispersion of tolnaftate in potassium bromide, in a disk of about 0.82 mm. thickness, is shown in Fig. 2.

Purity Tests—Dry about 1 Gm. of tolnaftate, accurately weighed, in vacuum at 65° for 3 hr.: it loses not more than 0.5% of its weight.

Char about 1 Gm. of tolnaftate, accurately weighed, cool the residue, add 1 ml. of sulfuric acid, heat cautiously until evolution of sulfur trioxide ceases, ignite, cool, and weigh: the residue does not exceed 0.1%.

Determine the heavy metals content of tolnaftate by the U.S.P. heavy metals test, method II: the heavy metals limit for tolnaftate is 20 p.p.m.

Assay—Dissolve 50 mg. of tolnaftate, accurately weighed, in sufficient methanol to make 250.0 ml. Dilute 5.0 ml. of this solution with methanol to 100.0 ml., and mix. Dissolve an accurately weighed quantity of tolnaftate reference standard in methanol, and dilute quantitatively and stepwise with methanol to obtain a standard solution having a concentration of about 10 mcg./ml. Concomitantly determine the absorbance of each solution in 1-cm. cells, at the wavelength of maximum absorbance at about 257 mμ, with a suitable spectrophotometer, using methanol as the blank. Calculate the quantity, in mg., of $C_{19}H_{17}NOS$ in the portion of tolnaftate taken by the formula $5\ C\ (A_u/A_s)$, in which C is the concentration, in mcg./ml., of tolnaftate in the standard solution, A_u is the absorbance of the sample solution, and A_s is the absorbance of the standard solution. The amount of tolnaftate found is not less than 98.0% and not more than 102.0% of the weight of the sample taken.

DOSAGE FORMS OF TOLNAFTATE

Tolnaftate Solution

Identity Test—The ultraviolet absorption spectrum of the chloroform solution obtained in the *Assay* exhibits an absorbance maximum and minimum at the same wavelengths as that of the standard solution.

Assay—Transfer an accurately measured volume of tolnaftate solution equivalent to about 10 mg. of tolnaftate, to a separator, add 50 ml. of chloroform, and extract with 50 ml. of 0.1 *N* sodium hydroxide. Filter the chloroform phase through chloroform-washed cotton into a 250-ml. volumetric flask and extract the aqueous phase with four 45-ml. portions of chloroform, filtering each portion into the flask. Make to volume with chloroform, and mix. Dilute 25.0 ml. of this solution to 100.0 ml. with chloroform, and mix. Concomitantly determine the absorbance of this solution and of a standard solution of tolnaftate reference standard, in the same medium, at a concentration of about 10 mcg./ml., in 1-cm. cells, at the maximum at about 260 mμ, with a suitable spectrophotometer, using chloroform as the blank. Calculate the quantity, in mg., of $C_{19}H_{17}NOS$ in each ml. of solution taken by the formula $(C/V) \times (A_u/A_s)$, in which C is the concentration, in mcg./ml., of tolnaftate in the standard solution, V is the volume, in ml., of solution taken, A_u is the absorbance of the sample solution, and A_s

Received February 28, 1967, from the * Drug Standards Laboratory, AMERICAN PHARMACEUTICAL ASSOCIATION FOUNDATION, Washington, DC 20037

Accepted for publication April 21, 1967.

† Schering Corp., Bloomfield, NJ 07003. Schering Corp. has cooperated by furnishing samples and data to aid in the development and preparation of this monograph.

The authors express their appreciation to John J. Callahan and Emanuel Zenno, Schering Corp., and Hannah Klein, Drug Standards Laboratory, for valuable contributions to the monograph.

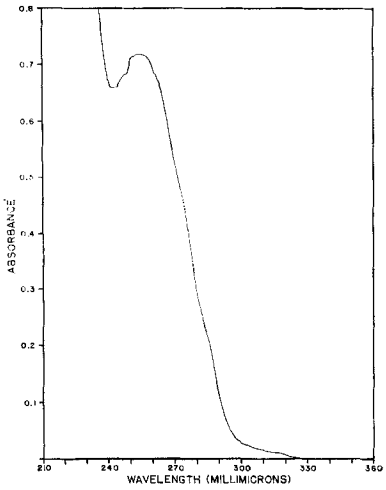


Fig. 1—Ultraviolet absorption spectrum of tolnaftate in methanol (10 mcg./ml.); Beckman model DK-2A spectrophotometer.

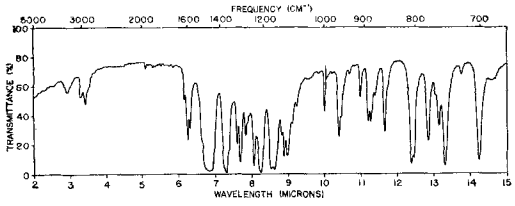

Fig. 2—Infrared spectrum of tolnaftate in potassium bromide disk (0.5%); Perkin-Elmer model 21 spectrophotometer, sodium chloride prism.

is the absorbance of the standard solution. The amount of tolnaftate found is not less than 90.0% and not more than 115.0% of the labeled amount.

Tolnaftate Cream

Identity Test—The ultraviolet absorption spectrum of the chloroform solution obtained in the *Assay* exhibits an absorbance maximum and minimum at the same wavelengths as that of the standard solution.

Assay—Weigh accurately an amount of tolnaftate cream equivalent to about 10 mg. of tolnaftate and transfer to a 250-ml. separator. Add 100.0 ml. of chloroform and shake the chloroform solution successively with two 25-ml. portions of 0.1 *N* sodium hydroxide, two 25-ml. portions of 0.1 *N* hydrochloric acid, and 25 ml. of water, transferring the bulk of the chloroform phase to a second separator after each extraction. Dilute 5.0 ml. of the chloroform solution to 50.0 ml. with chloroform, and mix. Concomitantly determine the absorbance of this solution and of a standard solution of tolnaftate reference standard, in the same medium, at a concentration of about 10 mcg./ml., in 1-cm. cells, at the maximum at about 260 mμ, with a suitable spectrophotometer, using chloroform as the blank. Calculate the quantity, in mg., of $C_{19}H_{17}NOS$ in the portion of cream taken by the formula $C\ (A_u/A_s)$, in which C is the concentration, in mcg./ml., of tolnaftate in the standard solution, A_u is the absorbance of the sample solution, and A_s is the absorbance of the standard solution. The amount of tolnaftate found is not less than 90% and not more than 110% of the labeled amount.

DISCUSSION

U.S.P. and N.F. terminology for solubility, melting range, reagents, *etc.*, has been used wherever feasible.

Tolnaftate[1] is an antifungal agent which is useful in the topical treatment of fungal infection caused by various species of *Trichophyton* and *Microsporum* (1–3). Tolnaftate, applied in a polyethylene glycol solution or cream, is particularly effective in the treatment of tinea pedis, tinea cruris, tinea corporis, and tinea manuum.

Identity Tests—Thin-layer chromatography may be included for testing the purity of bulk tolnaftate as well as an additional identity test for the drug and dosage forms. Benzene–alcohol (1:1) solutions of tolnaftate drug and reference standard are prepared at a concentration of about 1 mg./ml. The remainder of the *Assay* solutions obtained from tolnaftate solution and cream are evaporated to dryness and the residue dissolved in 1 ml. of benzene–alcohol (1:1). A 10-μl. portion of test and standard solutions is applied to a thin-layer plate prepared with Silica Gel G and the chromatogram developed using toluene as the mobile phase. The spots are visualized using ultraviolet light (254 mμ) and/or a 1 in 100 solution of iodine in carbon tetrachloride sprayed on the chromatogram and air dried.

Quantitative Tests—Analyses of bulk tolnaftate and tolnaftate solution and cream are based on ultraviolet spectrophotometric measurements. A solution of the basic drug in methanol compared to a similarly prepared reference standard solution gave an average recovery value of 100.5 ± 0.4%.[2] Absorbance measurements of tolnaftate in the commercial preparations are conveniently determined in chloroform solution. The ultraviolet absorption spectrum of tolnaftate in chloroform is similar to the spectrum shown in Fig. 1 with a slight shift in maximum absorbance to 260 mμ. Spectrophotometric analyses of tolnaftate solution and cream gave average values of 107.6 ± 1.3%[2] and 108.4 ± 0.7%[2] of the labeled amounts, respectively. The suitability of each procedure was verified by quantitative recovery of a standard tolnaftate solution carried through the extractive steps as included for the solution and cream.

Compression Characteristics of Some Pharmaceutical Materials

By S. LEIGH, J. E. CARLESS, and B. W. BURT

A commercial single-punch tablet machine (Manesty E 2) fitted with 1/2-in. punches was instrumented with strain gauges to monitor the forces simultaneously on the upper punch and the die-wall. The complete pressure cycles of a number of pharmaceutical materials at various levels of compression have been studied. The materials were sucrose granules and crystals, acetaminophen granules, aspirin crystals, and sodium chloride crystals. It has been found that these materials conform to three different types of compression pattern. The results indicate that materials which laminate on compression behave like a Mohr's body, *e.g.*, acetaminophen granules without binder. Granulation of acetaminophen with polyvinylpyrrolidone altered the compression pattern to that of a body with a constant yield stress. Aspirin compacts were found to exhibit elastic properties. Compression patterns are given for 20/40 mesh and 40/60 mesh crystals and granules of sucrose. No significant differences due to particle size were found, but differences were noted between the crystals and granules. The poisson ratios of these materials are given.

MEASUREMENTS of radial pressures exerted on the die-wall during uniaxial compression of materials to form compacts have been described by Nelson (1), Long (2), Windheuser (3), and Higuchi (4).

Nelson (1) and Higuchi (4), using load cells and strain gauges, respectively, mainly studied the transmission of forces to the die-wall, during the application of axial pressure, *i.e.*, on axial loading. The investigations failed to cover the relaxation/dissipation of pressure during removal of the compressional forces, *i.e.*, during unloading. Long (2) used a split die to measure the radial pressures. He studied the complete pressure cycles during loading and unloading of materials used in powder metallurgy and a theory was put forward regarding the nature of the residual radial pressure. No attention was paid to the effect of particle size, moisture content, and different physical forms.

The object of the present investigation was to find out the type and nature of the pressure cycles involved during compression of different pharmaceutical materials in granular and crystalline form. It was of particular interest to find out whether the ability of a material to form a "good" or "bad" tablet (particularly with respect to capping) was manifested in its pressure cycles.

APPARATUS

A Manesty E2 single-punch tableting machine, fitted with 1/2-in. plain punches was instrumented with strain gauges to monitor the forces involved during a compression cycle. The die-plate was suitably modified to house the die and the wires from the transducers without interfering with the movement of the upper punch and the hopper. To monitor the upper punch force and lower punch force, 1/4-in. linear foil gauges (Saunders Roe, resistance 120Ω, gauge factor 2.2) were used. Three foil gauges were bonded to the three slots around the lower punch holder, and connected in series, to form one active arm of a Wheatstone bridge. Three dummy gauges were used for the compensating arm as described by Shotton (5). In both cases, the transducers were connected as a half-bridge circuit with the resistors in the carrier amplifiers completing the circuit.

Silicone gauges (type 2A-1A-250 P)[1] were used to monitor the die-wall pressure. A 1/2-in. die was cut away on opposite sides, leaving a wall thickness of 1/8 in. on the die. One silicone gauge was bonded on either side of the cut-away surface. A silicone rubber solution was used to fill in the cut-away portions. With the solution hardened, the circumference of the die conformed to its original shape and size. The two silicone gauges formed opposite arms of a Wheatstone bridge. A full bridge was completed by using two resistors.

Type 2506 Carrier amplifiers[2] were employed to activate the transducers on the upper punch and lower punch holder. The oscillator frequency was set at 5 Kc./sec. and the output voltage was 3 v. A low gain amplifier (CA31)[2] of frequency 3 Kc./sec. and output adjusted at 6 v., powered by a power unit PU21,[2] was employed to energize the semiconductors.

The signals from the transducers were received in a 4 channel U.V. recorder (type 1706 Visicorder),[2] using suitably damped galvanometers (BB 250A)[2] and recorded at a chart speed of 6 mm./sec.

Received January 16, 1967, from the Department of Pharmacy, Chelsea College of Science and Technology, University of London, London, England.
Accepted for publication March 23, 1967.

[1] Ether Langham Thompson Ltd.
[2] Honeywell Controls Ltd.

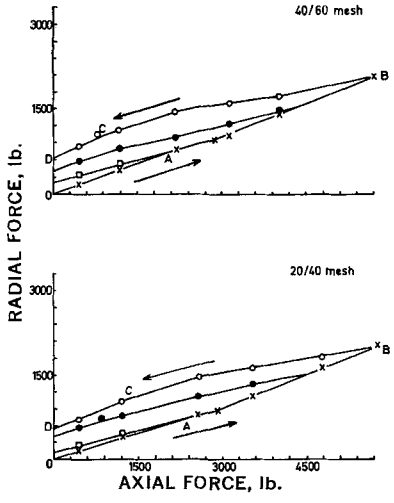

Fig. 1—Compressional cycle of sucrose granules.

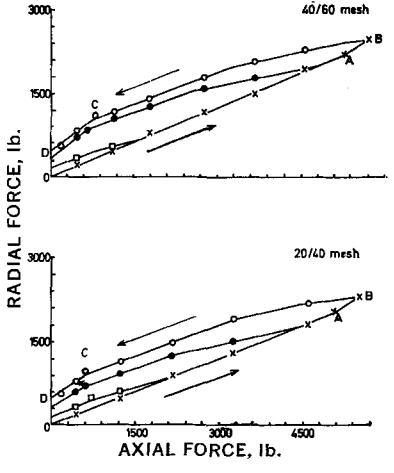

Fig. 2—Compressional cycle of sucrose crystals.

CALIBRATIONS

The upper punch and lower punch were calibrated by the method of Shotton and Ganderton (5). The die was calibrated by two different methods. First, it was clamped between two plates. Water, under pressure, was forced into the die. The height of the water column within the die was 0.16 in. This was of the same height as the tablets to be compressed. A linear relationship was obtained between the hydraulic pressures and the galvanometer deflections. A second calibration was carried out using a rubber plug as a confirmation. The die-wall response was of the same order as before.

EXPERIMENTAL

To investigate the type and nature of pressure cycles exhibited by different forms of the same material, sucrose granules and sucrose crystals were chosen. Two different sizes of each (20/40 mesh; 40/60 mesh) were compressed to investigate the effect of particle size.

The materials used were: sucrose granules (20/40 mesh, 40/60 mesh); sucrose crystals (20/40 mesh, 40/60 mesh); aspirin crystals (20/40 mesh); sodium chloride crystals (20/40 mesh); acetaminophen granules (20/40 mesh); and acetaminophen granules (97% acetaminophen, 3% polyvinylpyrrolidone (20/40 mesh).

The sucrose granules were prepared using distilled water. Acetaminophen granules were prepared using acetone. Granules of 97% acetaminophen and 3% polyvinylpyrrolidone (PVP) were prepared by moist granulation with the PVP in acetone. The granules were dried at 85° overnight. The

					0.70	2200

TABLE II—POISSON RATIOS (ν)

Material	Mesh Size	ν
Sucrose crystals	40/60	0.31
Sucrose crystals	20/40	0.31
Sucrose granules	40/60	0.27
Sucrose granules	20/40	0.27
Aspirin crystals	20/40	0.38
Acetaminophen + PVP granules	20/40	0.24
Acetaminophen granules	20/40	0.29
Sodium chloride crystals	20/40	0.30

two fractions, 20/40 mesh and 40/60 mesh, were obtained by sieving, using a test sieve shaker[3].

All materials were further dried over silica gel in an oven at 50° and stored over P_2O_5 in a desiccator prior to compression. The moisture content of each sample was determined by loss of weight after drying at 95° for 45 min. using infrared heat. Weight loss was found to be below 0.3% in each case.

All samples were lubricated with 0.5% magnesium stearate (100 mesh) and tumbled in a jar for 5 min. (A lubricant was included, because the object of this investigation was to determine the nature of the pressure cycles rather than die-wall friction.) The weight of material compressed in each case was such that a compact of 0.16 in. (height to diameter ratio 0.32) was obtained at the maximum loading. Each sample was weighed to the nearest mg. The compression cycle extended over 30 sec. for the loading and 30 sec. for the unloading. Loading and unloading were carried out evenly over the entire cycle. Five samples of each material were taken up in stages to load levels of approximately 2000, 3000, 4000, 5000, and 5600 lb. on separate occasions before unloading was commenced from these levels.

RESULTS

Figures 1–6 show the relationship between the radial forces and axial forces of the materials during a complete pressure cycle, *i.e.*, during loading and unloading. The slopes of OA, AB, BC, and CD are given in Table I.

Figure 1 shows the nature of the pressure cycles between two different sizes (20/40 and 40/60 mesh) of sucrose granules. Figure 2 shows the nature of the pressure cycles between different sizes (20/40 mesh and 40/60 mesh) of the sucrose crystals.

Table II gives the poisson ratio of the materials. Figure 4 shows the pressure cycle of acetaminophen granules which cap and laminate on compression, while Fig. 5 is the pressure cycle for the same material, granulated with 3% polyvinylpyrrolidone where capping and lamination were absent.

DISCUSSION

In general, a force acting on one part of a body will be transmitted across the section to the other part. This force may be resolved into two components, one normal to the body and the other in the tangential direction. The former is a normal stress and the latter a shearing stress (6). The normal component is consistent with volume changes, whereas the shearing forces (couples) are sources of, or response to, deformation of a body.

When granules or crystals are compressed within a die by means of two opposing punches, the axial load that is applied through the upper punch is transmitted to the die as a shearing force. In addition, force is transmitted radially to the die-wall. The pattern and magnitude of this latter force is governed by the elastic or plastic behavior of the compact. In studying the pressure transmitting characteristics of materials during tableting, using a single punch machine, it must be noted that although the forces involved in the sequence starting from loose material to close packing to compact formation are being monitored from the moment the upper punch enters the die, these forces cannot be recorded until the material forms a sufficiently firm compact to offer resistance to the downward movement of the upper punch. The moment that the compact is sufficiently firm, the upper punch force and the die-wall force can be recorded simultaneously. From this stage onward, the compact behaves more or less like a solid body and follows certain characteristics of solid bodies under uniaxial compression.

Consider the three following examples of solid bodies under uniaxial compression within a die. It is assumed that the die is perfectly rigid and that die-wall friction is absent. In the first case, it is assumed that the body is perfectly elastic. When an axial loading is applied, the transmitted radial force is of the same magnitude and the relationship is of the order:

$$\sigma = \nu(\tau) \qquad \text{(Eq. 1)}$$

where σ = axial force, τ = radial force, and ν = the poisson ratio.

Figure 7 shows this relationship in graphical form. This will be valid up to the elastic limit of the material. If the elastic limit has not been

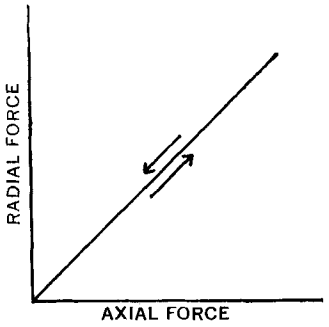

Fig. 7—Compressional cycle of an ideal elastic body.

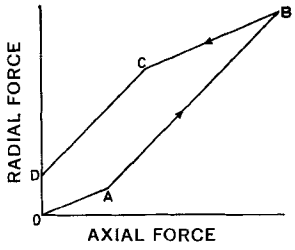

Fig. 8—Compressional cycle of a body with constant yield stress in shear.

exceeded, on unloading, the radial force will dissipate at the rate of ν times the axial force. When the axial force returns to zero, there will be no residual radial force exerted on the die-wall and the body will be free to move out from the die.

In the second case, the axial force is increased above the yield point (A) of the material, when the body starts to deform. The relationship between the axial and radial forces will now depend on the conditions of yield of the material. In this example it is assumed that the body has a constant yield stress in shear, independent of the magnitudes of the principal stresses to which it is subjected. Friction is assumed absent. The principal stresses are σ and τ. After yield has taken place, the following equation applies (2)

$$\sigma - \tau = 2S \qquad \text{(Eq. 2)}$$

S = yield stress in shear, and graphically it follows the course AB (Fig. 8). After a point B has been reached, if the axial force is allowed to fall, the body is no longer forced to yield. The radial force will fall at ν times the rate of fall of the axial force, following the course BC. The slope of the line BC = OA. Provided that the maximum axial loading has been sufficiently large, the point C will be reached at which the radial force is greater than the axial force by an amount equal to $2S$. Yield will again occur. The difference between the radial force and axial force ($\tau - \sigma$) will again be constant, and the relationship will follow the course CD. Taking this example, it is evident that after the upper punch has been withdrawn, the body will exert a residual radial force of $2S$ on the die-wall. Because of this force, the body will be constrained at the die-wall and will not be free to move out from the die. Whether this value is reached will depend on the maximum axial loading on the body. If this load is not large enough, the difference ($\tau - \sigma$) will not attain a value as high as $2S$. The change of the slope at C, the yield point on unloading, will not be evident from the graph of the pressure cycle.

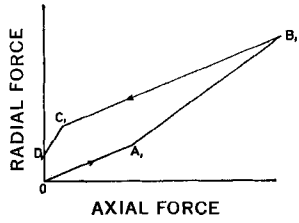

Fig. 9—Compressional cycle of a Mohr's body.

Consider the third case, where the body is also rigid, but after yield has taken place, the shearing stress (Mohr's theory) (7) in a plane of slip depends on the value of the normal stress σ_n acting in the same plane. In other words, the yield stress in shear is a function of the normal stress on the plane of shear. In the simple case where the body yields when:

$$\text{shearing stress} = S + \mu\sigma_n \qquad \text{(Eq. 3)}$$

the term μ is similar to a friction force, and the proportionality factor μ may be interpreted as a coefficient of internal solid (Coulomb type) friction. In this case, the normal stress on the plane of shear $= (\sigma + \tau)/2$ and the shearing stress $= (\sigma - \tau)/2$ (computed from Mohr's circle for principal stresses).

At yield from Eq. 3:

$$\sigma - \tau = 2S + \mu(\sigma + \tau) \qquad \text{(Eq. 4)}$$

$$\therefore \tau = [(1 - \mu)\sigma - 2S]/(1 + \mu) \qquad \text{(Eq. 5)}$$

On unloading, providing the axial loading has been sufficiently large (B'), the radial force will diminish according to the equation $\tau = \nu\sigma$, and then when the material yields again at the point C',

$$\tau = [(1 + \mu)\sigma + 2S]/(1 - \mu) \qquad \text{(Eq. 6)}$$

The slope $A'B' = (1 - \mu)/(1 + \mu)$. The final slope $C'D' = (1 + \mu)/(1 - \mu)$. The typical pressure cycle for this case takes the form shown in Fig. 9.

It must be realized that the pressure cycles described above are for models of solid, isotropic bodies under uniaxial compression, assuming that die-wall friction is absent. Compressing materials within a die to form a compact would obviously be somewhat different, as in this case, die-wall friction cannot be overlooked. In addition, the shape and size of the material (granules/crystals) could modify the pressure cycles.

Comparing the graphs of the pressure cycles of sucrose granules, sucrose crystals, aspirin crystals, sodium chloride crystals, acetaminophen granules, and acetaminophen granules with 3% polyvinylpyrrolidone (PVP), with the pressure cycles described, it can be seen that the cycles have certain features in common and certain analogies may be drawn. The pressure cycles of sucrose crystals, sucrose granules, sodium chloride crystals, and acetaminophen granules with 3% PVP are similar to the behavior of a solid body with a constant yield stress in shear, under uniaxial compression. Acetaminophen granules alone share a striking resemblance to that of a Mohr's body. It is interesting to note that the Mohr's body type pressure cycle of acetaminophen changes to that of a body with a constant yield stress in shear when granulated with 3% PVP. It is well known that acetaminophen on compression tends to cap and laminate. However, when granulated with 3% PVP no capping or lami-

nation is evident. The aspirin compact appears to have a very low yield stress. It behaves more like an elastic body. The hysteresis loss is comparable to that of an elastic body. On completely removing the axial load, the radial force dissipates almost completely. The small residual radial force that is recorded may be due to some die-wall friction.

With all the materials investigated, the axial loading was taken up to various levels from 1000–5600 lb. on separate occasions before unloading was commenced. However, in the plot of the axial-radial pressure cycles shown, only three loading levels (about 2200, 4000, and 5600 lb.) for each material are illustrated. Except in the case of aspirin crystals, it appears that after yield has started, the pressure cycles conform to the same pattern. However, the residual radial force increases with the increase in the axial loading. With aspirin crystals, the residual radial force appears to have reached a limiting value at an axial loading of about 4000 lb. This illustrates the behavior of the compact at different levels of axial loading and seems to support the assumption that the solid aspirin compact behaves like an elastic body. The direct relationship between the residual radial force and axial force of the materials (except for aspirin) may be attributed to the permanent deformation of the compacts after yield has started. It is probably significant that the ratio of height to diameter (0.32) of the aspirin compact remained constant after an axial loading of about 4000 lb. Since all the materials were lubricated with the same amount of lubricant, the difference in behavior would indicate a fundamental difference in the materials.

Table I shows the slopes of the lines corresponding to OA, AB, BC, and CD of Figs. 1–6. The slopes of the lines OA and BC are similar in the case of sucrose granules, sucrose crystals, sodium chloride crystals, and acetaminophen granules granulated with 3% PVP, having values ranging from 0.36 to 0.57. These slopes are directly related to poisson's ratio where the proportionality constant is the same for tablets of the same dimensions. The slopes of the lines BC and CD for sucrose granules, sucrose crystals, and acetaminophen granules with 3% PVP are more or less the same in each case as expected, for materials with a constant yield stress in shear.

The behavior of sodium chloride crystals is rather interesting. At an axial loading of about 2000 lb. it behaves almost like a perfect model of a body with a constant yield stress in shear. At the maximum axial loading of about 5600 lb., although the values of OA and BC are still the same, there is a break in the unloading curve at C′. After the yield point C has been exceeded in the unloading cycle, the radial force exerted is larger than the axial force.

In the three models described (Figs. 7–9) the yield points in each half of the cycle (representing loading and unloading) are clearly defined. With the materials under investigation this is not always the case. For instance, with sodium chloride it is seen that the slope of the line in the first half of the cycle is not constant. The initial change of the line may be taken as the yield point for the material. The subsequent change may be due to either (*a*) closer packing of the compacts, or (*b*) crystal slip or crystal twinning (*i.e.*, a shifting of the position of the lattice in a part of a crystal into a second position, so that the second part is in a symmetrical position relative to the first part and some plane of symmetry). It is likely that both phenomena contribute. On unloading the compact of sodium chloride, the slope of the line changes gradually down to the point C′ before it corresponds to the initial slope in the first half of the cycle (corresponding to poisson's ratio). This may be due to an "after flow" effect.

Comparing the behavior of sucrose granules with the crystals, it is seen that in the case of the crystals, the yield point A is higher and it has just been reached before unloading was commenced at B. The poisson ratio of the crystals is also higher than that of the granules. The residual radial pressure of the granules is, however, higher. After the yield point has been exceeded, the crystals appear to transmit more radial force. The slope of the line changes from 0.42 initially to 0.82, as compared with 0.36 to 0.42 in the case of the granules. The pressure cycles of the two sizes of sucrose granules are almost identical. However, the smaller of the sucrose crystals seem to have a higher yield point (A) at 5000 lb. compared to 4700 lb. for the larger crystals. This is to be expected as the yield point would depend more on the particle size of the material, but once a compact is formed the original particle size would not play a great role in its behavior, as the body now becomes a homogeneous isotropic mass.

Acetaminophen granules appear to behave like a Mohr's body. In this case, the final slope of the line C′D′ is 1. From the slope of A′B′ the value μ (coefficient of internal friction) is found to be 0.40.

The present investigation reveals significant differences between different granular and crystalline materials. Taking the case of acetaminophen it is seen that the change from a freely capping and laminating compact to a solid one is associated with the transformation from a Mohr's body type of pressure cycle to one with a constant yield stress in shear. It is perhaps more than coincidence that the materials which form firm and solid compacts exhibit the pressure cycle of a body with a constant yield stress in shear. At this stage, although no definite conclusion may be drawn, reasonable evidence exists that the classification of materials that form "good" or "bad" tablets may be carried out by an analysis of their pressure cycles, rather than from surmise. Admittedly, a wider range of materials will have to be investigated before any definite form of behavior can be predicted. No account has been taken in this investigation of the crystal shape. Indeed the crystal shape (anisotropy or isotropy) would modify the pressure cycles to a great extent. Further work is being conducted on the effect of lubrication on the pressure cycles.

Investigation of Hepatic Drug Metabolism by Isolated Perfused Liver *In Situ*

By G. BENZI, F. BERTÉ, and A. CREMA

The metabolizing activity of the hepatic tissues in an isolated *in situ* liver preparation has been examined. In this experiment the organ remained connected to the other parts of the body, but its blood circulation was supplied by a pump–oxygenator system. By this method some hepatic metabolic activities, such as demethylation, acetylation, and glucuronide-conjugation, have been evaluated.

THE TECHNIQUE of local perfusion of organs was developed with the specific purpose of minimizing the toxicity and increasing the chemotherapeutic activity of carcinolytic agents. Klopp *et al.* (1) maintained in 1950 that the therapeutic effect of drugs could be enhanced and the toxicity greatly reduced by intravascular injections into regions of the body containing tumors. In 1958 Creech *et al.* (2) and Ryan *et al.* (3) began the use of local therapy by isolating the tumor-bearing area from the remainder of the circulation and perfusing it with the aid of a pump–oxygenator system. According to these authors, the technique of regional perfusion is based on the concept that various anatomic regions can be isolated from the general circulation, supplied with a separate extraneous system for pumping and oxygenating the blood, and maintained for varying periods of time under these conditions without significant systemic effects.

Subsequently, these or related techniques have been utilized by many investigators, and Stehlin *et al.* (4), Creech *et al.* (5), Shingleton *et al.* (6), Ausman and Aust (7), Clarkson and Lawrence (8), and others have published excellent descriptions.

In the course of systematic investigations of drug metabolism (9–11), we developed a method to evaluate the liver metabolic activity *in situ*, utilizing the concepts of the authors quoted above. To test the method itself, we have also examined some metabolic transformations of aminopyrine and oxazepam.

EXPERIMENTAL

The abdominal technique of liver perfusion was carried out on 16 dogs (14.5 to 29.0 Kg.) and on 4 monkeys (*C. hamadryas;* 11.4 to 16.2 Kg.) preanesthetized with urethan (0.4 Gm./Kg. i.p.). Anesthesia was induced and maintained in closed circuit by nitrous oxide, cyclopropane, or ethyl ether. The animals were given artificial ventilation after tracheal intubation by Warne tube during succinylcholine chloride action (1 mg./Kg. i.v.). The operative procedures are indicated in Fig. 1 and are briefly summarized here.

Before laparotomy, a large outflow tube is inserted into the right external iliac vein (*via* femoral vein, 10) and connected with a large inflow tube inserted into the right external jugular vein, 9, in the dog or into the right internal jugular vein in the monkey; the connection is made by a large silicone coated para-rubber cannula joined to a Sigmamotor pump, 12.

After laparotomy, the inferior cava vein, 6, is ligated above the renal veins, 17. The phrenico-abdominal veins are also ligated or excluded. Into the inferior cava vein, clamped below the liver, a special three-way outflow cannula is inserted immediately above the ligature; this tube, 5, contains a movable rubber balloon (connected with a syringe, 14), which after clamp removal, is passed into the cava, 7, over the diaphragmatic foramen. The rubber balloon, 18, remains deflated, and the outflow tube, 5′, is clamped. It is necessary to tie the accessory portal veins, and particularly the gastro-hepatic, paraumbilical, diaphragmatic, and cardial groups.

A T-shaped outflow tube, 13, inserted into the porta or the mesenteric vein, is connected, by a silicone coated para-rubber cannula, with the Sigmamotor apparatus, 12.

An inflow cannula, 3, is inserted into the portal vein and ligated below the liver but immediately before the portal vein divides into two or more branches. Both the portal inflow cannula, 3, and the cava outflow cannula, 5, are connected with the pump–oxygenator system, 4.

The rubber balloon, 18, is inflated by the syringe, 14, and drawn back (under X-ray examination) to

Received January 16, 1967, from the Departments of Pharmacology, Pavia and Pisa Universities, Italy.
Accepted for publication March 9, 1967.

block, in the diaphragmatic foramen, both the cava vein and the blood flow from the phrenic tributaries, 16. At the end, the hepatic artery is ligated and the perfusion begins. It is necessary to make several ligatures to block the lymphatic ducts of the hepatic hilum and the pancreas.

The pump–oxygenator system consists of: a venous reservoir, an oxygenator with gasmeter, a roller-type pump with flowmeter, a blood filter, an apparatus to eliminate the blood foam, a perfusion pressure regulator, and a blood heat exchanger with telethermometer. Before the extracorporeal liver perfusion, the pump–oxygenator system is filled with 300–400 ml. of heparinized blood previously obtained from the animal itself that was infused with 300–400 ml. of blood from donor animals. The priming blood is circulated through the extracorporeal system, fully oxygenated, and warmed. A flow of oxygen into the oxygenator is maintained at the rate of 4–8 L./min. During the extracorporeal liver perfusion the blood flow rate was 4–10 ml./min./Kg.

The evaluation of any leakage from the extracorporeal circuit can be determined: (*a*) during the metabolic research, by taking samples from the general circulation of the blood and the lymph to verify the absence of the studied substance or its metabolites; (*b*) at the end of the metabolic research, by adding to the blood of the extracorporeal circuit either a dye (which can be examined, for its eventual leakage, by autopsy) or a radiopaque substance (which can be traced by radiography).

To confirm the proper function of the liver, the concentration of serum glutamate-oxalacetate transaminase (SGOT), serum glutamate-pyruvate transaminase (SGPT), sorbit dehydrogenase (SDH); leucine aminopeptidase (LAP) and seric hemoglobin was determined in blood samples from the extracorporeal circuit. From bile samples, the time of bromosulphonthalein (BSP) elimination from the blood of the extracorporeal circuit was determined.

To evaluate the metabolizing activity of the liver, the following were examined: (*a*) the demethylation by studying the transformation of aminopyrine to 4-aminoantipyrine, using the method of Brodie and Axelrod (12), after the addition of 150–300 mcg./ml. of aminopyrine into the extracorporeal circuit; (*b*) the acetylation, by studying the transformation of 4-aminoantipyrine to *N*-acetyl-4-aminoantipyrine under the above-mentioned conditions; (*c*) the glucurono-conjugation, by studying the transformation of oxazepam to glucuronide, using the method of Walkenstein *et al.* (13), after addition of 25–50 mcg./ml. of oxazepam (7-chloro-1,3-dihydro - 3 - hydroxy - 5 - phenyl - 2*H* - 1,4 - benzodiazepine-2-one) into the extracorporeal circuit.

RESULTS

Following these preparations, the venous blood from the hepatic veins (Fig. 1, 15) passes through the inferior cava into the pump–oxygenator system which is connected with the portal inflow tube. The abdominal venous blood by-passes through an artificial cava into the right side of the heart.

During the extracorporeal liver perfusion (from 2 to 3 hr.) no difference was observed between initial and terminal values of the following parameters: SGPT, SDH, LAP, and the time of BSP elimination. In contrast, there was a slight linear increase of SGOT during the perfusion depending on the increase of serum hemoglobin content. In fact, it has been shown that even a low-grade hemolysis leads to false positive values for SGOT (14).

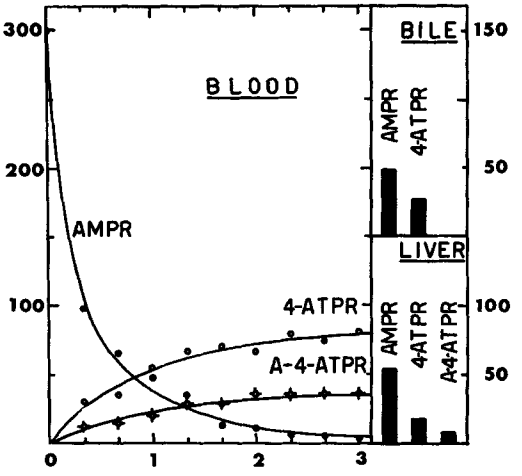

Fig. 2—Aminopyrine metabolism studied by the isolated liver perfusion in situ *in a dog weighing 25.8 Kg. Blood in extracorporeal circuit = 600 ml.; blood flow rate of the liver extracorporeal circuit = 130 ml./min.; initial concentration of aminopyrine in the plasma of the extracorporeal circuit = 300 mcg./ml. At left, the plasmatic concentration curves (mcg./ml., in ordinate) of aminopyrine (AMPR), 4-aminoantipyrine (4-ATPR), and* N*-acetyl-4-aminoantipyrine (A-4-ATPR) during 3 hr. (in abscissae) after aminopyrine addition. At right, bile and liver concentrations (mcg./ml. or mcg./Gm., in ordinate) of aminopyrine and its two metabolites, 3 hr. after adding the aminopyrine into the extracorporeal liver perfusion.*

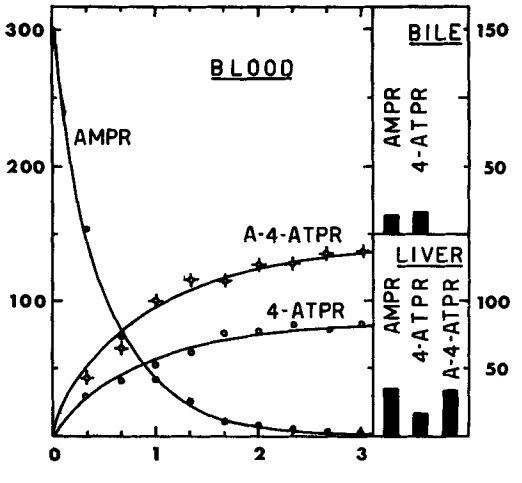

Fig. 3—Aminopyrine metabolism studied by the isolated liver perfusion in situ *in a monkey* (C. hamadryas) *weighing 13.8 Kg. Blood in liver extracorporeal circuit = 480 ml.; blood flow rate of the extracorporeal circuit = 70 ml./min.; initial concentration of aminopyrine in the plasma of extracorporeal circuit = 300 mcg./ml. Left and right same as Fig. 2.*

Concerning the metabolizing activity of *in situ* isolated liver preparation, aminopyrine and oxazepam disappear from the extracorporeal blood of dog and monkey at a very rapid rate: the half-life for aminopyrine ranges from 10 to 14 min. in dog and from 16 to 21 min. in monkey, and for oxazepam from 7 to 10 min. in both animals.

Figures 2 and 3 show two typical examples of the rate of transformation of aminopyrine in two metabolities: the demethylation is quite similar in dog and monkey, whereas the acetylation is higher in monkey than in dog. Likewise, at the end of the liver perfusion, the hepatic concentration of 4-aminoantipyrine is similar in both species, while the hepatic concentration of *N*-acetyl-4-aminoantipyrine is higher in the monkey than in the dog.

Figure 4 shows a typical example of the high glucurono-conjugation produced by the liver which eliminates the glucuronide into the bile.

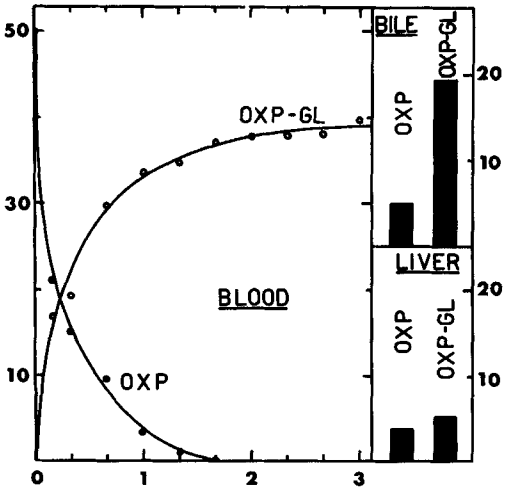

Fig. 4—Oxazepam metabolism studied by the isolated liver perfusion in situ *in a dog weighing 23.5 Kg. Blood in liver extracorporeal circuit = 600 ml.; blood flow rate of extracorporeal circuit = 120 ml./min.; initial concentration of oxazepam in the plasma of the extracorporeal circuit = 50 mcg./ml. At left, the plasmatic concentration curves (mcg./ml., in ordinate) of oxazepam (OXP) and its glucuronide (OXP-GL), assayed for 3 hr. (in abscissae) after oxazepam addition. At right, the bile and liver concentrations (mcg./ml. or mcg./Gm., in ordinate) of oxazepam and its glucuronide, assayed after 3 hr. of the extracorporeal liver perfusion with the addition of oxazepam.*

CONCLUSIONS

The described method permits us to investigate *in situ* the metabolizing activity of the liver normally connected with the body except that its blood circulation is supplied by a pump–oxygenator system. The liver functional tests remained within normal limits during the experiment (2 to 3 hr.). In such a way, the hepatic metabolic activity can be examined under experimental arrangements more similar to the normal conditions than traditional *in vitro* methods.

SUMMARY

The technique of the local perfusion of the organs *in situ* has been applied to evaluate the metabolizing hepatic activity. The liver can be isolated from general circulation, supplied with a separate extraneous system for pumping and oxygenating the blood, and maintained from 2 to 3 hr. under these conditions without significant local damage.

To test the method, the authors studied certain hepatic metabolic activities such as demethylation, acetylation, and glucurono-conjugation. The results suggest that the method could be useful in evaluating the metabolizing activity of the liver *in situ* without interference from other tissues.

Relationship Between Lesion Production, Absorption, and Distribution of ^{14}C-Labeled Acetylsalicylic Acid

By ERDIE MORRIS*, ANTOINE A. NOUJAIM†, TOM S. MIYA, and JOHN E. CHRISTIAN

Carbon-14-labeled acetylsalicylic acid in conjunction with liquid scintillation counting and autoradiography was used to study the absorption and localization of the drug in the rat stomach. Lesions were produced in rats following oral administration of from 50 to 600 mg./Kg. The concentration of acetylsalicylic acid in the rumen and corpus portions of the stomach and in other tissues was determined for various time intervals after administration. The localization of the drug was studied in both the mucosal and muscularis surfaces of the stomach.

ALTHOUGH MANY divergent reports have been made on the blood loss and the gastric lesions caused by acetylsalicylic acid, it is clear that gastric bleeding does occur in humans and in experimental animals administered acetylsalicylic acid. As early as 1938, Douthwaite and Lintott (1) found severe mucosal reactions in 13 of 16 subjects following oral administration of acetylsalicylic acid.

These observations were extended by Hurst in 1943 (2). However, Wolf and Wolff in 1943 (3) were unable to produce gastric lesions by direct application of acetylsalicylic acid to the mucosa of a gastrostomy subject. Paul (4) observed no lesions in 107 subjects after acetylsalicylic acid administration. Caravati and Cosgrove in 1946 (5) repeated this work with 12 subjects with similar results. Since 1955, however, many investigations (6–10) have been reported agreeing, in general, with the earlier findings of Douthwaite and Lintott (1) and Hurst (2).

Davenport (7), in extensive studies of the production of mucosal damage by acetylsalicylic acid in vagally denervated dogs, suggested that the damage may be the result of the exchange of H^+ and Na^+ with a consequent efflux of Na^+, K^+, and Cl^- ions, eventually leading to damage of the capillary walls and subsequent hemorrhage.

Based on studies of gastric damage in guinea pigs, Anderson (8) concluded that the acetylsalicylic acid-induced gastric damage depended upon gastric absorption probably originating at the cellular level when the rate of entry into the mucosal cells exceeded some critical value. Initially the surface epithelial cells are shed, and this is followed by necrosis of the underlying glandular but not muscular tissue. If this is the case, the mechanism would therefore appear to involve an effect on the mucosal cells and is not directly related to gastric hyperacidity or peptic activity.

Martin (9) has suggested that the gastric mucosal injury is brought about by an appreciable accumulation of the drug anion in gastric mucosal cells because of the high pH gradient (stomach *versus* inside of cell; pH 1.4–6.8).

Croft (10) concluded that the gastric bleeding following repeated ingestion of acetylsalicylic acid appeared to be a result of gastric erosions brought about by the loss of surface cells. Davison (11) demonstrated that undissolved particles of aspirin are necessary for bleeding to occur in the dog.

From these and other reports, it is evident that the mechanism by which acetylsalicylic acid causes gastric lesions and subsequent blood loss is not well understood. The present study was carried out to uncover additional information about the concentration, localization, and penetration of the drug.

The terminology applied to the gross anatomy of the stomach in this paper was adapted from Shay (12).

EXPERIMENTAL

Materials and Methods—Carbon-14-carboxyl-labeled acetylsalicylic acid (Tracerlab, Waltham, Mass.), was used for all radiometric phases of this study. Radiocompound purity was confirmed by means of thin-layer chromatographic assay using a solvent system composed of benzene–ether–acetic acid–methanol (120:60:18:1). Polyvinylpyrrolidone (Antara Chemicals, Chicago, Ill.) was used as the suspending agent for oral administration. Kodak No-Screen medical X-ray film was used for the gross autoradiography. Liquid scintillation counting was accomplished using a model 3003 TriCarb liquid scintillation spectrometer (Packard Instrument Co., LaGrange, Ill.), with external standard attachment for quench correction. Tissue samples were prepared for counting by dissolving them in 2 ml. of hyamine–hydroxide solution (1 *M* methanolic hyamine HCl, 3 parts; 30% potassium hydroxide, 1 part). Excessive color was removed with 0.5 ml. of 30% hydrogen peroxide. Each sample was then acidified with 1.0 ml. of glacial acetic acid after which 15 ml. of XDC scintillation fluid consisting of xylene–cellusolve–dioxane (1:3:3), PPO (2,5-diphenyloxazole) 10 Gm./L., dimethyl POPOP (dimethyl 1,1-4-bis-2-(5-phenyloxazolyl) benzene, 0.5 Gm./L., and naphthalene, 80 Gm./L.

Production of Lesions—Preliminary experiments were carried out to confirm the production of lesions by oral administration of acetylsalicylic acid. U.S.P. grade acetylsalicylic acid was suspended in 5.0% polyvinylpyrrolidone and administered to 24 male rats of the Holtzman strain, weighing 200 to 260 Gm., in doses of 10, 50, 100, and 600 mg./Kg. The animals were fasted for 36 hr. prior to administration of the drug and were allowed no food or water during the experiment. Lesions were produced in the corpus in every case with doses of from 50 to 600 mg./Kg. No lesions were observed in the control animals which were

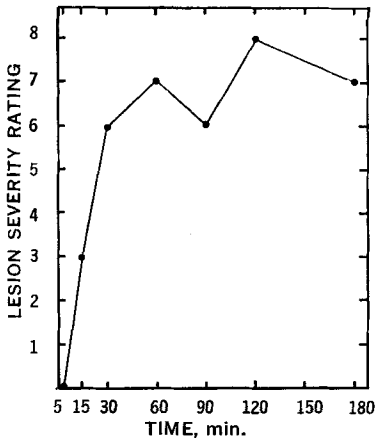

Fig. 1—Average gastric lesion ratings produced by oral 50 mg./Kg. acetylsalicylic acid. The condition of the stomachs was rated according to the following scale: No. 1, normal, no lesions, erythema or blood; No. 2, erythema only, no lesion or blood evident; No. 3, lesions present, less than 5, all of which are smaller than 1 mm. in diameter; No. 4, lesions present, less than 5 with one or more larger than 1 mm. in diameter; No. 5, lesions present, more than 5 but less than 10, all of which are less than 1 mm. in diameter; No. 6, lesions present, more than 5 but less than 10 with one or more larger than 1 mm. in diameter; No. 7, lesions present, more than 10, all of which are smaller than 1 mm. in diameter; No. 8, lesions present, more than 10 with one or more larger than 1 mm. in diameter.

given similar doses of polyvinylpyrrolidone alone in like volumes. The localization of lesions produced by aspirin to the corpus region has been previously noted by Gray (13).

Using time intervals between dose and sacrifice of 5, 15, 30, 60, 90, and 120 min., the time required to produce lesions and the severity of the lesions produced were studied. Three animals were used in each time group and a 50 mg./Kg. dose contained in 0.7 ml. of suspension was used in this and all subsequent experiments. The results are summarized in Fig. 1.

Surgical Techniques—The stomachs were removed, freed from all adhering tissue, and opened along the lesser curvature. Each stomach was pinned to a No. 14 rubber stopper such that the rugal folds were flattened out. All stomachs were washed with exactly 100 ml. of 0.9% saline solution by gently spraying from a plastic wash bottle. A previous experiment indicated that a 100-ml. wash was sufficient to remove surface contamination from the mucosa.

Determination of Drug Concentration in Selected Tissues—Twenty-one rats were administered a 50-mg./Kg. dose of ^{14}C-carboxyl-labeled acetylsalicylic acid having a specific activity of 0.625 μc./mg. Three control animals were given a similar dose of nonlabeled drug. The animals were sacrificed in groups of 3 at time intervals of 5, 15, 30, 60, 90, and 120 min. after dosing. After removal, the stomachs were washed with saline and random samples (50 to 100 mg.) were taken from the rumen and corpus portions, placed in a previously weighed Wheaton vial, and the wet weight of the tissue accurately determined. The samples were taken by cutting

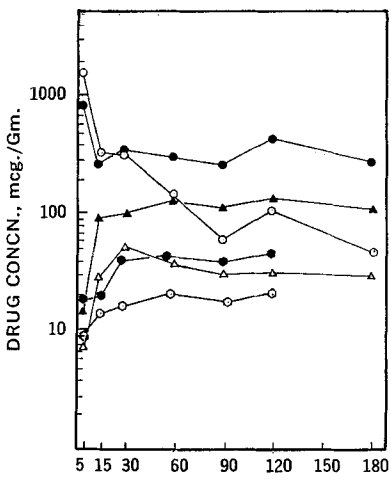

Fig. 2—Concentration of acetylsalicylic acid in the rumen and corpus portions of the stomach, skeletal muscle, kidney, blood, and adrenal gland of the rat. Key: ●, rumen portion; ○, corpus portion; △, skeletal muscle; ▲, kidney; ⬢, blood; ⬡, adrenal gland.

through the entire stomach wall with a hand cork borer. Samples were also taken from the liver, lung, kidney, adrenal gland, skeletal muscle, and blood (1 ml.). All samples were counted as previously described, and from the specific activity of the original dose, the amount of drug present per Gm. of tissue was determined for each sample (see Fig. 2).

Gross Autoradiography—Eighteen rats were dosed and sacrificed as previously described; 3 rats served as controls. After the stomachs had been removed, pinned, and washed, they were quick frozen with dry ice and removed from the rubber stoppers. In the dark room, the stomachs were covered on both sides with Saran wrap and arranged in groups according to the time intervals of 5, 30, and 120 min., respectively. Each group was then placed between 2 sheets of No-Screen medical X-ray film such that one film was in apposition to the mucosal surface and the other in apposition to the muscularis surface. The films with the stomachs in position were then placed in light tight cassets and stored at −20° for 60 days. The films were developed and photographic prints were made so that the dark areas corresponded to the areas of radioactivity where the drug was concentrated. Respresentative examples of these prints are shown in Figs. 3 through 8.

Intravenous Administration of Acetylsalicylic Acid—Eighteen animals were given *via* the caudal vein 50 mg./Kg. labeled drug dissolved in propylene glycol. Three control rats were used. Gross autoradiographs were prepared in the same manner as previously described (see Figs. 9 and 10). After exposure of the gross autoradiographs, samples were taken from the stomachs and counted to determine the drug concentrations. Drug concentration was found to be greatest 15 min. after intravenous administration in both the rumen and corpus portions.

DISCUSSION AND COMMENTS ON RESULTS

From the results of the drug concentration studies in selected tissues, it is apparent that very rapid

absorption occurs through the mucosa of the corpus portion of the stomach (Figs. 3–5). Five minutes after oral administration, the drug concentration in the corpus and rumen mucosa is greater by a factor of 10 than those concentrations found in any other tissue at any time. Furthermore, it was shown that the drug passes rapidly through the corpus mucosa into the muscularis where it is absorbed. Consequently, within 30 min. after administration, the concentration of drug

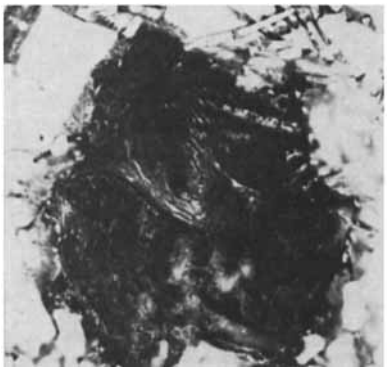

Fig. 3—Mucosal surface autoradiograph of a rat stomach 5 min. after oral administration. Note the high concentration of drug (acetylsalicylic acid and/or metabolites) in rumen and corpus portions.

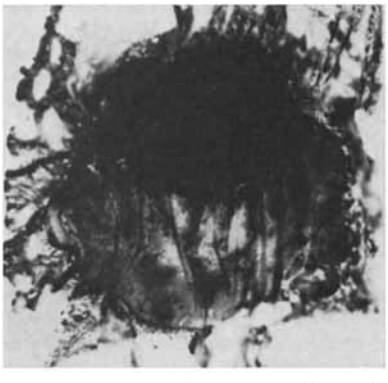

Fig. 4—Mucosal surface autoradiograph of a rat stomach 30 min. after oral administration. Note the decreasing concentration in the corpus portion with the rumen concentration remaining the same.

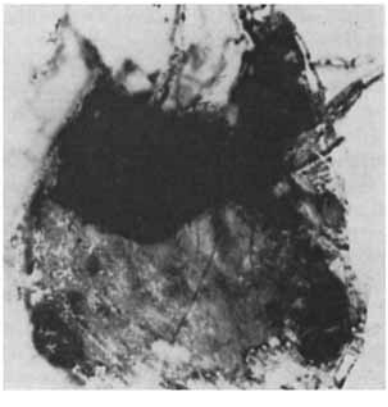

Fig. 5—Mucosal surface autoradiograph of a rat stomach 120 min. after oral administration. Note the lack of drug in the corpus portion.

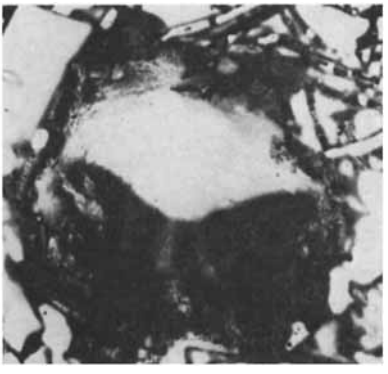

Fig. 6—Muscularis surface autoradiograph of a rat stomach 5 min. after administration. Note the high concentration of drug in the corpus portion and little or no concentration in the rumen portion.

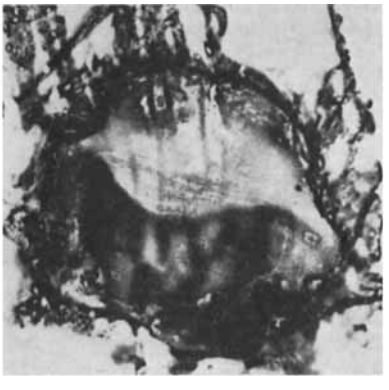

Fig. 7—Muscularis surface autoradiograph of a rat stomach 30 min. after administration. Note the drug in the corpus portion. The rumen concentration remains low.

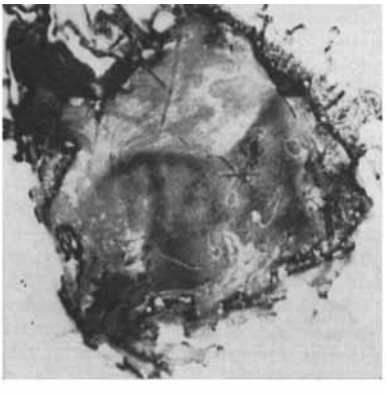

Fig. 8—Muscularis surface autoradiograph of a rat stomach 120 min. after administration. Note the greatly decreased drug in the corpus portion as compared to the 30-min. preparation. There is still little or no concentration of drug in the rumen portion.

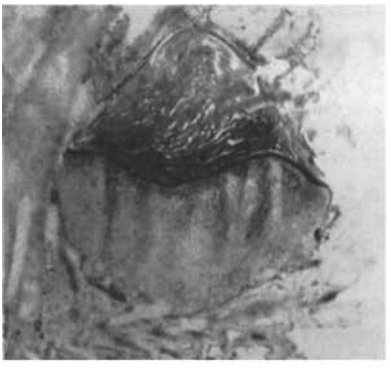

Fig. 9—Mucosal surface autoradiograph of a rat stomach 120 min. after intravenous administration.

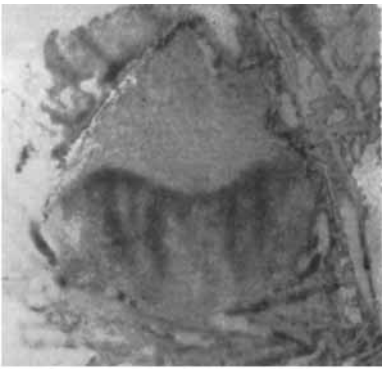

Fig. 10—Muscularis surface autoradiograph of a rat stomach 120 min. after intravenous administration.

remaining in the corpus mucosa is less than that found in the rumen mucosa. After 60 min. the drug levels in the corpus portion are essentially the same as those found in most other tissues. On the other hand, although the original absorption in the rumen portion is not nearly so great as in the corpus, there appears to be very little loss of drug from the rumen, so that 30 min. after administration until at least 3 hr., the concentration levels in the rumen are much greater than those found in any other tissue.

The gross autoradiographs clearly show the greater concentration of drug (acetylsalicylic acid and/or metabolites) in the corpus mucosa at 5 min. after administration and greater in the rumen mucosa after 120 min. The muscularis surface autoradiograms show increasing concentration in the corpus muscularis, followed by gradual decrease indicating absorption through this portion. No significant concentration is seen in the rumen portion of the muscularis indicating a lack of absorption through this portion.

SUMMARY AND CONCLUSIONS

The results may be summarized as follows. (*a*) Acetylsalicylic acid in doses of from 50 to 600 mg./Kg. produced gastric lesions in the corpus portion of the rat stomach. (*b*) Acetylsalicylic acid is absorbed through the mucosa of the corpus portion at a rapid rate with maximum concentration being reached within 5 min. after drug administration. (*c*) The drug concentration in the mucosa of the rumen portion remains relatively constant over a 3-hr. period following administration while the concentration in the corpus is initially high with steady decrease beginning 5 min. after oral administration. The drug concentration decreases in the corpus portion to a level comparable to that found in most other tissues after about 1 hr., while in the rumen it remains at a significantly higher level.

Although more work must be done before the entire mechanism of lesion production can be understood, the data presented here tend to refute the hypothesis of focal necrosis at least as the sole mechanism of gastric erosion. The data tend to support the concepts submitted by Davenport (7) as to the importance of tissue permeability and ion flux across the mucosa in the production of capillary wall damage eventually resulting in blood loss and erosion of the mucosa.

Synthesis of Pyrrolidine-2-^{14}C

By JOHN M. WALTS*, WAYNE V. KESSLER, and JOHN E. CHRISTIAN

The preparation of pyrrolidine-2-^{14}C picrate in satisfactory yields from potassium cyanide-^{14}C and from barium carbonate-^{14}C is reported. Reaction of pyrrolidine picrate with lithium hydroxide followed by distillation separated the free base.

THE SYNTHESIS of ^{14}C-labeled pyrrolidine was of interest since pyrrolidine is often found in a variety of biologically active compounds. The routes of synthesis were evaluated, and two were selected. The criteria used in selecting these routes were that relatively inexpensive starting materials were available, special equipment such as hydrogenators and autoclaves were not needed, vapors and gases were easily controlled, and an excessive number of reactions were not required. Pyrrolidine was labeled with ^{14}C at position 2 by both routes. It was isolated as its picrate salt for ease in handling and for convenience in purification and radioactivity determinations.

In method *A* (Scheme I), potassium cyanide-^{14}C and 3-methoxy-1-iodopropane (I) were refluxed in methyl alcohol to give 4-methoxybutyronitrile-1-^{14}C (II) (1). The latter compound was reduced with lithium aluminum hydride in ether to form the corresponding amine, 4-methoxybutylamine-1-^{14}C (III) (2). Heating this amine with hydrobromic acid produced 4-bromobutylamine-1-^{14}C hydrobromide (IV). Neutralization of IV with aqueous alkali followed by fractionation yielded pyrrolidine-2-^{14}C (V) (3). Addition of an ethereal solution of picric acid precipitated pyrrolidine-2-^{14}C picrate (VI) (3).

In method *B* (Scheme I), carbonation of the Grignard reagent of 3-methoxy-1-chloropropane (VII) in ether with carbon dioxide-^{14}C gave 4-methoxybutanoic-1-^{14}C acid (VIII) (4). Reduction of this acid with lithium aluminum hydride in ether produced the corresponding alcohol, 4-methoxy-1-butanol-1-^{14}C (IX) (2). Heating this alcohol with hydrobromic acid and acetic acid formed 1, 4-dibromobutane-1-^{14}C (X) (5). Reaction of the latter compound with *p*-toluenesulfonamide in ethyl alcohol and aqueous alkali yielded *N*-*p*-toluenesulfonylpyrrolidine-2-^{14}C (XI) (6). Acid hydrolysis of this amide, followed by neutralization and distillation, gave pyrrolidine-2-^{14}C (V) (6) in aqueous solution. Extraction with a solution of ether and petroleum ether followed by addition of an ether–petroleum ether solution of picric acid to the extractions precipitated pyrrolidine-2-^{14}C picrate.

The synthetic procedures reported in the literature were modified for preparing the labeled compounds. These modifications were necessary for ease in handling the small amounts of labeled materials and for obtaining maximum yields. Intermediate products were not isolated in certain reaction steps.

Pyrrolidine picrate was cleaved by aqueous lithium hydroxide (7). Distillation gave the free base in an ether–petroleum ether solution. The cleavage was proved by addition of an ethe solution of picric acid to the ether–petroleum et solution to obtain the starting material.

EXPERIMENTAL

Melting and boiling points are uncorrected. duced pressure refers to the use of a water aspira (8–20 mm.). Petroleum ether refers to the fract

boiling between 35–65° Fractional distillations were performed with a vacuum jacketed Vigreaux column.

Method *A*

Pyrrolidine-2-^{14}C picrate was prepared starting with potassium cyanide-^{14}C and I. The latter compound was prepared from the corresponding chloride (VII) in 62.7% yield (8). The chloride in turn was synthesized from 3-methoxy-1-propanol in 83.9% yield (9), and the alcohol was prepared from 1,3-propanediol in 64.8% yield (10).

4 - Methoxybutyronitrile - 1 - ^{14}C (II)—A solution containing 16.2 mg. (0.25 mmole, 0.123 mCi./mg.) of potassium cyanide-^{14}C (New England Nuclear Corp., Boston, Mass.), 1.61 Gm. (24.8 mmoles) of unlabeled potassium cyanide, and 4.75 Gm. (23.8 mmoles) of freshly distilled I in 50 ml. of methyl alcohol was refluxed for 30 hr. and cooled. The solvent was removed under reduced pressure, and the residue was washed portionwise with 100 ml. of ether. The washings were filtered by suction, combined, allowed to stand over anhydrous sodium thiosulfate for 12 hr., and decanted. The solvent was removed under reduced pressure, and the residue was distilled yielding 1.42 Gm. (57.4% based on potassium cyanide) of a colorless liquid boiling at 63–64° (10 mm.), n_D^{20} 1.4083; reported (11) b.p. 172–175° (Atm.).

Pyrrolidine-2-^{14}C Picrate (VI)—To 1.36 Gm. (35.9 mmoles) of lithium aluminum hydride in 50 ml. of anhydrous ether at 0–10° was added with stirring a solution containing 1.42 Gm. (14.3 mmoles) of II in 5 ml. of anhydrous ether. When the addition was complete (about 30 min.), two 2-ml. portions of anhydrous ether were added and stirring was continued for 2 hr. at 0–10°. To the mixture at 0–10° were added slowly with rapid stirring 30 drops of water, 23 drops of 20% sodium hydroxide, 5.0 ml. of water, and 20 ml. of ether. Stirring was continued for 30 min., the granular precipitate was filtered by suction, and washed portionwise with 100 ml. of ether, and the washings were combined with the filtrate.

The combined ethereal solution was saturated with hydrogen bromide and extracted with five 10-ml. portions of 10% hydrobromic acid. The extractions were combined and placed in a flask fitted with a fractionating column and adapter set for distillation. The solution was distilled under reduced pressure until about 30 ml. of liquid was removed. To the remaining volume was added 30 ml. of hydrobromic acid (d. 1.49), and the solution was distilled at atmospheric pressure until about 20 ml. of liquid was removed. This procedure was repeated using four 10-ml. portions of hydrobromic acid. The residual solution was then refluxed gently for 15 hr., and 20 ml. of liquid was removed by distillation under reduced pressure. The remaining volume was cooled to 0–10° and 15 ml. of 50% sodium hydroxide was added dropwise with stirring. When the addition was complete, the solution was heated slowly, and the fraction distilling below 95° was collected in a 25-ml. flask immersed in an acetone–dry ice bath and containing 1 Gm. of anhydrous sodium carbonate and 10 ml. of an ether–petroleum ether solution (4:1).

This solution was filtered by suction into a 500-ml. flask. The drying agent was washed portionwise with 100 ml. of an ether–petroleum ether solution (4:1), and the washings were combined with the filtrate. To the combined solution was added, through a filter and with stirring, a solution containing 3.29 Gm. (14.4 mmoles) of picric acid (N.F. grade) in 250 ml. of anhydrous ether. When the addition was complete, the mixture was stirred for 15 min., and the precipitate was filtered by suction. Recrystallization of the pale yellow colored, light solid two times with ethyl propionate (b.p. 98–100°) and *n*-heptane (b.p. 97–98°) yielded 1.41 Gm. (18.8% based on potassium cyanide) of fine, yellow colored needles melting at 113–114°. [Reported (6) m.p. 113°.] The melting point did not change upon further recrystallization of a small sample.

Method *B*

Pyrrolidine-2-^{14}C picrate was prepared starting with barium carbonate-^{14}C and the Grignard reagent of VII.

4 - Methoxy - 1 - butanol - 1 - ^{14}C (IX)—The procedure of Dauben *et al.* (4) for preparing carboxylic acids was followed for preparing 4-methoxybutanoic-1-^{14}C acid (VIII).

Carbonation of 25.8 mmoles of the Grignard reagent of VII, prepared from 4.13 Gm. (0.17 mole) of magnesium and 16.3 Gm. (0.15 mole) of VII, was effected using 123.0 mg. (0.62 mmole, 0.129 mCi./mg.) of barium carbonate-^{14}C (Oak Ridge National Laboratories, Oak Ridge, Tenn.) and 4.50 Gm. (22.8 mmoles) of unlabeled barium carbonate. The reaction mixture was worked up in the usual way; however, the product was not purified.

The crude material was dissolved in 20 ml. of anhydrous ether and added with stirring to 1.03 Gm. (27.1 mmoles) of pulverized lithium aluminum hydride in 40 ml. of anhydrous ether. When the addition was complete (about 15 min.), two 5-ml. portions of anhydrous ether were added, and stirring was continued for 4 hr. at room temperature. The mixture was cooled to 0–10° and decomposed by adding, slowly with stirring, 23 drops of water, 18 drops of 20% sodium hydroxide, and 3.8 ml. of water. Stirring was continued for 15 min., and the granular precipitate was filtered and washed portionwise with 100 ml. of ether. The washings and filtrate were combined, dried over anhydrous potassium carbonate, and decanted. The solvent was removed under reduced pressure, and the residue was fractionated giving 2.04 Gm. (83.7% based on barium carbonate) of a colorless liquid boiling at 77–79° (10 mm.). [Reported (12) b.p. 63–64° (7 mm.).]

1,4-Dibromobutane-1-^{14}C (X)—Hydrogen bromide was bubbled through a solution consisting of 2.04 Gm. (19.6 mmoles) of IX, 7.5 ml. of glacial acetic acid, and 7.5 ml. of water while the temperature was increased slowly to 95°. When the solution was saturated (about 1–1.5 hr.), it was heated for 15 hr. between 90–100°, cooled, and poured into 20 ml. of water. The organic layer was separated and the aqueous layer was extracted exhaustively with petroleum ether. The extractions and organic layer were combined and washed with 5 ml. of 20% sodium hydroxide followed by 10 ml. of water. The aqueous washings were extracted with two 10-ml. portions of petroleum ether. The extractions and organic solutions were combined, dried over anhydrous sodium sulfate, and

decanted. The solvent was removed under reduced pressure, and the residue was distilled. There was obtained 3.47 Gm. (68.6% based on barium carbonate) of a colorless liquid boiling at 83–85° (14 mm.). [Reported (5) b.p. 85° (15 mm.).]

N-p-Toluenesulfonylpyrrolidine-2-^{14}C (XI)—A mixture consisting of 3.47 Gm. (16.1 mmoles) of X, 2.75 Gm. (16.1 mmoles) of *p*-toluenesulfonamide, and 9 ml. of ethyl alcohol was heated with stirring until a clear solution resulted. A solution containing 3.3 ml. of 58% potassium hydroxide in 6.8 ml. of ethyl alcohol (95%) was then added portionwise with stirring over a 9–10-hr. period. When the addition was complete, the mixture was refluxed for 20 hr. and cooled. The alcohol was removed by distillation at atmospheric pressure, and 10 ml. of water was added to the residue. The mixture was poured while still hot into a 250-ml. flask, cooled, and extracted exhaustively with ether. The extractions were combined, and the solvent was allowed to evaporate. The residue was warmed for 20 min. with 15 ml. of 15% sodium hydroxide, filtered by suction, and washed with water. This process was repeated using 10 ml. of 15% sodium hydroxide. The residue was then allowed to dry, washed with 25 ml. of ice-cold ligroin (b.p. 100–115°), allowed to dry, and sublimed under reduced pressure (0.4 mm.). There was obtained 2.78 Gm. (52.7% based on barium carbonate) of a white crystalline powder melting at 120–121°. [Reported (6) m.p. 123°.]

Pyrrolidine-2-^{14}C Picrate (VI)—A mixture consisting of 2.78 Gm. (12.4 mmoles) of XI and 15 ml. of hydrochloric acid (d. 1.19) was heated in a Pyrex bomb tube (19 × 25 × 400 mm.) for 15 hr. between 170–180°. The mixture was then cooled slowly and frozen in an acetone–dry ice bath. The tube was opened, the contents were allowed to liquefy, and 10 ml. of water was added. The organic layer was separated, and the aqueous layer was extracted with three 10-ml. portions of petroleum ether. The extractions and organic layer were combined and washed with two 5-ml. portions of water, and the washings were added to the aqueous layer. Approximately 15–20 ml. of the combined aqueous solution was removed by distillation at atmospheric pressure. The remaining volume was cooled to 0–10°, and 10 ml. of 40% sodium hydroxide was added with stirring. The mixture was distilled at atmospheric pressure until crystals began to form in the distilling flask. The distillate was then collected in a 100-ml. flask immersed in an acetone–dry ice bath and containing 5 Gm. of potassium hydroxide and 5 Gm. of sodium chloride. The distillate was allowed to liquefy and was extracted exhaustively with an ether–petroleum ether solution (4:1). The extractions were combined, dried over anhydrous potassium carbonate, and filtered by suction into a 500-ml. flask containing a magnetic stirring bar. The drying agent was washed portionwise with 100 ml. of an ether–petroleum ether solution (4:1). The washings were combined with the filtrate.

To the ether–petroleum ether extractions was added, through a filter and with stirring, a solution containing 3.27 Gm. (14.3 mmoles) of picric acid in 230 ml. of an ether–petroleum ether solution (9:1). When the addition was complete the mixture was stirred for 15 min., and the precipitate was filtered by suction. Recrystallization of the pale yellow-colored, light solid once with ethyl propionate and *n*-heptane yielded 2.69 Gm. (38.3% based on barium carbonate) of fine, yellow colored needles melting at 113–114°. [Reported (6) m.p. 113°.] The melting point did not change upon further recrystallization of a small sample.

Cleavage of Pyrrolidine Picrate—Pyrrolidine picrate, 1.50 Gm. (5.0 mmoles), was cleaved by the method of Burger (7). The free base was recovered in 68.7% yield as the picrate salt by the procedure described above for preparing the picrate salt.

Radioactivity Determinations—The specific activity of pyrrolidine-2-^{14}C picrate obtained by methods *A* and *B* was determined using a Tri-Carb liquid scintillation spectrometer. The XDC liquid scintillator (13) was used. Counting efficiency was determined using a benzoic-^{14}C acid standard. The specific activities of the products from methods *A* and *B* were 0.203 μCi./mg. and 1.75 μCi./mg., respectively. These specific activities did not change upon further recrystallization.

SUMMARY

Pyrrolidine-2-^{14}C was prepared by two different methods for the purpose of evaluating a suitable isotopic synthesis. Both methods were satisfactory. Method *B* is better than method *A* with respect to chemical yield (38.3% *versus* 18.8%). In addition, method *B* is more economical. Method *A*, however, is less time consuming.

Hydrogenation of 1,1-Diphenyl-4-dimethylamino-2-butyn-1-ol to 1,1-Diphenyl-4-dimethylamino-2-buten-1-ol with a Modified Lindlar Catalyst

By MORRIS FREIFELDER

The selective reduction of 1,1,-diphenyl-4-dimethylamino-2-butyn-1-ol to 1,1-diphenyl-4-dimethylamino-2-buten-1-ol is described using a modified Lindlar catalyst.

THERE ARE many reports in the literature which claim that selective reduction of acetylenic compounds to the corresponding olefins can be achieved by the use of palladium catalyst. Ott and Schroter (1), for example, obtained selectivity with palladium on carbon catalyst. A better method of accomplishing this is to carry out the hydrogenation in the presence of a lead-poisoned palladium catalyst such as the one described by Lindlar (2). However, such a catalyst at times may be inhibited too strongly by the amount of lead present. This point was well illustrated in an attempt in this laboratory to convert 1,1-diphenyl-4-dimethylamino-2-butyn-1-ol (I) to the corresponding 2-buten-1-ol (II).

The hydrogenation of I with commercial palladium on carbon yielded a mixture of products which consisted of over 50% of recovered I, 34% of II, and about 12% of the saturated compound III. When the author used Lindlar catalyst prepared according to the described directions (2), reduction was slow and incomplete. However, when half the amount of lead acetate was added to poison palladium on calcium carbonate during its preparation successful reduction took place.

EXPERIMENTAL[1]

Compound III was prepared as a standard for comparison with some of the reduction products of I.

α-(3-Dimethylaminopropyl)benzhydrol (III)—A solution of 2.65 Gm. (0.01 mole) of 1,1-diphenyl-4-dimethylamino-2-butyn-1-ol (I)[2,3] in 75 ml. of absolute ethyl alcohol was hydrogenated in the presence of 0.03 Gm. of platinum oxide under 2 Atm. pressure. Uptake was complete in about 30 min. After filtration from the catalyst the solution was concentrated to dryness and 2.3 Gm. (85%) of III was obtained, m.p. 118–119°, after recrystallization from hexane; hydrochloride salt, m.p. 197°.[3,4]

Anal.—Calcd. for $C_{18}H_{23}NO$: C, 80.25; H, 8.61; N, 5.20. Found: C, 80.08; H, 8.76; N, 5.14.

1,1-Diphenyl-4-dimethylamino-2-buten-1-ol (II)—A solution of 2.65 Gm. (0.01 mole) of I in 50 ml. of absolute alcohol was hydrogenated in the presence of 0.27 Gm. of Lindlar catalyst prepared as described (2) but modified by the addition of 50% of the amount of lead acetate used in its preparation. The reaction, conducted at 1.25 Atm. pressure, was complete in about 1 hr. After filtration from the catalyst, concentration of the solution, and recrystallization of the residue from hexane, 1.6 Gm. (60%) was obtained, m.p. 93–94° (the crude product melted at 88–91°; yield, 79%).

Anal.—Calcd. for $C_{18}H_{21}NO$: C, 80.83; H, 7.91; N, 5.24; O, 6.02. Found: C, 81.01; H, 7.86; N, 5.31; O, 6.03.

A hydrochloride salt of II was prepared. It melted at 177–178°. Mixed melting points with samples of the hydrochloride of III were greatly depressed.

Hydrogenation of I with Lindlar Catalyst—When the reduction of 2.65 Gm. of I in ethyl alcohol was carried out in the presence of 0.27 Gm. of Lindlar catalyst, prepared in the exact manner as described (2), hydrogen uptake was 12% in 3 hr. Warming produced little additional uptake. Filtration and addition of 0.54 Gm. of Lindlar catalyst and warming induced further reaction in 3 hr. However, uptake stopped of its own accord at about 35% of 1 mole equivalent.

Hydrogenation of I with Palladium on Carbon—The hydrogenation of 0.01 mole of I in alcohol was carried out in the presence of 0.05 Gm. of 5% palladium on carbon and under slight hydrogen pressure, about 0.7 Atm. The low catalyst ratio was resorted to in an effort to keep hydrogen uptake from proceeding beyond 1 mole equivalent. The amount of hydrogen present was only 0.0125 mole, also to prevent overhydrogenation. Uptake was complete in 1 hr. After removal of catalyst, the filtrate was concentrated to dryness. The residual solid was treated with anhydrous ether. The insoluble portion melted between 130–140°. It was shown by infrared examination to be identical to I. The residue, obtained by concentration of the ether filtrate, was recrystallized from pentane. The first crop, 0.3 Gm., melted at 116–120°. It appeared to be a mixture of II and III. Further concentration of the filtrate gave 0.9 Gm. of material melting at 90°. On conversion to the hydrochloride salt, it melted at 166–170°. On recrystallization from alcohol or dry ether the melting point rose to 171–172°. It was odd that when mixed with the hydrochloride salt of III the melting point dropped only to 170°. Nevertheless, on treatment of the salt with aqueous ammonia the base melted at 93–94°, as did the analytical sample of II obtained from the reduction of I with the modified Lindlar catalyst. Elemental analysis of the base, however, showed low carbon, but higher hydrogen values to suggest that it was contaminated with III.

Examination of Structural Effect on Thin-Layer Chromatographic Multiple Spot Formation of Sympathomimetic Amines in the Presence of Hydrochloric Acid

By N. H. CHOULIS

From a number of solutions of sympathomimetic amines in (*a*) water or (*b*) 10 *N* hydrochloric acid, chromatographed on thin layer of alumina, cellulose, or silica gel using a water–hydrochloric acid–phenol solvent system, only two produced multiple spots when the solvent system and an amine solution in excess hydrochloric acid, on cellulose layers, were used. The appearance of multiple spots does not depend upon the chemical structure of the compounds used, since the phenomenon was not reproduced when alumina or silica gel layers were used. The combination of adsorption and partition forces, the presence of the carboxyl groups in prepared cellulose, and the continuity of the thin layer are the main factors leading to the formation of multiple spots.

THE PHENOMENON of multiple spot formation of sympathomimetic amines when paper or cellulose thin layers are used has often been reported. Shepherd and West (1) observed that adrenaline, liberated from tissues using trichloroacetic acid, gave two spots when chromatographed in various solvent systems; they suggested that the multiple spot formation is due to the presence of trichloroacetic acid.

West (2) also observed double spots with trichloroacetic acid and tryptamine derivatives of sympathomimetic amines, and later Beckett *et al.* (3, 4) showed that the spot deformation and multiplication occurs with many bases in the presence of many diverse acids. Robinson and Shepherd (5) considered that the formation of the additional amine spot which was obtained in the presence of trichloroacetic acid is assisted by the formation of loose complexes between the bases, acting as electron donors, and the trichloroacetic acid, acting as electron acceptor by virtue of the marked electronegativity of the three chlorine atoms.

Roberts (6) also observed the phenomenon of multiple spot formation in an attempt to examine some factors which were affecting the R_f values of sympathomimetic amines, but on paper chromatography only. It was found that hydrochloric acid present in the developing solvent converted some of the norepinephrine acid tartrate to norepinephrine hydrochloride. The presence or absence of multiple spots, according to Roberts (7), depends upon the chemical structure of each amine.

The application of thin-layer chromatography for the examination of these phenomena (8–10) indicated that, just as in paper chromatography, it is possible to obtain two amine spots of an amine salt (or pure amine in the presence of one or more equivalents of acid) when a neutral or acidic solvent system is used in thin-layer chromatography involving cellulose as the thin layer.

EXPERIMENTAL

Materials—The amines used were: amphetamine hydrochloride, norepinephrine hydrochloride, normetanephrine hydrochloride, metanephrine hydrochloride, dopamine, ephedrine hydrochloride, isopropylarterenol hydrochloride, nordefrin hydrochloride, dopa, epinephrine, and phenylephrine hydrochloride.

Developing Systems—(*a*) Phenol containing 15% v/v of 0.1 *N* hydrochloric acid in water. (*b*) *n*-Butanol–acetic acid–water (4:1:5 v/v); the liquids were mixed together, left aside overnight, separated, and the organic layer was used.

Detection Methods—The spots were detected using either (*a*) a solution of 0.6 Gm. of potassium ferrocyanide and 0.5 Gm. of sodium hydroxide in 100 ml. of water or (*b*) ninhydrin in butanol (0.2% w/v) and heating the chromatograms at 100° for 3 min.

Thin-Layer Plates—All plates used were 20 × 20 cm.

Using MN 300 G cellulose powder (Machery, Nagel and Co.), Silica Gel G (Merck), and aluminum oxide G (Merck), plates were prepared according to Stahl (11).

The plates were kept in a desiccator using calcium chloride and reactivated at 100° for 5 min. before use.

General Method—The amines, 0.1-μl. quantities, were chromatographed on alumina, cellulose, or silica gel plates from freshly prepared solutions (10 mg./ml.) in distilled water or 10 *N* hydrochloric acid. The solutions were subjected to further chromatographic development at intervals of 1 day, 2 days, 1 week, 3, 6, and 8 weeks.

All chromatograms were carried out at room temperature (22–24°) and until the solvent front

TABLE I—RESULTS USING CELLULOSE THIN-LAYER PLATES

Amines	R_f Values[a] Freshly Prepared Soln.	Aged Soln.
Amphetamine HCl	84 ± 0.05	85 ± 0.05
Normetanephrine HCl	67 ± 0.05	66 ± 0.05
Metanephrine HCl	80 ± 0.03	79 ± 0.05

[a] R_f values and number of spots of various sympathomimetic amines in 10 *N* hydrochloric acid solution, when chromatographed in water–hydrochloric acid–phenol solvent system.

Received January 6, 1967, from the School of Pharmacy, Texas Southern University, Houston, TX 77004
Accepted for publication March 5, 1967.

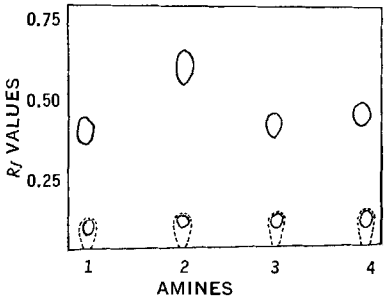

Fig. 1—TLC of certain amines freshly prepared in 10 N *HCl, on cellulose, when* n*-butanol–acetic acid–water solvent system is used. Continuous line indicates amines. Dotted line indicates acid. Key: 1, arterenol HCl; 2, isopropylarterenol HCl; 3, dopa; 4, epinephrine.*

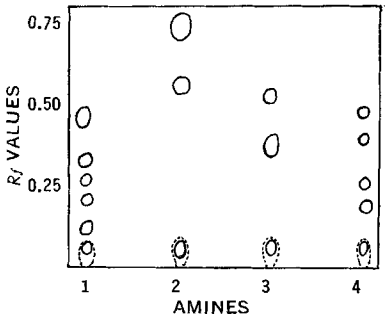

Fig. 2—TLC of certain amines as aged solutions in 10 N *HCl, on cellulose, when* n*-butanol–acetic acid–water solvent system is used. Continuous line indicates amines. Dotted line indicates acid. Key: 1, arterenol HCl; 2, isopropylarterenol HCl; 3, dopa; 4, epinephrine.*

was advanced 10 cm. (65 to 75 min.). The chromatoplates were removed from the solvent, air dried, and the detecting reagents were used to locate the spots.

The R_f values were measured from the center of the spots.

RESULTS

Using silica gel thin-layer plates, freshly prepared aqueous solutions of all amines used produced one spot. The spots, with the exception of arterenol (R_f value 0.75) and dopa (R_f value 0.81), were moved with the solvent front. A similar pattern was observed for the same solutions when chromatographed in intervals of up to an 8-week period, with the exception of dopa which gave an elongated spot, when an 8-week-old solution was chromatographed.

In the presence of 10 *N* hydrochloric acid, the amine spots were completely separated from the acid spots and moved with the solvent front, with the exception of arterenol and dopa, where the spots were moved faster (about 0.8 cm.) than those of the free amines. Hydrochloric acid, in all cases, gave elongated spots, having an R_f value of 0.53 ± 0.03.

However, when an 8-week-old solution was chromatographed, only dopa gave an elongated amine spot having the same R_f value as that of the free base.

In all cases where alumina thin-layer plates were employed, no movement of the amine spots was observed.

The results when cellulose thin-layer plates were used are summarized in Table I.

These results indicated that only arterenol and epinephrine appeared to produce a second spot when the 10 *N* hydrochloric acid solution was used. The second spot was observed in a freshly prepared as well as in an aged solution.

Using *n*-butanol–acetic acid–water solvent system and the cellulose thin layer, arterenol, isopropylarterenol, dopa, and epinephrine gave two discrete spots, when a fresh solution of the amines in 10 *N* hydrochloric acid was chromatographed (Fig. 1). However, when an 8-week-old solution of the amines in 10 *N* hydrochloric acid was used, isopropylarterenol and dopa gave three spots, while epinephrine gave five; six spots were observed during the development of arterenol (Fig. 2).

On alumina or silica gel thin layers and the above solvent system, only elongated spots were detected.

DISCUSSION

From the results obtained, it is noted that when the water–hydrochloric acid–phenol solvent system and alumina thin layers were used, only one spot of the utilized amines was always produced in the presence of 10 *N* hydrochloric acid. The amine spots remained at the starting line, which indicates that the spots were unaffected by the presence of even an excess of acid.

In thin-layer chromatograms with alumina, adsorption forces are operating exclusively.

The results, using silica gel thin layers and the same solvent system as above, showed that the amine spots moved faster than when alumina layers were used, and that most of them followed the solvent front. However, single spots of the amines are obtained, with the exception of dopa, which in an 8-week-old solution, either in water or 10 *N* hydrochloric acid, gave an elongated spot.

With silica gel thin layers, partition effect will in general be more important than adsorption forces.

In a thin layer of cellulose, both partition and adsorption forces exist and their relative role depends upon the conditions (8–10).

Since the added acid has a negligible effect on the movement of the amines on alumina, the effect of single adsorption forces does not account for the multiple spots of amines in cellulose (arterenol and epinephrine). On silica gel plates, the added acid has an effect on the movement of the amines and it seems probable that the added acid, as it moves along the plate, has a substantial effect on the partition of the amines between the mobile solvent and the stationary phase, but two spots were not produced on silica gel layers.

However, using the *n*-butanol–acetic acid–water solvent system and cellulose thin layers, most of the amines chromatographed developed a second spot when in a freshly prepared 10 *N* hydrochloric acid solution; moreover, the number of the spots was increased with the age of the acid solution, presumably due to the oxidation products of the amines which were developed during the prolonged presence of the acid of the solution, leading to the formation of the additional spots.

It is suggested that the formation of double spots does not depend upon the structure of the amine,

since amines giving two spots in one acidic solvent (*i.e.*, *n*-butanol–acetic acid–water) give only one spot in another (*i.e.*, water–hydrochloric acid–phenol). Moreover, amines which appeared to give six or more spots when chromatographed from freshly prepared solutions in 10 *N* hydrochloric acid on cellulose paper (7) gave only two spots when chromatographed from the same freshly prepared solution on cellulose thin layer. In the former, a gradual decrease, while in the latter, a gradual increase in the number of the spots with the age of the solution was observed.

It is therefore concluded that the formation of two amine spots, when cellulose thin layers are used, results from the following factors: (*a*) a continuity of adsorption forces along the direction of the mobile solvent on cellulose thin layers (9, 10), (*b*) a combination of adsorption and partition forces, and (*c*) the presence of the carboxyl groups in the prepared cellulose. That the presence of the carboxyl groups in the prepared cellulose is leading to the formation of double spots, has been previously discussed (10) and therefore further discussion here is unnecessary.

This investigation shows that the presence of more than one spot in cellulose chromatograms, using extracted biological material, does not necessarily indicate that two or more amines are present.

Modified Synthesis of *dl-N*-Norarmepavine and *dl*-Armepavine

By JOSEPH SAM and A. J. BEJ

The synthesis of *dl-N*-norarmepavine and *dl*-armepavine, utilizing the carboethoxy protecting group, is described.

THE POTENTIAL of *dl*-1-(4-hydroxybenzyl)-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline (V*a*) as an intermediate to medicinal agents prompted an investigation of its synthesis. The levorotatory base (V*a*) was first isolated by Kupchan and coworkers (1, 2) from *Nelumbo lutea* and named (−)-*N*-norarmepavine. The alkaloid subsequently was isolated by Tomita, Yang, and Lu (3), and by Yang (4).

A total synthesis of V*a* *via* the Bischler-Napieralski reaction has been reported by Yamaguchi and Nakano (5). The benzyl group was utilized for the protection of the phenolic hydroxyl group. This report describes the use of the carboethoxy protecting group in the preparation of V*a* and V*b*.

The requisite amide (III*b*) for the Bischler-Napieralski reaction was prepared either from III*a* or by the condensation of I with the acid chloride (6) of II*b*. The cyclization of III*b* to IV*a* was accomplished with phosphorus oxychloride. The low pressure reduction of IV*a* followed by hydrolysis gave V*a*. Alternately, V*a* was prepared by the hydrolysis of IV*a* to IV*b*, followed by sodium borohydride reduction. It was observed also that sodium borohydride converts IV*a* directly to V*a*. Treatment of V*a* with formic acid and formaldehyde provided *dl*-armepavine (V*b*). Since V*a* was converted to *dl*-armepavine (V*b*), as described above, this sequence also comprises a total synthesis of the alkaloid (Scheme I.)

The nuclear magnetic resonance (NMR) spectrum of V*a* in deuteriochloroform showed six aromatic protons (τ = 3.0–3.4), two labile protons (τ = 5.4, by D_2O exchange), one tertiary proton (quadruplet centered at τ 5.85), and six methoxyl protons (broad doublet centered at τ 7.05), which is in good agreement with the reported NMR spectrum of (−)-*N*-norarmepavine (2).

Sufficient work has not been done to make a critical comparison of the various methods of protecting the phenolic hydroxyl group in the preparation of *dl-N*-norarmepavine. The use of sodium borohydride in the reduction of IV*a* with attendant hydrolysis of the carboethoxy group, however, provides a means of removing the protecting group under alkaline conditions.

EXPERIMENTAL[1]

N-β-(3,4-Dimethoxyphenethyl)-4-hydroxyphenylacetamide (IIIa)—A mixture of 3.6 Gm. (0.02 mole) of homoveratrylamine, 3.0 Gm. (0.02 mole) of *p*-hydroxyphenylacetic acid, 10 ml. of dry decalin, and 10 ml. of tetralin was refluxed at 180–185° for 8 hr. The solvent was decanted from the semisolid; the last traces of solvent were removed by steam distillation. The residual solid was washed successively with 10% sodium bicarbonate, water,

The shifts were measured on the τ-scale relative to the internal standard TMS (τ 10.0). Assignment of protons in a certain area is based on correct integral information from the NMR spectrum.

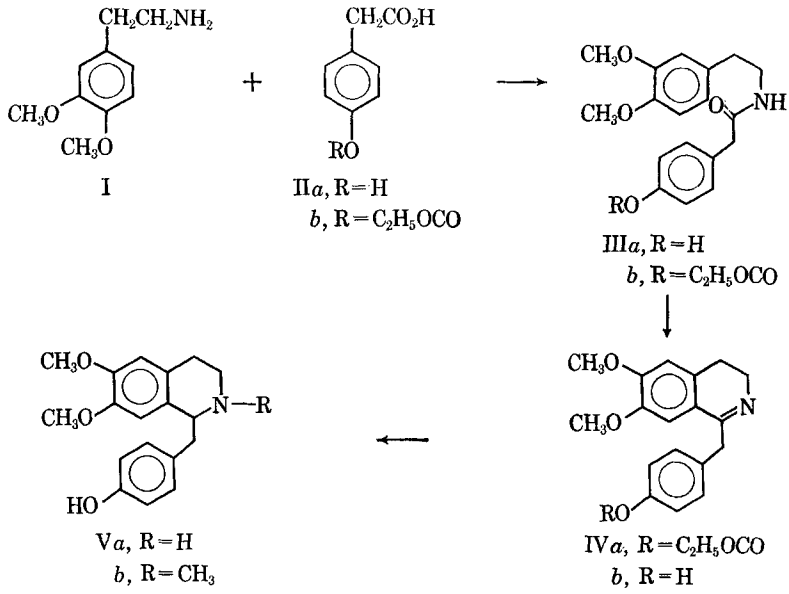

Scheme I

10% hydrochloric acid, and water. The recrystallization of the residual material from ethanol gave 5.0 Gm. (81%) of an amorphous solid, m.p. 153–155°. The infrared spectrum possessed an absorption peak at 6.1 μ characteristic of an amide function. The methoxy analog was prepared in the usual manner and recrystallized from ethanol, m.p. 123–124°. [Lit. (7) m.p. 123–125°).]

N-β-(3,4-Dimethoxyphenethyl)-4-ethoxycarbonyloxyphenylacetamide (IIIb)—*Method A*—A solution of 3.1 Gm. (0.01 mole) of *N*-β-(3,4-dimethoxyphenethyl)-4-hydroxyphenylacetamide (III*a*) in 45 ml. of 5% potassium hydroxide was treated slowly, with shaking, with 1.1 Gm. (0.01 mole) of ethyl chloroformate. The mixture was shaken for 15 min. and then filtered to remove the solid product. The filtrate again was treated with 1.1 Gm. (0.01 mole) of ethyl chloroformate as above. The combined solid product was washed with a copious amount of water and then recrystallized from a mixture of benzene and petroleum ether (30–60°). There was obtained 3 Gm. (81%) of feathery needles, m.p. 95–96°. The infrared spectrum possessed two carbonyl absorption peaks at 5.8 μ and 6.1 μ, characteristic of esters and amides, respectively.

Anal.—Calcd. for $C_{21}H_{25}NO_5$: C, 65.1; H, 6.5; N, 3.6. Found: C, 65.3; H, 6.5; N, 3.8.

Method B—A solution of 4-ethoxycarbonyloxyphenylacetyl chloride (6) [from 5 Gm. (0.022 mole) of the acid] in 15 ml. of tetraethylene glycol dimethyl ether was added dropwise at approximately 16° to a stirred mixture of 3.6 Gm. (0.02 mole) of homoveratrylamine, a solution of 2 Gm. of sodium hydroxide in 6 ml. of water, and 15 ml. of tetraethylene glycol dimethyl ether. During the mixing the temperature rose to about 30°. After the addition was complete (5 min.), the reaction mixture was poured into 100 ml. of cold water and adjusted to pH 10. The crude product was removed by filtration and washed with water. The recrystallization of the crude material from a mixture of benzene and petroleum ether (30–60°) gave 2.5 Gm. (31%) of product, m.p. 95–96°. A mixed melting point with the product obtained from method *A* showed no depression.

1-(4-Ethoxycarbonyloxybenzyl)-6,7-dimethoxy-3,4-dihydroisoquinoline Hydrochloride (IVa)—The method described by Finkelstein (6) was followed using 2.6 Gm. (0.007 mole) of *N*-β-(3,4-dimethoxyphenethyl)-4-ethoxycarbonyloxyphenylacetamide (III*b*), 30 ml. of dry toluene, and 1.5 Gm. (0.01 mole) of phosphorus oxychloride. The toluene was decanted from the reaction mixture and the unreacted phosphorus oxychloride was distilled under reduced pressure. The residual solid was recrystallized from ethanol to give 2.2 Gm. (76%) of product, m.p. 210–211°.

Anal.—Calcd. for $C_{21}H_{24}ClNO_5$: C, 62.1; H, 6.0; Cl, 8.7; N, 3.5. Found: C, 62.1; H, 6.1; Cl, 8.9 N, 3.4.

1-(4-Hydroxybenzyl)-6,7-dimethoxy-3,4-dihydroisoquinoline Hydrochloride (IVb)—Six grams (0.015 mole) of 1-(4-ethoxycarbonyloxybenzyl)-6,7-dimethoxy-3,4-dihydroisoquinoline hydrochloride (IV*a*) was heated on a steam bath with 70 ml. of 20% hydrochloric acid until evolution of carbon dioxide ceased (90 min.). The solvent was distilled under reduced pressure. The residual semisolid was treated with 200 ml. of dry benzene and distilled to remove the water. The residual solid (m.p. 195–200°, 4.7 Gm., 94%) was triturated with 30 ml. of acetone and recrystallized from methanol, m.p. 202.5–204°.

Anal.—Calcd. for $C_{18}H_{20}ClNO_3$: Cl, 10.6; N, 4.2. Found: Cl, 10.1; N, 3.9.

dl-1-(4-Hydroxybenzyl)-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline (dl-N-Norarmepavine) (Va)—*Method A*—A solution of 2.0 Gm. (0.005 mole) of 1-(4-ethoxycarbonyloxybenzyl)-6,7-dimethoxy-3,4-dihydroisoquinoline hydrochloride (IV*a*) in 50 ml. methanol was treated with 50 mg. of PtO_2 and hydrogenated at 25° for 1.7 hr. The product was isolated in the usual manner. The crude hydrogenation product was treated with 5 ml. of 15% hydrochloric acid and heated on a steam bath for 20 min. The acid solution was cooled to room

temperature and refrigerated for 10 hr. The hydrochloride (0.8 Gm., 50%, m.p. 194–196°) was removed by filtration and recrystallized twice from a mixture of methanol and ethyl acetate, m.p. 194–196°.

Anal.—Calcd. for $C_{18}H_{22}ClNO_3$: C, 64.4; H, 6.6; Cl, 10.5; N, 4.1. Found: C, 64.2; H, 6.6; Cl, 10.5; N, 4.3.

The free base was prepared in the usual manner and recrystallized from a mixture of ethyl acetate and *n*-hexane, m.p. 99–101°, softens around 94°. [Lit. (5) m.p. 95–96°.] The oxalate was prepared in the usual manner and recrystallized from methanol, m.p. 214–215°. [Lit. (5) m.p. 202–204°.]

Method B—A mixture of 1.6 Gm. (0.005 mole of 1 - (4 - hydroxybenzyl) - 6,7 - dimethoxy - 3,4 - dihydroisoquinoline hydrochloride (IV*b*), 50 ml. of methanol, and 3.5 Gm. of sodium borohydride was stirred for 30 min. The reaction mixture was treated with 2 ml. of water and refluxed with stirring on a steam bath for 1.7 hr. Most of the methanol was distilled under reduced pressure. The residue was poured onto a mixture of crushed ice and water (250 Gm.). The mixture was adjusted to pH 8 and extracted with three 50-ml. portions of ether. The ether extract was dried over anhydrous sodium sulfate. The evaporation of the ether left 1 Gm. (62%) of an oil. The hydrochoride was prepared in the usual manner and recrystallized from a mixture of methanol and ethyl acetate, m.p. 194–196° A mixed melting point with a sample prepared by method *A* showed no depression. The oil was crystallized from a mixture of ethyl acetate and hexane or from acetone to give 0.5 Gm. (31%) of an amorphous solid, m.p. 99–101°, softens around 94°. The infrared spectrum in chloroform of this sample was identical with the infrared spectrum of the sample obtained by method *A*. The oxalate was prepared in the usual manner and recrystallized from methanol, m.p. 214–215°.

Method C—A solution of 4.0 Gm. (0.01 mole) of 1 - (4 - ethoxycarbonyloxybenzyl) - 6,7 - dimethoxy-3,4-dihydroisoquinoline hydrochloride (IV*a*) in 100 ml. of methanol was reduced with 10 Gm. of sodium borohydride and worked up as described in method *B*. The free base (1 Gm., 34%), the hydrochloride, and the oxalate were identical (mixed melting point showed no depression) with the samples obtained by methods *A* and *B*.

dl-Armepavine (Vb)—A mixture of 0.5 Gm. (0.0017 mole) of *dl*-1-(4-hydroxybenzyl)-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline (V*a*), 6 ml. of 98% formic acid, and 6 ml. of 40% formalin was heated under reflux for 6 hr. The mixture was diluted with water, adjusted to pH 9, and extracted three times with 50-ml. portions of chloroform. The chloroform extract was washed with water and dried over anhydrous sodium sulfate. The distillation of the chloroform under reduced pressure left an oil which was chromatographed on a column of Woelm neutral alumina (activity I) with acetone as the eluent. From the acetone eluent was obtained an oil which was crystallized from a mixture of ethyl acetate and hexane to yield 0.15 Gm. (29%) of *dl*-armepavine, m.p. 158.5–160.5°. [Lit. (8, 9) m.p. 159–161°.]

Ursolic Acid in *Retanilla ephedra*

By MARIO SILVA

Ursolic acid was isolated from *Retanilla ephedra*.

In connection with a study on sapogenins and alkaloids (1–8) of certain typical Chilean species now under way in this laboratory, it appeared of interest to study *Retanilla ephedra* (Vent.) Brongn., Chilean *Rhamnaceae*, in order to study the sapogenin described by Moyano (9) and to elucidate the presence or absence of alkaloids.

This is a chemical study of the petroleum ether and alcohol-soluble fractions of dried and pulverized plant. The petroleum ether-soluble fraction yielded two products, an alcohol and an acidic compound. The defatted plant material was dried and then extracted with alcohol. This extract gave a water-soluble glycosidic fraction. Acid hydrolysis of this material yielded an acidic sapogenin, identical with the acidic compound isolated from the petroleum ether fraction. This acid was identified as ursolic acid and further characterized through its acetate, methyl ester, and methyl ester acetate. The isolation of an alkaloid present in this water-soluble fraction is now in progress.

Received January 9, 1967, from the Laboratorio de Fitoquímica, Departamento de Botánica, Instituto Central de Biología, Universidad de Concepción, Concepción, Chile.
Accepted for publication March 27, 1967.

EXPERIMENTAL[1]

Petroleum Ether Extract—Stems of *R. ephedra* collected in February 1962 near Buchupureo

[1] Melting points (uncorrected) were determined on a Kofler block. Rotations wereme asured at 20°. The ultraviolet spectrum was recorded in solution in absolute ethanol on a SP 700 spectrophotometer. Infrared spectra were recorded on a Perkin Elmer 137 spectrophotometer.

(Maule) were dried at 80–90°. A 1550-Gm. quantity of dried and ground plant was extracted in a Soxhlet extractor with petroleum ether (b.p. 65–75°) to exhaustion. This dark solution was concentrated to yield 50 Gm. of a dark green product. This product was refluxed for 1 hr. in a 5% sodium hydroxide ethanolic solution. The neutral product was found to be a polymethylenic alcohol of low melting point. The acidic fraction yielded, after several recrystallizations, 100 mg. of a compound, m.p. 273–275°; $[\alpha]_D^{20°}$ + 61° (pyridine c 0.45).

Alcoholic Extract—The defatted plant material was dried and the ethanol-soluble constituents were extracted. This dark solution was concentrated to yield 415 Gm. of a water-soluble product. This product was treated with 2.5 *N* ethanolic hydrochloric acid. The mixture was then refluxed for 5 hr. and poured into ice water. After 48 hr. the precipitate was collected on a filter and washed with water, yielding 215 Gm. of a light green mass. The crude ursolic acid was partially purified by continuous extraction, first with petroleum ether (b.p. 65–75°), then with a mixture of petroleum ether–benzene and, finally, with benzene. After recrystallizations of the product extracted with the mixture petroleum ether–benzene and benzene, 450 mg. of an acid, m.p. 267–279°, was obtained.

Ursolic Acid—Several recrystallizations of the previously obtained compound yielded ursolic acid, m.p. 281°; $[\alpha]_D^{20°}$ +61° (pyridine c 0.6), $\nu_{max.}^{KCl}$ 3350 and 1695 cm.$^{-1}$.

Ursolic Acid Acetate—The pure compound was obtained as needles after crystallization from methanol–chloroform, m.p. 281°.

Ursolic Acid Methyl Ester—This ester was prepared by diazomethane treatment of the acid in ethereal solution, crystallized from methanol–chloroform as colorless crystals, m.p. 170°; $\lambda_{max.}^{EtOH}$ 206 mμ ε 5000, $\nu_{max.}^{CHCl_3}$ 3410, 1754, and 1642 cm.$^{-1}$.

The melting point of this compound was undepressed upon admixture with an authentic specimen, m.p. 171°, and was found to be identical with the methyl ester of the acidic compound, m.p. 273–275°, previously isolated from the petroleum ether extract.

Ursolic Acid Methyl Ester Acetate—It was obtained as needles after crystallization from methanol–chloroform, m.p. 243–244°; $[\alpha]_D^{20°}$ +60° (chloroform c 0.48).

Synthesis and Basic Pharmacology of *N*-Substituted and *N,N'*-Disubstituted Allyl Barbiturates

By M. H. WEINSWIG, A. M. BURKMAN*, W. D. JONES, and E. J. ROWE

***N*-Substituted and *N,N'*-disubstituted allyl derivatives of barbital, phenobarbital, hexobarbital, and diallylbarbital have been synthesized by the use of a strongly basic anion-exchange resin. The barbiturate is first absorbed on the resin and the resin then agitated mechanically with an ethanol solution of benzyl chloride. None of the allyl barbiturates approached phenobarbital in terms of pharmacological potency.**

IN PREVIOUS reports (1, 2) a method was described for the synthesis of benzyl ethers of a variety of phenols and of 5,5-disubstituted barbiturates by the use of a strongly basic anion-exchange resin. The method involved the reaction of the phenolate or the barbiturate form of the resin with benzyl chloride. The synthesis of the *N*-allyl and the *N,N'*-diallyl barbiturate derivatives seemed feasible, using this method, since the allyl and the benzyl halides are believed equally reactive chemically. This report presents an analogous method for the synthesis of *N*-allyl and *N,N'*-diallyl derivatives of four 5,5-disubstituted barbituric acids (phenobarbital, barbital, hexobarbital, and diallylbarbital) and the synthesis of 5,5-diallylbarbituric acid.

SYNTHESIS

The synthesis of these derivatives involved the reaction of the barbiturate form of a strongly basic anion-exchange resin with allyl bromide. The resin employed was a polystyrene polymer containing reactive quaternary ammonium groups. Proceeding at room temperature, a mixture of *N*-allyl and *N,N'*-diallyl derivatives was obtained from the reaction. Separation of the derivatives was effected by taking advantage of the solubility of the *N*-allyl derivative in dilute alkali. Table I presents the analytical data for allyl derivatives of barbituric acid, phenobarbital (5-ethyl-5-phenyl barbituric acid), barbital (5,5-diethyl barbituric acid), and hexobarbital (*N*-methyl-5-methyl-5-cyclohexenyl barbituric acid) prepared by the use of a strongly basic anion-exchange resin. The *N,N'*-diallyl derivative is the main product when an equivalency of the resin in the OH form is used with the barbiturate form and the quantity of the allyl bromide is doubled plus 10% excess.

Resin Preparation—Synthetic ion-exchange resin made from styrene-divinylbenzene copolymer[1] supplied commercially in the chloride form (20–50

Synthesis and Basic Pharmacology of *N*-Substituted and *N,N'*-Disubstituted Allyl Barbiturates

By M. H. WEINSWIG, A. M. BURKMAN*, W. D. JONES, and E. J. ROWE

***N*-Substituted and *N,N'*-disubstituted allyl derivatives of barbital, phenobarbital, hexobarbital, and diallylbarbital have been synthesized by the use of a strongly basic anion-exchange resin. The barbiturate is first absorbed on the resin and the resin then agitated mechanically with an ethanol solution of benzyl chloride. None of the allyl barbiturates approached phenobarbital in terms of pharmacological potency.**

IN PREVIOUS reports (1, 2) a method was described for the synthesis of benzyl ethers of a variety of phenols and of 5,5-disubstituted barbiturates by the use of a strongly basic anion-exchange resin. The method involved the reaction of the phenolate or the barbiturate form of the resin with benzyl chloride. The synthesis of the *N*-allyl and the *N,N'*-diallyl barbiturate derivatives seemed feasible, using this method, since the allyl and the benzyl halides are believed equally reactive chemically. This report presents an analogous method for the synthesis of *N*-allyl and *N,N'*-diallyl derivatives of four 5,5-disubstituted barbituric acids (phenobarbital, barbital, hexobarbital, and diallylbarbital) and the synthesis of 5,5-diallylbarbituric acid.

SYNTHESIS

The synthesis of these derivatives involved the reaction of the barbiturate form of a strongly basic anion-exchange resin with allyl bromide. The resin employed was a polystyrene polymer containing reactive quaternary ammonium groups. Proceeding at room temperature, a mixture of *N*-allyl and *N,N'*-diallyl derivatives was obtained from the reaction. Separation of the derivatives was effected by taking advantage of the solubility of the *N*-allyl derivative in dilute alkali. Table I presents the analytical data for allyl derivatives of barbituric acid, phenobarbital (5-ethyl-5-phenyl barbituric acid), barbital (5,5-diethyl barbituric acid), and hexobarbital (*N*-methyl-5-methyl-5-cyclohexenyl barbituric acid) prepared by the use of a strongly basic anion-exchange resin. The *N,N'*-diallyl derivative is the main product when an equivalency of the resin in the OH form is used with the barbiturate form and the quantity of the allyl bromide is doubled plus 10% excess.

Resin Preparation—Synthetic ion-exchange resin made from styrene-divinylbenzene copolymer[1] supplied commercially in the chloride form (20–50

mesh), was converted to its hydroxyl form by the usual column technique with 5% aqueous sodium hydroxide (2, 3).

Absorption of the Barbiturate on the Resin—A general procedure was followed. The barbiturate as the sodium salt (0.05 mole) was dissolved in 300 ml. of distilled water and passed through a resin column 25 mm. in diameter. The resin was first rinsed with distilled water until the washings were neutral to phenolphthalein T.S., then with two 100-ml. portions of ethanol.

Synthesis of Allyl Barbiturates—A general procedure was followed for the synthesis of all allyl barbiturates. A description of the preparation of *N*-allyl and *N,N'*-diallylbarbital illustrates the procedure used.

N-Allylbarbital—A 4.1-ml. (0.041 mole) quantity of allyl bromide dissolved in 200 ml. of ethanol was added to the column containing the resin[1] (25 Gm.) upon which 7.0 Gm. (0.038 mole) of sodium barbital had been adsorbed. The mixture was then agitated for 48 hr. by rotating the column horizontally with an electric motor at 78 r.p.m. At the end of this period, the column was drained and the resin washed with three 75-ml. portions of ethanol. Evaporation of the eluate and washings left a yellow oily residue. The combined residue was dissolved in 30 ml. of ether and then extracted with 1 *N* sodium hydroxide solution. The alkaline aqueous portion, from which any *N,N'*-diallylbarbital was removed, was acidified with diluted hydrochloric acid and extracted with several portions of ether. The combined ether extractives were washed free of acid and evaporated to dryness. A crystalline residue was obtained which, when recrystallized from 50% methanol in water, melted at 80–81°. [Lit. (4) m.p. 80°.] The yield was 3.75 Gm. (47%).

Anal.—Calcd. for $C_{11}H_{20}N_2O_3$: C, 58.93; H, 7.14; N, 12.50. Found: C, 59.13; H, 7.40; N, 12.46.

N,N'-Diallylbarbital—A 6.6-ml. (0.066 mole) quantity of allyl bromide dissolved in 200 ml. of ethanol was added to the column containing the resin[1] (25 Gm.) upon which 6.18 Gm. (0.03 mole) of sodium barbital had been adsorbed. The mixture was agitated as described previously. At the end of this period, the column was drained and the resin washed with ethanol. The ethanolic solution was evaporated down to a yellow oily residue. The residue was washed with 1 *N* sodium hydroxide solution and extracted with several portions of ether. Evaporation of the ether extractives, first washed free of alkali, yielded *N,N'*-diallylbarbital which, when crystallized from 50% methanol in water, melted at 121°. [Lit. (4) b.p. 156–157°.] The yield was 2.65 Gm. (30%).

Anal.—Calcd. for $C_{14}H_{20}N_2O_3$: C, 63.64; H, 7.57; N, 10.60. Found: C, 63.71; H, 7.77; N, 10.95.

PHARMACOLOGY

Preparation—Each of the barbiturates was suspended, with the aid of a motorized Ten Broeck tissue homogenizer, in 25 ml. of distilled water containing 1% w/v of methylcellulose (1500 cps.). The resulting suspensions were diluted to 50 ml. with water yielding stock preparations containing 0.5% methylcellulose and 10^{-3} moles of barbiturate per ml. of suspension. Further dilutions were made, when necessary, with a 0.5% methylcellulose vehicle.

Animals—Male albino mice, 18–28 Gm., were employed as test subjects. They were selected from stock colonies of 200–300 animals and isolated 1–2 hr. prior to drug administration. Tests were conducted in rooms having an air temperature of 24–26°.

Standard—Phenobarbital was adopted as the reference standard against which the allyl barbiturates were compared.

Protocol—Mice were weighed, injected intra-

TABLE II—INFLUENCE OF ALLYL BARBITURATES ON THE RIGHTING REFLEX OF MALE MICE

Drug	Nominal Mol. Wt.	Dose mole/Kg.	Dose mg./Kg.	Incidence of R.R. Loss	Mean Onset Time, min.	Mean Duration, min.

		2×10^{-3}	576	0/8	...	...

[a] One animal.

peritoneally with the appropriate doses of barbiturate (maximum volume injected was 0.6 ml.), and placed in individual 4-L. glass observation chambers. The animals were observed continuously during the first 4-hr. postinjection and periodically during the next 20-hr. period for the appearance of behavioral symptoms characteristic of barbiturate medication, *e.g.*, prodromal excitation, sedation, loss of righting reflex.

Results—A summary of the results is presented in Table II. In terms of both subtle and gross evidence of CNS depression, none of the allyl barbiturates approached phenobarbital in potency. *N*-Allylphenobarbital, *N*-allylbarbital, and *N,N'*-diallylbarbital exhibited mild hypnotic action at doses below those necessary to influence the righting reflex. The first instances of righting reflex loss occurred at 3×10^{-4} mole/Kg. (phenobarbital), 5×10^{-4} mole/Kg. (*N*-allylphenobarbital), 7×10^{-4} mole/Kg. (*N*-allylbarbital), and 10^{-3} mole/Kg. (*N,N'*-diallylbarbital). The most active depressant among the allyl barbiturates was *N*-allylphenobarbital. *N,N'*-Diallylphenobarbital evoked only the mildest degree of sedation and doses up to 2×10^{-3} mole/Kg. failed to influence the righting reflex. *N*-Allylhexobarbital and tetraallylbarbituric acid were devoid of all obvious CNS actions at doses up to 2×10^{-3} mole/Kg.

The appearance of mild prodromal excitability characterized the initial response to several of the compounds. Phenobarbital induced the characteristic locomotor excitability in mice at doses of 5×10^{-4} mole/Kg. and higher. Similar but less intense effects were observed when 7×10^{-4} mole/Kg. of *N*-allylphenobarbital was administered. *N*-Allylbarbital induced a severe clonus of short duration in animals receiving doses above 7×10^{-4} mole/Kg. The remaining compounds evoked no evidence of CNS stimulation.

The ranking of depressant potencies of the allylbarbiturates is in good agreement with the ranking of acute LD_{50}'s reported by Kaku *et al.* (4). Gylys and Proctor (6) examined the anticonvulsant properties of *N*-allylbarbital and *N*-allylphenobarbital. They reported that *N*-allyl substitution on barbital increased anticonvulsant activity but decreased duration of action while *N*-allyl substitution on phenobarbital decreased anticonvulsant activity both in terms of intensity and duration. Doses of the two drugs at which activity was observed were in the range of 50–100 mg., concentrations too low to alter the righting reflex.

Diazoxide Blood Levels in Man

By S. SYMCHOWICZ, L. WINSTON, J. BLACK*, M. SMITH, B. CALESNICK, and I. I. A. TABACHNICK

Blood diazoxide levels were measured in six adult human males at various times after i.v. drug administration. On the basis of these results, the diazoxide half-life in blood was determined as 28.0 ± 8.3 hr. The presence of diazoxide in blood was verified by thin-layer chromatography (TLC) and by its U.V. spectrum. This communication describes a simple spectrophotometric quantitative method and a useful TLC method for determination of diazoxide in biological fluids.

DIAZOXIDE is a nondiuretic benzothiadiazine which was originally developed for the treatment of hypertension. Early observations showed that diazoxide produced hyperglycemia in animals and man (1–5) which limited its use as an antihypertensive agent in man (6–8). However, the hyperglycemic effect of diazoxide is being increasingly utilized for treatment of patients with severe hypoglycemia (9–16).

A relationship was shown (17) between diazoxide dosage forms, dissolution rates, and blood levels. This report presents data on blood half-life of diazoxide in man and describes the methods for diazoxide analysis in biological fluids.

MATERIALS AND METHODS

Diazoxide was given intravenously at 5 mg./Kg. to six young adult males (weighing between 66 and 88 Kg.) in good physical health with no known cardiovascular or renal disease, and no abnormal glucose tolerance curve or family history of diabetes. The sterile diazoxide solution contained the equivalent of 300 mg. of the drug in 20 ml. of water adjusted to pH 11.4 with NaOH. Blood samples were drawn at 0, 5, 15, 30, and 60 min. and 2, 4, 6, 12, 24, 48, and 72 hr. after injection of diazoxide which lasted 2 min. All morning samples were taken before breakfast. Strenuous physical activity was avoided and normal diet was maintained.

The diazoxide blood levels were determined quantitatively as follows: 1 ml. of distilled water and 2 ml. of whole blood were mixed vigorously in a 15-ml. glass-stoppered centrifuge tube for 1 min. with 4 ml. of ethyl acetate. After brief centrifugation (2–3 min. at 1,300 r.p.m., International centrifuge PR-2), 2.5 ml. of the organic phase was transferred to another centrifuge tube containing 2.5 ml. of 4% sodium carbonate solution. The contents of the tube were mixed thoroughly (1–2 min.) and after centrifugation, the clear, aqueous phase was transferred to a quartz cell (1 cm. light path). The absorbance was read at 280 mμ in a Beckman DU spectrophotometer. A 4% sodium carbonate solution was used to set the instrument to zero absorbance. All samples were corrected for individual "blank" readings (zero hour sample).

The diazoxide blood concentration was determined from a standard curve. A linear relationship was obtained with diazoxide standards over a wide range of drug concentration (1–25 mcg./ml.). Studies with blood, plasma, and water, by our procedure, yielded on the average about 80% recovery of the drug.

Thin-layer chromatography was employed as an additional tool for identification of diazoxide and for its semiquantitative estimation. One to two milliliters of plasma was extracted with 4 ml. of ethyl acetate. The organic solvent was concentrated to a small volume (under nitrogen or on a rotating evaporator) and then applied quantitatively to Silica Gel F 254 precoated plates (Brinkmann Co.) which were developed with benzene–methanol (1:4) for 30–45 min. Diazoxide was visualized as a purple spot on the chromatographic plates with a short-wave U.V. lamp.

The half-life of diazoxide was estimated from the mathematical function $\log \hat{y} = a + bt$, where $\hat{y}$ = drug concentration (mcg./ml.), t = time in hours, a = y intercept (value of y when $t = 0$), and b = slope.

The function was fitted by the method of "least squares" (18).

RESULTS AND DISCUSSION

Table I summarizes the results obtained by spectrophotometric analysis of diazoxide blood levels at various time intervals. The half-lives were estimated from the function $\log y = a + bt$ (see *Methods*) and they range from 20.9 hr. (subject 1) to 34.7 hr. (subject 2). All slopes (b) are significantly different from 0 ($p < 0.01$, Student t test).

The mean blood half-life in man was estimated after testing the homogeneity of the regression lines (derived from Table I) by analysis of covariance. A weighted regression estimate for diazoxide is given by the function; $\log \hat{y} = 1.0483 - 0.0110t$ (Fig. 1) from which the half-life was derived as 28.0 + 8.3 hr. (95% confidence interval). The individual drug blood concentrations at various time intervals are shown in Fig. 1.

TABLE I—HALF-LIFE OF DIAZOXIDE IN HUMAN BLOOD

Subject	a	b	Estimated[a] Half-Life, hr.
1	0.9928	0.0142	20.9
2	0.9701	0.0087	34.7
3	1.1083	0.0136	22.2
4	1.0584	0.0094	32.1
5	1.0989	0.0096	31.4
6	1.1087	0.0107	28.2

[a] Derived from function $\log \hat{y} = a + bt$, where a = log mcg./ml. at time 0 and b = (rate of change per unit change in time), log mcg./ml.

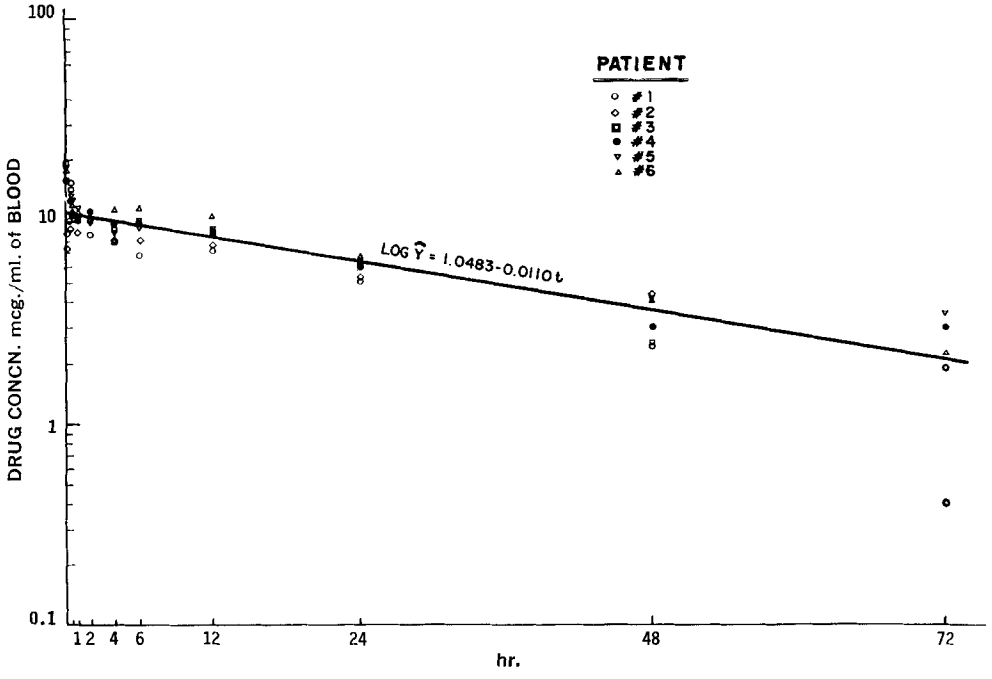

Fig. 1—Least square regression line for blood half-life evaluation in man.

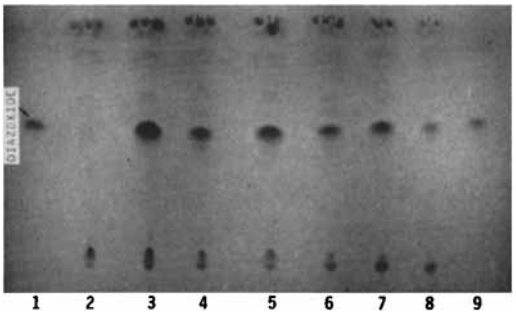

Fig. 2—TLC pattern of diazoxide extracted from plasma (photographed under U.V. light). Samples 1 and 9 show the position of diazoxide standards (5 mcg.). Sample 2 represents the pattern of untreated (0 hr.) plasma. Samples 3 and 4 are from subject 1, at 30 min. and 24 hr., respectively. Samples 5 and 6 are corresponding time intervals for subject 2 and samples 7 and 8 for subject 6.

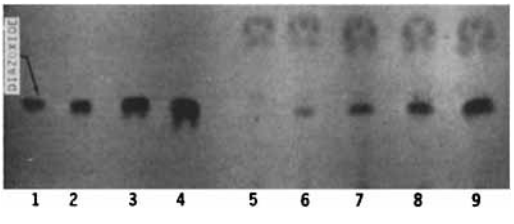

Fig. 3—TLC analysis of diazoxide recovered from plasma (photographed under U. V. light). Samples 1, 2, 3, and 4 are diazoxide standards spotted directly at concentrations of 5, 10, 20, and 40 mcg., respectively. Samples 6, 7, 8, and 9 represent the same respective diazoxide concentrations recovered from plasma. Sample 5 is plasma control (0 hr.).

To identify the material read at 280 mμ, particularly at the later time intervals, thin-layer chromatography was employed. Thirty-minute and 24-hr. plasma samples from subjects 1, 2, and 6 were extracted with ethyl acetate (see *Methods*) and chromatographed. The results in Fig. 2 clearly show that diazoxide is the only major component visible in plasma when compared with control (0 hr., spot 2). Samples from each subject show, as expected, more intense diazoxide spots at the earlier time interval. Other spots visible under U.V. light (Fig. 2) correspond to unidentified constituents of plasma (compare with control plasma, spot 2). Samples 1 and 9 are the diazoxide standards (5 mcg.).

Further identification of the diazoxide spot visible upon chromatography of plasma samples was obtained as follows. The areas on the glass plate (samples 2, 3, and 4, Fig. 2) were scraped out, and extracted with ethyl acetate, which was then extracted with 4% sodium carbonate. The U.V. spectrum of the sodium carbonate solution was recorded on a Perkin-Elmer recording spectrometer and compared with 5 mcg. of a chromatographed standard diazoxide solution (sample 1, Fig. 2) subjected to the same procedure. Both the standard and plasma samples showed identical U.V. characteristics, thus verifying the identity of the diazoxide spot on TLC plates.

The TLC procedure in this investigation is quite sensitive for diazoxide and gives good plasma recoveries. Figure 3 shows that the intensities of spots are proportional to the amounts (5, 10, 20, and 40 mcg.) of diazoxide standard spotted. Similar results were obtained by adding the same amounts of diazoxide standard to 1-ml. plasma samples and subjecting them to the described extraction procedure (samples 6–9, Fig. 3). Sample 5 is plasma control (no drug added).

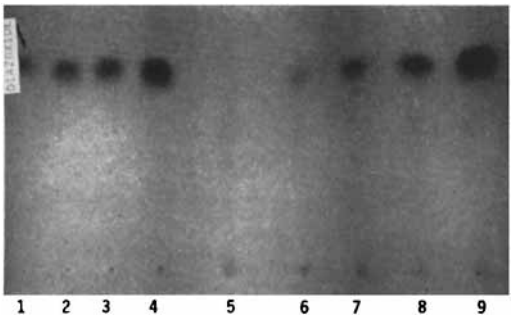

Fig. 4—TLC analysis of diazoxide recovered from urine (photographed under U. V. light). Samples 1, 2, 3, and 4 represent diazoxide standards 5, 10, 20, and 40 mcg., respectively. Samples 5, 6, 7, 8, and 9 represent diazoxide recovered from urine to which 0,5, 10, 20, and 40 mcg. of the drug was added, respectively.

Although no attempt was made to analyze diazoxide levels in urine, the TLC procedure is applicable to urine as well. It is recommended, however, that after extraction of urine with ethyl acetate, the organic solvent be washed with 2.5 ml. of 4% sodium bicarbonate solution before it is concentrated for chromatography. This will remove many interfering materials present in urine and give good diazoxide recoveries. Samples 6–9 (Fig. 4) present results obtained on recovery from urine of 5, 10, 20, and 40 mcg. of diazoxide, respectively. The size and intensity of diazoxide spots compare favorably (assuming some losses due to extraction procedure) with that obtained by direct chromatography of respective diazoxide standards (samples 1 4). Sample 5 represents control urine with no drug added.

Proteinaceous Antitumor Substances from Plants III. *Caesalpinia gilliesii* (*Leguminosae*)

By A. ULUBELEN*, W. F. MCCAUGHEY†, and J. R. COLE

Preliminary screening of the aqueous extracts of *Caesalpinia gilliesii* have shown activity against sarcoma 180 in mice and Walker 256 in Sprague rats. The isolation, purification, and partial characterization of six proteinaceous materials are reported.

As a result of a routine screen of Southwestern plants for potential antitumor activity, the aqueous extracts of *Caesalpinia gilleisii*[1] (Wall) demonstrated activity toward the sarcoma 180 test system in mice.[2] This screening program was carried out by the Cancer Chemotherapy National Service Center, Bethesda, Md. Further fractionation has resulted in activity against Walker 256 (5WM) in Sprague rats as well as the sarcoma 180 (3SA) test system in mice.

The plant is an odoriferous, glandular shrub 2.3 M. tall, collected near Greaterville, Ariz., where it has become naturalized in a pasture.

EXPERIMENTAL

Ten Kg. of the dry pods of *C. gilliesii* was extracted with approximately 15 L. of water at room temperature. The aqueous extract was lyophilized in a Repp Industries model 15 sublimator and then washed with MeOH and EtOH. The yield was 760 Gm. One-hundred grams of this crude compound was added to 1 L. of water at room temperature. The insoluble part was separated by centrifuge and discarded.

The aqueous solution was extracted with 5 × 200 ml. of ether to remove fatty materials, and increased in volume threefold by the addition of 95% ethanol. A light-colored precipitate appeared and was separated by centrifuge, dissolved in water, and dialyzed against running water at room tem-

[2] Preparation of the preliminary extraction was carried out by Dr. M. E. Caldwell.

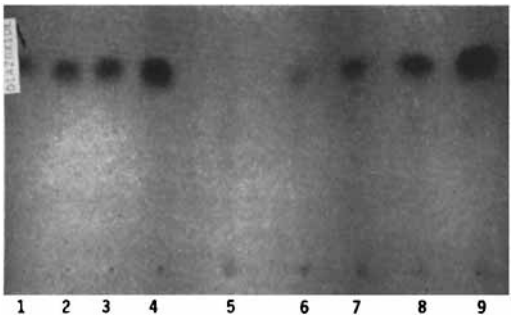

Fig. 4—TLC analysis of diazoxide recovered from urine (photographed under U. V. light). Samples 1, 2, 3, and 4 represent diazoxide standards 5, 10, 20, and 40 mcg., respectively. Samples 5, 6, 7, 8, and 9 represent diazoxide recovered from urine to which 0,5, 10, 20, and 40 mcg. of the drug was added, respectively.

Although no attempt was made to analyze diazoxide levels in urine, the TLC procedure is applicable to urine as well. It is recommended, however, that after extraction of urine with ethyl acetate, the organic solvent be washed with 2.5 ml. of 4% sodium bicarbonate solution before it is concentrated for chromatography. This will remove many interfering materials present in urine and give good diazoxide recoveries. Samples 6–9 (Fig. 4) present results obtained on recovery from urine of 5, 10, 20, and 40 mcg. of diazoxide, respectively. The size and intensity of diazoxide spots compare favorably (assuming some losses due to extraction procedure) with that obtained by direct chromatography of respective diazoxide standards (samples 1 4). Sample 5 represents control urine with no drug added.

Proteinaceous Antitumor Substances from Plants III. *Caesalpinia gilliesii* (*Leguminosae*)

By A. ULUBELEN*, W. F. MCCAUGHEY†, and J. R. COLE

Preliminary screening of the aqueous extracts of *Caesalpinia gilliesii* have shown activity against sarcoma 180 in mice and Walker 256 in Sprague rats. The isolation, purification, and partial characterization of six proteinaceous materials are reported.

As a result of a routine screen of Southwestern plants for potential antitumor activity, the aqueous extracts of *Caesalpinia gilleisii*[1] (Wall) demonstrated activity toward the sarcoma 180 test system in mice.[2] This screening program was carried out by the Cancer Chemotherapy National Service Center, Bethesda, Md. Further fractionation has resulted in activity against Walker 256 (5WM) in Sprague rats as well as the sarcoma 180 (3SA) test system in mice.

The plant is an odoriferous, glandular shrub 2.3 M. tall, collected near Greaterville, Ariz., where it has become naturalized in a pasture.

EXPERIMENTAL

Ten Kg. of the dry pods of *C. gilliesii* was extracted with approximately 15 L. of water at room temperature. The aqueous extract was lyophilized in a Repp Industries model 15 sublimator and then washed with MeOH and EtOH. The yield was 760 Gm. One-hundred grams of this crude compound was added to 1 L. of water at room temperature. The insoluble part was separated by centrifuge and discarded.

The aqueous solution was extracted with 5 × 200 ml. of ether to remove fatty materials, and increased in volume threefold by the addition of 95% ethanol. A light-colored precipitate appeared and was separated by centrifuge, dissolved in water, and dialyzed against running water at room tem-

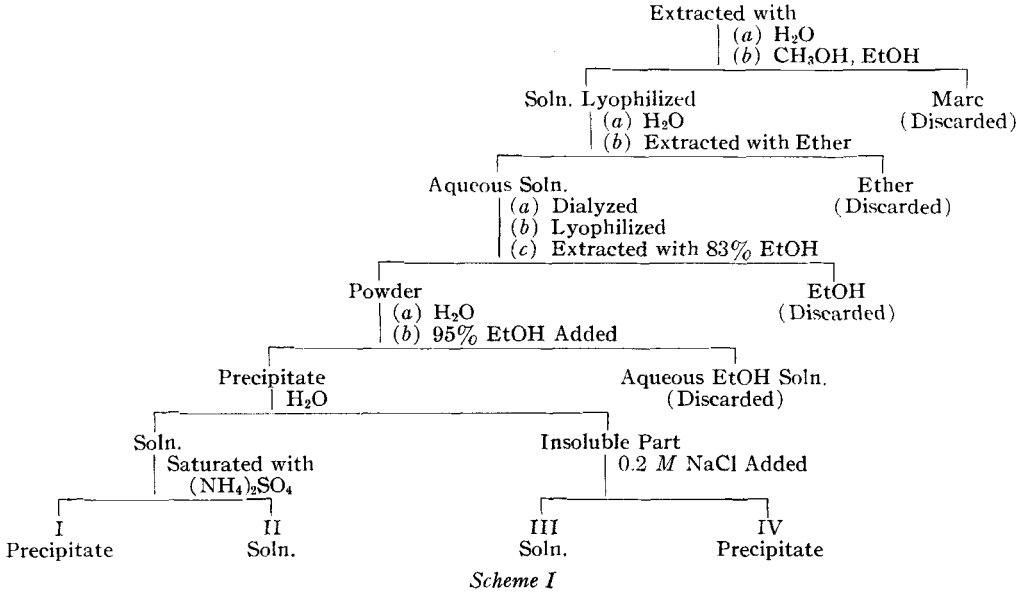
Schematic Presentation of Extraction
C. gilleisii



Scheme I

perature using a dialyzing tube of 5/8 in. diam. (No. 4465-A2, Arthur H. Thomas Co., Philadelphia, Pa.). After a period of 7 days, the solution in the tubes was lyophilized. The material thus obtained was extracted with 83% boiling ethanol. A red-colored solution was obtained. The remaining powder was dissolved in water and lyophilized. Twenty-five grams of compound was obtained. This crude material showed a marked activity against the sarcoma 180 test system and showed a reduction in tumor size of 82% and 89% at a dose of 4.4 mg./Kg. This corresponds to a T/C[3] value of 18 and 11%, respectively. The elementary analysis showed 17.3% inorganic material which consists mostly of calcium and phosphate. Sulfur and nitrogen were also present.

Four grams of the crude material was added to 50 ml. of water. The insoluble part was separated by centrifuge. To the soluble portion, $(NH_4)_2SO_4$ was added until saturation. A precipitate was then separated by centrifuge. The precipitate (I) and the solution (II) after being dissolved in water were dialyzed and lyophilized. The insoluble part was dissolved in 0.2 *M* NaCl (pH 8), and was separated by centrifuge. The soluble part (III) and the insoluble part (IV) were both dialyzed and lyophilized (Scheme I).

Column chromatography was employed to further separate these fractions (I, II, III, and IV). Substrates used included ion-exchange resins[4] and synthetic dextran derivatives.[5] The columns, upon treatment with the following buffer systems, gave the following test results: I when washed with 0.02 *M* phosphate buffer solution pH 5.6 yielded one fraction (a) and with a barbital buffer solution pH 8.6 a second fraction (b). II yielded two fractions (c, d) with the buffer solution pH 5.6; III gave one fraction (e) with the same buffer solution. No other fraction was obtained. IV yielded only one fraction (f) with a buffer solution pH 8.6. The four fractions indicated above were tested against the 5WM system. I exhibited a T/C[6] value of 3% at 33 mg./Kg and III a value of 28% at 100 mg./Kg.

PHYSICAL AND CHEMICAL CHARACTERISTICS OF PROTEIN FRACTIONS

Paper electrophoresis of the six fractions was run utilizing a barbital buffer solution of pH 8.6, 0.05 ionic strength in a Spinco model Beckman instrument, and after 14 hr of electrophoresis using a 2 ma. current, the papers were developed using periodic acid and Schiff reagent. Mobilities of the six different fractions are shown in Table I.

The fractions were hydrolyzed with 6 *N* hydrochloric acid in a sealed and evacuated glass tube at 105°. The resulting solution was applied on Whatman No. 1 paper using the same solvent systems previously reported (2, 3).

One hundred milligrams of the six fractions were hydrolyzed separately with 3 *N* HCl in a boiling water bath for 24 hr. in preparation for characterization of the sugars. Three different solvent systems previously reported (3) were employed to detect the sugars using paper chromatography. Aniline phthalate and silver nitrate solutions were used to develop the chromatograms. The results are described in Table I. Results of nitrogen determination of six fractions using micro-Kjeldahl method and U. V. absorption are also shown in Table I.

Infrared curves of the six fractions showed characteristic protein peaks at 3400, 2950, 1650, and

[3] The criteria for activity is defined as being a per cent T/C (test/control) value of less than 42 in a satisfactory dose response test (1).

Synthesis of Some Substituted Amides of Terephthalic and Isophthalic Acids

By JOSEPH P. LAROCCA* and MOHAMED A. Y. SHARKAWI†

The syntheses of 14 diamide derivatives of terephthalic acid and six diamide derivatives of isophthalic acid are described. Evaluation of reaction conditions and solvent systems led to the use of anhydrous ether at 0° as the preferred method of preparing these amides from the corresponding acid chloride and amine. Preliminary pharmacological screening is reported.

A LARGE NUMBER of drugs are available which depress the central nervous system. These drugs elicit sedative, hypnotic, anticonvulsant, and psychotherapeutic effects. Many of these drugs contain a carbonyl-nitrogen-carbonyl group-

[a] Footnote same as Table I.

of activity on the central nervous system, the synthesis of the diamides of terephthalic and isophthalic acids was undertaken.

EXPERIMENTAL

Methods—The best and most general reaction for the preparation of amides has been reported to be the acylation of amines by acyl halides (7). A study of the reaction medium best suited for the synthesis of the desired compounds was undertaken. For this purpose the reaction of terephthaloyl chloride with alkyl amines (propylamine and *N*-di-*n*-butyl amine) was selected for detailed investigation. The results are summarized in Table I.

As a result of these studies anhydrous ether was chosen as the reaction medium. The following procedure was employed for the synthesis of the compounds reported.

A fourfold excess of the amine was dissolved in 100 ml. of anhydrous ether and cooled to 4°. A solution of the chloride (0.05 mole in 150 ml. anhydrous ether) was added slowly with vigorous stirring. The reaction temperature was not allowed to exceed 20° during the addition process. After the addition was complete, the stirring was continued for 15 min. The reaction mixture was stored overnight at 4° during which time the desired product crystallized (if the product failed to crystallize, the ether was removed by evaporation). The crystals or residue obtained were washed with distilled water to remove the amine hydrochloride and recrystallized from 50% ethanol. The melting points, yields, and analytical data for the amides of terephthalic acid are given in Table II, and for the amides of isophthalic acid in Table III.

Pharmacological Survey[1]—The preliminary mouse toxicity study showed that, in general, these compounds are nontoxic and free of any major CNS activity. The *N,N'*-di-*n*-butylterephthalamide and the *N,N,N',N'*-tetra-isopropylisophthalamide were also screened as antidepressants. Although both showed some activity, the activity was not sufficient to warrant further study.

Multi-Chamber System for Toxicity Studies in Mice at Simulated High Altitude

By I. P. BAUMEL, S. M. ROBINSON, and W. F. BLATT

Plastic desiccators have been adapted to serve as chambers in a simulated high altitude system. The multi-chambered system is convenient for observations of grouped mice or other small animals subjected to decompression. Toxicity data are given for representative drugs at sea level and a simulated altitude of 19,000 ft.

In examining the effects of simulated high altitude on drug toxicity in mice, it was necessary to utilize chambers which could accommodate a group of animals and permit a clear, unobstructed view of them. Accordingly, the authors devised a system incorporating relatively inexpensive plastic desiccators designed for routine laboratory use. The simulated altitude afforded by this system was used to evaluate the lethality to mice of agents representative of various drug classes.

EXPERIMENTAL

Apparatus—The modified spherical desiccators[1] shown in the lower portion of Fig. 1 can be evacuated to below 0.01 μ, a value considerably below that normally required for altitude studies. In single chamber operation, the air valve at the top portion of the chamber was attached directly to a vacuum pump. For air entry, a hole was drilled 2 in. above the level of the porcelain platform in the lower portion of the desiccator, and a suitable tubing adapter was inserted. If desired, additional openings can be made to accommodate separate manometers and/or monitoring equipment.

The operation of several chambers through a multi-port manifold requires the exact duplication of size and length for the air evacuation and entry lines. The $^3/_4$-in. tubing assembly, shown in the top portion of Fig. 1, was devised to serve four chambers. The upper manifold was attached to the pump; the lower section provided for the constant fresh air intake regulated by the control valve. Uniform pieces of thick-walled rubber tubing ($^1/_2$ in.) were used to attach the chambers to the manifold. A $^1/_{12}$-h.p. pump[2] was adequate for establishing a simulated altitude of 19,000 ft. at an air flow of 2.5 L./min. The barometric pressure within the system was monitored by a mercury manometer attached to the end chamber. The unit, during normal operation, is shown in the lower portion of Fig. 1. The speed of ascent was controlled by the air intake valve—more than adequate air flow was maintained at the 1,000

of activity on the central nervous system, the synthesis of the diamides of terephthalic and isophthalic acids was undertaken.

EXPERIMENTAL

Methods—The best and most general reaction for the preparation of amides has been reported to be the acylation of amines by acyl halides (7). A study of the reaction medium best suited for the synthesis of the desired compounds was undertaken. For this purpose the reaction of terephthaloyl chloride with alkyl amines (propylamine and *N*-di-*n*-butyl amine) was selected for detailed investigation. The results are summarized in Table I.

As a result of these studies anhydrous ether was chosen as the reaction medium. The following procedure was employed for the synthesis of the compounds reported.

A fourfold excess of the amine was dissolved in 100 ml. of anhydrous ether and cooled to 4°. A solution of the chloride (0.05 mole in 150 ml. anhydrous ether) was added slowly with vigorous stirring. The reaction temperature was not allowed to exceed 20° during the addition process. After the addition was complete, the stirring was continued for 15 min. The reaction mixture was stored overnight at 4° during which time the desired product crystallized (if the product failed to crystallize, the ether was removed by evaporation). The crystals or residue obtained were washed with distilled water to remove the amine hydrochloride and recrystallized from 50% ethanol. The melting points, yields, and analytical data for the amides of terephthalic acid are given in Table II, and for the amides of isophthalic acid in Table III.

Pharmacological Survey[1]—The preliminary mouse toxicity study showed that, in general, these compounds are nontoxic and free of any major CNS activity. The *N,N'*-di-*n*-butylterephthalamide and the *N,N,N',N'*-tetra-isopropylisophthalamide were also screened as antidepressants. Although both showed some activity, the activity was not sufficient to warrant further study.

Multi-Chamber System for Toxicity Studies in Mice at Simulated High Altitude

By I. P. BAUMEL, S. M. ROBINSON, and W. F. BLATT

Plastic desiccators have been adapted to serve as chambers in a simulated high altitude system. The multi-chambered system is convenient for observations of grouped mice or other small animals subjected to decompression. Toxicity data are given for representative drugs at sea level and a simulated altitude of 19,000 ft.

In examining the effects of simulated high altitude on drug toxicity in mice, it was necessary to utilize chambers which could accommodate a group of animals and permit a clear, unobstructed view of them. Accordingly, the authors devised a system incorporating relatively inexpensive plastic desiccators designed for routine laboratory use. The simulated altitude afforded by this system was used to evaluate the lethality to mice of agents representative of various drug classes.

EXPERIMENTAL

Apparatus—The modified spherical desiccators[1] shown in the lower portion of Fig. 1 can be evacuated to below 0.01 μ, a value considerably below that normally required for altitude studies. In single chamber operation, the air valve at the top portion of the chamber was attached directly to a vacuum pump. For air entry, a hole was drilled 2 in. above the level of the porcelain platform in the lower portion of the desiccator, and a suitable tubing adapter was inserted. If desired, additional openings can be made to accommodate separate manometers and/or monitoring equipment.

The operation of several chambers through a multi-port manifold requires the exact duplication of size and length for the air evacuation and entry lines. The $^3/_4$-in. tubing assembly, shown in the top portion of Fig. 1, was devised to serve four chambers. The upper manifold was attached to the pump; the lower section provided for the constant fresh air intake regulated by the control valve. Uniform pieces of thick-walled rubber tubing ($^1/_2$ in.) were used to attach the chambers to the manifold. A $^1/_{12}$-h.p. pump[2] was adequate for establishing a simulated altitude of 19,000 ft. at an air flow of 2.5 L./min. The barometric pressure within the system was monitored by a mercury manometer attached to the end chamber. The unit, during normal operation, is shown in the lower portion of Fig. 1. The speed of ascent was controlled by the air intake valve—more than adequate air flow was maintained at the 1,000

[2] Gelman Co., Ann Arbor, Mich.

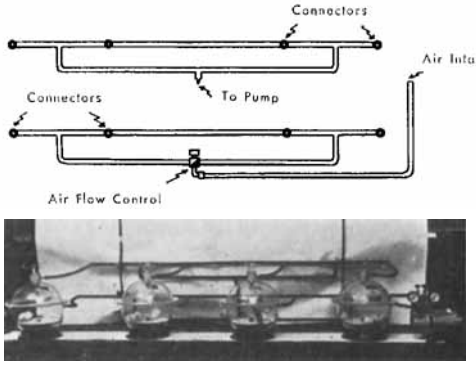

Fig. 1—Four-unit simulated altitude system. Key: top, manifold assembly for chambers showing tubing connections to pump and air entry lines; bottom, assembled system attached to $^1/_{12}$-h.p. pump.

ft./min. ascent rate utilized in this system. The sufficiency of the air flow obviated a possible problem; the turnover was such that normal room air conditioning could maintain the chambers within one degree of the external ambient temperature.

Drugs and Procedure—Male albino mice (CD_1, Charles River Mouse Farms), approximately 20.0 Gm., were placed in the chambers in groups of four, with 16 mice per dosage level. As part of ongoing studies on the interaction of altitude and drugs affecting the central nervous system (1), the following representative agents were selected for preliminary evaluation: sodium phenobarbital, reserpine, and tranylcypromine sulfate. Drugs were administered intraperitoneally at a constant dosage volume of 0.1 ml./10.0 Gm. of body weight. For the altitude determinations, the mice were then brought to 19,000 ft. at a rate of 1,000 ft./min. The number dead were noted for the 4-hr. period following arrival at the specified altitude. Occasionally an animal succumbed during ascent and as such was discarded from group computation. LD_{50} values and 95% confidence limits were determined by the method of Litchfield and Wilcoxon (2).

RESULTS AND DISCUSSION

Representative data for altitude and comparable sea level determinations are shown in Table I. An increased toxicity was obtained with reserpine in altitude-exposed mice; in contrast, no differences between sea level and simulated altitude could be demonstrated with phenobarbital or tranylcypromine. The observations thus far, while attesting to the feasibility of the system, are too limited to permit speculation on the mechanisms operative in the increased toxicity.

TABLE I—INTRAPERITONEAL LD_{50} DETERMINATIONS OF DRUGS AT SEA LEVEL AND ALTITUDE (19,000 ft.)

Dose, mg./Kg.	Observed/Tested		LD_{50}, mg./Kg.	
	Sea Level	Altitude	Sea Level	Altitude
Na Phenobarbital				
200	0/16	.....	290	273
250	2/16	2/16	(277–303)[a]	(256–286)
275	5/16	8/16		
300	10/16	15/16		
375	16/16	.....		
Reserpine				
75	.....	3/15	188	101
100	1/16	9/16	(138–256)	(80–127)
125	.....	8/16		
200	9/16	.....		
300	14/16	.....		
Tranylcypromine SO_4				
40	1/16	.....	107	122
80	2/16	1/16	(86–134)	(105–142)
100	2/16	3/16		
125	.....	7/12		
160	13/16	.....		
200	16/16	.....		

[a] Figures in parentheses represent values for 95% confidence limits. [b] Solubilized in 20% ascorbic acid.

Although the authors have used this system mainly for acute studies, the apparatus can be used for more protracted periods of exposure. For the latter application, cages containing standard feed and watering devices can be placed within the chamber and, following descent, rapid cleaning made by complete change of cage unit. During prolonged stay at altitude, it is suggested that a safety release valve be inserted within the system to protect against sudden unforeseen increases in altitude.

The apparatus can be expanded to accommodate an increased number of chambers by modification and expansion of the pipe assemblies, holding to the same general principle of equal connecting lengths. It also lends itself, with no major changes, to studies that require varied gas mixtures.

Trichloroethyl Carbonate I. Synthesis, Physical Properties, and Pharmacology

By H. C. CALDWELL, H. J. ADAMS, DONALD E. RIVARD, and JOSEPH V. SWINTOSKY*

Trichloroethyl carbonate was prepared from trichloroethanol and phosgene. It is a tasteless, crystalline solid with limited solubility in water. Pharmacological comparisons of trichloroethyl carbonate and trichloroethanol reveal that these compounds are about equitoxic and equipotent in decreasing spontaneous motor activity in mice after oral administration. These observations suggest that this carbonate is a prodrug of trichloroethanol.

CHLORAL HYDRATE which was used as a sedative by Liebreich (1) as early as 1869 is still one of the least toxic and most beneficial sedatives and hypnotics available (2). A hypnotic dose produces drowsiness within 15 to 30 min. and physiological sleep, which lasts for 6 to 8 hr., soon follows, and no hangover reaction is observed. However, the usefulness of the drug has been restricted by certain undesirable properties; it has a penetrating odor, and it possesses a bitter taste. Furthermore, it frequently causes stomach irritation, and it may produce nausea and vomiting at high doses. These factors, in addition to the popularity of the barbiturates, may account for the neglect of this drug. Chloral hydrate is rapidly converted in the body to trichloroethanol (3–5), which is also a potent sedative and hypnotic. Mackay and Cooper (3) studied this conversion in detail and showed chloral hydrate to be a potent hypnotic agent of short duration, and that the long duration of action observed was due to the metabolite trichloroethanol. Thus, the pharmacological effects noted after administration of chloral hydrate are chiefly due to its metabolite trichloroethanol.

While trichloroethanol has long been known to possess these pharmacological properties and has been studied at length in humans (6, 7), it has nonetheless been neglected as a therapeutic agent. No doubt its physical properties had much to do with this neglect because it is a bad tasting, hygroscopic liquid that often produces gastric irritation.

Recognizing that chloral hydrate and trichloroethanol are useful drugs, the authors felt it would be desirable to convert one of them to a more acceptable chemical form that would, after oral ingestion, be reconverted to the parent drug. Ideally this form should be a solid that can be conveniently formulated as tablets, capsules, or liquid forms, and it was thought that the carbonate derivative of trichloroethanol bis-(2,2,2-trichloroethyl) carbonate (or trichloroethyl carbonate[1]) might meet these criteria. This compound was reported in recent communications (8, 9).

EXPERIMENTAL

Chemistry—*Synthesis*—To a solution of 20 ml. of phosgene in 100 ml. of toluene was slowly added with stirring and cooling a mixture of 74.7 Gm. (0.5 mole) of trichloroethanol and 39.6 Gm. (0.5 mole) of pyridine. The mixture was stirred for 3 hr. at room temperature and the excess phosgene was removed *in vacuo*. Pyridine hydrochloride was filtered off and the filtrate was washed with 10% sodium hydroxide, dried, and concentrated. Dilution with hexane gave 58.4 Gm. of product, m.p. 86–87°.

Anal.—Calcd. for $C_5H_4Cl_6O_3$: C, 18.49; H, 1.24; Cl, 65.49. Found: C, 18.59; H, 1.28; Cl, 65.30.

Pharmacology—Initial testing of the trichloroethyl carbonate was aimed primarily at comparing its (*a*) acute oral toxicity and (*b*) CNS depressant activity with the parent drug trichloroethanol. For the latter, the effects of the two drugs on spontaneous motor activity in mice was measured, since it is well known that agents causing CNS depression in rodents will cause a concomitant decrease in spontaneous motor activity (10).

Acute Oral Toxicity in Mice—Male Carworth Farms mice (18–23 Gm.) were randomly divided into groups of 10 and dosed orally with suspensions of drug in 1% tragacanth. Suspensions were prepared with the aid of a Thomas glass-Teflon tissue grinder. Grinding was just sufficient (1–3 min.) to ensure a uniform suspension. Concentrations of drug were calculated so that each animal received a dose-volume of 10 ml./Kg. and a control group of 10 mice received 10 ml./Kg. of vehicle. After dosing, the animals were housed 10 per cage. They were observed for several hours immediately after dosing and then checked daily until no deaths occurred for 2 successive days following the fifth day post-drug. All deaths occurred within 48 hr. after dosing. The LD_{50}'s and 95% confidence limits were calculated by the logit χ^2 method of Berkson (11).

CNS Depressant Activity—Spontaneous Motor Activity (SMA) in Mice—Male Carworth Farms mice (15–25 Gm.) were randomly divided into groups of 10 and dosed with suspensions of drug in 1% tragacanth. Suspensions were prepared with the aid of a Thomas glass-Teflon tissue grinder as before and concentrations were calculated so that each animal received a dose volume of 10 ml./Kg. A control group received 10 ml./Kg. of vehicle. A 30-min. optimal pretreatment time for the drugs was determined in exploratory trials. Spontaneous motor activity was measured by means of an actophotometer. Exactly 30 min. after being dosed, an animal was placed into the activity chamber and its SMA, measured by the number of times the animal interrupted the light beams in the chamber, was determined for a 10-min. period. All counts were made on individual animals, and the reduction in SMA for each group was calculated by means of the following equation:

$$\% \text{ reduction in SMA} = \frac{\left(\begin{matrix}\text{mean count of}\\ \text{control group}\end{matrix}\right) - \left(\begin{matrix}\text{mean count of}\\ \text{treated group}\end{matrix}\right)}{\text{mean count of control group}} \times 100$$

400	84	
500	83	

[a] Not statistically significantly different from trichloroethanol.

The ED_{50}'s and 95% confidence limits were calculated by the method described by Tedeschi *et al.* (12).

RESULTS AND DISCUSSION

Synthesis and Properties of Trichloroethyl Carbonate—No particular difficulties were encountered in the synthesis of this new compound, though cognizance must be taken of its latent capability for undergoing hydrolytic cleavage. By the laboratory method employed, yield of compound was 72%.

Conversion of trichloroethanol to its carbonate results in a profound change in physical-chemical properties. Whereas trichloroethanol is a dense, hygroscopic liquid of ethereal odor, the carbonate is an odorless, friable, white, crystalline, solid, m.p. 86–87°. Trichloroethanol has a disagreeable taste, but the carbonate is virtually tasteless. Trichloroethanol is soluble in water to about 1 in 12, but the carbonate dissolves in water only to about 4 mcg./ml. Trichloroethyl carbonate is essentially a lipophilic compound showing the following approximate solubilities at room temperature in several solvents: ethanol (2.6%), methanol (4.9%), ethyl ether (43%), chloroform (49%), carbon tetrachloride (37%).

Trichloroethanol has not lent itself to convenient use in therapeutics, but trichloroethyl carbonate possesses pharmaceutical characteristics that permit it to be encapsulated or tableted. In conjunction with appropriate suspending agents, it can be dispersed in water for convenient oral administration.

Acute Oral Toxicity in Mice—The oral LD_{50}'s of the carbonate and the alcohol are 1003 and 930 mg./Kg., respectively (Table I). This indicates the two compounds are equitoxic in mice.

CNS Depressant Activity—Spontaneous Motor Activity in Mice—The oral ED_{50}'s of the carbonate and the alcohol are 288 and 212 mg./Kg., respectively. This indicates the two compounds are equipotent in depressing spontaneous motor activity in mice.

These studies show that, mg. for mg., trichloroethyl carbonate and trichloroethanol are approximately equipotent in depressing spontaneous motor activity and also about equitoxic orally in mice. Studies with other carbonate derivatives, which will be reported in subsequent papers, show that the carbonate linkage is quite labile and subject to enzymatic cleavage by enzymes present in dilute human plasma. The authors infer from these observations that the pharmacological activities manifested after oral administration of trichloroethyl carbonate are the result of *in vivo* regeneration of the parent drug, trichloroethanol. Hydrolytic cleavage of trichloroethyl carbonate yields two molecules of trichloroethanol and a molecule of carbon dioxide for each molecule of parent drug:

$$CCl_3CH_2OCOCH_2CCl_3 + H_2O \rightarrow 2\ CCl_3CH_2OH + CO_2$$

Subsequent pharmacological studies have been aimed at qualitative as well as quantitative comparisons between trichloroethyl carbonate, trichloroethanol, and chloral hydrate. The results of these studies and of pharmaceutical studies will be reported in future publications. Pharmacology, safety, and utility of this compound in humans have been reported elsewhere (13).

Constituents of *Helenium plantagineum*

By MARIO SILVA

From flowers of *Helenium plantagineum* four compounds were isolated—a polymethylenic alcohol, β-sitosterol, linifolin A, and deacetoxylinifolin A.

In recent years there has been considerable interest in the study of the constituents of the *Helenium* genus (1–5).

During a current project dealing with Chilean flora (6) the authors had occasion to re-examine *Helenium plantagineum* (D.C.) Macbride in order to study the compounds isolated by Taito (7).

The petroleum ether soluble fraction yielded four compounds characterized as: a high molecular weight aliphatic alcohol, which was not further studied; β-sitosterol; linifolin A (8); and deacetoxylinifolin A. Deacetoxylinifolin A was also isolated through crystallizations from the benzene soluble fraction.

EXPERIMENTAL[1]

Petroleum Ether Extract—Flowers of *Helenium plantagineum*, collected in January 1962 near Florida (Concepción), were dried at 80–90°. A 2064-Gm. quantity of dried powder was extracted to exhaustion in a Soxhlet extractor with petroleum ether (b.p. 65–75°). This solution was concentrated to yield 461 Gm. of a dark product. This product was chromatographed many times on neutral alumina to give four compounds. The first compound is probably a polymethylenic alcohol, m.p. 78°, $[\alpha]_D$ 0° (chloroform, c 1), molecular weight 432 (Rast), which was not further studied.

β-Sitosterol—After several crystallizations of the second compound from ethanol, β-sitosterol was obtained, m.p. 137–138°, $[\alpha]_D$ −33.5° (chloroform, c 0.39), $\nu_{max.}^{KCl}$ 3380 cm.$^{-1}$.

The mixed melting point of this compound with authentic β-sitosterol showed no depression.

β-Sitosterol Acetate—The pure compound was obtained as needles after crystallizations from ethanol, m.p. 128–129°, $[\alpha]_D$ −49° (chloroform, c 0.43), $\nu_{max.}^{Nujol}$ 1736, 1250 cm.$^{-1}$.

Linifolin A—From the third product, through crystallizations from ethanol, 167 mg. of linifolin A was obtained, m.p. 202–203°, $[\alpha]_D$ +28.1° (chloroform, c 0.39), $\lambda_{max.}^{EtOH}$ 217 mμ, ϵ 13000, $\nu_{max.}^{Nujol}$ 1745, 1706, 1658, 1590, and 1235 cm.$^{-1}$.

Anal.—Calcd. for $C_{17}H_{20}O_5$: C, 67.09; H, 6.62. Found: C, 67.35; H, 6.36.

This compound did not show depression with an authentic sample of linifolin A on mixed melting point determination.

Deacetoxylinifolin A—The fourth compound, after recrystallizations from ethanol, gave 250 mg. of deacetoxylinifolin A, m.p. 251°, $[\alpha]_D$ +58.4° (pyridine c 0.38), $\lambda_{max.}^{EtOH}$ 217 mμ, ϵ 15150, $\nu_{max.}^{Nujol}$ 3717, 1745, 1698, and 1582 cm.$^{-1}$.

Anal.—Calcd. for $C_{15}H_{18}O_4$: C, 68.68; H, 6.92. Found: C, 68.48; H, 7.00.

Deacetoxylinifolin A Acetate—Deacetoxylinifolin A on acetylation with pyridine–acetic anhydride at room temperature gave, after crystallization from methanol–chloroform, the acetate, m.p. 194°, $[\alpha]_D$ +28.8° (chloroform, c 0.52), $\lambda_{max.}^{EtOH}$ 217 mμ, ϵ 14400, $\nu_{max.}^{Nujol}$ 1745, 1706, 1658, 1590, and 1236 cm.$^{-1}$.

This acetate did not show depression with an authentic sample of linifolin A on mixed melting point determination.

Benzene Extract—The defatted plant material was dried and the benzene soluble constituents were extracted. This solution was concentrated to yield 80 Gm. of a dark product. This product, after several recrystallizations from ethanol, yielded 2.5 Gm. of deacetoxylinofolin A, m.p. 253–254°, $[\alpha]_D$ +59° (pyridine, c 0.7).

The mixed melting point of this compound with deacetoxylinifolin A, previously isolated, showed no depression.

Received January 9, 1967, from the Laboratorio de Fitoquímica, Departamento de Botánica, Instituto Central de Biología, Universidad de Concepción, Chile.

Accepted for publication March 27, 1967.

This work was generously supported by the Scientific Research Council of the University of Concepción.

The author acknowledges his indebtedness to Professor D. H. R. Barton for making available an authentic sample, and for his constant help and encouragement. The authentic sample of linifolin A was obtained from Professor Werner Herz through Professor Barton.

[1] Melting points (uncorrected) were performed on a Kofler block. Rotations were measured at 20°. The microanalyses were performed at Dr. Alfred Bernhardt's Institute, Ruhr, Germany. Ultraviolet spectra were recorded in solution in absolute ethanol on a SP 700 spectrophotometer. Infrared spectra were recorded on a Perkin Elmer 137 spectrophotometer.

N-Bromohydantoins in Pharmaceutical Analysis I. Determination of Sulfonamides and Some Local Anesthetics with 1,3-Dibromo-5,5-dimethylhydantoin

By MARÍA MARTÍNEZ DE BERTORELLO

This communication reports the use of 1,3-dibromo-5,5-dimethylhydantoin in the quantitative determination of sulfanilamide, 3,4-dimethyl-5-sulfanilamidoisoxazole, 5-methoxy-2-sulfanilamidopyrimidine, ethyl aminobenzoate, and *p*-aminobenzoyldiethylaminoethanol hydrochloride in acid aqueous medium.

THE *N*-BROMOHYDANTOINS occupy a very important position in preparative organic chemistry because of their efficient bromating and oxidizing action. They are simply and economically prepared, stable, and the dibromated derivatives have a high positive bromine content. They have been successfully tested with a wide variety of organic compounds as shown in numerous publications (1).

Reactions with *N*-bromohydantoins take place under mild conditions and are highly selective. Halogenating experiments are usually carried out under the conditions recommended by Ziegler *et al.* (2) for other similar reagents, using nonpolar solvents, preferably carbon tetrachloride. The few examples studied with these reagents using polar solvents, such as acetic acid (3), indicate an exceptional reaction rate even at low temperatures (15–20°), nuclear halogenation being particularly favored (4).

N-Bromohydantoin has not yet been used for analytical purposes. In the present paper the application of a derivative, 1,3-dibromo-5,5-dimethylhydantoin (I) has been studied for the evaluation of some organic substances of pharmaceutical interest.

This stable halogenating reagent of high bromine content (55.9%), when tested in an aqueous acid medium under conditions similar to those used by Barakat *et al.* (5) for *N*-bromosuccinimide (II), proved to be an excellent brominating agent for several sulfonamides and some local anesthetics. This property made it useful for the volumetric determination of these drugs.

Under these conditions it reacts quantitatively with sulfanilamide (III), 3,4-dimethyl-5-sulfanilamidoiso xazole (sulfisoxazole) (IV), 5-methoxy-2-sulfanilamidopyrimidine (V), ethyl aminobenzoate (benzocaine) (VI), and *p*-aminobenzoyldiethylaminoethanol hydrochloride (procaine hydrochloride) (VII), with the reagent/substrate molar relationships of 1:1, 3:2, 1:1, 1:1, 1:1, respectively. The end point is directly visualized using methyl red as an indicator.

1,3-Dibromo-5,5-dimethylhydantoin decolorizes the indicator in an aqueous acidic medium, but halogenates preferentially the substrates; only when the halogenation has been total does a small excess of reactant decolorize the indicator. To achieve further accuracy a blank experiment is recommended with the indicator under the same conditions.

EXPERIMENTAL

Reagents—(*a*) 1,3-Dibromo-5,5-dimethylhydantoin[1] was prepared according to the method described by Orazi *et al.* (6) by means of bromine acting on an alkaline solution of 5,5-dimethylhydantoin. By means of repeated crystallizations in hot water (70–80°), the pure product is obtained with a 55.9% bromine content.

The positive quality of bromine in 1,3-dibromo-5,5-dimethylhydantoin permits the liberation of iodine from an acid solution of potassium iodide which makes it possible to carry out its quantitative determination by the iodometric method (7).

(*b*) Solution of 1,3-dibromo-5,5-dimethylhydantoin[2] at 0.1% w/v in distilled water: it is prepared by dissolving the pure substance in hot distilled water (70°), cooling it at once after the solution is obtained. Once the environmental temperature is reached, distilled water is added up to a total of 100 ml. The titer of the solution is iodometrically determined. The solution must be kept in a cool place and must be protected from light, controlling its factor every 3 days. Solutions prepared for more than 7 days should not be used.

(*c*) Solution 0.1%, of III, IV, V, VI, and VII in 10% hydrochloric acid.

(*d*) Hydrochloric acid solution, 10% w/v in distilled water.

(*e*) Methyl red solution (0.02%) in 50% ethanol.

(*f*) Acetic acid, glacial.

(*g*) *N*-Bromosuccinimide solution at 0.1% w/v in distilled water.

Procedure—A convenient volume of the substrate solution, accurately measured, *i.e.*, 5 ml. is poured into a conical flask, then 5 ml. of acetic acid and 2 drops of the indicator are added and titrated with the 0.1% titrant, shaking frequently until the indicator is decolorized. The volume required for the blank assay is deduced from the number of milliliters used.

Blank Experiment—The same procedure is followed using, instead of the substrate solution, an equivalent volume of 10% hydrochloric acid solution (in the given sample, 5 ml.).

The results obtained in the tested samples are indicated in Tables I, II, and III. Each value represents the average of three parallel determinations.

The range of applicability of I and other similar titrants is currently under study in this laboratory.

CONCLUSIONS

The results in Tables I and II indicate that 1,3-dibromo-5,5-dimethylhydantoin is a suitable analytical reagent for the quantitative determination of some sulfonamides and local anesthetics; the reaction takes place rapidly and quantitatively at room temperature, experimental errors range about 1% and, moreover, quantities as small as 1 mg. can be determined.

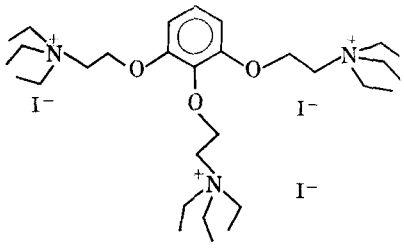
Quaternary Salts of 2,4-Bis(dialkylaminoalkoxy)quinazolines. Potential Curaremimetics

By RONALD E. ORTH

Bis-quaternary salts of 2,4-bis(dialkylaminoalkoxy)quinazolines were prepared from the corresponding bis-tertiary amines as potential curaremimetic agents.

TUBOCURARINE CHLORIDE and drugs which act in a similar manner are utilized to induce muscle relaxation in neuromuscular disorders and during abdominal surgery. These applications were made only after it was demonstrated that the drug acts at the myoneural junction. However, tubocurarine chloride exerts undesirable autonomic ganglionic effects which have led investigators to continue the quest for a more specific myoneural blocking agent. Numerous investigations have ensued. Brown and Fraser suggested the pharmacological activity of various quaternary salts (1) and Craig found that all "onium" containing compounds may be expected to exhibit curare-like activity (2). Two or more quaternized moieties within a single substance were shown to produce higher activity by virtue of a more firm attachment at the site of action (3, 4). A distance of approximately 15 Å. between "onium" heads in a homologous series was suggested for maximum curariform activity. Stenlake *et al.* studied linear chemicals with three, four, and five "onium" heads and found that the number of these centers influenced potency, reversibility, and the duration of action



Gallamine Triethiodide N.F. XII

(5, 6). In 1949 Bovet *et al.* attempted to reproduce synthetically a simplified version of the tubocurarine molecule (7). They achieved the synthesis of a series of bis-quinoline derivatives wherein the aromatic structures were connected through a methylene chain by ether linkages. The same group examined some simple mono- and polyphenolic ethers of certain aminoalcohols and found that these substances also possessed a striking curariform activity. The best-known of this latter series is the triethiodide of tris(β-diethylaminoethoxy)-1,2,3-benzene (gallamine triethiodide).

Hohmann and Jones demonstrated high curare-like activity in several quaternary salts of 2,4,6-tris(dialkylaminoalkoxy)-1,3,5-triazines and 2,4-bis(dialkylaminoalkoxy)quinazolines (8). The paralyzing doses required in the mouse sloping-screen and rabbit head drop tests were calculated and sum-

marized using gallamine as a standard. In both tests 2,4,6-tris(β-diethylaminoethoxy)-1,3,5-triazine tribenzchloride proved superior to gallamine and other salts of the triazine and quinazoline series. Unfortunately, the LD_{50} for this substance was 5.05 mg./Kg. The quinazolines, however, were potent and much less toxic than the corresponding triazines. No obvious increase in potency was attributed to the trimethylene side chain moiety over dimethylene in the quinazoline series. It was noted in both series that *N,N*-diethyl substitution produced more potent activity than *N,N*-dimethyl. Since only the methiodides of the quinazolines were prepared, several of the potentially more active ethiodides and benzchlorides are synthesized. (Scheme I.)

EXPERIMENTAL

2, 4 - Bis (dialkylaminoalkoxy) quinazolines—Twelve grams of 2,4-dichloroquinazoline, prepared by the method of Lange *et al.* (10), was dissolved in 50 ml. of dry benzene and added to a cooled suspension of sodium aminoalkoxide prepared by reacting 2.8 Gm. (0.12 *M*) of sodium with 0.18 *M* of the dialkylaminoalkanol. The mixture is refluxed for 2 hr., cooled, washed with water, and dried over Na_2SO_4. Most of the benzene is then removed at atmospheric pressure. The remaining mixture is distilled twice to obtain the pure amine (8). 2,4-Bis(diethylaminoethoxy)quinazoline: 225–226°/4 mm. (54% yield). 2,4-Bis(diethylaminopropoxy)quinazoline: 230–233°/2 mm. (40% yield). 2,4-Bis(dimethylaminoethoxy)quinazoline: 234–236°/9 mm. (35% yield).

Diethiodide and Dibenzchloride Salts—Reflux 0.1 *M* of the amine and 0.5 *M* of the halide in 50 ml. of absolute ethanol for 2 hr. Absolute ether is then added until the quaternary salt precipitates. The solid is collected on a filter, washed with dry ether, and dried in a vacuum oven at 60°. The yields, melting points, and analytical data are given in Table I.

Isolation of Ergosterol from *Gibberella zea* Mycelium

Sir:

Gibberella zea Schwabe is the perfect stage of *Fusarium graminearum*, a plant pathogen causing stalk, ear, and root rot of corn and scab diseases on barley. This organism has been implicated in many reports of animal toxicities. Two different types of effects have been reported from studies of animals having ingested infested grains. Christensen *et al.* (1) and Stob *et al.* (2) have isolated a fungal product having uterotrophic activity. Curtin and Tuite (3) have reported on the emetic principle contained in *G. zea* infested corn. Christensen *et al.* (1) have also given evidence that ergosterol is produced by the fungus when cultured on cracked corn.

The authors wish to report the isolation of ergosterol as the major sterol product of *G. zea* when grown in an agitated, submerged, completely defined fermentation medium.

A growth medium composed of 3% glucose and 0.5% succinic acid plus salts [a modification of a synthetic medium described by Pacifici *et al.* (4) for the production of *Claviceps purpurea*] was inoculated with a liquid culture of *G. zea*, incubated at 26° for 5 days, and the mycelium removed by filtration. The mycelium was frozen immediately, freeze-dried, and powdered. This was extracted in a Soxhlet apparatus for 36 hr. with Skelly B.

The solvent was removed from the extract by evaporation *in vacuo*. The extract (0.69 Gm.), representing 34 Gm. freeze-dried mycelium, was extracted twice with 5 ml. of 90% ethanol each time. To the combined extracts was added 4 ml. of 1% digitonin solution. The resultant precipitated digitonide was recovered by filtration and dissolved in 6 ml. dimethylsulfoxide and treated according to the procedure of Issidorides *et al.* (5). The solution was heated for 15 min. on a steam bath, then cooled to room temperature and extracted once with 15 ml. and then 4 times with 6 ml. of *n*-hexane. The hexane solution was dried over anhydrous $MgSO_4$, filtered, and evaporated to dryness. The sterol isolated (0.11 Gm.) was recrystallized twice from ethanol.

This sterol was chromatographed on Silica Gel G (250 μ layer) buffered (pH 9.3) thin-layer plates using a solvent composed of methylene chloride–carbon tetrachloride–methanol (64:32:5). The hR_f values of the *G. zea* sterol and a recrystallized sample of authentic ergosterol were identical. The same results were obtained when both substances were chromatographed on Silica Gel G thin-layer nonbuffered plates with a solvent composed of cyclohexane–chloroform (1:1). The melting point was not depressed with mixtures of authentic ergosterol and the *G. zea* sterol. The ultraviolet spectrum of the *G. zea* sterol was identical in all respects to the spectrum of an authentic sample of ergosterol (maxima at 262, 271, 282, and 293.5 mμ). Infrared spectra of the *G. zea* sterol and ergosterol were also identical in every respect.

Although earlier reports of ergosterol as a product of *G. zea* were based upon extraction of not only the mycelium of this fungus but also the substrate upon which it was produced, the authors have conclusively proven that ergosterol is in fact the major sterol of *G. zea*, and that this organism can produce ergosterol when grown in a simple medium containing glucose and succinic acid as the sole source of carbon.

Effect of Bed Rest on Distribution and Elimination of Drugs

Sir:

Most pharmacokinetic studies are conducted on healthy ambulatory subjects. It is recognized, however, that many of these investigations should be carried out also on sick patients in order to assess the effect of various pathological conditions on the kinetics of drug absorption, distribution, and elimination. Such comparative studies will ordinarily involve bedridden patients and a control group of healthy ambulatory subjects (or the same patients upon complete restoration of health). It is the purpose of this communication to point out that bed rest *per se* can have an appreciable effect on drug distribution and elimination. This effect, if unrecognized, can cause considerable errors in the interpretation of pharmacokinetic data.

Schmidt and Roholt (1) have recently determined serum levels and urinary excretion of benzylpenicillin after intramuscular injection of 5 million units of benzylpenicillin sodium in six subjects while these were in bed and, subsequently, while they were ambulatory. For the purpose of this report, data for 5 of these subjects have been subjected to pharmacokinetic analysis. (Data for subject *3* were incomplete and had to be excluded.) It was found that penicillin concentrations in the plasma declined exponentially with time over a concentration range of three orders of magnitude. Half-life values ($t_{1/2}$) were determined graphically and were used to calculate apparent first-order rate constants for elimination (k). Apparent first-order rate constants for excretion of unchanged drug (k_e) were obtained from fk, where f is the fraction of the dose excreted unchanged. Rate constants for metabolism (k_m) were determined by subtracting k_e from k. The apparent volume of distribution (V_d) was calculated on the basis of the relationship A = dose $k^{-1}V_d^{-1}$, with the area (A) under the serum level *versus* time curve obtained by planimetry. Renal clearance was calculated as the product of k_e and V_d. Mathematical derivations for these equations may be found in the review by Nelson (2).

The pharmacokinetic constants for five subjects while ambulatory and during bed rest are listed in Table I. The fraction of the administered dose excreted unchanged and the renal clearance of benzylpenicillin were significantly increased and k_m was significantly decreased during bed rest ($p < 0.05$ by t-test, paired comparisons). The average V_d was increased during bed rest; this effect was not quite statistically significant, but it occurred in all five subjects.

The most interesting effect of bed rest is the apparent decrease in the first-order rate constant for metabolism (and possibly extra-renal excretion) of benzylpenicillin (k_m) to one-half the value observed while the subjects were ambulatory. It is conceivable that similar results, if obtained in the course of a comparative study of ambulatory normal subjects and bedridden patients suffering from certain disease(s), would be interpreted as being indicative of impaired drug metabolizing capacity due to the disease. In fact, it appears that bed rest *per se* can bring about pronounced changes in the distribution, metabolism, and excretion of drugs relative to values obtained in ambulatory subjects. This may be due to the higher metabolic rate of ambulatory subjects (1), or to the marked circulatory and plasma volume differences found in upright and recumbent subjects, respectively. These latter differences are due to the increased hydrostatic pressure of plasma associated with an upright as opposed to a recumbent posture (3). The increased hydrostatic pressure in the lower parts of the upright body causes plasma water to enter the interstitial space and leads to an increase in the concentration of plasma proteins (4). Similar effects are observed following physical exercise (5). This in turn results in higher plasma concentrations of plasma protein-bound drugs, although the total amount of drug in the plasma may be decreased due to the smaller plasma volume. A remarkable example of this effect and the type of artifact it can produce have been described recently by Dettli and Spring (4). These investigators determined plasma levels of sulfasymazine in hospitalized patients at 12-hr. intervals; apparent $t_{1/2}$ values calculated for any given 12-hr. period were much higher if the patient left the bed prior to removal of the second blood sample. In some instances the plasma obtained from a patient who had left the bed before the blood sample was drawn had a higher sulfonamide concentration than the plasma obtained 12 hr. earlier while the patient was in bed!

Pharmacokinetic models in current use do not provide for variations in plasma volume, variable blood flow rates through organs, and other region- or organ-specific circulatory changes. The effects of such variations will appear in the V_d and rate constants of presently used pharma-

cokinetic models. Thus, the pronounced difference in the k_m values for benzylpenicillin during the ambulatory state and during bed rest, respectively, is probably only an apparent one which is not necessarily indicative of an intrinsically impaired capacity for drug biotransformation during bed rest.

A review of general physiology (3) and particularly of renal physiology (6) suggests to this author that the circulatory and distributive changes in man due to changes in posture [or due to physical exercise (5, 7)] may be too complex to incorporate in pharmacokinetic models. It appears therefore that comparative pharmacokinetic studies on sick, bedridden patients and healthy controls require that the latter be in bed also. An additional complication arises from the fact that prolonged bed rest causes a gradual deterioration of cardiovascular function which is associated with a *decrease* of plasma volume (8). Such selective effects of bed rest give rise to potentially formidable problems in the pharmacokinetic interpretation of drug disposition during disease.

REVIEWS

Accepted Dental Remedies 1967. 32nd ed. Council on Dental Therapeutics, American Dental Association, 211 E. Chicago Ave., Chicago, IL 60611, 1966. xvi + 287 pp. 15.5 × 23 cm. Price $3.00.

The annual revision of this reference, especially for the practicing dentist, is now available. This new edition includes the Provisions for Acceptance of Products which have been revised recently. These Provisions were simplified because they originally included principles which are now legal requirements as a result of the 1962 Drug Amendments. Also provisions relating to devices have been deleted as a result of the formation of the Council on Dental Materials and Devices.

The book itself retains the style and format of the last edition. New information has been added to the section on clinical problems, and additional products have been added to the chapter on current therapeutic trends.

The Merck Manual of Diagnosis and Therapy. 11th ed. CHARLES E. LYGHT, Editor. Merck Sharp & Dohme Research Laboratories, Division of Merck & Co., Inc., Rahway, NJ 07065, 1966. xvi + 1850 pp. 12 × 18 cm. Price $7.50 regular edition, $9.75 deluxe edition.

To keep pace with advances in modern medicine, this well-known manual is now available in its eleventh edition. More than one hundred leading clinicians in the U.S., Canada, and abroad have aided in the preparation of this revision.

New chapters include family planning, pulmonary alveolar proteinosis, fevers of undetermined origin, cervical root syndrome, carcinoid, and neurological examination technique. Revised and up-to-date coverage has been given to the chemotherapy of infections, adrenocortical therapy, gout, sarcoidosis, measles and polio vaccination, pulmonary emphysema, diagnostic use of radioisotopes, drug reactions, cystic fibrosis, heart sounds and murmurs, and arteriosclerosis and atherosclerosis.

The prescriptions have been revised also in keeping with recent advances in chemotherapy. In addition to diseases and conditions, other useful information in the book covers clinical procedures, pre- and postoperative routines, guides for weights, measures, and dosage calculations, bedside nursing techniques, office laboratory tests, and pediatric and immunization methods. The manual is well indexed and overall is an extremely practical, comprehensive, and current reference text.

Reagent Chemicals and Standards. 5th ed. By JOSEPH ROSIN. D. Van Nostrand Co., Inc., 120 Alexander St., Princeton, NJ 08540, 1967. vii + 641 pp. 15.5 × 23.5 cm. Price $16.15.

More than 600 reagents, solvents, indicators, and other substances, organic and inorganic, used in general laboratory work are covered in this book. The composition or formula, the physical and chemical properties, limits of impurities, and tests for these impurities are given for each item, and assays are given for some.

A new chapter with this edition is Flame Photometry by Dr. T. C. Rains of the National Bureau of Standards. More than seventy-six elements can be determined by the method, and here it is used to determine (quantitatively) minute amounts of alkali and alkaline earth metals in these reagents. Approximately thirty new reagents which have become useful in titrimetry, colorimetry, and instrumental analyses have been added with this edition.

In addition to the reagents, various general analytical procedures and tables of pertinent analytical data are included. Although there are more sophisticated techniques available to determine arsenic, the author continues to use the Gutzeit method.

American Pharmacy. 6th ed. An Introduction to Pharmaceutical Technics and Dosage Forms. Edited by J. B. SPROWLS, JR. and H. M. BEAL. J. B. Lippincott Co., E. Washington Sq., Philadelphia, PA 19105, 1966. xv + 426 pp. 18 × 26 cm. Price $12.00.

In keeping with the changes in pharmacy education, this standard text has undergone the first major change in presentation since its beginning. The section of fundamental principles has been dropped—basic scientific knowledge has been deleted and basic pharmaceutical technology not covered in other sciences is included with the dosage form(s) to which it applies.

As the editor points out, this sixth edition is essentially a treatise on dosage forms. This book is intended to cover the material between pharmacy orientation courses and prescription and hospital pharmacy. The text has been updated also to coincide with U.S.P. XVII and N.F. XII and to reflect the advances in technology. In addition to its use as a textbook, this edition should prove a worthwhile reference for the practicing pharmacist or physician.

Received from the Department of Chemistry, University of Kansas, Lawrence, KA 66044

All errors of fact, judgment, and concept in this article are my own, but the same cannot be said for any truths which may be present. I wish especially to thank Professor E. E. Smissman for his encouragement and aid. Some of these ideas were presented in a lecture at the Fourth Annual Medicinal Chemistry Meeting-in-Miniature (MIKI Meeting) in Lawrence, Kan., last year, and I was greatly influenced by discussions with that group. Professor Bernard Belleau, who visited Lawrence in the Chemical Biology Seminar, and Dr. R. J. Thorn, whose visit was sponsored by the Chemical Physics Seminar, both contributed a number of insights. I would like to thank my colleagues and coworkers, especially Professors Earl S. Huyser and John A. *Landgrebe and Stephen* C. Hoops, H. Jayaraman, Larry Kershner, and C. G. Mitton, for many ideas and criticisms. I am grateful also for financial support by the National Science Foundation and National Institutes of Health of work discussed herein.

AN INTEREST in the phenomenon of catalysis, the acceleration of chemical reactions by substances having little or no effect on the gross stoichiometry, is shared by physical organic chemists and by medicinal chemists whose desire is to understand the character of enzyme action for purposes of drug design. The use of the concepts and theories of physical organic chemistry in the solution of problems of medicinal chemistry, such as the analysis of receptor sites and the synthesis of active compounds, is already well known to readers of the *Journal of Pharmaceutical Sciences*. In this article, the author would like to call attention to some current ideas in physical organic chemistry which are believed to have special relevance to the problems faced by pharmaceutical scientists, and to present some elementary applications of them to questions of catalysis.

Transition-State Theory—It is a nearly universal practice of solution kineticists today to present their results in terms of the transition-state theory (1–5), a custom justified by the enormous success enjoyed by this theory in producing a detailed understanding, in molecular language, of the mechanisms of a wide variety of organic and inorganic reactions. According to this theory, the reactants are viewed as participating in a quasi-equilibrium with the species (or configuration) at the maximum of energy separating the reactants from the next minimum of the Gibbs

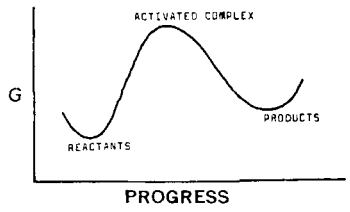

Fig. 1—Free energy profile for a simple reaction.

free energy surface[1] (Fig. 1). The maximum energy configuration (the *activated complex* or, colloquially, the *transition state*) is treated as a molecule for which "thermodynamic" functions (the free energy of activation, ΔG^*, the enthalpy of activation, ΔH^*, and the entropy of activation, ΔS^*) may be defined using a quasi-equilibrium constant, K^*, for its formation from reactants[2] (Eqs. 1 and 2):

$$\Delta G^* = -RT \ln K^* \qquad \text{(Eq. 1)}$$

$$\Delta G^* = \Delta H^* - T\Delta S^* \qquad \text{(Eq. 2)}$$

The rate constant k is then given by Eq. 3:

$$k = (\mathbf{k}T/h)K^* \qquad \text{(Eq. 3)}$$

where $\mathbf{k}$ is the Boltzmann constant, h the Planck constant, and T the absolute temperature. In addition to the free energy, enthalpy, and entropy of activation, other quasi-thermodynamic functions of activation may be defined and measured, notably the heat capacity and volume of activation, but these will not concern us here, although the volume of activation, in particular, may be of importance in catalytic processes (7).

The relevance of these considerations to problems of catalysis lies in the accuracy, economy, and elegance with which the activation parameters can be used to describe the molecular origins of reaction-rate variation with conditions (1–5, 7, 8). The understanding of the function of a catalyst must consist in the specification of the way in which it affects the activation parameters of the reaction of interest by interaction with the substrate and the activated complex.

Any mechanistic model, if formulated in sufficient detail, includes the relevant interactions. If the effect of each of these on the enthalpy and entropy of activation, and thus on the free energy of activation, is estimated, then the sum over all interactions gives the rate of the catalyzed reaction, relative to the rate of the uncatalyzed reaction or to the reaction catalyzed by another substance, *i.e.*, the *catalytic efficiency*. A similar estimation of the effect of changing the substrate structure on these quantities can yield the relative rates of the catalyzed reaction for various substrates, or the *catalytic specificity*.

The estimation process can be aided, and some general statements can be made, by use of relations which have been observed between the enthalpy and entropy changes associated with certain interactions, so that the two variables are not independent. In fact, it will be shown that the existence of such relations permits the formulation of a simple quantity which expresses numerically the catalytic specificity associated with a given kind of interaction in terms of its biological value.

Table I—Some Important Factors Which Contribute to the Enthalpy and Entropy Changes for Solution Reactions

Enthalpy: Potential and Kinetic Energies; Work	*Entropy:* Statistical Probability
Covalent bonding	Number of particles (translational freedom)
Electrostatic attractions and repulsions, including those of dipoles	Freedom of external and internal rotations
Nonbonded attractions and repulsions (van der Waals and London forces)	Low-frequency vibrations
Hydrogen bonding	Freedom of translation and rotation of solvent molecules
Charge-transfer bonding	Symmetry
Strain and distortion of bond lengths and angles	
Solvation energies	
Resonance energies	
Zero-point energies	
Pressure-volume work	

Free Energy, Enthalpy, and Entropy—For the convenience of the reader, Table I recalls the major factors contributing to the magnitudes of enthalpy and entropy changes for reactions in solution. From the standpoint of transition-state theory, it is immaterial whether these quantities refer to the conversion of reactants into products in an equilibrium process or to the conversion of reactants into activated complex in a rate process. No comment is really required about these factors, which are familiar to most people from discussions of reaction mechanisms. Wiberg (3) has discussed the subject in great detail in a very clear fashion. It should be mentioned that the form of the transition-state theory given here (unit transmission coefficient) is inapplicable to reactions involving changes in electron-spin multiplicity (9).

[1] This is the appropriate variable for the vertical axis of such plots (see the discussion in *Reference 6*). Johnston's objection (*Reference 5*, chap. 16) can be met by use of an appropriate standard state for the stoichiometric assembly for each set of experimental conditions. The step functions shown by Johnston are correct, rather than the curves shown here (and usually).

[2] K^* is a quasi-equilibrium constant and the associated 'thermodynamic" functions are given quotation marks (or are designated quasi-thermodynamic) because the degree of freedom for decomposition of the activated complex has been removed from consideration. (See *Reference 4* for a recent, lucid discussion.)

ISERGONIC RELATIONS

Should there exist a relation between the enthalpy change and the entropy change which occur during a chemical process? A number of models suggest that the answer is yes. Consider the formation of a bond between two polyatomic species. As the two particles combine, enthalpy (bond energy) is liberated and the translational and rotational entropy is decreased by the conversion of two particles into one. If a series of such association processes, of progressively stronger binding, were studied, the enthalpy liberated would increase with the stronger binding, but the translational entropy loss would be the same in all cases and the rotational entropy loss little different. However, stronger binding usually means shorter bonds, and for polyatomic species, the smaller separation of the more strongly bound moieties could easily lead to greater losses of entropy due to restriction of bending vibrations and internal rotations through mutual interaction. Thus stronger and more exothermic binding might well be accompanied by a progressively more negative entropy of combination.

Consider also the ionization of a neutral molecule in a solvent which interacts readily with ions. Suppose a series of dissociation rates is studied, such that the degree of conversion of the reactant into its ionic fragments at the activated complex steadily increases. As the ions become more fully formed, the solvent will interact more strongly with the activated complex with liberation of a correspondingly greater amount of solvation energy. At the same time, the tighter bonding of the solvent molecules will lead to an increasing reduction in entropy, as more solvent molecules become involved (translational and rotational entropy) and as the rotational and vibrational motions of those already bound are further restricted. Thus the solvation process should make increasingly more negative enthalpy and entropy contributions to the free energy of activation as the degree of charge separation at the activated complex increases.

Both of these models predict a *compensatory* relation of enthalpy and entropy, *i.e.*, a correspondence such that the effect of one quantity on the free energy tends to be cancelled by the effect of the other, but neither model (in the form above at least) is detailed enough to determine the functional form of the relation. For this we turn to experiment.

Linear Compensatory Relations—Alder and Leffler (10) observed that the enthalpies and entropies of activation for the decomposition of phenylazotriphenylmethane into free radicals in a series of solvents were related *linearly*, according to Eq. 4:

$$\delta_M \Delta H^* = \beta \delta_M \Delta S^* \qquad \text{(Eq. 4)}$$

with $\beta = 310°$ K.; the positive value of β expresses the fact that the behavior is compensatory. The symbol δ_M occurring in Eq. 4 is the very useful Leffler-Grunwald operator (11) for medium variation. $\delta_M \Delta G^* = \Delta G_M^* - \Delta G_0^*$, where the subscript M refers to some arbitrary solvent and the subscript 0 to a standard solvent. The expression $\delta_M \Delta G^*$ can conveniently be read, "the effect of medium on ΔG^*." Other operators can be defined for any variable, such as structure (δ_R), catalyst (δ_C), *etc.* The net effect on the free energy of activation in the Alder-Leffler system is obtained by substitution of Eq. 4 into Eq. 2, after application of δ_M to the latter, yielding Eq. 5.

$$\delta_M \Delta G^* = (\beta - T)\delta_M \Delta S^* \qquad \text{(Eq. 5)}$$

This study illustrated that lack of a solvent effect on rate at a given temperature ($\delta_M \Delta G^* \sim 0$) could not be taken as evidence that no solvent-interaction change was arising on activation. In this case, at temperatures near 310° K., the solvation enthalpies and entropies cancel each other and no rate effect is found. The molecular interactions responsible for these observations for free radical reactions are still under investigation (12).

Since, in principle, no variation in rate at all would be observed if the reaction were studied at a temperature equal to β, this quantity was denoted the *isokinetic temperature* (13, 14). If enthalpy–entropy compensation is observed for an equilibrium process, this terminology is etymologically incorrect. Perhaps a more desirable general term is *isergonic temperature* (the slope of an *isergonic relation*, such as Eq. 4), which we adopt here.

Leffler and Grunwald (11) have collected a large number of isergonic relations for both rate and equilibrium processes, all approximately linear with positive slope, *i.e.*, compensatory in nature. The values of β ranged from about 100° K. to about 1300° K.

The same authors have further shown that some data sets which did not yield isergonic reactions (in which enthalpy *versus* entropy plots either showed no correlation or a nonlinear one) could be analyzed in terms of a superposition of more than one isergonic relation (Eqs. 6–8):

$$\delta\Delta H = \sum_i \delta\Delta H_i; \quad \delta\Delta S = \sum_i \delta\Delta S_i \qquad \text{(Eq. 6)}$$

$$\delta\Delta H_i = \beta_i \delta\Delta S_i \qquad \text{(Eq. 7)}$$

$$\delta\Delta H = \sum_i \beta_i \delta\Delta S_i \qquad \text{(Eq. 8)}$$

They reason that each of these terms in the summations corresponds to a particular interaction mechanism and that the observed enthalpies and entropies are merely the resultant. The plots may be analyzed by vector addition of the individual relations to obtain the locus of a given point. As shown in Eq. 7, each interaction mechanism is presumed to have its own characteristic isergonic temperature β_i. The reader will agree that such cases as this are likely to be of the greatest value in analyzing the most interesting cases of catalysis, in which manifold interactions between catalyst and substrate are expected.

The Role of Experimental Error—Two important criticisms of the use of isergonic relations have appeared. Petersen, Markgraf, and Ross (15) criticized most of the relations which had appeared before 1961 on the grounds that (*a*) the errors in ΔH and ΔS are related—if the temperature dependence of a rate or equilibrium constant is used to evaluate them, ΔH is obtained from the slope and ΔS from the intercept (effectively) of the same line—so that spurious relations may arise from experimental error, and (*b*) that a number of reactions showing apparent isergonic relations in fact had total ranges of variation of the enthalpy smaller than the maximum error in ΔH, as estimated from the errors of the extreme temperature points of the Arrhenius or Eyring plots.

Leffler and Grunwald (11, 14) have shown, however, that this method of error analysis is incorrect, since if the maximum error of ΔH is placed on the enthalpy–entropy plot, it will include regions of impossibly high or low ΔG (in which the error is always much less than in ΔH). The true error contour is thus an ellipse tilted with its major axis along a line of slope equal to the mean experimental temperature. It would appear that most of the originally described isergonic relations do in fact represent actual correspondences of enthalpy and entropy, although it emerges clearly from this controversy that larger temperature ranges than have been usual ought to be employed in the measurement of activation and thermodynamic parameters, inasmuch as the maximum error in ΔH increases as the inverse of the absolute temperature range studied.

Petersen (16) has raised a further objection to the use of isergonic reactions. If an isergonic temperature actually exists, he points out, then it is clear that the Arrhenius or Eyring plots for all the individual systems correlated must intersect at that point. No variation in rate at the isergonic temperature will then be observed. Petersen (*a*) constructed a set of artificial data which displayed a satisfactorily linear isergonic relation (correlation coefficient 0.998), but for which the individual Eyring plots did not intersect at a common point, and (*b*) found that in no case of an isergonic system from the literature did the Eyring plots have the requisite intersection property.

This demonstrates very convincingly that isergonic relations are approximate, a result which on reflection is more satisfying than the existence of exact relations. It would be amazing if the shift in enthalpy change produced by a structural or environmental variation were always accompanied by an exactly proportional entropy change; we are unaccustomed to such rigor in chemistry. On the other hand, the fact that structurally induced variations in ΔH and ΔS are in the same direction and approximately proportional is a very informative observation from a mechanistic point of view. Indeed, the isergonic temperature (or approximate change in ΔH per unit change in ΔS) is directly useful inasmuch as it must be quantitatively consistent with an acceptable mechanistic model. Herein is the utility of the concept, rather than in the existence of an experimental temperature at which no rate variation is observed.

It is certainly true that Petersen's work shows the term isergonic temperature (or isokinetic temperature) to be a misnomer. Nevertheless, as Leffler has said (14), such a term is conveniently mnemonic as a name for the slopes of linear enthalpy–entropy relations.

Solvation Phenomena and Electrostatic Interactions—As we noted in the initial arguments above, an isergonic relation due to solvation effects might be expected for a series of reactants in an ionization rate process. The same arguments indicate that solvation energy and solvation entropy ought in general to be related in a compensatory way and that processes in which solvation changes contribute in a significant way to the energetics may exhibit the effects of this compensation.

In the case of solvation phenomena involving electrically charged species, however, we must consider the values of the enthalpy and entropy changes associated with the electrostatic work of separating the charges (in ionization) or the work done by their combination. The free energy change, enthalpy change, and entropy change [as obtained by Frost and Pearson (17) in a simple way] are given by Eqs. 9, 10, and 11:

$$\Delta G = (-Z_A Z_B e^2/Dr) \qquad \text{(Eq. 9)}$$

$$\Delta S = (-Z_A Z_B e^2/Dr)\,(\partial \ln D/\partial T)_P \qquad \text{(Eq. 10)}$$

$$\Delta H = (-Z_A Z_B e^2/Dr) \times (1 - T[\partial \ln D/\partial T]_P) \quad \text{(Eq. 11)}$$

where the Z's are the charges (in units of the electronic charge) on the ions, e the charge on the electron, D the dielectric constant of the medium, and r the charge separation in the initial state; the values are for separation of the ions to infinity. These and related expressions have been used and discussed critically by Frost and Pearson, by Lumry (7), and by Linderstrøm-Lang and Schellman (18) as well as many others. Their limitations are rather severe inasmuch as they ignore the difference between macroscopic and microscopic dielectric constant, treat the solvent as a continuum, and ignore particulate interactions of the solvent with the ions. As is evident from inspection, they do not predict any dependence on the structure of the ions; for example, ΔS of combination for univalent ions in water should be about -10 e.u. A number of cases do not depart seriously from this rule (17).

However, the heat and entropy of combination of all ions of the same charge type are not equal, as is implied by this treatment. Duncan and Kepert (19) collected the data of a number of workers on the thermodynamics of ion-pair formation for many different types of salts in several protic solvents. These data are correlated isergonically with a slope of 200° K. The explanation probably lies in the interaction of solvation energies and entropies in the hydration shells, as discussed above.

Brown (20), in a wide ranging study of isergonic relations, found that the data for ionization of a variety of organic acids were correlated by lines with an isergonic temperature of 280° K. This number is in striking agreement with an estimate by Belleau (21) of the isergonic temperature associated with the "melting" of the "icebergs" which, according to the Frank-Evans theory of the structure of aqueous solutions,[3] surround nonpolar solutes in water. The term "iceberg" being taken literally, the heat of fusion of ice (1440 cal./mole) was divided by the entropy of fusion of ice (5.6 e.u.) to obtain $\beta = 273°$ K. This agreement with Brown's finding supports an *ad hoc* hypothesis that these correlations are arising from formation and destruction of solvation shells surrounding the reactants and products, and that these shells bear some resemblance to ice.

Hepler,[4] in a landmark contribution to the understanding of chemistry in protic solvents, applied the isergonic temperature of 280° K. suggested by Brown's observations for solvation phenomena in water to the data for phenol ionization and arrived at a completely meaningful interpretation of the substituent effect on this reaction. This theory will be discussed in more detail under *Linear Free Energy Relations*, but at this point a particular property, noted by Hepler, conferred on solvation phenomena in water by the isergonic temperature of 280° K. should be brought to light. According to Eq. 5 above, the total contribution of solvation phenomena in any process to its free energy change is given by the change in solvation entropy times $(\beta - T)$; but since β is very close to room temperature, the very important conclusion emerges from Hepler's theory that *solvation changes will have little effect on the rate or site of equilibrium of a reaction studied in aqueous solution near room temperature.*

Linear Free Energy Relations[5]—In his original discussion of the limitations of the Hammett equation (Eq. 12):

$$\log k/k_0 = \rho\sigma = \frac{\delta_R \Delta G^*}{-2.3\ RT} \quad \text{(Eq. 12)}$$

Hammett (24) noted that if the entropy change for a series of reactions were constant, then the free energy change would be equal to the enthalpy change, which might reasonably be expected to vary according to the potential energy changes which are usually considered to lie at the basis of such linear correlations. At a later time, Taft (25) showed this criterion to be too restrictive and demonstrated that linear free energy relations could result from data sets in which the entropy changes were not constant along the series but instead varied linearly (isergonically) with the enthalpy changes (Eqs. 4 and 13).

$$\delta_R \Delta G^* = \left(\frac{\beta - T}{\beta}\right) \delta_R \Delta H^* \quad \text{(Eq. 13)}$$

Studies of the ionization of substituted phenols in water by Hepler (23), already mentioned, produced data which were correlated by the Hammett equation but which fulfilled neither of the criteria just mentioned: the changes in entropy were far from constant (in fact, the major part of the substituent effect appeared in the entropy term) and they were not linearly related to the corresponding enthalpy changes. Hepler proposed to explain the data in a way which can be formulated as a two-interaction–mechanism isergonic relation. He assumed the enthalpy effects to be a sum of internal contributions ($\delta\Delta H_i$, essentially the potential energy effects customarily invoked for substituents) and external contributions due to solvation ($\delta\Delta H_e$) as expressed by Eq. 14:

[3] See Kavanau (22) for a summary of this and other ideas.
[4] See Hepler (23) and other papers by the same author.
[5] Readers unfamiliar with free energy relations should consult Wiberg (3) and then Leffler and Grunwald (8).

$$\delta\Delta H = \delta\Delta H_i + \delta\Delta H_e \quad \text{(Eq. 14)}$$

He assumed the observed entropies to comprise a similar sum but hypothesized the internal entropy changes (in the rigid aromatic system) to be negligible compared to those derived from solvation effects (an infinite isergonic temperature was thus assumed for internal changes since $\delta\Delta S_i = 0$). Thus, the observed $\delta_R\Delta S$ were taken equal to $\delta_R\Delta S_e$. Furthermore, on the basis of the observations of Brown cited above, he assumed the solvation energies and entropies to be isergonically related with an isergonic temperature of 280° K. (Eq. 15):

$$\delta_R\Delta H_e = (280)\delta_R\Delta S_e = (280)\delta_R\Delta S \quad \text{(Eq. 15)}$$

The observed enthalpies of ionization are then related to the corresponding entropies by Eq. 16:

$$\delta_R\Delta H = \delta_R\Delta H_i + (280)\delta_R\Delta S \quad \text{(Eq. 16)}$$

Notice that this relation could be represented graphically by an isergonic plot with $\beta_e = 280°$ with each experimental point displaced vertically (parallel to the $\delta\Delta H$ axis since $\beta_i = \infty$) from the line by an amount $\delta\Delta H_i$. Now if the substituent effect on the free energy is examined, Eq. 17 is obtained:

$$\delta_R\Delta G = \delta_R\Delta H_i + (280 - T)\delta_R\Delta S \quad \text{(Eq. 17)}$$

Since the experimental temperature for which the observed Hammett correlation of these data was made is near 280° (the data were for 298° as usual), the contribution of the entire solvation effect (contained in the last term of Eq. 17) is almost completely lost from the free energy. In fact, as Hepler points out, if the 280° isergonic temperature is generally applicable to solvation phenomena in water, then solvation effects are nearly always negligible and the Hammett equation "sees" only the potential energy contributions to the free energy. This explains why the Hammett equation in aqueous solution (or, as we shall see below, in other protic solvents) near room temperature is so much more successful than it "should be" in providing data explicable in simple potential energy terms.

It has been found (26) that Hepler's theory is not limited to aqueous solution, to ionization processes, or to equilibrium data. The enthalpies of activation and the entropies of activation for the methoxide-catalyzed methanolysis of aryl methyl carbonates in methanol (to give dimethyl carbonate and the phenol) appear to be unrelated. Rates of methoxyl exchange from tritium-labeled esters were found to be much slower than solvolysis so that addition to the carbonyl group of the ester by methoxide ion is the rate-determining step. The rate process under study then is essentially addition to an aryloxy-substituted carbonyl group. According to the Hepler theory, the vertical displacements of the individual points from an isergonic line for solvation interactions should give $\delta\Delta H_i$* for each substituent, the effect of the substituent on the internal enthalpy (roughly the internal potential energy) of activation. If 320° K. is adopted as the solvation isergonic temperature for methanol, these deviations in fact give an excellent correlation with the Hammett σ. The slope is consistent with inductive stabilization of the negative charge being introduced in the activated complex and with resonance stabilization of the electron density being released from the carbonyl group onto the aryl oxygen by addition of the methoxide ion. As predicted by the Hepler theory, the free energies are correlated (roughly) by the Hammett σ and very well by the free energies of ionization of the phenols, determined under the same conditions.

Under the discussion of catalytic interactions, we shall see that Hepler's theory probably explains the great success of the Brønsted equation in correlating catalytic constants and basicities or acidities. It also seems entirely possible that the new and extremely successful applications of linear free energy relations to biological phenomena such as drug action, by Hansch (27) and others, will be found to rest in part on the existence of isergonic relations for certain perturbing interactions which cause their cancellation or near-cancellation from the observed free energy data.

Arnett and Burke (28) have recently shown as well that Hepler's theory explains the correlation they found between heats of ionization of acids in nonaqueous or water-poor media and free energies of ionization in water-rich media. They cite other data to support their opinion, which agrees with mine, that this theory underlies a "vast array of free-energy–structure correlations."

Nonbonded Interactions—This term is probably used most often to refer to the repulsive interactions between groups forced to exist closely enough to experience mutual repulsion of their outer electron clouds. No entropy change would be expected to result from this kind of interaction among structureless groups. However, if the groups contain a sufficient array of substructure that close steric interaction causes the restriction of internal rotations, or increases the frequency of vibrations (usually bends) which have a low enough initial frequency to have

some population of molecules in the excited vibrational states at ordinary temperature (and thus initially some vibrational entropy), then a reduction in entropy is expected to arise coincidentally with the onset of steric repulsion. If both of these processes came about concurrently and gradually, an enthalpy–entropy relation would be expected, with an increase in enthalpy (incursion of repulsion) being accompanied by a reduction in entropy (restriction of motions). This model thus predicts a negative isergonic temperature, which has not been observed for cases of this kind.

The reason perhaps lies in the very steep distance dependence of steric interactions: they arise only at very short distances and the associated energies then increase very rapidly as the distance is further shortened between the interacting groups (3). Furthermore, rotational motion can probably be restricted by mere development of a potential well within which the former rotor now sits stationary, but not experiencing any increase in potential energy; in fact the energy will have decreased due to the loss of the kinetic energy of the rotor. Thus as the two interacting groups approach, the internal rotations of the substructure probably are lost at distances too great for severe steric repulsion. Later, when the repulsion begins to increase the energy, the groups are already frozen and no further entropy can be lost.

The latter model is in agreement with some data collected and tabulated by Taft (25). The steric strain energies of activation for esterification and hydrolysis reactions of esters were (in effect) taken as equal to the deviations (in energy units) from the Taft equation plot of the experimental enthalpies. These are plotted *versus* the entropies of activation in Fig. 2. The model predicts effectively a sharp change from an isergonic temperature of zero (entropy loss with no accompanying energy change) to an isergonic temperature of infinity (energy increase with no further entropy change), which Fig. 2 shows to be the case.

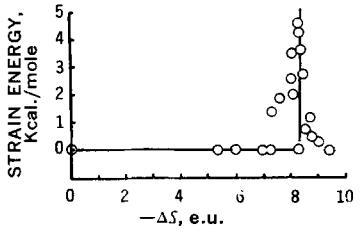

Fig. 2—Strain energies of activation versus *entropies of activation for hydrolysis and esterification of esters under various conditions, from the tabulation by Taft (25).*

Charge–Transfer Interactions—We have just seen that the restriction of internal rotations by steric interaction is unlikely to produce an observed relation due to contributions from the entropy loss of the former and the enthalpy increase of the latter; if some longer range force is simultaneously coming into operation, however, it might be possible to observe a relation between the enthalpy change from this source and the entropy loss from the restriction of internal rotations mentioned above. A possible system is offered by charge–transfer complexation of structured molecules.

A number of cases have been collected and examined for such correlations by Andrews and Keefer (29) An isergonic relation (β = 690° K.) is found for the complexation in carbon tetrachloride solution of iodine and iodine monochloride with alkylbenzenes, *tert*-butyl alcohol, and dioxane (although most oxygen bases do not fit the same equation). A similar correlation is obtained for iodine with aliphatic amines in *n*-heptane solution (β = 637° K.) and with nitriles, and for iodine, iodine monochloride, and iodine monobromide in carbon tetrachloride solution (β = 540° K.). The absolute magnitudes of the entropy losses in the first cited series are from 3 to 9 e.u. The range (6 e.u.) is not inconsistent with the ascription of the variation to losses of internal rotations, for which values of 2–3 e.u. per rotation are probably appropriate.

The model fits the data in all respects, as noted by Andrews and Keefer. For example, the data for complexation of iodine with hexamethylbenzene (ΔH = −4 Kcal./mole, ΔS = −7 e.u.) and hexaethylbenzene (ΔH = −2 Kcal./mole, ΔS = −3 e.u.) indicate that the greater steric bulk of the ethyl groups restricts the complexing agent to a greater distance from the π-cloud, thus making the bonding less exothermic, but also requiring the restriction of fewer rotations, thus making the entropy change less negative. The values in general of β about 600° appear to show that closer approach of the complexing agent, such that entropy equivalent to that of one internal rotation is lost ($-\Delta S \sim$ 2–3 e.u.), produces a bond about 1.2–1.8 Kcal./mole tighter than before.

Hydrogen Bonding—Hydrogen bonding is a long range force because the proton bridge, which *per se* has practically no steric requirement, serves to keep the two bonding moieties at a sufficient removal from one another that little or no steric interaction (an exceedingly short-range force) between the bonding groups is ex-

pected.[6] Thus, if a single hydrogen bond binds two species together, only the loss of translational entropy is expected, together with some entropy loss from restriction of rotation about the bonds forming the hydrogen bridge itself. Neither of these should vary much with the strength of the hydrogen bond, so that enthalpy–entropy relations would not be expected from this source. In aqueous solution, some changes in solvation on formation of the hydrogen bond might occur, leading to an isergonic relation with $\beta \sim 280$–$300°$, as discussed above.

The situation differs if more than one hydrogen bond forms between the same two bodies, or if the hydrogen bond is one of several forces binding the two moieties together. In this case the formation of the hydrogen bond should nearly always be accompanied by a loss of entropy, from restriction of internal rotational motions on conversion of linear into cyclic conformations and from conversion of low-frequency chain-deformation vibrational modes into higher frequency ring-deformation modes. Furthermore, ring formation of this type will promote closer steric interaction between the sides of the new ring, thereby restricting internal rotational motion to a still greater degree and probably increasing the frequency of some bending vibrations. In general, a stronger hydrogen bond, formed with greater liberation of enthalpy, ought to lead to a more rigidly restricted product and thus to a greater loss in entropy.

Although the data are not ideal for a test of this hypothesis, an isergonic plot has been constructed in Fig. 3 from a variety of measurements reported by Davies (31). The scatter is not surprising in view of the variety of types and sources of information included, but the correlation is satisfactory, with an isergonic temperature of about 270°. An entropy loss equivalent to freezing of one internal rotation (2–3 e.u.) thus results from strengthening of the hydrogen bonding system by about 0.5–0.8 Kcal./mole.

Covalent Bonding—Covalent bonding between structured species might be expected to generate isergonic relations in the same fashion described in the cases above for other types of bonding. Some of the many isergonic relations tabulated by Leffler and Grunwald (11) for association and displacement reactions may fall in this category, but the possibility of other origins remains open because of the universal complexity of the systems studied. Covalent bonds in organic compounds are generally formed with exothermicities of 30 to more than 100

[6] Covitz and Westheimer (30) have shown that such steric effects are not entirely negligible.

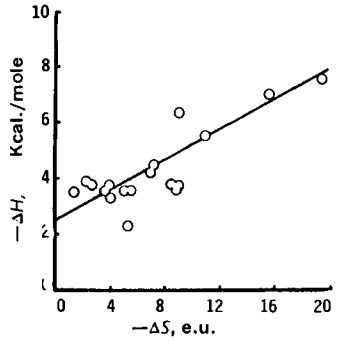

Fig. 3—Compensation of energy and entropy in the formation for hydrogen bonds. The data are taken from Davies (31) and are for dimerization and polymerization in benzene solution of amides, measured by Davies and Thomas (32), and association of diphenylamine, phenol, and benzyl alcohol with dimethylformamide, dioxane, acetonitrile, benzyl acetate, and azobenzene in carbon tetrachloride solution, determined by Flett (33).

Kcal./mole; if the formation is accompanied by the combination of two species into one, the entropy may decrease by as much as 50–60 e.u., while if the bond is formed intramolecularly, only 2–3 e.u. may be lost in the process. The simple ratios of $\Delta H/\Delta S$ thus range from 500 to 50,000° K., although this model cannot generate a continuously varying sequence of enthalpies and entropies.

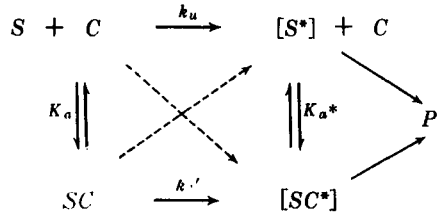
Thorn and his co-workers (34) have observed energy–entropy correlations in high temperature systems and have attributed the results to a fundamental relation between the energy of formation of a substance at the absolute zero and the entropy of the substance at higher temperatures, since structural information is present in both quantities. Thorn's efforts to develop the underlying theory promise to provide a complete statistical-mechanical basis for both isergonic and linear free-energy relations.

QUESTIONS IN CATALYSIS

A Simple Model of Catalysis—To facilitate the consideration of catalytic processes, we will develop a simple model, based on the concept of virtual equilibria among activated complexes, recently applied by Kurz (35) to several mechanistic problems.

Scheme I portrays a system of reactions in which a substrate S may be converted to a product P by (a) a route catalyzed by C, involving formation of a substrate–catalyst complex SC^*, or (b) an uncatalyzed route through activated complex S^*. The rate law is given by Eq. 18:

$$v = k_c'[SC] + k_U[S] = [S](K_a k_c'[C] + k_U) \quad \text{(Eq. 18)}$$



Scheme I

It is readily shown that introduction of the extra, dashed routes makes no change. Scheme I also includes the equilibrium constant, K_a^*, for virtual interconversion of the activated complexes S^* and SC^*, according to Eq. 19:

$$S^* + C \rightleftarrows SC^* \quad K_a^* \qquad \text{(Eq. 19)}$$

It does not matter that the actual interconversion does not occur directly; the concentrations of the two are the same as if it did. Then, since $k_c'K_a = k_UK_a^*$, the rate law may also be written as in Eq. 20:

$$V = [S](k_U + k_UK_a^*[C]) \qquad \text{(Eq. 20)}$$

This can be written in terms of the analytical concentration of S ($[S]_{tot}^{\circ}$), for conditions of excess catalyst as Eq. 21, or in terms of the analytical concentration of C ($[C]_{tot}$) for conditions of excess substrate (as in many enzyme experiments) as in Eq. 22:

$$V = k_U[S]_{tot}\left\{\frac{1 + K_a^*[C]}{1 + K_a[C]}\right\} \qquad \text{(Eq. 21)}$$

$$V = k_U[S]\left\{1 + \frac{K_a^*[C]_{tot}}{1 + K_a[S]}\right\} \qquad \text{(Eq. 22)}$$

The point is clear from either of these expressions that the larger K_a^* is relative to K_a, the more efficient C is as a catalyst. In other words, the stronger the association of catalyst with S^* to form SC^*, the more rapidly the catalyzed reaction will proceed. Quasi-thermodynamic functions are of course associated with K_a^* (Eq. 23):

$$\Delta G_a^* = -RT\ln K_a^* = \Delta H_a^* - T\Delta S_a^* \qquad \text{(Eq. 23)}$$

Let us divide up the free energy (and enthalpy and entropy) change on association of S^* and C into contributions from each of the interactions which occurs (Eq. 24):

$$\Delta G_a^* = \sum_i g_i = \sum_i h_i - T\sum_i s_i \qquad \text{(Eq. 24)}$$

Assume that h_i and s_i for each of these interactions are related, at least roughly, isergonically (Eq. 25):

$$h_i = \beta_i s_i \qquad \text{(Eq. 25)}$$

Then ΔG_a^* can be written as a sum in either enthalpies or entropies or both, for individual interactions (Eq. 26):

$$\Delta G_a^* = \sum_i (\beta_i - T)s_i = \sum_i (1 - T/\beta_i)h_i = \sum_j (\beta_j - T)s_j + \sum_k (1 - T/\beta_k)h_k \qquad \text{(Eq. 26)}$$

Notice that if the catalyzed reaction is to proceed faster than the uncatalyzed reaction, ΔG_a^* must be negative. Thus any interaction which contributes effectively to catalysis must have $g_i = (\beta_i - T)s_i < 0$. For interactions which involve binding of some kind, s_i will usually be negative. Thus only if $\beta_i > T$ (the isergonic temperature exceeds the experimental temperature) is the interaction likely to enhance catalytic efficiency. Of the interactions considered in the last section, covalent bonding (probable $\beta \sim$ 500–50,000° K.) and charge-transfer bonding ($\beta \sim$ 500–700° K.) are clearly catalytic near room temperature, while hydrogen bonding ($\beta \sim$ 270° K.) and ion-pairing ($\beta \sim$ 200° K.) are noncatalytic.

Use of the average values for β_i's obtained in the last section may give spurious results, however. All those values were obtained by use of systems where the forces were involved as primary (or very important) binding forces. In a catalytic activated complex, other forces may already hold a functional group in such a position that the interaction can occur with an abnormally small loss in entropy; the effective value of $\beta(\delta\Delta H/\delta\Delta S)$ will then be increased and the interaction becomes more catalytically effective. Thus, if a hydrogen bond with an enthalpic strength of 2 Kcal./mole were able to form with only a restriction of a single internal rotation (say, loss of 3 e.u.) in a preformed environment, $\beta_{eff} = 2000/3 \sim 700°$ K., and the interaction is nicely catalytic.

Conceivable interactions which come under scrutiny in the formulation of a mechanistic model can be designated (in the context of the activated-complex model) as *obligatory* (the model requires that they occur) or *elective* (the model makes no statement). Models will sometimes include obligatory interactions with positive g_i, *i.e.*, anticatalytic interactions. Steric repulsions which necessarily must be included to allow other, more favorable, interactions are examples. Of the elective interactions, those with $g_i > 0$ will not occur and may be omitted from the summation (that is, it is unreasonable to postulate that they occur). Those with $g_i < 0$ will occur and are catalytic. The best model is of course the one in which the obligatory and elec-

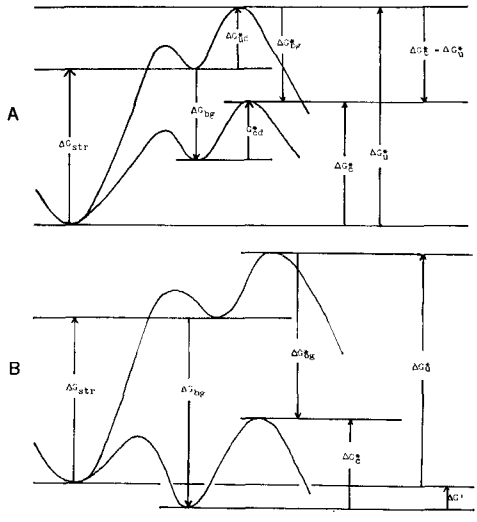


Fig. 4—Key: A, *distortion-catalysis in a system where the substrate is chiefly free;* B, *distortion-catalysis in a system where the substrate is chiefly complexed.*

tive interactions have been so balanced as to make ΔG_a^* as negative as possible.

Is the present model sufficiently sophisticated to apply to the complex kinetic systems frequently encountered in practice, particularly with enzymes? With some qualification, an affirmative answer is possible. Equation 22 is readily shown to be equivalent to the Michaelis-Menton equation. Lumry (7) has discussed in detail how experimental activation parameters from such a treatment can be related to mechanisms for more complex reactions. For our purposes, we need to regard ΔG_a^* as referring not to formation of a single activated complex SC^* but rather an abstract weighted-average entity for all activated complexes along the reaction path. The weighting factor for the ith activated complex is exp (G_i^*/RT).

Catalysis by Strain and Distortion—The view seems widely current[7] that many enzymes are catalytically active by virtue of the ability to induce in the substrate molecule some sort of strain or distortion, increasing its energy and thereby decreasing the energy required to transform it into a (presumably no longer strained) activated complex. Notable examples of such ideas are the "rack" hypothesis of Eyring and his co-workers (38) according to which the enzyme stretches bonds of the substrate, rendering their fission more facile; the proposal of Westheimer and his co-workers (39) that ribonuclease functions by intermediate formation of strained cyclic five-membered phosphate esters which, demonstrably in model systems, hydrolyze enormously more rapidly than their open-chain analogs; and the proposal of Bruice and Pandit (40) that esterases may bind esters in the unfavorable *trans* rotameric form, facilitating attack at the carbonyl group by nucleophilic reagents.

These hypotheses must be considered in two different ways, depending upon whether the major form of the reactant in limiting concentration under the conditions of interest is the free substance or the substance bound in the enzyme–substrate complex. Both circumstances are shown in Fig. 4. Figure 4A, refers to the former situation (free reactants). We compare the catalyzed reaction (lower curve) with the (perhaps hypothetical) uncatalyzed reaction passing through the strained or distorted form (pictured as the high minimum) along the upper curve. Shown on the diagram are ΔG_{str}, the increase in free energy of the substrate on conversion to the strained form; ΔG_{bg}, the free energy released on binding of the strained form of the substrate to the catalyst; ΔG_{ud}^*, the free energy of activation for conversion of the strained substrate to the uncatalyzed activated complex; ΔG_{cd}^*, the similar quantity for conversion of the strained-substrate–catalyst complex to the catalyzed activated complex; ΔG_U, the over-all free energy of activation for the uncatalyzed reaction; and ΔG_C, the over-all free energy of activation for the catalyzed reaction. It is graphically obvious that the entire catalytic efficiency, $\Delta G_U - \Delta G_C$, is given by the free energy of binding of the catalyst to the activated complex, the distortion energy cancelling out of the observable quantities. Thus the distortion, while surely an interesting characteristic of the catalytic mechanism, does not directly enter into the catalytic efficiency. This model applies to enzymatic catalysis at such reactant concentrations that the velocity is considerably less than maximum.

Figure 4B, shows the other possibility, the same quantities being displayed on the diagram. Here the complex is more stable than the free reactants. Inspection now shows that the catalytic efficiency is given by $-\Delta G_{bg} + \Delta G'$, where $\Delta G'$ is the excess of binding free energy over strain free energy for the complex (expressed as a positive number). The larger $\Delta G'$, the less effective the catalysis; the more negative ΔG_{bg}, the more effective the catalysis. Once again, the important point is that the catalyst bind strongly to the activated complex relative to the reactant.

Thus the methods of reasoning given above apply to these cases equally well.

[7] For a discussion of this and the enthalpy–entropy question in intramolecular catalysis, omitted here for lack of space, see *References 36* and *37*.

TABLE II—ACTIVATION PARAMETERS FOR THE MUTAROTATION OF GLUCOSE ANALYZED BY HEPLER'S ISERGONIC THEORY[a]

Catalyst	$\Delta H^*)$ [b]	$\Delta S^*)$ [c]	$\delta_C \Delta H^*)$ [d]	$\delta_C \Delta S^*)$ [d]	$\delta_C \Delta H$	$\delta_C \Delta H_i$

[a] Data are from Schmid, H., and Bauer, G., *Monatsh Chem.*, **96**, 1503(1965) All enthalpy data are in Kcal./mole; entropies in e.u. [b] Errors are about ±0.4 Kcal./mole. [c] Errors are about ±1.5 e.u. All figures are given, even if not significant.

Acid–Base Catalysis and Catalytic Efficiency—Catalytic efficiencies for acid-base catalysis are most frequently described by the Brønsted relation (Eq. 27), one of the oldest linear free energy relations (41–43):

$$\delta_C \Delta G^* = \alpha \delta_C \Delta G^\circ \qquad \text{(Eq. 27)}$$

Here ΔG^* is the free energy of activation, ΔG° the free energy of neutralization or ionization of the catalyst, and δ_C the Leffler-Grunwald operator for catalyst variation. It was early rationalized (41) in terms of intersecting Morse curves, implying that potential energy variations were at its basis, while Leffler (44) later provided a noncommittal free-energy argument. In any case, examination of activation parameters for various catalysts correlated by the equation frequently reveals startling irregularities (45). Exemplary are the data of Schmid and Bauer (46) for the mutarotation of glucose, shown in Table II.

The validity of the Brønsted relation under these circumstances is understandable in terms of Hepler's isergonic theory, outlined above. Following Hepler, we assume $\delta_C \Delta S^* = \delta_C \Delta S_e$, entirely due to solvation. Furthermore, we assume $\delta_C \Delta H_e = 280 \delta_C \Delta S_e$ and that $\delta_C \Delta H^* = \delta_C \Delta H_i + \delta_C \Delta H_e$. These quantities are all listed in Table II. Note that the $\delta_C \Delta H_i$ are all negative and decrease with increasing basicity of the catalyst. These quantities are the enthalpies for the process shown in Scheme II.

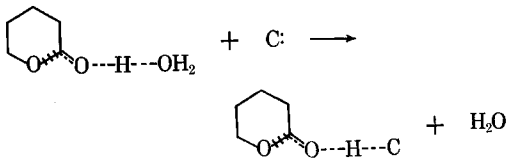
They are therefore effectively the strengths of the hydrogen bonds by which each catalyst is bound to the activated complex. The values are unreasonably large for ordinary hydrogen bonds, in agreement with a recent suggestion that unusually strong hydrogen-bonding capabilities are displayed by polarizable activated complexes.[8]

The Brønsted relation holds because, as shown in Eq. 28,

$$\delta_C \Delta G^* = \delta_C \Delta H_i + (\beta - T)\delta_C \Delta S \approx \delta_C \Delta H_i \qquad \text{(Eq. 28)}$$

$\delta_C \Delta G^* \approx \delta_C \Delta H_i$, because $\beta = 280^\circ \approx 298^\circ$

[8] See *Reference 47*. For another point of view, see *References 48* and *49*.



Scheme II

Furthermore, this makes the Morse curve argument and the Leffler rationale essentially equivalent.

The Hydrophobic Bond—Many discussions of this phenomenon have emphasized the "entropic" driving force of the liberated water molecules in stabilizing the combined form of nonpolar solutes or side chains in water, while others (7) have postulated an increase in the strength of hydrogen bonding by these liberated molecules.

If the solvation changes involved here are also described by Hepler's isergonic theory, then we can write for the free energy of combination of two nonpolar solutes:

$$\Delta G = \Delta G_i + \Delta H_e - T\Delta S_e = \Delta G_i + (\beta - T)\Delta S_e \qquad \text{(Eq. 29)}$$

and regardless of which effect is postulated above, $\beta \approx 280^\circ \approx T$ and $\Delta G \approx \Delta G_i$. This suggests that the actual driving forces are simply dispersion forces, *etc.* Of course the driving force may experimentally *appear* to be entropic if $\Delta G_i \approx -\Delta H_e$ by coincidence.

Catalytic Specificity and Free Energy—By a simple extension of the above model for catalysis we can examine the relative rates of reaction of two different substrates (catalytic specificity) by using the virtual equilibrium constant of Eq. 30 and its associated functions (Eqs. 31 and 32):

$$S_1 + S_2C^* \rightleftarrows S_2 + S_1C^* \; K_{12}^* \qquad \text{(Eq. 30)}$$

$$\Delta G_{12}^* = -RT \ln K_{12}^* = \sum_i g_i \qquad \text{(Eq. 31)}$$

$$g_i = h_i - Ts_i = (\beta_i - T)s_i \qquad \text{(Eq. 32)}$$

which, as before, are divided into contributions from individual interactions. g_i is then the change in free energy of the ith interaction of the

catalyst on interchange of S_2 for S_1 at the binding site. A negative value of ΔG_{12}^* means a faster reaction for S_1; a negative value of g_i means that the ith interaction favors a faster reaction with S_1.

A large negative value of ΔG_{12}^* means that the reaction is much faster for S_1 than for S_2 and the catalyst is said to be "specific" for S_1.

Assume the catalyst is reasonably specific for S_1. The interactions which confer this specificity are likely to be binding interactions for which the s_i (Eq. 32) is negative. In order for the interaction actually to contribute to specificity, $(\beta_i - T)$ must also then be positive; the more positive it is, the more effective the interaction in aiding the catalyst to discriminate between S_1 and S_2, for a given amount of binding.

Just as was found with efficiency, above, a large value of β_i permits an interaction to contribute strongly to catalytic specificity. The phenomena of specificity and efficiency, as Lumry (7) predicted, would appear strongly linked.

The Biological Value of Specificity: Information and Entropy (50–54)—The present treatment permits an interesting look at catalytic specificity in a living system in terms of its value to the system. Why are biological catalysts generally unusually capable of selecting one substrate over another? The probable answer is that any other course would lead to chaos in the cell—to a general breakdown of the intricate metabolic scheme which underlies continued life. This intricate metabolic scheme is a pattern of information and the value of enzymatic specificity is that it preserves this information.

Many authors have discussed the relation of information to entropy and the fact that living systems, because of their high information content, are reservoirs of negative entropy. As was seen above, the interactions which lend specificity to catalysts are likely to be ones of negative entropy—in order to "see" that it has the right substrate, the enzyme must bind it intimately (the *total* entropy of binding or catalysis may, of course, have any sign or magnitude).

Consider the free energy change when a "wrong" substrate is bound in preference to a "right" one (in Eq. 30 let S_1 now be "wrong" and S_2 "right"); ΔG_{12}^* must be positive (in order for the "wrong" reaction to be slower). For specificity-conferring interactions, as was just argued, s_i will be positive. The more "wrong" the substrate is, the more positive s_i will be. This is reasonable since if the "wrong" reaction occurs, information will be lost to the system (and its entropy will increase). In fact, if one bit (binary unit) of information (the amount required to answer one yes-or-no question) is lost, the associated increase in entropy is $R \ln 2$, or 1.4 e.u.[9] By what factor will the rate decrease if this much information is to be lost? The answer is given by g_i: for each increment of 2.3 RT (1.42 Kcal./mole of 37° C.), the rate will decrease by a factor of 10. The ratio g_i/s_i for any interaction then gives the ratio of decrease in rate of the specific reaction (x powers of 10) which will occur if the structure of the substrate is sufficiently "wrong" that y bits of information are lost (Eq. 33):

$$\frac{g_i}{s_i} = \frac{(2.3\ RT)x}{(R \ln 2)y} \cong 1000\ \frac{x}{y} = (\beta_i - T) \quad \text{(Eq. 33)}$$

This is just $\beta_i - T$ for the interaction in question. In fact x/y (in units of orders/bit) $= (\beta_i - T)/1000$ can be called the *informational specificity* of an interaction. For reasonable ranges of β_i, estimated above, these are listed for a few interactions in Table III.

TABLE III—INFORMATIONAL SPECIFICITY AT 37° C. FOR SOME CATALYTIC INTERACTIONS

Interaction	$[(\beta_i - T)/1000]$ orders/bit
Covalent bonding	0.2 to 50
Hydrogen bonding	0 to 2.2
Electrostatic bonding	0 to 1
Charge-transfer bonding	0.5 to 0.8

Modification of the model should be possible to include specificity hypotheses such as "wrong-way binding" (56).

Simultaneous Determination of Dissolution and Partitioning Rates *In Vitro*

By P. J. NIEBERGALL, M. Y. PATIL, and E. T. SUGITA

An *in vitro* method is presented for the simultaneous determination of the dissolution and partitioning rates of drugs. The kinetics of the system is described, and a number of methods are given for evaluating the rate constants. The effects of stirring rate and temperature upon the rate constants were investigated and found to be in agreement with what would be expected for diffusion-controlled processes.

THE DISSOLUTION rate of a drug may have a marked effect upon the absorption of the drug from a solid dosage form. This has led to an increasing interest in developing *in vitro* dissolution rate tests that can be correlated with *in vivo* absorption rate studies for possible use in quality control or for use in setting official standards. In addition, dissolution rates have been used to evaluate formulation variables under the assumption that all other things being equal, the drug formulation that dissolves most rapidly would have the greatest chance of clinical success.

The over-all absorption process for solid drugs, however, consists of the dissolution step followed by drug partitioning into an essentially lipid barrier. The three phase "rocking apparatus," developed by Doluisio and Swintosky (1), appears to have great promise in studying the effects of additives or of molecular modification upon the partitioning rates of drugs. This apparatus, however, cannot be used to investigate the dissolution process, and therefore is useful only for drugs in solution. Thus, the over-all process of absorption

Simultaneous Determination of Dissolution and Partitioning Rates *In Vitro*

By P. J. NIEBERGALL, M. Y. PATIL, and E. T. SUGITA

An *in vitro* method is presented for the simultaneous determination of the dissolution and partitioning rates of drugs. The kinetics of the system is described, and a number of methods are given for evaluating the rate constants. The effects of stirring rate and temperature upon the rate constants were investigated and found to be in agreement with what would be expected for diffusion-controlled processes.

THE DISSOLUTION rate of a drug may have a marked effect upon the absorption of the drug from a solid dosage form. This has led to an increasing interest in developing *in vitro* dissolution rate tests that can be correlated with *in vivo* absorption rate studies for possible use in quality control or for use in setting official standards. In addition, dissolution rates have been used to evaluate formulation variables under the assumption that all other things being equal, the drug formulation that dissolves most rapidly would have the greatest chance of clinical success.

The over-all absorption process for solid drugs, however, consists of the dissolution step followed by drug partitioning into an essentially lipid barrier. The three phase "rocking apparatus," developed by Doluisio and Swintosky (1), appears to have great promise in studying the effects of additives or of molecular modification upon the partitioning rates of drugs. This apparatus, however, cannot be used to investigate the dissolution process, and therefore is useful only for drugs in solution. Thus, the over-all process of absorption

Accepted for publication May 5, 1967.

is generally studied *in vitro* as two separate processes, each of which might be rate limiting.

It is conceivable that certain factors might increase the dissolution rate of a drug while simultaneously decreasing its partitioning rate, and possibly reverse the importance of each process in the absorption of the drug. For example, *in vitro* dissolution rate studies have shown that surfactants are capable of increasing the dissolution rate of drugs (2, 3). It has also been shown, however, that surfactants can decrease the *in vivo* absorption of a drug such as salicylic acid (4), the absorption of which would be expected to be rate controlled by the dissolution process. The authors decided, therefore, to investigate the possibility of simultaneously determining the *in vitro* drug dissolution and partitioning rates in a single system.

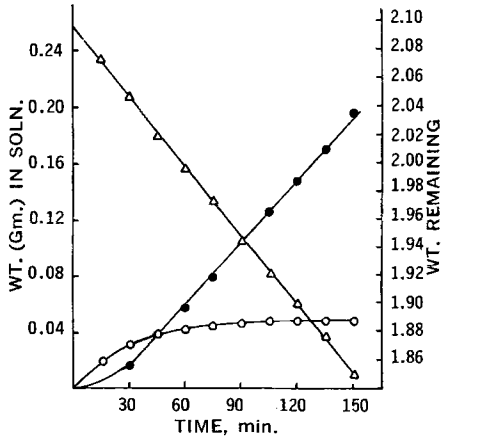

Fig. 1—Dissolution and partitioning rates of salicylic acid at 100 r.p.m. and 30°. Key: △, weight remaining in tablets; ○, weight in pH 2.00 buffer; ●, weight in octanol.

EXPERIMENTAL

Reagents—Potassium chloride, hydrochloric acid, sodium hydroxide, and salicylic acid were of analytical reagent grade obtained from the J. T. Baker Co. Standard grade *n*-octyl alcohol was obtained from Matheson Coleman and Bell. This grade octanol did not interfere with the spectrophotometric determination of salicylic acid.

Apparatus—The apparatus chosen for the study consisted of a 500-ml. round bottom, three-necked standard taper flask fitted with a mercury seal stirrer in the center opening. A 1-in. three-blade propeller was attached to the bottom of the stirring shaft which was inserted into the chuck of a variable speed stirrer.[1] The bottom edge of a second 1-in. three-blade propeller was placed on the stirring shaft exactly 3 cm. above the upper edge of the lower propeller. When 250 ml. of the aqueous phase was added to the flask, the upper edge of the bottom propeller was 2 cm. below the liquid surface. A large diameter glass tube was inserted into one of the remaining standard taper openings, and the closure sealed with aluminum foil. Octyl alcohol (250 ml.) was added through the remaining opening which was closed with a standard taper glass stopper. The lower edge of the upper propeller was 2 cm. above the octanol–water interface.

Procedure—Hard, nondisintegrating tablets of salicylic acid were prepared on a Carver model B laboratory press, without the aid of a lubricating agent. Four tablets were weighed and used in each study. In no instance was the weight loss permitted to extend beyond 10% (2.5% per tablet), thus enabling the assumption of constant surface area.

The apparatus described above was placed in a water bath until both liquid phases had reached constant temperature. The stirrer was started and adjusted to the desired speed, which was measured with a tachometer. The four tablets were introduced into the pH 2.00 buffer solution (hydrochloric acid–potassium chloride, Clark-Lubs, U.S.P. XVII) through the glass tube. One-

[1] Model 102, Talboys Instrument Co., Emerson, N. J.

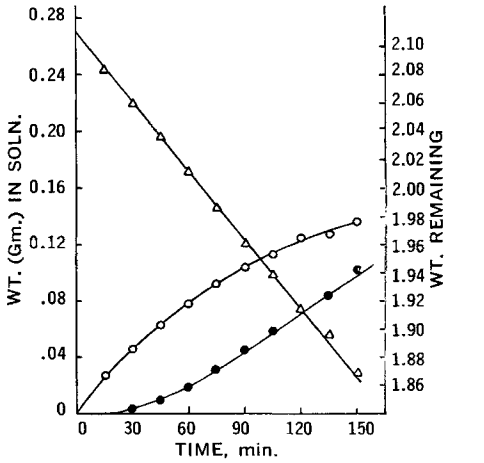

Fig. 2—Dissolution of salicylic acid into 0.1% w/v solution of polysorbate 80 at pH 2.00 and partitioning into octanol. Stirring rate was 100 r.p.m. at 30°. Key: △, weight remaining in tablets; ○, weight in polysorbate 80 solutions; ●, weight in octanol.

milliliter samples of both phases were obtained at 15-min. intervals and assayed at 298 mμ using a Beckman model DU spectrophotometer. The samples were diluted when necessary with either the pH 2.00 buffer or octanol. A total of 10 samples was taken for each run.

RESULTS

Kinetic Analysis of the Data—Typical results obtained are shown in Figs. 1 and 2. The simplest mechanism to be expected in a system such as we have described might be:

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C$$

in which A represents the drug in the tablets, B represents the drug in the aqueous phase, and C represents the drug in the octanol. In this study,

the amount of drug in each compartment is given as weight, rather than concentration, to aid in the evaluation of the constants. This causes no difficulty due to the nature of the dissolution process, and because the volumes in compartments B and C are kept constant. The following equations would describe the kinetics of the proposed mechanism:

$$-\frac{dA}{dt} = k_1 (W_s - B) \quad \text{(Eq. 1)}$$

$$\frac{dB}{dt} = k_1 (W_s - B) - k_2 B \quad \text{(Eq. 2)}$$

$$\frac{dC}{dt} = k_2 B \quad \text{(Eq. 3)}$$

in which W_s is the weight of drug needed to saturate the aqueous phase, and the other terms have the meanings previously given. The solubility of the salicylic acid in the pH 2.00 buffer and in octanol at various temperatures is given in Table I. In the early stage of the dissolution process, $W_s \gg B$ and:

$$-\frac{dA}{dt} = k_1 W_s \quad \text{(Eq. 4)}$$

Thus, a plot of weight remaining *versus* time should give a straight line, as shown in Figs. 1 and 2.

The weight of drug in the aqueous phase as a function of time can be obtained from the following:

$$\frac{dB}{dt} = k_1 W_s - k_1 B - k_2 B = K - K' B \quad \text{(Eq. 5)}$$

in which $K = k_1 W_s$ and $K' = k_1 + k_2$. The use of an integrating factor, and the condition that at time zero, $B = 0$, gives:

$$B = \frac{K}{K'} (1 - \exp.^{-K't}) \quad \text{(Eq. 6)}$$

The method of Guggenheim (5) can be used to obtain K'. Plots for typical data utilizing this method are shown in Figs. 3 and 4. Once the value of K' is obtained by least squares evaluation of the lines, B can be plotted according to Eq. 6 to yield a straight line with a slope equal to K/K'. A knowledge of W_s then enables k_1 and k_2 to be evaluated. Representative plots of Eq. 6 are shown in Figs. 5 and 6.

Steady-State Treatment—The data shown in Fig. 1 indicate that a steady state may be obtained rather quickly in the aqueous phase. If this assumption can be made:

$$\frac{dB}{dt} = 0 = k_1 (W_s - B) - k_2 B \quad \text{(Eq. 7)}$$

TABLE I—SOLUBILITY OF SALICYLIC ACID IN pH 2.00 BUFFER AND IN OCTANOL AT VARIOUS TEMPERATURES

Temp., °C.	Phase	Solubility, Gm./250 ml.
30	pH 2.00 buffer	0.56
30	Octanol	29.44
32.5	pH 2.00 buffer	0.68
32.5	Octanol	31.88
35	pH 2.00 buffer	0.75
35	Octanol	34.32

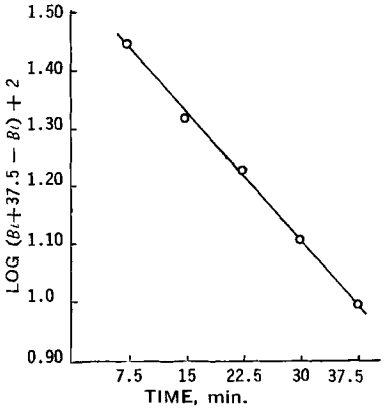

Fig. 3—Guggenheim plot for the appearance of salicylic acid in the pH 2.00 buffer. Stirring rate was 100 r.p.m. at 30°.

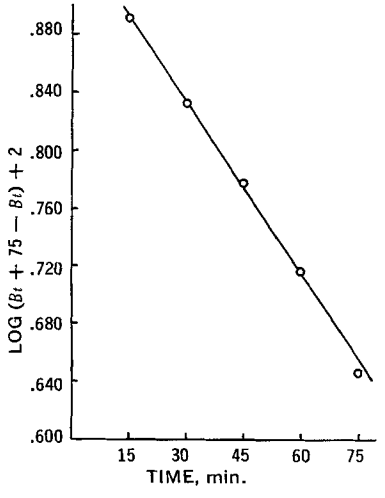

Fig. 4—Guggenheim plot for the appearance of salicylic acid in the 0.1% w/v polysorbate 80 solution at pH 2.00. Stirring rate was 100 r.p.m. at 30°.

and therefore:

$$k_2 B = k_1 (W_s - B) \quad \text{(Eq. 8)}$$

Thus, Eq. 3 becomes:

$$\frac{dC}{dt} = k_2 B = k_1 (W_s - B) = \frac{-dA}{dt} \quad \text{(Eq. 9)}$$

in which B is the steady-state weight of drug in the aqueous phase. The rate of change of C with time thus becomes constant and is equal to the dissolution rate $-dA/dt$ of the tablets. Division of dC/dt by $(W_s - B)$ yields k_1, while division of dC/dt by B yields k_2. The values of k_1 and k_2, evaluated by the various methods for the data shown in Fig. 1, are given in Table II.

The fact that the rate of appearance of the drug in the lipid phase becomes equal to the dissolution rate of the drug when B reaches a steady state is of great potential value in dissolution rate studies. This would be useful, for example, for studies involving poorly water-soluble drugs which would re-

TABLE II—COMPARISON OF k_1 AND k_2 OBTAINED BY VARIOUS METHODS

Constant, min.$^{-1}$	Method		
	Eq. 6	Eq. 4	Eq. 9
k_1	0.00293	0.00292	0.00291
k_2	0.0316	.....	0.0314

quire large volumes of dissolution medium to obtain meaningful results. Large, and sometimes unwieldy, volumes of dissolution medium are also used in dissolution rate studies to prevent build up of the drug in the dissolution medium so the assumption of $W_s \gg B$, or its equivalent in concentration terms, can safely be assumed. The presence of the lipid phase acting as a sink, as it did in these studies, would obviate this difficulty. In some instances, the assay for a drug in the aqueous phase might be difficult or perhaps time consuming in that an extraction into a lipid phase is necessary. The ability to measure dissolution rates by analyzing a lipid phase, as done in these studies, would then be of great value.

Effect of Stirring Rate—The effect of stirring rate upon both constants was determined from 50–

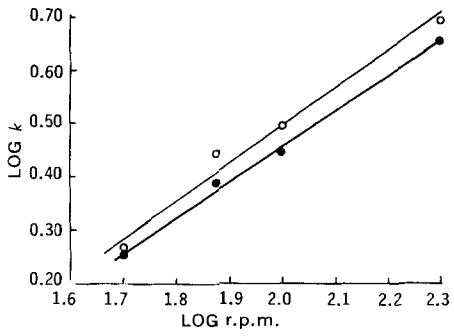

Fig. 7—Effect of stirring rate upon k_1 *and* k_2 *at 30°. Key: ●, (log* k_1*) + 3; ○, (log* k_2*) + 2.*

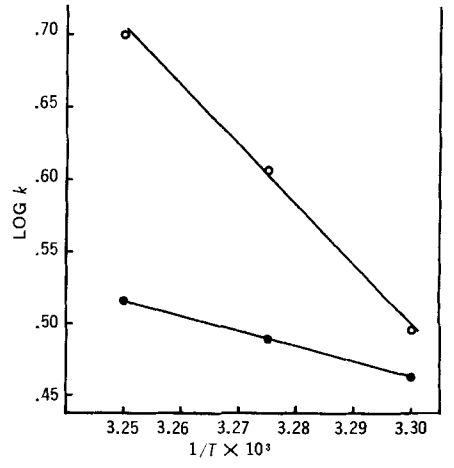

Fig. 8—Arrhenius plots for k_1 *and* k_2 *at a stirring rate of 100 r.p.m. Key: ●, (log* k_1*) + 3; ○, (log* k_2*) + 2.*

200 r.p.m. at 30 ± 0.05° using the steady-state equations. The relationship between rate constants and stirring rate may be given by:

$$k = a\,(\text{r.p.m.})^b \qquad \text{(Eq. 10)}$$

in which a and b are constants. The constant b has been found to range from zero for a nondiffusion-

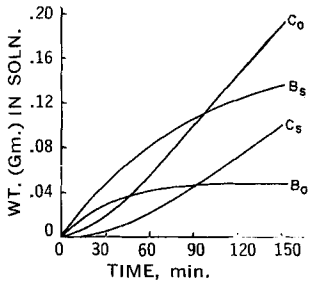

Fig. 10—Effect of polysorbate 80 upon the dissolution and partitioning rates of salicylic acid at a stirring rate of 100 r.p.m. and 30°. Key: B_0 represents the dissolution into pH 2.00 buffer, B_s represents the dissolution into the polysorbate 80 solution, C_0 represents the partitioning into octanol in the absence of the polysorbate 80, and C_s represents the partitioning into octanol in the presence of polysorbate 80.

controlled process to approximately one for a diffusion-controlled process (6). Plots of log k *versus* log (r.p.m.) are shown in Fig. 7. The constant, b, was found to be 0.67 and 0.70 for k_1 and k_2, respectively, indicating both processes are diffusion controlled.

Effect of Temperature—The effect of temperature upon both rate constants was determined at 100 r.p.m. through the temperature range of 30–35° ± 0.05° using the steady-state equations. The data are plotted according to the Arrhenius relationship in Fig. 8. The energy term associated with k_1 was found to be 4,690 cal./mole, which is in good agreement with the values of 4,446–4,548 cal./mole reported by Edwards (7) for the energy of diffusion within this temperature range. The energy term associated with k_2, however, was found to be 19,100 cal./mole which would indicate a nondiffusion-controlled process. This is not in agreement with the findings of the stirring rate data. The basic mechanism was therefore modified to include a diffusion process for the transport of solute from the aqueous to the lipid phase:

$$\frac{dC}{dt} = k_2 B (W_c - C) \qquad \text{(Eq. 11)}$$

in which W_c represents the weight of drug needed to saturate the lipid phase. Table I and Figs. 1 and 2 show that for these studies $W_c \gg C$ and:

$$\frac{dC}{dt} = k_2 B W_c = k_2' B \qquad \text{(Eq. 12)}$$

in which $k_2' = k_2 W_c$. This modification would not change the kinetic picture, as given by Eqs. 1–9, or the stirring rate data. It merely indicates that our previously determined k_2 probably contains the term W_c. A plot of the corrected k_2 *versus* temperature is shown in Fig. 9. The energy term associated with the corrected k_2 was found to be 4,640 cal./mole, which is in good agreement with what would be expected for a diffusion-controlled reaction. The modification, as shown by Eq. 11, accounts for dC/dt decreasing as C approaches W_c and for its becoming equal to zero when C becomes equal to W_c. This is more realistic than Eq. 3 which indicates that the transfer of solute into the lipid phase would continue at a constant rate, and does not provide for the eventual saturation of the lipid phase.

Effect of Polysorbate 80[2]—Sufficient polysorbate 80 was added to the pH 2.00 buffer to give a final concentration of 0.20% w/v. The data were obtained in the usual manner for a stirring rate of 100 r.p.m. at 30 ± 0.05°. The results are shown in Fig. 10. The dissolution rate, as shown by the plots of B *versus* time, is indeed increased in the presence of the surfactant, in agreement with the literature (2,3). The partitioning rate, however, as shown by the plots of C *versus* time is decreased in qualitative agreement with the findings of Levy and Reuning (4). Thus, the value of this system for a screening procedure, as opposed to the usual dissolution rate studies, becomes readily apparent. The exact mechanism for the effect of surfactants upon the dissolution and partitioning rates of drugs is currently being studied and will be reported in a future communication.

Quantitative Estimation of Diosgenin in *Dioscorea* Tubers by Densitometric Thin-Layer Chromatography

By G. BLUNDEN, R. HARDMAN*, and J. C. MORRISON

Thin-layer chromatography was employed to separate diosgenin from other plant constituents present in *Dioscorea* tuber extracts. The diosgenin was rendered visible by antimony trichloride and the colored spot estimated by scanning with a photoelectric densitometer attached to an integrating logarithmic recorder. Diosgenin could be estimated with an experimental error of approximately 7 per cent when applied in concentrations between 10 and 75 mcg. Assay results obtained for diosgenin by this method were slightly lower than those obtained by conventional infrared spectrophotometry, since the 25 D-spirosta-3,5-diene formed during the extraction of diosgenin was not estimated in the chromatographic procedure.

STEROIDAL SAPOGENINS are of considerable economic importance as precursors of the pharmacologically active steroids, including the oral contraceptives and corticosteroids. The most important steroidal sapogenin is diosgenin, which is obtained commercially from the tubers of several *Dioscorea* species.

Diosgenin is usually assayed by gravimetric (1, 2) or infrared techniques (3, 4); the naturally occurring saponin is acid-hydrolyzed and the sapogenin then extracted with a hydrocarbon solvent. The gravimetric methods are applicable to plant material with high sapogenin content containing little contaminating matter, but are less satisfactory where the proportion of contaminants is high, or when a sensitive method is required for studying the factors affecting the yield of sapogenin from a given source, or screening botanical specimens for steroidal sapogenins. In these circumstances infrared spectrometric methods are more suitable. Based on the spirostan structure of the sapogenin, they are specific for steroidal sapogenins, but take no account of the nature of the steroidal nucleus; the 3,5-diene of diosgenin, for example, being assayed as diosgenin. Furthermore, the authors have found that nonsapogenin compounds extracted by the sapogenin solvent, both saponifiable and nonsaponifiable, can also interfere with the infrared assay method and cause high results. Consequently, it was felt that a convenient analytical technique, suitable for small quantities of plant material and overcoming some of the disadvantages of the existing methods, would be valuable. The authors report the development of such a technique and its application, in the first instance, to the assay of diosgenin in tubers of species of *Dioscorea*. Extension of the method to other species and morphological parts, such as seeds, will be reported.

Received March 10, 1967, from the School of Pharmacy, College of Technology, Portsmouth, Hampshire, England.

Accepted for publication May 19, 1967.

The authors thank Mr. A. Wood, Ministry of Overseas Development, Tropical Products Institute, London, England, for the infrared spectrometric assays and Mr. A. G. Kenyon, Mr. J. Parham, and Miss A. P. Wilson for tubers or seeds.

EXPERIMENTAL

Development and Treatment of the Chromatogram—Glass plates, 15 × 20 cm., were spread with a layer of Silica Gel G to a thickness of 250 μ according to the method of Stahl (5) and air-dried before use.

Known quantities of diosgenin, dissolved in chloroform, were applied to the plates by micropipets and the chromatogram developed with *n*-hexane–ethyl acetate (4:1 v/v) using the supersaturated method of Stahl (6). When the solvent had advanced 15 cm. from the starting line, the plates were removed, dried, and double developed with the same solvent system. Following development, the plates were dried and sprayed uniformly with a solution of 3 Gm. of antimony trichloride in 1 ml. of concentrated hydrochloric acid (7). The sapogenins were then located by heating the plates evenly at 100° in a circulating air stream until the diosgenin spot was developed to a green-black color. This normally took 30 min.

After the plates had cooled, the absorbances of the spots were estimated by a Vitatron densitometer,[1] using a slit width of 20 mm. by 2 mm. and a mercury lamp source. The values so obtained were calculated by an automatic integrator. Spots were scanned in the direction opposite to that of solvent flow and erratic readings from extraneous light were eliminated by the use of a light-tight box.

Preparation of the Standards—Pure diosgenin was applied to thin-layer plates in concentrations ranging from 5 mcg. to 100 mcg. Following development, the spots produced were scanned and a linear relationship between concentration and absorbance was established for concentrations of diosgenin between 10 mcg. and 75 mcg.

Preparation of Plant Material—Diosgenin was extracted from *Dioscorea* tubers of known weight and moisture content (4). This involved maceration of the fresh tuber, incubation of the disintegrated material, acid-hydrolysis of the saponins by refluxing with 2 *N* hydrochloric acid for 2 hr., and extraction of diosgenin from the dry, acid-insoluble

[1] Fison's Scientific Apparatus Ltd., Loughborough, Leicestershire, England.

residue with petroleum ether (40–60°). After evaporating to dryness, the extract was dissolved in chloroform and made to volume. Dried, powdered tuber was first incubated with water before being treated by the above procedure.

Known volumes of the *Dioscorea* extract were applied to prepared thin-layer plates along with a standard diosgenin solution. The applied spots of the plant and standard solutions were alternated on the plate to minimize the effects of variation in thickness and opacity of the adsorbent layer. The diosgenin content of the *Dioscorea* extract was calculated relative to the standard solution, and the resulting value obtained from the mean of six plates, each containing two spots of the plant extract.

To determine the recovery of diosgenin added to a plant extract, 5 Gm. of a powdered edible *Dioscorea* tuber was extracted and assayed as above. To this extract of known volume, 40 mg. of diosgenin was added and the chromatographic assay carried out to estimate the recovery of the added diosgenin. The assay was repeated following the addition of 40 mg. cholesterol to the *Dioscorea* extract containing the added diosgenin, to show that this sterol did not interfere with the recovery of diosgenin. Cholesterol is a fairly common plant sterol (8) which occurs in *Dioscorea* tubers (9) and co-chromatographs with the common phytosterols β-sitosterol and stigmasterol in the silica gel system used. These procedures were then repeated using an assayed sample of dried, powdered *D. floribunda* Mart. et Gal. tuber.

Similarly, to determine the extent of breakdown of the sapogenin during extraction, 40 mg. of diosgenin was refluxed with 100 ml. of 2 *N* hydrochloric acid for 2 hr. and subsequently extracted with chloroform. This solution was then assayed and compared with an appropriate standard of untreated diosgenin.

Samples of the extracted *Dioscorea* tubers were assayed by the thin-layer chromatographic and infrared spectroscopic methods for purposes of comparison.

RESULTS

Relationship Between Spot Absorbance and Weight of Diosgenin—The relationship between the logarithm of the weight applied and the square root of the absorbance of the spot produced was found to be linear for weights of diosgenin from 10 mcg. to 75 mcg. (Fig. 1 and Table I).

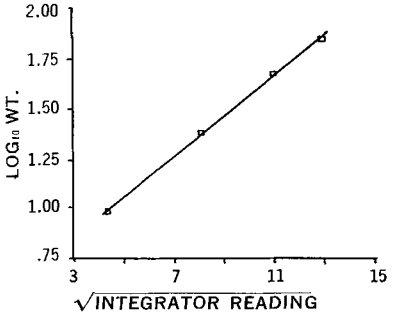

Fig. 1—Relationship between spot absorbance and weight of diosgenin.

TABLE I—RELATIONSHIP BETWEEN WEIGHT OF DIOSGENIN APPLIED AND ABSORBANCE OF THE SPOT, EXPRESSED AS A READING FROM THE AUTOMATIC INTEGRATOR

Diosgenin Wt.[a], mcg.	Log_{10} Wt.	Integrator Reading	Integrator √Reading
5	0.6990	13.0	3.61
10	1.0000	18.0	4.24
25	1.3979	64.0	8.00

75	1.8751	163.0	12.77
100	2.0000	250.0	15.81

[a] Mean results from 6 plates.

TABLE II—QUANTITATIVE RESULTS FOR DIOSGENIN RECOVERY

Applied mcg.	Diosgenin Recovered mcg.	Diosgenin Recovered %[a]	No. of Estimations
20	20.32 ± 1.4	101.6 ± 6.9	40
40	40.08 ± 2.9	100.2 ± 7.3	40
60	58.2 ± 4.4	97.0 ± 7.4	40

[a] Recovered per cent is expressed as the mean of all determinations ± one standard deviation.

TABLE III—COMPARISON OF DENSITOMETRIC AND INFRARED ASSAY PROCEDURES

Plant Source	% Diosgenin m.f.b.[a] Densitometric	% Diosgenin m.f.b.[a] Infrared
D. floribunda sample *1*	3.91	3.95
D. floribunda sample *2*	4.25	4.55
D. floribunda sample *3*	2.38	2.40
D. sylvatica sample *1*	2.50	2.80
D. sylvatica sample *2*	3.65	3.85
D. deltoidea sample *1*	3.06	3.40
D. deltoidea sample *2*	3.14	3.35

[a] Moisture free basis.

The percentage error in the method was calculated by applying 20, 40, and 60 mcg. of diosgenin to thin-layer plates and estimating the variation observed in spot intensity. Ten chromatograms each of four spots were prepared in these determinations (Table II).

Estimation of Diosgenin in Dioscorea Tubers—The diosgenin content of the tuber of the edible *Dioscorea* species was found by the densitometric method to be 0.1%. When diosgenin was added to this extract, a recovery of 99.5% of the added diosgenin was obtained. Similarly, a recovery of 101% of the added diosgenin was obtained when estimated in the presence of an equal quantity of cholesterol. Similar results were obtained with a sample of *D. floribunda* tuber assayed by the same procedure.

Comparison of Densitometric and Infrared Assays—Comparison of assay results obtained from *D. floribunda*, *D. sylvatica* Ecklon., and *D. deltoidea* Wall. using both the densitometric and infrared methods is given in Table III.

DISCUSSION

Purdy and Truter (10) found that the relationship between the logarithm of the weight of substance applied and the square root of the area of the spot produced gave a linear relationship. This linear relationship was found to hold for the logarithm of the weight of diosgenin applied and the absorbance of the spot produced for diosgenin from 10 mcg. to 75 mcg. The results obtained show that densitometric thin-layer chromatography provides a suitable method for the assay of diosgenin in *Dioscorea* tubers.

In this study a number of experimental factors were found to be important in obtaining reproducible results. For example, plates of uniform gel thickness were essential, since variations in the layer produced variations in the amount of light transmitted through the plate, which affected the result recorded by the densitometer (11). Therefore, plates were selected which were uniform in appearance. It was also important to spray the plates evenly and ensure even heating to avoid development of uneven color intensity by the spots. All spots were scanned in the same direction, namely opposite to that in which the plates were developed, since considerable variations were obtained when the spots were scanned in different directions.

Using the solvent syftem *n*-hexane–ethyl acetate, diosgenin was separated from the other constituents in the *Dioscorea* extract. It was, however, observed that the sterol spot of higher R_f value and another spot of lower R_f value were sufficiently close to the diosgenin to interfere with accurate densitometric estimation. This was particularly noticeable when the proportion of sterol to diosgenin was high. This difficulty was easily overcome by double development of the chromatogram in *n*-hexane–ethyl acetate, when the diosgenin spot was well separated from the two interfering spots.

To determine the sensitivity of the procedure, known weights of diosgenin were added to *Dioscorea* tuber extracts of known diosgenin concentration. In other tests, equal weights of cholesterol and diosgenin were added to the *Dioscorea* extracts but in all cases quantitative recoveries of the added diosgenin were recorded, showing that the diosgenin was separated from the other plant constituents which did not interfere with the assay. This was also verified by the close correlation between the infrared assay results and the quantitative thin-layer chromatographic results. The results from the infrared method were always slightly higher than those obtained by quantitative thin layer. This was as expected, as during the extraction procedure of diosgenin, a certain quantity of 25 D-spirosta-3,5-diene is formed (12) on heating diosgenin with 2 *N* hydrochloric acid. The diene is estimated with the diosgenin in the infrared method, but by thin-layer chromatography the diene is well separated from diosgenin and is not estimated. In test experiments, by heating diosgenin with boiling 2 *N* hydrochloric acid for 2 hr., the degree of decomposition was estimated as being between 5.1 and 7.3%.

Using the solvent system described, diosgenin is not separated from its isomer yamogenin, hence the yamogenin present in the samples will be estimated as diosgenin. This is also the case with the infrared method of assay (4).

A major advantage of a quantitative thin-layer method for estimating diosgenin is that the quantity of plant material required is very small. One gram of dry, powdered tuber, of diosgenin content 2.5%, moisture free basis, has been successfully assayed.

SUMMARY

A thin-layer chromatographic technique using Silica Gel G as the adsorbent and hexane–ethyl acetate (4:1 v/v) as the solvent system has been devised for the separation and analysis of diosgenin in *Dioscorea* tubers. It was demonstrated that a linear relationship exists between the logarithm of the weight of diosgenin applied and the square root of the absorbance of the spot produced. Quantitative evaluation was achieved by using a photoelectric densitometer coupled to an integrating logarithmic recorder which computed the absorbance of the spot. The experimental error was found to be approximately 7%. The technique gave quantitative results when diosgenin was applied in concentrations between 10 and 75 mcg. The results were compared with those obtained by infrared spectrometry and were found to be slightly lower due to the nonestimation of 25 D-spirosta-3,5-diene by the quantitative thin-layer method. Several experimental factors which influence the accuracy of the method are discussed.

Protection of Sympathetic α-Receptors *In Vivo*

By F. P. LUDUENA and M. J. BRANIN

An intravenous dose of 100 mcg./Kg. of phenoxybenzamine in rats completely blocked the lethal effect of 1 mg./Kg. of epinephrine injected intravenously 3 hr. later. Alpha-sympathetic receptors were protected against the effect of phenoxybenzamine by the simultaneous injection of competitive α-adrenolytics. If the α-receptor protection was maximal, a 100 per cent mortality followed the injection of the 1 mg./Kg. dose of epinephrine. Graded degrees of receptor protection were obtained by the administration of graded doses of α-adrenolytics. A rank correlation coefficient of 0.902 was obtained between the α-receptor protective $dose_{50}$ and the adrenolytic $dose_{50}$ of 17 compounds tested including *dextro*-isoproterenol and *dextro*-hyoscyamine.

BETA-HALOALKYLAMINES produce a long-lasting inactivation of the sympathetic α-receptors (1). In 1949 Seed and McKay (2) demonstrated that previous administration of piperoxan in the anesthetized dog prevented the development of the adrenolytic action of *N*-(2-chloroethyl)dibenzylamine.[1] Nickerson and Gump (3) reported that the injection of epinephrine in anesthetized cats reduced the developing of the α-receptor blocking effect of β-haloalkylamines suggesting a certain degree of α-receptor protection. Clear evidence of α-receptor protection *in vitro* by both agonists and antagonists was provided by the results reported by Furchgott (4).

The experiments described below were carried out in order to quantitate α-receptor protection activity *in vivo* and to determine the relationship between this activity and adrenolysis.

METHODS

All injections were made in the tail vein of male white rats weighing approximately 100 Gm. Doses were expressed in terms of the bases.

Adrenolytic Activity—The technique, reported previously (5), consists of injecting intravenously a dose of epinephrine (200 mcg./Kg.) simultaneously (procedure *A*) with one of three or four graded doses of the experimental compound and plotting per cent survival against the dose on probit-log paper; in some experiments the compound was injected approximately 5 min. before epinephrine administration (procedure *B*).

Sympathetic α-Receptor Protection Test—Alpha-receptors were protected by adrenolytics against the long-lasting inactivation produced by phenoxybenzamine (0.1 mg./Kg.) injected intravenously. The "protectors" were injected in the same solution (procedure *C*) or 5 min. before phenoxybenzamine (procedure *D*). After an interval of 3 hr. a dose of epinephrine of 1 mg./Kg. was injected intravenously. If the sympathetic α-receptor had been protected and the adrenolytic effect of the "protector" had worn off, epinephrine would reach the unchanged α-receptor causing all the rats to die. With graded doses of the protector, the higher the α-receptor protective effect the higher the mortality. The ED_{50} was obtained by plotting mortality against dose on probit-log paper (Fig. 1).

RESULTS

In an effort to develop a test to measure the ability of certain compounds to protect sympathetic α-receptors from the inactivating action of phenoxybenzamine, the following variables were studied: dose of phenoxybenzamine, dose of epinephrine, dose of the α-receptor "protector," and the time intervals between the administration of the "protector" and phenoxybenzamine and between the administration of phenoxybenzamine and epinephrine. The results obtained using phentolamine as the "protector" are summarized in Table I.

Experiment *1* showed that the 20-min. interval between injections of phenoxybenzamine and epinephrine was too short, as 80% mortality resulted. When the interval was increased to 40 min. in experiment *2*, only 30% of the animals died, indicating that a higher proportion of α-receptors had been inactivated at the time of epinephrine injection. Using the time interval of 40 min. between the injection of graded doses of phenoxybenzamine and a dose of 0.20 mg./Kg. of epinephrine ($2.7 - 5 \times LD_{50}$), the adrenolytic ED_{50} of phenoxybenzamine was determined to be 0.014 ± 0.003 mg./Kg.[2] Further experiments with increasing doses of epinephrine (experiments *3–7*) indicated that once the adrenolytic ED_{100} of phenoxybenzamine had been reached further increases in the dose of epinephrine could not surmount the blockade of α-receptors.

The effect of the time interval between phenoxybenzamine and epinephrine administrations is shown in the results of experiments *8–11*. When the doses of phenoxybenzamine were 0.1 mg./Kg., high doses of epinephrine partially surmounted the blockade 7 hr. after phenoxybenzamine (experiment *10*) and killed all the rats 11 hr. later (experiment *11*). While the time parameter remained constant (18 hr.) in experiments *11*, *12*, and *13*, the dose of epinephrine was varied. Both 5.0 mg./Kg. (experiment *11*) and 1 mg./Kg. (experiment *12*) of epinephrine resulted in 100% mortality. However, at a still lower dose of epinephrine (0.20 mg./Kg., experiment *13*) none of the treated rats died, demonstrating that even at this prolonged time interval there was still some α-receptor blockade produced by phenoxybenzamine. Experiments *14*, *15*, and *16* showed that the adrenolytic effect of phentolamine (5 mg./Kg.), a competitive adrenolytic, did not last

[a] Adrenolytic ED_{50} of phenoxybenzamine, 40 min. before epinephrine: 0.014 ± 0.003 mg./Kg. [b] Time interval between phentolamine and epinephrine. [c] Phentolamine was injected 15 min. before phenoxybenzamine; in experiments *18* to *25* the two drugs were injected in the same solution.

3 hr. against a high dose of epinephrine (5 mg./Kg.). The injection of phentolamine together with phenoxybenzamine abolished the long-acting adrenolytic action of the latter (experiments *18–25;* experiment *9 versus* experiments *18–20*). It was clear that at the doses used there was a "protection" of the sympathetic α-receptors. Experiments *22–25* showed that graded doses of phentolamine produced graded degrees of receptor protection and that an ED_{50} value could be obtained.

On the basis of the results obtained with phentolamine, the procedure previously described was adopted to test the α-receptor protective activity of a series of adrenolytics. Compounds were chosen which had weak, moderate, and strong adrenolytic activity.

The doses of phenoxybenzamine and epinephrine (0.1 and 1 mg./Kg., respectively) and the 3-hr. interval between the two injections, which the authors adopted to test the 17 compounds in the correlation study, may not be the most satisfactory. For example, although the adrenolytic effect of phentolamine disappears within 3 hr., the effect of trifluoperazine and tolazoline lingers beyond the 3-hr. interval giving false α-receptor "protection" readings. For this reason these two compounds could not be tested by the method described above. Another difficulty was the result of differences in onset of action between some adrenolytics and phenoxybenzamine. In order to demonstrate "protective" activity compounds I and III had to be injected 5 min. before phenoxybenzamine (Table II, procedure *D*). The time of onset of action might have been reduced by increasing the dose of the "protector." However, in the case of compounds I and III the increase in dosage prolonged

TABLE II—RELATIONSHIP BETWEEN ADRENOLYTIC AND SYMPATHETIC α-RECEPTOR PROTECTIVE ACTIVITIES IN RATS

their adrenolytic effect beyond the 3-hr. interval. The adrenolytic activity of these two compounds was also determined in the same manner; *i.e.*, by injecting the compound 5 min. before epinephrine. It is interesting to note that the adrenolytic ED_{50} values obtained in this manner (procedure *B*, see under *Methods*) were lower than those obtained by the standard method (procedure *A*). The values in mg./Kg. were for compound I: 0.020 ± 0.002 (*B*) *versus* 0.032 ± 0.008 (*A*); and for compound

TABLE IV—EFFECT OF (−) AND (+)-EPINEPHRINE MIXED WITH PHENOXYBENZAMINE

First Injection			2nd Injection 3 hr. Later

[a] Several rats died following the first injection.

III: 0.033 ± 0.006 (*B*) *versus* 0.11 ± 0.022 (*A*). It is obvious that the full effect of these adrenolytics could not develop when injected simultaneously with epinephrine.

Correlation Study—The degree of association between adrenolytic activity (ED_{50}) and sympathetic α-receptor protective activity (ED_{50}) of 17 compounds was determined using the Spearman rank correlation method (6). The rank correlation coefficient found was 0.902. The ED_{50} values obtained are listed in Table II and the chemical structures of some of the compounds are shown in Table III.

In addition to some standard adrenolytics, a few weak adrenolytics were tested in order to widen the activity range of the groups of compounds studied. Among the latter (+)-hyoscyamine, which is responsible for the adrenolytic activity of atropine (7), and (+)-isoproterenol (8, 9) were found to be weak α-receptor protectors.

Other (+)-isomers of sympathomimetic amines were tested, but since the two ED_{50} values could not be obtained, they were not included in the correlation study. The *dextro*-isomer of *N*-ethyl norepinephrine (compound IX, Table III) was found to have a very weak adrenolytic activity (17.5 ± 8.9 mg./Kg.). Partial protection (37.5% mortality) of α-receptors was obtained at a dose of 80 mg./Kg. Higher doses were not tested. The other compound (X, Table III), the *dextro*-isomer of the *meta*-desoxy analog of isoproterenol, protected α-receptors (ED_{50}: 40 ± 3.2 mg./Kg.), but its adrenolytic ED_{50} could not be determined by the standard method. However, in rats receiving 40 mg./Kg. in the same intravenous injection with epinephrine, the LD_{50} of epinephrine was increased to 0.1 ± 0.011 mg./Kg. from a control value of 0.05 ± 0.008 mg./Kg.

Effect of Agonists on the Adrenolytic Activity of Phenoxybenzamine—Adrenergic agonists in high concentrations protect sympathetic α-receptors from the inactivating action of *N*-(2-chloroethyl)-dibenzylamine *in vitro* (4). The authors tested the effect of (−) and (+)-epinephrine mixed with another haloalkylamine, phenoxybenzamine, to determine whether agonists could occupy a sufficiently large proportion of receptors to allow epinephrine injected 3 hr. later to produce its lethal effect (Table IV).

The results in Table IV show that the isomers of epinephrine could not protect the α-receptors. If the dose of the agonist injected together with phenoxybenzamine was increased, some of the animals died. From these experiments it may be concluded that if the proportions of α-receptors occupied by the agonists in competition with phenoxybenzamine are sufficiently large, the rats die, and that in the animals that survive (Table IV) an insufficient number of receptors were protected from the action of phenoxybenzamine.

Effect of Catecholamines with No α-Receptor Activity—Since in experiments with the *dextro*-isomers of catecholamines, very large doses had been used, it was of interest to test as controls, compounds which have strong β-receptor agonist activity and no action on α-receptors. Compound XII, the *levo* form, is one of the most potent β-receptor agonists. At a dose of 20 mg./Kg. it had no adrenolytic activity when injected together with epinephrine (0.2 mg./Kg.). Injected with phenoxybenzamine (20 mg./Kg.) it had no α-receptor protective activity. On the other hand, the racemic form (compound XI) had an approximate adrenolytic ED_{50} of 15 mg./Kg. and an α-receptor protective ED_{50} of 17.8 ± 2.4 mg./Kg., indicating that in both tests the *dextro*-isomer was responsible for the observed activities. Compound XIII at 50 mg./Kg. had neither adrenolytic activity nor any protective effect on the receptor. Since XIII is the racemic form of the compound, it may be concluded that α-ethyl substitution in the molecule of (+)-isoproterenol abolishes its α-receptor blocking activity.

DISCUSSION

The results reported above have demonstrated that complete protection of the sympathetic α-receptor *in vivo* can be obtained by the injection of adrenolytics in intravenous doses as low as 0.1 mg. (or less)/Kg. The correlation study indicated a close relationship between adrenolytic and receptor protective activity. This strongly suggests that the degree of affinity of the competitive adrenolytic for the sympathetic α-receptor is involved whether the compound blocks the access of epinephrine (adrenolytic test) or phenoxybenzamine (α-receptor protective test) to the receptors.

The results obtained with the α-receptor protective test confirm the findings indicating that (+)-isoproterenol is a sympathetic α-receptor blocker (8, 9) against the negative results reported by Levy and Ahlquist (10). It has been reported (11) that in the series of *N*-alkyl analogs of norepinephrine the ethyl, propyl, and isopropyl analogs have intrinsic activity between 1 and 0 (partial agonism) and that the same was true for the *N*-*tert*-butyl and the *N*-propyl analogs of octopamine. When the adrenolytic activity of (+)-isoproterenol was discovered, it was suggested (8) that the partial agonism of isoproterenol shown by the racemic form was due to the mixture of an agonist (*levo*-isomer)

and an antagonist (*dextro*-isomer). The results obtained with (+)-isoproterenol and compounds IX, XI, XII, and XIII strongly suggest that the same explanation applies to all the compounds in the sympathomimetic amine series reported as partial agonists by Ariëns and Simonis (11).

CONCLUSIONS

Phentolamine, trifluoperazine, promazine, phenindamine, benztropine, and other competitive sympathetic α-receptor blockers injected intravenously with phenoxybenzamine in rats blocked the long-acting adrenolytic effect of the latter. A highly significant correlation was found between the sympathetic α-receptor protective and adrenolytic activities of 17 compounds.

Irreversible Enzyme Inhibitors XCII

Inhibition of Xanthine Oxidase by Some Purines and Pyr midines

By B. R. BAKER and J. L. HENDRICKSON

Twenty-six selected compounds were investigated as inhibitors of xanthine oxidase, the enzyme that can also detoxify 6-mercaptopurine; these compounds consisted of 19 purines, four pyrimidines, two 8-azapurines, and one imidazole. Among the inhibitors that complexed to xanthine oxidase as well or better than the substrate, hypoxanthine, were thioguanine, adenine, and 6,8-dihydroxy-2-methylthiopurine (XXVI). The larger 2-benzylthio-6,8-dihydroxypurine (XXVII) was synthesized and found to inhibit equally as well as XXVI. Then 2-benzylthiohypoxanthine (XXVIII) and 8-benzylthiohypoxanthine (XXIX) were synthesized; these two compounds were complexed elevenfold and threefold better, respectively, to the enzyme than the substrate. Thus the enzyme showed bulk tolerance for the benzylthio group of XXVII–XXIX; the benzylthio group is a logical group for placement of electrophilic groups to give candidate active-site-directed irreversible inhibitors of xanthine oxidase.

XANTHINE OXIDASE is a catabolic enzyme involved in degradation of purines in a cell; the enzyme normally oxidizes hypoxanthine (I) and xanthine (II) to uric acid (III) (1, 2); the latter is then either excreted or further catabolized depending upon the species. The enzyme can also oxidize 2-hydroxypurine (IV) or 8-hydroxypurine to uric acid (III) (3) and adenine (V) to 6-amino-2,8-dihydroxypurine (VI) (4). The enzyme slowly oxidizes 4-hydroxypyrazolo-[3,4-*d*]pyrimidine (IX) to the 4,6-dihydroxy derivative (X), both of which are good inhibitors of xanthine oxidase (5, 6); in fact, IX is now marketed[1] for the treatment of gout since IX slows formation of uric acid. Other known inhibitors of xanthine oxidase are an assortment of N^6-substituted 2-hydroxyadenines (XI) and S^6-substituted 2-hydroxy-6-mercaptopurines (XII) (7).

Of interest to cancer chemotherapy is the oxidation of the anticancer agent, 6-mercaptopurine (VII), to thiouric acid (VIII) (8–10) by xanthine oxidase in mammals, thus detoxifying the drug. It has been proposed (11) that the selective action on cells by 6-mercaptopurine (VII) may be due in part to selective detoxification; if a cell can activate 6-mercaptopurine (VII) to its lethal ribonucleotide (12–14), but due to a lack of sufficient xanthine oxidase cannot detoxify VII by oxidation to the nontoxic thiouric acid, then the cell will be killed. Those normal and cancer cell lines that can oxidize VII to VIII would be less affected by VII; thus some cancer cell lines that can activate 6-mercaptopurine (VII) to the ribonucleotide may not respond to the drug due to the rapid detoxification of VII. (Scheme I.)

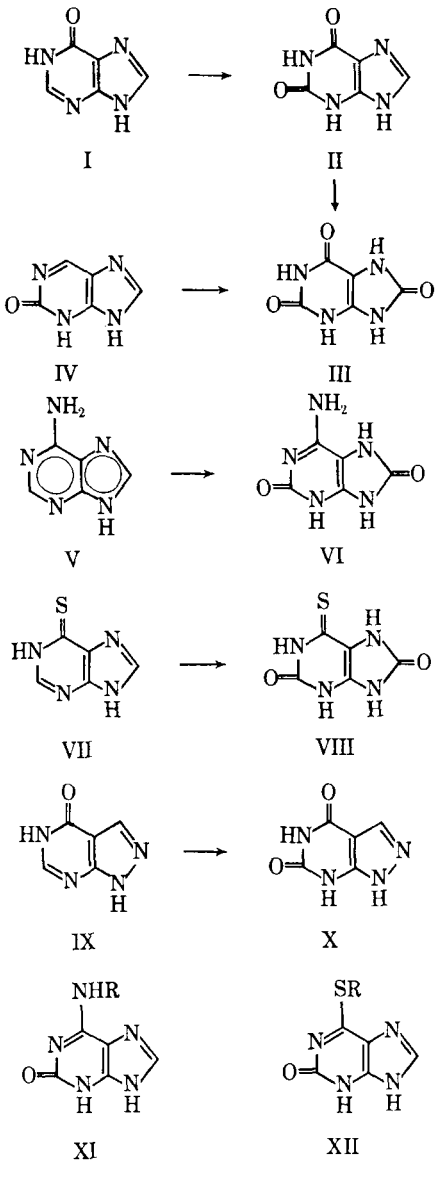
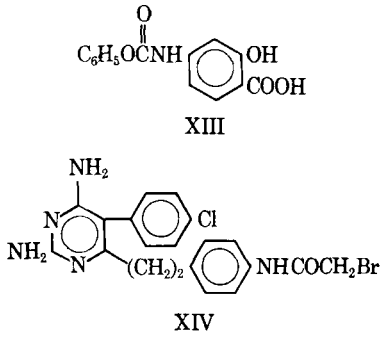


Scheme I

An inhibitor that could block xanthine oxidase in a cancer cell line with minimal blockade of the xanthine oxidase in normal cells could be a useful adjunct to treatment with 6-mercaptopurine. Reversible inhibitors rarely show sufficient tissue specificity to be of direct chemotherapeutic use without relying on unpredictable secondary considerations for selectivity such as an impaired active-transport system (15) or a lowered amount of detoxification enzyme (11, 16). In contrast, active-site-directed irreversible enzyme inhibitors can show tissue specificity since this type of inhibitor has an extra dimension of specificity not present in reversible inhibitors (14, 17, 18). For example, XIII can inactivate the lactic dehydrogenase from skeletal muscle, but not the lactic dehydrogenase from heart, and *vice versa* with the 5-isomer of XII (17, 19, 20). Another example is XIV, which will inactivate dihydrofolic reductase from *E. coli* B, but not pigeon liver (21).



In order to design an active-site-directed irreversible inhibitor of an enzyme, the following *modus operandi* has been developed (17, 19).

Phase I—The binding points on a reversible inhibitor should be determined, at least to the extent that substrate properties are destroyed, but binding is not; some binding points can be eliminated if compensated by a structural change that will give stronger binding at some other point in the molecule.

Phase II—The determination of areas on the inhibitor where bulky groups can be placed without interfering with the ability of the inhibitor to complex with the enzyme, known as either bulk tolerance within the enzyme–inhibitor complex or as a noncontact area between enzyme and inhibitor within the complex.

Phase III—A covalent bond-forming group should then be placed on a noncontact area of the inhibitor; if the dimension between the reversible complexing region on the enzyme and an enzymic nucleophilic group are correct, then a facile neighboring group reaction will occur between the inhibitor and enzyme that leads to selective inactivation of the enzyme by formation of a covalent bond.

Phase IV—The irreversible inhibitor from phase III is then modified to take advantage of the bridge principle of specificity (18–20) until the desired tissue specificity for the given enzyme is achieved.

Initial studies on phases I and II are the subjects of this paper.

DISCUSSION

Since xanthine oxidase can oxidize purines at the 2-, 6-, or 8-position, either several catalytic sites are present on the enzyme with one mode of purine binding or the purines can bind in one of several different

[a] Ratio of concentration of inhibitor to 8.1 μM hypoxanthine giving 50% inhibition; $K_m = 8.5 \times 10^{-6}$ M has been reported (22). [b] Sources: Aldrich, Aldrich Chemical Co.; NBC, Nutritional Biochemical Corp.; BW, Burroughs Wellcome Co.; Robins, a gift from Professor Roland K. Robins; Exptl., see under *Experimental*; Sigma, Sigma Chemical Co. [c] Previously reported (22) as a substrate with 5% of the rate of hypoxanthine and $K_m = 7.8 \times 10^{-6}$ M. [d] Previously reported (23) as an inhibitor, but the relative amount of binding to the enzyme was not recorded. [e] Estimated from 20% inhibition at a concentration of 60 μM, the limit of solubility. [f] Estimated from 11% inhibition at a concentration of 200 μM. [g] No substrate properties at 100 μM. [h] Previously reported (22) as a substrate with 1% of the rate of hypoxanthine ($K_m = 12 \times 10^{-6}$ M) and as an inhibitor of hypoxanthine with $K_i = 11 \times 10^{-6}$ M.

rotomeric conformations and the enzyme has only one catalytic site; the latter seems a more plausible concept and has been previously invoked to explain the oxidation of aminopurines by xanthine oxidase (3). The concept of several rotomeric binding configurations has also been invoked for (*a*) binding to chymotrypsin (24, 25), (*b*) the binding of adenosine and adenylic acid to certain enzymes (26), and (*c*) the binding of pyrimidines to dihydrofolic reductase (27-31). When different rotomers of a molecule can bind to an enzyme which depends upon the substituents on the inhibitor, the exact groups of the inhibitor complexing to the enzyme are difficult to ascertain with reasonable probability (30, 31). Therefore, with xanthine oxidase it is possible to make some generalizations about binding, but what specific groups of the inhibitor are complexed to the enzyme is fraught with uncertainty at this time. However, these generalizations are sufficient to lead to phase II for construction of candidate active-site-directed irreversible inhibitors of xanthine oxidase. The following generalizations from the data in Table I seem reasonable.

A—If no hydroxyl, thiol, or amino group is present on the purine, binding is poor; note that 6-chloropurine (XXII) and 6-butylmercaptopurine (XXIII) are complexed poorly to the enzyme, but hypoxanthine (the substrate), and adenine (XXX) are complexed well; 6-mercaptopurine (VII) is a known substrate (8-10).

B—A thiol group gives better binding than a hydroxyl group in some cases; note that thioguanine (XXI) binds fivefold better than guanine (XX), and XVI is a tenfold better inhibitor than XV. However, 2,6,8-trimercaptopurine (XVII) is not a better inhibitor than 2,8-dimercaptohypoxanthine (XVI). *S*-Methylation of thioguanine (XXI) to XXXI is extremely detrimental to binding, indicating that NHC=S moiety of thioguanine (XXI) is involved in binding to the enzyme.

C—More than one hydroxyl group can be detrimental to binding. Note that 2-benzylthiohypoxanthine (XXVIII) is a thirteenfold better inhibitor than its 8-hydroxy derivative (XXVII). If two hydroxyl groups are already present, an additional thiol can be detrimental to binding; note that 2-methylthio-6,8-dihydroxypurine (XXVI) is a tenfold better inhibitor than 2-thio-6,8-dihydroxypurine (XV). An exception occurs with aminopurines; 8-hydroxyguanine (XVIII) is a slightly better inhibitor than guanine (XX) and adenine (XXX) is a considerably better inhibitor than guanine (XX).

D—Guanine (XX) is a reasonably good inhibitor of xanthine oxidase, being complexed one-fifth as well as the substrate, hypoxanthine. Introduction of the 8-aza group, as in 8-azaguanine (XXXIII) gives a fivefold increment in binding. Replacement of the 6-hydroxyl group of guanine (XX) by amino (XIX) or introduction of a 9-methyl (XXIV) gives little change in binding; contrariwise, introduction of the 7-methyl group (XXV) is severely detrimental to binding.

[a] Ratio of concentration of inhibitor to 8.1 μM hypoxanthine giving 50% inhibition; see under *Experimental*. [b] Aldrich Aldrich Chemical Co.; NBC, Nutritional Biochemicals Corp.; EKC, Eastman Kodak Co.

Since 2-methylthio-6,8-dihydroxypurine (XXVI) was complexed to the enzyme nearly as well as the substrate, hypoxanthine, bulk tolerance at the 2-position was investigated. 2-Benzylthio-6,8-dihydroxypurine (XXVII) was complexed as effectively as the 2-methylthiopurine (XXVI) thus showing tolerance for the bulk of the *S*-benzyl group within the enzyme–inhibitor complex. Removal of the 8-hydroxyl group of (XXVII) to give 2-benzylthiohypoxanthine (XXVIII) gave the most effective inhibitor in Table I, XXVIII being complexed elevenfold better than the substrate hypoxanthine. 8-Benzylthiohypoxanthine (XXIX) was not so good an inhibitor as its 2-isomer (XXVIII), but XXIX was still complexed threefold better than hypoxanthine; thus, there is also bulk tolerance for an 8-benzylthio group within the enzyme–inhibitor complex. Introduction of an N^6-phenyl group (XXXII) on 2,6-diaminopurine (XIX) did not decrease binding, indicating bulk tolerance for this phenyl group.

Compounds XXVII, XXVIII, and XXIX are good candidates for phase III studies on the construction of active-site-directed irreversible inhibitors of xanthine oxidase; attachment of covalent forming groups to these three compounds for phase III studies is underway.

Table II lists the inhibition results with four pyrimidines and one imidazole; none were sufficiently good inhibitors to warrant further pursuit. However, an interesting contrast can be noted on the relative binding of 5-aminoimidazole-4-carboxamide (XXXIX) and guanine (XX) to xanthine oxidase and guanase (32). Guanine (XX) complexes twice as well as XXXIX to guanase, but 24-fold better than XXXIX to xanthine oxidase; thus, the mode of binding of guanine to the two enzymes is clearly different.

EXPERIMENTAL

Methods

Melting points were taken in capillary tubes on a Mel-Temp block and are uncorrected. Ultraviolet spectra were determined in water with a Perkin-Elmer 202 spectrophotometer. Infrared spectra were determined in KBr pellet with a Perkin-Elmer 137B spectrophotometer. Thin-layer chromatograms were run on Brinkmann Silica Gel GF in 3:1 chloroform–ethanol and spots were detected by visual examination under ultraviolet light. The analytical samples moved as a single spot and had infrared spectra in agreement with their assigned structures.

2 - Benzylmercapto - 6, 8 - dihydroxypurine (XXVII)—To a solution of 553 mg. (3 mmoles) of 6,8-dihydroxy-2-mercaptopurine (XV) in 3 ml. of 1 *N* aqueous sodium hydroxide was added 30 ml. of water and 0.35 ml. (3 mmoles) of benzyl chloride. After being stirred at ambient temperature for 5 hr., the mixture was acidified with acetic acid. The product was collected on a filter, then washed successively with hot water, acetone, and hot ethanol. The crude product was dissolved in dilute aqueous sodium hydroxide, then the solution was clarified with decolorizing carbon and acidified with acetic acid to give 406 mg. (49%) of product. Recrystallization from *N,N*-dimethylformamide gave 224 mg. (27%) of a white solid, m.p. over 300°. $\lambda_{max.}$ (pH 1): 278 mμ; (pH 13): 284 mμ.

Anal.—Calcd. for $C_{12}H_{10}N_4O_2S$: C, 52.5; H, 3.68; N, 20.4. Found: C, 52.7; H, 3.80; N, 20.3.

2-Benzylmercapto-6-hydroxypurine (XXVIII)—Reaction of 505 mg. (3 mmoles) of 6-hydroxy-2-mercaptopurine with benzyl chloride, as described for the preparation of XXVII, gave after recrystallization from aqueous 2-methoxyethanol 195 mg. (26%) of white powder, m.p. 263–265°. $\lambda_{max.}$ (pH 1): 272 mμ; (pH 13): 280 mμ.

Anal.—Calcd. for $C_{12}H_{10}N_4OS$: C, 55.8; H, 3.91; N, 21.7. Found: C, 55.9; H, 3.99; N, 21.9.

8-Benzylmercapto-6-hydroxypurine (XXIX)—This was prepared from 6-hydroxy-8-mercaptopurine hydrate in the same fashion as XXVIII; yield, 295 mg. (40%), m.p. 273–274° $\lambda_{max.}$ (pH 1): 280 mμ; (pH 13): 284 mμ.

Anal.—Calcd. for $C_{12}H_{10}N_4OS$: C, 55.8; H, 3.91; N, 21.7. Found: C, 55.9; H, 3.92; N, 21.8.

Inhibition of Xanthine Oxidase (2)—Xanthine oxidase from milk was obtained as a 5–10 unit suspension per ml. of 60% saturated ammonium sulfat from Nutritional Biochemicals Corp.; 1 unit supposedly converts 1 μmole of xanthine to uric acid per minute. For 1 day's assay, 0.05 ml. of enzyme was diluted with 2.95 ml. of buffer. Tris buffer (0.05 *M*), pH 7.4, was employed. Hypoxanthine was stocked as a 50 m*M* solution in 1 *N* aqueous sodium hydroxide; for 1 day's assays the stock solution was diluted 1:100 with buffer to give an 0.5 m*M* solution. Inhibitors XXIII–XXV, XXVII–XXIX, and XXXII were dissolved in dimethylsulfoxide and di-

luted with the same; the remainder of the inhibitors were dissolved in 10 mM aqueous sodium hydroxide and diluted with water.

In a 3-ml. cell were placed 2.70 ml. of buffer, 0.30 ml. of dimethylsulfoxide, and 50 μl. of 0.5 mM hypoxanthine. The solution was vigorously shaken for about 20 sec. to absorb air. Then 50 μl. of diluted enzyme solution was added and the rate of increase in absorbance at 290 mμ was noted with a Gilford recording spectrophotometer; sufficient enzyme was employed to give about 0.01 absorbance units change per minute. If the inhibitor was dissolved in water, up to 0.3 ml. could be used in the cell by decreasing the buffer by the corresponding amount. If the inhibitor was dissolved in dimethylsulfoxide, up to 0.30 ml. could be used, keeping the total volume of dimethylsulfoxide at 0.30 ml. Sufficient inhibitor was used to give 30–70% inhibition; the μM concentration of inhibitor necessary for 50% inhibition ($V_0/V_I = 2$) was determined by plotting V_0/V_I against I, where V_0 = velocity without inhibitor, V_I = velocity with inhibitor, and I = inhibitor concentration (33).

The cell concentration of hypoxanthine was 8.1 μM; the velocity was the same in the presence or absence of 10% dimethylsulfoxide.

Irreversible Enzyme Inhibitors XCIII

Hydrophobic Bonding to Xanthine Oxidase by Some Phenylpurines

By B. R. BAKER

Nine derivatives of guanine with alkyl, aryl, or aralkyl groups at the 8- or 9-position were investigated as inhibitors of xanthine oxidase. Maximum hydrocarbon interaction with the enzyme was observed with the in-plane 9-phenyl substituent, a 100-fold increment in binding being observed. The "2"-position of purines was also investigated with phenyl substituents on the 6-position of 4-mercaptopyrazolo[3,4-*d*]pyrimidine; a thirtyfold increment in binding was observed with either a *p*-nitrophenyl or a *p*-methoxyphenyl substituent at the 6-position of the pyrazolopyrimidine.

THE PREVIOUS PAPER of this series discussed the possible chemotherapeutic use for a blockade of xanthine oxidase (1): since 6-mercaptopurine can be detoxified by oxidation to the nontoxic 6-thiouric, an active-site-directed irreversible inhibitor that is sufficiently tissue specific on a given tumor line would be a useful adjunct to 6-mercaptopurine therapy. The normal substrates of xanthine oxidase, hypoxanthine and xanthine, are highly polar molecules; therefore, if a hydrophobic region could be detected by purines substituted by hydrocarbon groups, this hydrophobic region would most probably be just adjacent to the active site, but not part of

the active site. It is outside the active site where evolutionary changes of amino acids could more easily occur and still maintain the integrity of the active site (2). Such hydrophobic regions adjacent to the active site have been discovered on dihydrofolic reductase (3–5), guanase (6, 7), and thymidine phosphorylase (8, 9); the exploitation of hydrophobic regions adjacent to the active site for the design of reversible (5, 10) and irreversible inhibitors (5, 11) has been discussed. Therefore, a search for a hydrophobic bonding region on xanthine oxidase was initiated and the results are the subject of this paper.

DISCUSSION

It was noted in the previous paper that 8-azaguanine (II) was complexed as well as the substrate, hypoxanthine, and guanine (I) was complexed one-fifth as well (Table I). Since substitution of the 9-hydrogen of guanine (I) by methyl (III) gave less than a twofold loss in binding, variation of the 9-substituent of guanine was investigated for detection of hydrophobic bonding; these compounds were kindly supplied by Professor Roland K. Robins (12).

The 9-(*n*-amyl)-substituent of IV and the cyclohexyl substituent of V gave no appreciable increase in binding over guanine, and the 9-benzyl substituent (VI) gave only about twofold increase in binding. A large increment in binding was observed with the in-plane 9-phenyl substituent of VII, VII being complexed 100-fold better than guanine (I) and 140-fold better than 9-methylguanine (III). 9-(*p*-Chlorophenyl)guanine (VIII) also showed hydrophobic bonding to the enzyme with a 22-fold increment in binding over that of guanine (I), but which was less than that noted with 9-phenylguanine (VI). Similarly, the 9-(*p*-chlorophenyl) substituent (IX) of 8-azaguanine showed a 31-fold increment in binding over the parent 8-azaguanine (II). Thus, IX is the most potent inhibitor in Tables I and II, being complexed 33-fold better than the substrate, hypoxanthine which has $K_m = 7.8 \times 10^{-6}$ *M* (13).

Two guanine derivatives with an 8-phenyl (X) and 8-phenylpropyl (XI) substituent (6) were investigated for hydrophobic bonding; both showed about a fivefold increment in binding over guanine (I), but this increment was considerably less than that observed with the 9-phenyl substituent (VII).

Through a generous gift from Professor E. C. Taylor, the 4-mercaptopyrazolo[3,4-*d*]pyrimidines with hydrocarbon groups at the 2-position (14), were studied; these were of interest since 4-hydroxypyrazolo[3,4-*d*]pyrimidine is a known substrate and inhibitor (15) of xanthine oxidase and since hydrophobic bonding had been detected with 9-phenylguanine (Table I).

The 2-methyl derivative (XII) (Table II) was complexed fifteenfold less than hypoxanthine, the substrate. When the 2-methyl group of XII was replaced by the in-plane *p*-nitrophenyl group (XIII), a 38-fold increment in binding was observed; this is similar to the 31-fold increment observed in replacing the 9-methyl group (III) on guanine by *p*-chlorophenyl (VIII), but not so good as the increment in 9-phenylguanine (VII).

[c] A measurement of hydrophobic character on a log scale, a minus value being more polar than hydrogen; data from *Reference 24*.

The *p*-methoxyphenyl substituent (XV) was complexed as well as the *p*-nitrophenyl substituent (XIII); these results indicate that there is no donor-acceptor character in the mode of complexing of the phenyl group in this series to the enzyme, else considerable difference in binding should have been seen due to the strong electron-donating methoxyl group and the strong electron-withdrawing nitro group. Replacement of the *p*-methoxy group of XV with *p*-amino (XIV) gave a thirteenfold loss in binding. This result could be due to repulsion of the weakly basic amino group from an electron-donor site on the enzyme or due to the difference in polarity between amino on one hand and methoxy and nitro on the other; note in Table II that the amino group is by far the most polar of the three groups.

That an in-plane phenyl group can give hydrophobic bonding on either the 9-position or "2" position of a purine or related compound agrees with the postulate of Bergmann *et al.* (16) that various rotomers of the purine can bind to the active site of xanthine oxidase. Strong hydrophobic bonding can be determinate on which rotomer binds to the enzyme, as previously postulated with binding to chymotrypsin (17, 18), dihydrofolic reductase (4, 5, 19, 20), some adenylate using enzymes (21), and adeno-

sine deaminase (22). By substitution of the phenyl group on various purines and related heterocycles, such as those in Tables I and II, it should then be possible to study the mode of binding of other substituents on the heterocyclic ring such as OH, NH, and SH; if good phenyl binding is observed compared to the corresponding methyl or benzyl purine, then it can be logically assumed that the phenyl group anchors one rotomer to the enzyme, but with two "flip" configurations (5, 20).

Also of interest would be to establish whether the phenyl group complexes to the enzyme only by hydrophobic bonding and the accompanying van der Waal's forces—as seen with dihydrofolic reductase (5, 23)—or if there is additional donor-acceptor character in the phenyl ring (unlikely). Furthermore, the use of these phenyl heterocycles for construction of active-site-directed irreversible inhibitors is worthy of pursuit.

Some seven enzymes using a heterocyclic substrate have been investigated in this laboratory for hydrophobic bonding by hydrocarbon groups attached to the heterocycle. Hydrophobic bonding has yet to be detected with thymidine kinase (9, 25, 26) and thymidylate synthetase (27) even though such a search was performed; weak hydrophobic bonding with 9-alkyl and 9-aralkyladenines to succinoadenylate kinosynthetase has been observed (28); strong hydrophobic bonding with 6-aralkyluracils to thymidine phosphorylase (8, 9), with 9-phenylguanines to guanase (6), and with 9-phenylpurines and related heterocycles to xanthine oxidase has been observed. The strongest hydrophobic bonding observed in this set of seven enzymes was with dihydrofolic reductase (3, 5, 23) where the in-plane phenyl group gives a 700-fold increment and the phenylbutyl group gives a 40,000-fold increment in binding.

These comparisons are summarized in Table III. Note that the type of hydrocarbon giving maximum hydrophobic bonding varies with the enzyme and with the position of the hydrophobic group on the inhibitor; for example, the in-plane phenyl group gives maximum hydrocarbon bonding with guanase and xanthine oxidase, but higher phenylalkyl groups are more effective on the other enzymes. Also note that the benzyl group on the 6-position of uracil gives maximum hydrocarbon interaction, but that higher phenylalkyl groups are more effective on the 1- and 5-positions of uracil. Although the 9-phenyl group on guanine is the most effective for hydrocarbon interaction with guanase and xanthine oxidase, substitution on the phenyl group has shown that the enzymic environment in the region of 9-phenyl bonding is not the same with the two enzymes; for example, a *p*-carboxylate on the 9-phenyl group aids binding to xanthine oxidase, but is extremely detrimental to binding to guanase (31).

Synthesis of 1-Methylpyrazolidine and Some of Its Derivatives

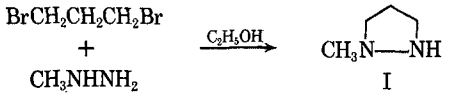
By MILTON J. KORNET

1-Methylpyrazolidine has been prepared *via* a two-step reaction sequence from ethyl acrylate and methylhydrazine, and also directly from trimethylene bromide and methylhydrazine. The *N*-methylpyrazolidino group was substituted for the dialkylamino group in a limited number of clinically effective agents. These derivatives are to be screened for pharmacologic activity.

RECENTLY, a series of esters which has a *N*-alkylated pyrazolidinyl group substituted for a dialkylamino group has been synthesized and found to possess local anesthetic activity (1). One of the compounds, 3-(*N*,*N'*-diethylpyrazolidinyl)methyl *p*-(*n*-butylamino) benzoate was found to be six times as effective as piperocaine[1] when tested on earthworms of genus *Lumbricus*. In view of these encouraging results, it appeared desirable to extend this work and to incorporate the pyrazolidine ring into other types of drug molecules. To this end, the previously unknown 1-methylpyrazolidine has been synthesized, and substituted for the customary dialkylamino group, as a *N*-methylpyrazolidino group, in a number of clinically active agents.

DISCUSSION

1-Methylpyrazolidine (I) was obtained *via* a two-step reaction sequence from methylhydrazine and ethyl acrylate. The intermediate product obtained by distillation was not characterized, but was reduced directly by lithium aluminum hydride and afforded 1-methylpyrazolidine (I) in an over-all yield of 68%. Presumably the intermediate is predominantly 1-methyl-3-pyrazolidinone rather than the 2-methyl isomer. Reduction of either isomer would give 1-methylpyrazolidine. The above structure is proposed for the intermediate because reaction of methylhydrazine with methacrylic acid reportedly gave 1,4-dimethyl-3-pyrazolidinone as the sole product (2). The structure of I is supported by its elemental analysis and infrared spectrum. With excess phenyl isothiocyanate, I forms a monophenylthiourea derivative. Further support for structure I is an alternate one-step synthesis from methylhydrazine and trimethylene bromide. (Scheme I.)



Scheme I

The infrared spectrum of the product obtained by this pathway was identical to that of the product obtained *via* the methylhydrazine–ethyl acrylate route. Furthermore, no depression was observed when a melting point determination was performed on a mixture of the phenylthiourea derivatives of the two products, and the infrared spectra of these derivatives were identical (see under *Experimental*). Because of a higher yield and purer product, 1-methylpyrazolidine (I) is best prepared *via* the longer two-step route.

The preparation of the *N*-methylpyrazolidino analog of the local anesthetic lidocaine[2] was attempted by reacting *N*-chloroacetyl-2,6-dimethylaniline with excess 1-methylpyrazolidine. A crystalline salt having the correct elemental analysis was obtained in 92% yield. However, the salt is not the desired 2-(2-methylpyrazolidino)-2′,6′-dimethylacetanilide hydrochloride but is instead a hydrazinium chloride, 1-methyl-1-[2-(2′,6′-dimethylanilino)-2-oxoethyl]pyrazolidinium chloride (II). The infrared spectrum of the salt supports structure II since it revealed the absence of absorption in the NH^+ region. Treatment of an aqueous solution of the salt with sodium bicarbonate failed to evolve carbon dioxide, behavior which rules out a hydrochloride salt. Furthermore, an aqueous solution of the salt reacted with silver oxide to precipitate silver chloride and gave a strongly alkaline solution (pH ~ 11, Hydrion E paper) indicating the conversion of a hydrazinium chloride to a hydrazinium hydroxide. This observation is in agreement with the report that hydrazinium hydroxides are slightly less basic than quaternary ammonium hydroxides (3). Studies concerned with the alkylation of alkylhydrazines have shown that substitution occurs at the substituted nitrogen atom to give good yields of the trialkylated quaternary hydrazinium halide unless the alkyl halide contains bulky groups (4, 5). Thus α-bromopropiophenone reacts with 1,1-dimethylhydrazine at the methylated nitrogen atom, resulting in the formation of a quaternary hydrazinium bromide product (6). In view of these earlier findings, it is not surprising that II is the product of the reaction between *N*-methylpyrazolidine and *N*-chloroacetyl-2,6-dimethylaniline.

The *N*-methylpyrazolidino analog of an aminoalkyl ether type of antihistaminic agent, of which chlordiphenhydramine[3] is the prototype, was realized in the following way. Reaction of I with ethyl acrylate proceeded smoothly and afforded the adduct, 1-(2-ethoxycarbonylethyl)-2-methylpyrazolidine (IV) in 85% yield. Lithium aluminum hydride reduction of IV gave an 87% yield of the

Received December 5, 1966, from the Department of Pharmaceutical Chemistry, College of Pharmacy, University of Kentucky, Lexington, KY 40506

[1] 3-(2-Methylpiperidino)propyl benzoate.

[2] 2-(Diethylamino)-2′,6′-acetoxylidide.

[3] 2-(*p*-Chlorobenzhydryloxy)-*N*-dimethylethylamine.

corresponding alcohol (V), which was condensed with *p*-chlorobenzhydryl chloride to give the ether, 1-[3-(*p*-chlorobenzhydryloxy)propyl]-2-methylpyrazolidine (VI). The preparation of a pyrazolidinoethyl ether was abandoned in favor of a pyrazolidinopropyl ether when it was found that I could be converted to 1-(2-hydroxyethyl)-2-methylpyrazolidine (III) in only 9% yield by reaction with ethylene oxide.

Cyanoethylation of 1-methylpyrazolidine proceeded readily and in 77% yield to give the nitrile, 1-(2-cyanoethyl)-2-methylpyrazolidine (VII) which was reduced by lithium aluminum hydride and afforded the propylamine derivative (VIII) in 83% yield. The latter compound, upon reaction with *S*-methylisothiourea sulfate, was converted into the guanidino derivative, 1-(3-guanidinopropyl)-2-methylpyrazolidine sulfate (IX). Compound IX may be regarded as a relative of the hypotensive agent guanethidine.[4]

1-Nicotinoyl-2-methylpyrazolidine (X), related to the respiratory stimulant nikethamide,[5] was prepared from 1-methylpyrazolidine and ethyl nicotinate using sodium methoxide as the catalyst. In addition, I reacted with ethyl chloroformate and gave 1-ethoxycarbonyl-2-methylpyrazolidine (XI). This compound bears structural resemblances to 1-ethoxycarbonyl-4-methylpiperazine, a potent filaricidal agent (7). The above transformations are summarized in Scheme II. The derivatives described in this paper are to be screened for pharmacological activity.

EXPERIMENTAL[6]

1-Methylpyrazolidine (I)—*Method A*—To a solution of 50.6 Gm. (1.10 moles) of methylhydrazine in 25 ml. of absolute ethanol was added dropwise a solution of 100 Gm. (1.00 mole) of ethyl acrylate in 65 ml. of absolute ethanol with stirring (magnetic) and ice-bath cooling. The reaction mixture was stirred and allowed to come to room temperature overnight, and refluxed for 24 hr. The ethanol was distilled *in vacuo* on a water bath, and the residue was distilled and gave 98.6 Gm. of a nearly colorless liquid, b.p. 90–110° (0.7 mm.). The liquid was partially dissolved in 500 ml. of anhydrous ether and the resulting mixture (2-phase) was added dropwise to a suspension of 70.0 Gm. (1.85 moles) of $LiAlH_4$ in 1300 ml. of anhydrous ether with stirring (mechanical). After refluxing for 18 hr. the complex was decomposed with 40% aqueous KOH, with cooling of the reaction mixture by means of a brine and ice cooling mixture. The ether layer was separated and the inorganic sludge was washed twice with 100-ml. portions of ether. The combined ether layers were dried ($MgSO_4$) and the filtered solution was distilled through a Todd column (12 × 90 mm.) packed with glass helices (4 mm. diameter). After removal of the ether fraction and a small fraction of b.p. 78° (probably ethanol), the product distilled and gave 58.9 Gm. (68.5% yield based on ethyl acrylate) of a colorless liquid, b.p. 118° (739 mm.); n_D^{20} 1.4561; $\lambda_{max.}^{film}$ 3.06 μ (NH). In addition, 10 Gm. of a higher boiling residue remained which was not further investigated.

Anal.—Calcd. for $C_4H_{10}N_2$: C, 55.77; H, 11.70; N, 32.52. Found: C, 55.73; H, 11.62; N, 32.58.

A phenylthiourea derivative (8) was prepared and recrystallized from 95% ethanol, m.p. 90–91°.

Anal.—Calcd. for $C_{11}H_{15}N_3S$: C, 59.69; H, 6.83; N, 18.99. Found: C, 59.58; H, 6.72; N, 18.93.

The dihydrobromide was recrystallized from absolute ethanol–ether, m.p. 181–182.5°.

Anal.—Calcd. for $C_4H_{10}N_2 \cdot 2HBr$: C, 19.37; H, 4.88. Found: C, 19.83; H, 5.16.

Method B—To a mechanically-stirred solution of 34.5 Gm. (0.75 mole) of methylhydrazine in 100 ml. of 98% ethanol was added 75.7 Gm. (0.375 mole) of trimethylene bromide in small portions over a period of 30 min. with cooling by means of a cold water bath. The mixture was stirred for 1 hr. at room temperature and refluxed for 17 hr. The clear yellow solution was treated with 45 Gm. (0.8 mole) of KOH pellets with stirring whereupon KBr precipitated. After stirring for 1 hr. the reaction mixture was filtered and the filtrate was distilled through the Todd column described above. The fraction of b.p. 75–84° was collected and discarded. The contents of the still pot was cooled, dissolved in 250 ml. of tetrahydrofuran, and dried over KOH pellets overnight. After filtering, the solution was distilled through the Todd column and afforded 11 Gm. (34%) of a fraction, b.p. 107–115° (735 mm.). Redistillation (without a fractionating column) from KOH pellets gave 8.5 Gm. of liquid, b.p. 110–116° (735 mm.). The infrared spectrum (film) of the product obtained by method *B* was the same as the I.R. spectrum of the product obtained by method *A*, except that the intensity of the NH band was somewhat weaker in the spectrum of the product obtained *via* method *B*. The phenylthiourea derivative was prepared, m.p. 90–91°. A mixed melting point with the phenylthiourea derivative obtained by method *A* was 90–91°, and the infrared spectra of the two derivatives were identical.

1-Methyl-1-[2-(2′,6′-dimethylanilino)-2-oxoethyl]pyrazolidinium chloride (II)—To a solution of 8.25 Gm. (0.096 mole) of 1-methylpyrazolidine (I) in 35 ml. of dry benzene was added 7.90 Gm. (0.040 mole) of *N*-chloroacetyl-2,6-dimethylaniline (9) and the mixture was refluxed for 1.75 hr. The mixture was cooled and filtered to give 10.5 Gm. (92.5%) of a white crystalline salt, m.p. 189–197°. Two recrystallizations from absolute ethanol afforded the analytically pure compound, m.p. 200–201.5°; $\lambda_{max.}^{Nujol}$ 6.0 μ (C=O), 3.2 μ (NH).

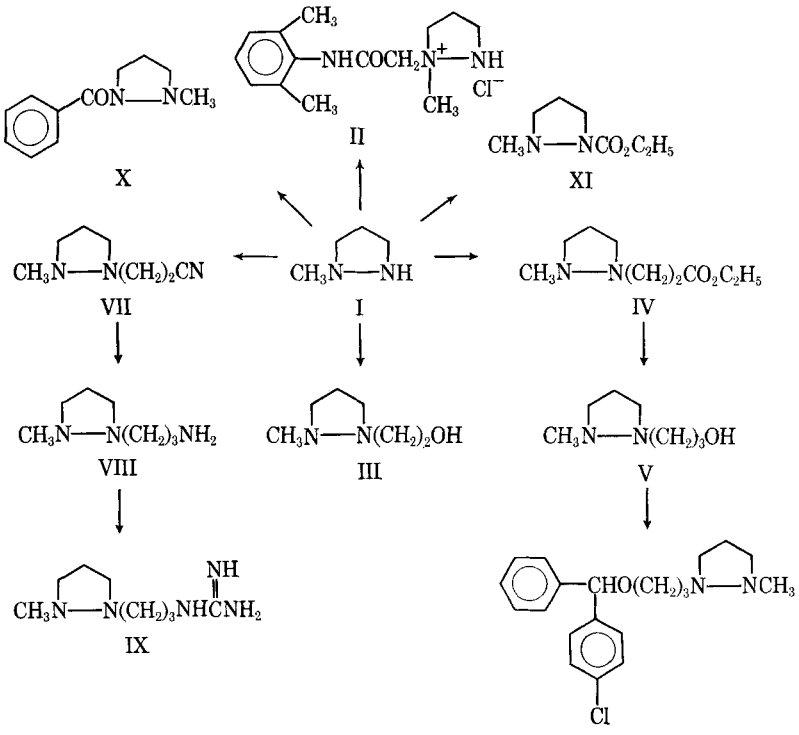
Anal.—Calcd. for $C_{14}H_{22}ClN_3O$: C, 59.25; H, 7.81. Found: C, 59.19; H, 7.83.

1-(2-Hydroxyethyl)-2-methylpyrazolidine (III)—To a solution of 17.2 Gm. (0.2 mole) of 1-methylpyrazolidine (I) in 40 ml. of methanol was added dropwise a solution of 13.3 Gm. (0.30 mole) of ethylene oxide in 65 ml. of anhydrous ether over a period of 30 min. with ice-salt bath cooling. The stoppered reaction mixture was allowed to reach room temperature overnight and was stored for 4 days. An additional 3 ml. of ethylene oxide was added and the reaction mixture was refluxed for 5 hr. using a dry ice–acetone condenser and allowed to stand overnight. The solvents were removed on a water bath *in vacuo* and the residue was fractionally distilled to give 2.4 Gm. (9.2%) of a colorless liquid,

[4] [2-(Octahydro-1-azocinyl)ethyl]guanidine.

[5] *N,N*-Diethylnicotinamide.

[6] Melting points were determined with the Fisher-Johns melting point apparatus and are corrected. Infrared spectra were recorded on a Beckman IR 8 spectrophotometer using sodium chloride optics. Microanalyses were performed by Dr. Kurt Eder, Geneva, Switzerland.



Scheme II

b.p. 78–83° (28 mm.); n_D^{20} 1.4432. The picrate was prepared and recrystallized from absolute ethanol, m.p. 146.5–148.5°.

Anal.—Calcd. for $C_{12}H_{17}N_5O_8$: N, 19.49. Found: N, 19.31.

1-(2-Ethoxycarbonylethyl)-2-methylpyrazolidine (IV)—A solution of 13.7 Gm. (0.137 mole) of ethyl acrylate in 16 ml. of absolute ethanol was added dropwise to a stirred (magnetic) solution of 11.8 Gm. (0.137 mole) of 1-methylpyrazolidine (I) in 6 ml. of absolute ethanol with ice-bath cooling. After stirring overnight at room temperature the reaction mixture was refluxed on the steam bath for 44 hr. The ethanol was removed (rotary evaporator) and the residue was distilled to give 21.7 Gm. (85%) of a colorless liquid, b.p. 105° (8 mm.); b.p. 60° (0.08 mm.); n_D^{20} 1.4533. In a second experiment with a 20-hr. reflux period the yield was 21.8 Gm. (85.4%).

Anal.—Calcd. for $C_9H_{18}N_2O_2$: C, 58.04; H, 9.74. Found: C, 58.19; H, 9.77.

A picrate derivative was prepared and recrystallized from absolute ethanol, m.p. 118–119°.

Anal.—Calcd. for $C_{15}H_{21}N_5O_9$: C, 43.37; H, 5.10; N, 16.86. Found: C, 43.52; H, 5.07; N, 17.00.

1-(3-Hydroxypropyl)-2-methylpyrazolidine (V)—A solution of 20.6 Gm. (0.111 mole) of 1-(2-ethoxycarbonylethyl)-2-methylpyrazolidine (IV) in 75 ml. of anhydrous ether was added to a suspension of 4.20 Gm. (0.111 mole) of $LiAlH_4$ and the resulting mixture was refluxed for 17 hr. After decomposing the complex with 40% aqueous KOH (about 50 ml.), the inorganic salts were extracted with ether and the combined ether layers were dried ($MgSO_4$). The spent drying agent was filtered and the filtrate was distilled at atmospheric pressure to remove the ether. The residue was distilled and afforded 13.97 Gm. (87.5%) of a colorless oil, b.p. 112° (11 mm.); n_D^{20} 1.4788; $\lambda_{max.}^{film}$ 2.97 μ (broad H-bonded OH).

Anal.—Calcd. for $C_7H_{16}N_2O$: C, 58.30; H, 11.18. Found: 58.36; H, 11.56.

1-[3-(p-Chlorobenzhydryloxy)propyl]-2-methylpyrazolidine (VI)—A solution of 11.8 Gm. (0.050 mole) of *p*-chlorobenzhydryl chloride in 75 ml. of dry xylene was added dropwise with stirring (mechanical) to a refluxing mixture of 7.2 Gm. (0.05 mole) of 1-(3-hydroxypropyl)-2-methylpyrazolidine (V) and 5.3 Gm. (0.05 mole) of anhydrous sodium carbonate in 30 ml. of dry xylene. The mixture was refluxed for 27 hr. After cooling, the reaction mixture was extracted several times with 10% aqueous HCl and the combined extracts were made alkaline with 40% aqueous NaOH and extracted with chloroform. The chloroform solution was dried ($MgSO_4$) and distilled at atmospheric pressure to remove the chloroform. The residue was distilled and gave 2.0 Gm. (11.6%) of a pale yellow oil, b.p. 169° (0.1 mm.); n_D^{20} 1.5615; $\lambda_{max.}^{film}$ 9.2 μ (COC), 13.3, 14.3 μ (monosubstituted benzene).

Anal.—Calcd. for $C_{20}H_{25}ClN_2O$: C, 69.65; H, 7.31; N, 8.12. Found: C, 69.67; H, 7.40; N, 8.13.

1-(2-Cyanoethyl)-2-methylpyrazolidine (VII)—To 12.9 Gm. (0.15 mole) of 1-methylpyrazolidine (I) was added dropwise 7.59 Gm. (0.15 mole) of acrylonitrile with stirring (magnetic) and ice-bath cooling. The resulting mixture was stirred at room temperature overnight and then heated on the steam bath for 2 hr. The yellow mixture was

distilled and afforded 15.96 Gm. (76.6%) of a colorless liquid, b.p. 128–130° (26 mm.); b.p. 64° (0.17 mm.); n_D^{20} 1.4663; $\lambda_{max.}^{film}$ 4.44 μ (C≡N).

Anal.—Calcd. for $C_7H_{13}N_3$: C, 60.40; H, 9.41; N, 30.19. Found: C, 60.38; H, 9.64; N, 29.98.

A picrate derivative was prepared and recrystallized from absolute ethanol, m.p. 151–152.5°.

Anal.—Calcd. for $C_{13}H_{16}N_6O_7$: C, 42.39; H, 4.38. Found: C, 42.31; H, 4.90.

1-(3-Aminopropyl)-2-methylpyrazolidine (VIII)—A solution of 10.0 Gm. (0.0719 mole) of 1-(2-cyanoethyl)-2-methylpyrazolidine (VII) in 50 ml. of anhydrous ether was added dropwise with stirring (mechanical) to a suspension of 5.0 Gm. (0.132 mole) of $LiAlH_4$ in 450 ml. of anhydrous ether. The mixture was refluxed overnight and cooled, and the complex was decomposed with 40% aqueous KOH. The ether layer was decanted, the inorganic sludge was extracted twice with ether, and the combined ether layers were dried ($MgSO_4$). The drying agent was filtered and the ether distilled on a water bath at atmospheric pressure. The residue was distilled to give 8.56 Gm. (83.1%) of a colorless liquid, b.p. 45° (0.25 mm.); n_D^{20} 1.4777; $\lambda_{max.}^{film}$ 3.02 μ (NH).

Anal.—Calcd. for $C_7H_{17}N_3$: C, 58.70; H, 11.96; N, 29.34. Found: C, 58.59; H, 12.28; N, 29.30.

A dipicrate derivative was prepared and recrystallized from 95% ethanol, m.p. 175.5–176.5°.

Anal.—Calcd. for $C_{19}H_{23}N_9O_{14}$: C, 37.94; H, 3.85. Found: C, 38.07; H, 3.96.

1-(3-Guanidinopropyl)-2-methylpyrazolidine Sulfate (IX)—A mixture of 5.0 Gm. (0.035 mole) of 1-(3-aminopropyl)-2-methylpyrazolidine (VIII) and 8.8 Gm. (0.032 mole) of *S*-methylisothiourea sulfate (10) in 35 ml. of 95% ethanol was refluxed with stirring for 6 hr. After cooling, the reaction mixture was filtered and the solid obtained (2.66 Gm.) was identified as *S*-methylisothiourea sulfate. The filtrate was evaporated *in vacuo* and the oily residue was dried (P_2O_5) in an evacuated desiccator for 3 days. Trituration with anhydrous ether gave a hygroscopic crystalline solid which was filtered and redried (P_2O_5). The dried solid weighed 6.0 Gm. (61%) and was recrystallized by dissolving it in water and adding absolute ethanol to the cloud point, m.p. 223.5–224°.

Anal.—Calcd. for $C_8H_{19}N_5 \cdot H_2SO_4$: C, 33.91; H, 7.47; N, 24.72. Found: C, 34.02; H, 7.47; N, 24.70.

1-Nicotinoyl-2-methylpyrazolidine (X)—A solution of 4.3 Gm. (0.05 mole) of 1-methylpyrazolidine (I), 7.55 Gm. (0.05 mole) of ethyl nicotinate (11), and 53 ml. of hexane was dried by azeotropic distillation using a Dean-Stark trap. After 1 hr., 0.3 Gm. of anhydrous sodium methoxide was added and the refluxing was continued for 19 hr. The hexane was distilled *in vacuo* on a water bath. About 10 ml. of water was added, and the mixture was extracted three times with chloroform. The chloroform solution was dried ($MgSO_4$) and the solvent was removed *in vacuo* on a water bath. The residue was distilled and gave 5.1 Gm. (53%) of a colorless oil, b.p. 124° (0.08 mm.). The oil crystallized upon standing, m.p. 50.5–52.5°; $\lambda_{max.}^{Nujol}$ 6.2 μ (C=O).

Anal.—Calcd. for $C_{10}H_{13}N_3O$: C, 62.81; H, 6.85; N, 21.97. Found: C, 62.62; H, 6.97; N, 21.90.

A dipicrate was prepared and recrystallized from aqueous ethanol, m.p. 167–168°.

Anal.—Calcd. for $C_{22}H_{19}N_9O_{15}$: C, 40.69; H, 2.95; N, 19.41. Found: C, 40.76; H, 3.29; N, 19.43.

1-Ethoxycarbonyl-2-methylpyrazolidine (XI)—In a 250-ml. three-necked flask provided with a mechanical stirrer and cooled by an ice–salt mixture were placed 25 ml. of ether and 25.8 Gm. (0.1 mole) of a 33% aqueous 1-methylpyrazolidine solution. When the stirred mixture had cooled to 5°, 10.9 Gm. (0.1 mole) of ethyl chloroformate was added without allowing the temperature to rise above 5°. After all of the chloroformate had been added, a solution of 4.0 Gm. (0.1 mole) of NaOH in 6 ml. of water was added dropwise keeping the temperature below 5°. The reaction mixture was stirred for 10 min. longer, the ether layer was separated, and the aqueous solution was extracted with 15 ml. of ether. The combined ether layers were dried ($MgSO_4$) and the ether was distilled using a rotary evaporator. The residue was distilled and afforded 3.03 Gm. (19.2%) of a colorless liquid, b.p. 118° (18 mm.); n_D^{20} 1.4630; $\lambda_{max.}^{film}$ 5.92 μ (C=O).

Anal.—Calcd. for $C_7H_{14}N_2O_2$: C, 53.14; H, 8.92; N, 17.71. Found: C, 53.24; H, 8.93; N, 17.57.

Medicinal Folklore Evaluation I

Alleged Androgenic and Aphrodisiac Action of Pega Palo (*Rhynchosia pyramidalis*)

By NORMAN R. FARNSWORTH, MELVIN HESS*, ALAN E. FISHER†, ROBERT E. MARTELLO, and LAWRENCE V. CAMMARATO

Pega palo is a plant that has received recent and widespread publicity as an alleged aphrodisiac and androgenic agent. One literature report claims clinical efficacy for these effects; however, other investigators could not confirm these activities in laboratory animals. In the present investigation, using a variety of biological test procedures, neither androgenic activity nor an aphrodisiac effect could be demonstrated in laboratory animals.

RHYNCHOSIA PYRAMIDALIS (Lam.) Urb. (*Leguminosae*), is a woody vine found extensively in the Dominican Republic and in Haiti. Dominican folklore and tradition, dating to pre-Columbian times, reveal that alcoholic extracts prepared from the stems of this plant have been used empirically for the purpose of increasing libido and strengthening of sexual performance in the male (1–3). More recently, several popular magazines and newspapers have reported on the more sensational aspects of the biological activity associated with *R. pyramidalis* (2). The use of pega palo (virility vine) in the United States for these purposes has been widely publicized, and its availability to the general public advertized in newspapers and magazines. Since labeling of such material failed to indicate adequate directions for use, and since scientific evidence establishing any specific biological activity was not available, and because new drug applications had not been filed, both the Federal Food and Drug Administration and the U. S. Post Office Department have prevented further distribution of pega palo through interstate commerce (1).

Objective evidence concerning the alleged aphrodisiac and/or androgenic effect of *R. pyramidalis* is restricted to two reports. In 1960, Danowski and Price (4) determined that the inclusion of 5% *R. pyramidalis* in the diet of normal and hypophysectomized rats for 26 and 56 days, respectively, resulted in observations of no appreciable effect on the testes, prostate, or seminal vesicles of treated animals. On the other hand, Sobá *et al.* (3) reported that in a controlled clinical study, which involved 50 cases of sexual impotence, an androgenic effect was observed in 82% of the patients receiving a pega palo tincture.

Folkers and Unna (6) have reported that in old seeds of *R. pyramidalis*, traces of alkaloids could be detected. Furthermore, they indicated that extracts from these seeds possessed some curare-like activity. More recently, Ristić and Thomas (7) have isolated an alkaloid (picrate, m.p. 132°), which by thin-layer chromatography was shown to be different from yohimbine. Santesson (8) examined the closely related *Rhynchosia phaseoloides* and found it to contain alkaloids and glucosides, but further indicated that it was devoid of curare-like activity in the frog. No other reports in the literature have been found concerning the phytoconstituents of *Rhynchosia* species.

The controversy in the literature regarding the biological activity of *R. pyramidalis*, together with a desire to explore the value of this plant as a source of new medicinal agents, prompted the evaluation of extracts of the vine of *R. pyramidalis* through a variety of biological screening tests.

EXPERIMENTAL

Materials—The plant material used in this investigation was the vine of *R. pyramidalis* (Lam.) Urb. (*Leguminosae*), collected in Haiti during September of 1961 and supplied by S. B. Penick & Co., New York, N. Y. A voucher specimen has been deposited there.

Preparation of Extracts for Biological Testing—A defatted ethanol extract was utilized for the antimicrobial test, the antitumor test, and for the mouse behavior evaluation. The method for preparing this extract has been previously described (5).

According to Sobá *et al.* (3), the native custom in Haiti for preparing pega palo tincture is to steep the dried vine in rum for several days. In the clinical studies conducted by this group, a 15% "hydro-alcoholic" extract of the vine was used (5).[1] Extracts utilized in the present investigation

Received March 23, 1967, from the Department of Pharmacognosy and the †Department of Psychology, University of Pittsburgh, Pittsburgh, PA 15213

Accepted for publication May 19, 1967.

* Present address: Department of Anatomy, School of Medicine, Louisiana State University, New Orleans, LA 70112

This investigation was supported in part by grants MH-1951 and NB-04400 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md., and from the Riker Laboratories, Northridge, Calif.

[1] Identified as Tintura Pega Palo Fortidum, Laboratorio Quimico Dominicano, Ciudad Trujillo, D.N., Dominican Republic.

for the androgenic activity assays, and for the sexual behavior studies were prepared in the following manner.

In a typical extraction, 125 Gm. of coarsely powdered vine was moistened with 50% (w/v) ethanol and allowed to stand for 1 hr. The moistened drug was then packed into a suitable cylindrical glass percolator, sufficient 50% ethanol was added to cover the drug, and the mixture was allowed to macerate for 24 hr. Percolation was then initiated at a moderate rate until 1000 ml. of percolate was collected. The tincture prepared in this manner was then reduced to a volume of 250 ml. using a flash evaporator (*in vacuo*, 40°), thus removing any ethanol that might alter the biological activity of active constituents in the vine when evaluated in animals. A cloudy aqueous suspension resulted, which was of high viscosity and required no suspending agent. This extract, which contained the extractives of 0.5 Gm. of vine in each 1.0 ml., was labeled extract *A*, and was used in all evaluations requiring an oral route of administration. In experiments involving intraperitoneal administration of the extract, a less concentrated aqueous suspension was prepared by dilution with water so that each 1.0 ml. was equivalent to the extractives from 0.13 Gm. of vine (extract *B*).

General Biological Evaluation—Using methods previously described for screening native plants (5), a defatted ethanol extract of *R. pyramidalis* vine was evaluated for activity against 16 bacterial animal pathogens and saprophytes, three fungal animal pathogens and saprophytes, four bacterial plant pathogens, 15 fungal plant pathogens and material degrading organisms, and three protozoa. Using the agar diffusion technique, the extract was found to be inhibitory for *Mycobacterium avium* and *Lactobacillus casei* at the 100 mcg./ml. level. No activity was demonstrated against any of the other test organisms.

Similarly, the extract was devoid of activity against the C-1498 leukemia, P-1534 leukemia, adenocarcinoma 755, mecca lymphosarcoma, and the X-5563 myeloma, all in mice (5). In the general mouse behavior evaluation (5), the defatted ethanol extract was classified as having weak central nervous system depressant properties.

Assay for Androgenic Activity—Extract *B* (0.13 Gm./ml.) was administered i.p. daily to each of six albino Wistar male rats, previously castrated in the usual manner. Injections were initiated 24 hr. following the surgical procedure, and continued for nine successive days at a dose of 5.0 ml./Kg. (0.65 Gm./Kg.). No unusual effects were noted in the treated animals during this period of time. A second group of six rats were similarly castrated and received daily i.p. injections (5.0 ml./Kg.) of normal saline solution. Twenty-four hours following the final injection, all animals were sacrificed, the seminal vesicles and prostate gland removed from each animal, blotted between paper to remove seminal fluid and excess moisture, and carefully weighed.

The androgenic activity of extracts can be ascertained by noting the lack of any significant increment in relative weights of the prostate and seminal vesicles over saline-treated controls. The results are presented in Table I.

Following autopsy of the animals, it was observed that the peritoneum of each extract-treated rat was colored dark brown. The absence of androgenic activity, together with this observation, presented the possibility of hindered absorption of active principles in the extract due to the presence of tannins. In addition, Sobá *et al.* (3) have reported that administration of pega palo tincture to humans over extended periods of time usually gave more satisfactory results. This seemed to apply in this study as an additional explanation for the negative results, since nine doses could have been inadequate. The authors therefore modified the initial androgenic assay by: (*a*) utilizing a more concentrated extract (extract *A*), (*b*) administering the extract at three different dosage levels (5.0 ml./Kg., 10.0 ml./Kg., and 20.0 ml./Kg.), (*c*) giving the extract orally by means of a suitable stomach tube, and (*d*) continuing the extract administration for a longer period of time (single daily doses for 79 successive days).

TABLE I—EFFECT OF *R. pyramidalis* EXTRACT *B* ON THE WEIGHT OF CASTRATE RAT SEMINAL VESICLES AND PROSTATE GLAND

Animal	Dose,[a] ml./Kg.	Type Extract	Prostate Wt., mg./ 100 Gm. Body Wt.	Seminal Vesicles Wt., mg./ 100 Gm. Body Wt.	Body Wt. at Autopsy
1	5.0	*B*[b]	35	32	177
2	5.0	*B*	22	33	160
3	5.0	*B*	37	37	200

			—	—	—
			$\bar{x}$ 33	36	175

[a] Nine successive daily i.p. injections were made. [b] Extract *B* contained the extractives from 0.13 Gm. of vine in each 1.0 ml.

The results of this study, utilizing extract *A* (0.5 Gm./ml.) are presented in Table II and substantiate the negative findings of the initial study. It was further observed that no unusual gross effects were seen in the drug-treated animals during the 79 days of the study.

Representative tissue specimens from the prostate, seminal vesicles, penis, bladder, kidney, and liver were removed from several drug-treated and control rats at autopsy and these were examined for evidence of pathological or abnormal effects. No evidence of abnormal tissue was observed in the specimens examined.

Effect of Extract A on the Sexual Behavior of Normal Rats—Twenty hooded male rats, 120–150 days of age, were randomly assigned to experimental and control groups. Following a series of five 1 hr.–once weekly copulation tests with receptive females, the drug phase of the study was initiated. Experimental rats received extract *A* daily by stomach tube (4.4 ml./Kg., equivalent to 2.2 Gm./Kg.), while controls were given an equivalent volume of water by stomach tube. Weekly, hour-long copulation tests with receptive females were continued for 20 weeks, with the 10th and 15th test following initiation of drug administration being

[a] Seventy-nine successive single oral daily doses. [b] Extract *A* contained the equivalent of 0.5 Gm. of extractives in each 1.0 ml.

satiation tests. Satiation tests have no specific time limit, but continue until the male spends 30 min. without making a sexual response. During the time course of the experiment, males were kept in isolation except during the actual sexual tests.

Measures taken during sexual behavior tests included latency to first mount, number of incomplete mounts (no intromission), number of complete mounts (intromissions), number of ejaculations, length of refractory periods (time from ejaculation to the next sexual response), and amount of time spent in actual sexual behavior. For all of the measures taken, *t* tests were run between experimental and control groups with separate tests run for the pre-drug tests and the total post-drug tests. Also, in case the results of drug administration were cumulative, or gradual in onset, post-drug tests were split into first 10 test and last 10 test categories. These data were then compared within and between control and experimental groups.

No significant ratios were found for any of the above measures or comparisons. It is therefore concluded that the administration of *R. pyramidalis* extract *A* to male rats under these conditions, and at the dosage level indicated, has no significant effect on any of the sexual parameters measured.

Phytochemical Screening—Using the methods of Wall *et al.* (9–11), *R. pyramidalis* vine was found to contain trace amounts of alkaloids, tannins of the catechin type, saponins, and organic acids and phenols. Flavonoids could not be detected using these methods.

Examination of R. pyramidalis Alkaloids—Using the U.S.P. assay for belladonna alkaloids, *R. pyramidalis* vine was found to contain 0.19% of total crude alkaloids (as strychnine) (12).

A thin-layer chromatogram of the total crude alkaloids from *R. pyramidalis* vine was prepared as follows. One hundred grams of powdered vine was moistened with 28% NH_4OH, air-dried, and continuously extracted with chloroform. The chloroform extract was concentrated to 10.0 ml. Twenty microliters was applied to a Silica Gel G plate (0.25 mm.), prepared in the usual manner, and eluted with methanol. After air-drying the plate, it was sprayed with Dragendorff's reagent. Three typical orange-colored alkaloid spots were noted at R_f 0.08, 0.22, and 0.35.

DISCUSSION

The results of this study clearly indicate that the *R. pyramidalis* extracts utilized were devoid of androgenic activity as evidenced by an absence of accessory organ stimulation in castrate rats. These findings are in agreement with those of Danowski and Price (4), who also used rats as assay animals. However, both our results and those of Danowski and Price are contradictory to those reported by Sobá *et al.* (3), who evaluated pega palo tincture in 50 clinical cases of sexual impotence with partial or complete loss of libido and erections. On the other hand, the paper by Sobá *et al.* (3) is entitled "Androgenic Action of Pega Palo," but the biological activity described in this paper alluded to a restoration of libido and erections. These workers performed no assays to indicate that their extracts contained truly androgenic materials. Furthermore, although the authors mention that, "For comparison, in many cases, a placebo was substituted for the Pega Palo," (3), no details are given concerning the type of placebo used, or the results obtained with the placebo preparation. In addition, it was reported that 50 cases of sexual impotence with partial or complete loss of libido and erections were included in the study, and their conclusions indicated that 41 patients were restored to normal activity during the period of medication, whereas nine (making a total of 50) showed no increase in libido or erectile power. If these 50 patients constituted the entire group studied, and no statements to the contrary were made, it is difficult to ascertain how a placebo preparation was used for comparison.

When plant material is being evaluated for biological activity, it is often difficult to make valid comparisons between the results obtained in any two different laboratories, even under ideal conditions. One must consider not only variations in the test methods but also variability in the chemical constituents of investigational plant material due to ecological factors, the age of the plant at harvest, methods of processing the collected specimens, and the possibility of working with chemical races of the same species. Further complicating factors, which appear to apply in the present situation, are the possibility of improper identification of the material being investigated, as well as the problem of selecting the correct plant material when reference is made only to the vernacular name.[2]

Danowski and Price (4) in their studies utilized a sample of plant material identified only as "Pega Palo." An authentic voucher specimen of their

[2] Sobá *et al.* (3) have pointed out that two unrelated low shrubs are also sometimes referred to by the vernacular names "pega pallo" and "pega palo," but these resemble *R. pyramidalis* neither in appearance nor herbal properties.

material was not made (13). Thus the distinct possibility exists that their plant material was not, in reality, *R. pyramidalis*. Along similar lines, no mention was made in the paper of Sobá *et al.* (3) that they deposited a voucher specimen representative of their investigational material for reference purposes.

With regard to chemical variability, the authenticated material gave definite positive tests for alkaloids (*vide supra*), which has been duplicated and confirmed by the studies of Ristić and Thomas (7). The material studied by Sobá *et al.* (3) was devoid of alkaloids, although their test methods were not defined.

SUMMARY

The vine of *R. pyramidalis* (Lam.) Urb. (*Leguminosae*), popularly known as pega palo and used in folkloric medicine as an aphrodisiac, has been the subject of the present investigation. Extracts from this plant were found to be devoid of androgenic activity and did not significantly alter the sexual behavior of normal rats when the following measures were taken: latency to first mount, number of incomplete mounts (no intromission), number of complete mounts (intromission), number of ejaculations, length of refractory periods (time from ejaculation to the next sexual response), and amount of time spent in actual sexual behavior.

In a general biological screening of a defatted ethanol extract of *R. pyramidalis* vine, inhibitory activity was observed against *Mycobacterium avium* and *L. casei* (*in vitro*). The extract was devoid of antitumor activity, and in gross observation studies using mice, central nervous system depression was observed.

The vine was found to contain three alkaloids by means of thin-layer chromatography, comprising 0.19% of total crude bases. Tannins, saponins, and organic acids and phenols were also found to be present, but tests for the presence of flavonoids were negative.

Trifluoromethyl Analogs of Amphetamine and Norephedrine

By ROGER M. PINDER and ALFRED BURGER

Trifluoromethyl analogs of amphetamine (I) and norephedrine (II) were synthesized for pharmacological evaluation. They showed no activity in profile tests for anorectic activity (I), antiemetic activity (I), CNS activity (I), MAO-inhibitory activity (I, II), and pressor activity (II).

THE SYNTHESIS and pharmacological investigation of organic fluorine compounds has led to the development of such important drugs as the fluorinated inhalation anesthetics (1), the fluorinated corticosteroids (2), the trifluoromethylphenothiazine tranquilizers and the trifluoromethylthiazide diuretics (1, 2). A number of compounds containing the trifluoromethyl group have been found to possess anesthetic, ataractic, and antiemetic (1), diuretic (1, 3), antihistaminic (4), tumor inhibitory (5, 6), and antimicrobial (7, 8), hypotensive (9), and spasmolytic (10) properties.

The trifluoromethyl group is particularly suited to replace the methyl group in known pharmacologically active compounds, both because of the similarity in physical properties of the two classes of compounds and because of the unique chemical and physiological stability of the trifluoromethyl group. The pronounced electron-withdrawing properties of the group will also be expected to play a part in modifying the activity of the prototype compounds.

The authors have now carried out a synthesis of 2-amino-3-phenyl-1,1,1-trifluoropropane (I),

Received February 27, 1967, from the Department of Chemistry, University of Virginia, Charlottesville, VA 22901
Accepted for publication May 5, 1967.
Presented in part to a Medicinal Chemistry Meeting in Miniature, School of Pharmacy, University of North Carolina, Chapel Hill, February 1967.
This investigation was supported by a research grant from Smith Kline & French Laboratories, Philadelphia, Pa., to whom the authors express their appreciation.

material was not made (13). Thus the distinct possibility exists that their plant material was not, in reality, *R. pyramidalis*. Along similar lines, no mention was made in the paper of Sobá *et al.* (3) that they deposited a voucher specimen representative of their investigational material for reference purposes.

With regard to chemical variability, the authenticated material gave definite positive tests for alkaloids (*vide supra*), which has been duplicated and confirmed by the studies of Ristić and Thomas (7). The material studied by Sobá *et al.* (3) was devoid of alkaloids, although their test methods were not defined.

SUMMARY

The vine of *R. pyramidalis* (Lam.) Urb. (*Leguminosae*), popularly known as pega palo and used in folkloric medicine as an aphrodisiac, has been the subject of the present investigation. Extracts from this plant were found to be devoid of androgenic activity and did not significantly alter the sexual behavior of normal rats when the following measures were taken: latency to first mount, number of incomplete mounts (no intromission), number of complete mounts (intromission), number of ejaculations, length of refractory periods (time from ejaculation to the next sexual response), and amount of time spent in actual sexual behavior.

In a general biological screening of a defatted ethanol extract of *R. pyramidalis* vine, inhibitory activity was observed against *Mycobacterium avium* and *L. casei* (*in vitro*). The extract was devoid of antitumor activity, and in gross observation studies using mice, central nervous system depression was observed.

The vine was found to contain three alkaloids by means of thin-layer chromatography, comprising 0.19% of total crude bases. Tannins, saponins, and organic acids and phenols were also found to be present, but tests for the presence of flavonoids were negative.

Trifluoromethyl Analogs of Amphetamine and Norephedrine

By ROGER M. PINDER and ALFRED BURGER

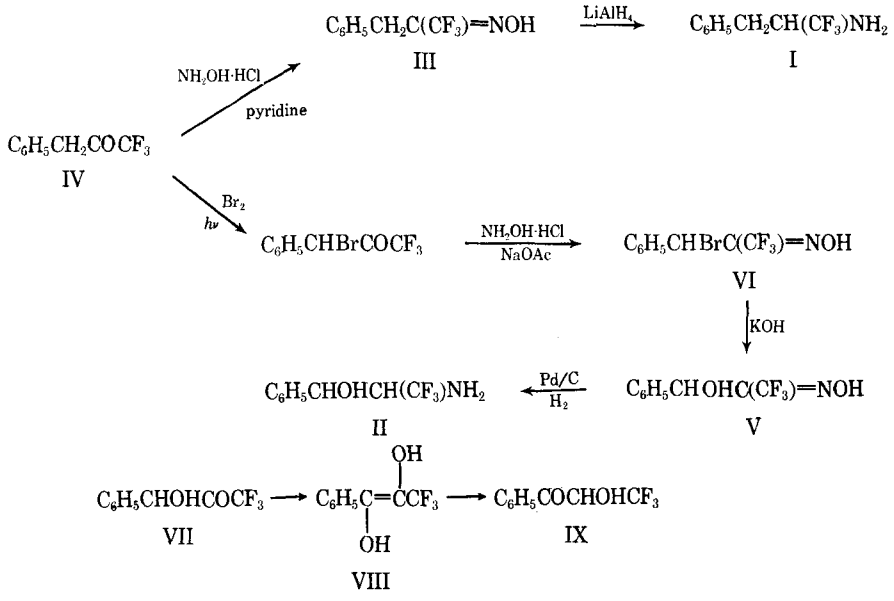
Trifluoromethyl analogs of amphetamine (I) and norephedrine (II) were synthesized for pharmacological evaluation. They showed no activity in profile tests for anorectic activity (I), antiemetic activity (I), CNS activity (I), MAO-inhibitory activity (I, II), and pressor activity (II).

THE SYNTHESIS and pharmacological investigation of organic fluorine compounds has led to the development of such important drugs as the fluorinated inhalation anesthetics (1), the fluorinated corticosteroids (2), the trifluoromethylphenothiazine tranquilizers and the trifluoromethylthiazide diuretics (1, 2). A number of compounds containing the trifluoromethyl group have been found to possess anesthetic, ataractic, and antiemetic (1), diuretic (1, 3), antihistaminic (4), tumor inhibitory (5, 6), and antimicrobial (7, 8), hypotensive (9), and spasmolytic (10) properties.

The trifluoromethyl group is particularly suited to replace the methyl group in known pharmacologically active compounds, both because of the similarity in physical properties of the two classes of compounds and because of the unique chemical and physiological stability of the trifluoromethyl group. The pronounced electron-withdrawing properties of the group will also be expected to play a part in modifying the activity of the prototype compounds.

The authors have now carried out a synthesis of 2-amino-3-phenyl-1,1,1-trifluoropropane (I),

Received February 27, 1967, from the Department of Chemistry, University of Virginia, Charlottesville, VA 22901
Accepted for publication May 5, 1967.
Presented in part to a Medicinal Chemistry Meeting in Miniature, School of Pharmacy, University of North Carolina, Chapel Hill, February 1967.
This investigation was supported by a research grant from Smith Kline & French Laboratories, Philadelphia, Pa., to whom the authors express their appreciation.

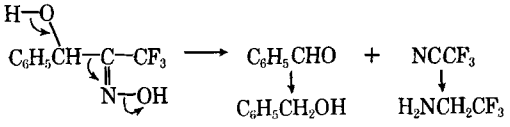


Scheme I

the trifluoromethyl analog of amphetamine (11), by a new sequence in order to make available material for additional pharmacological investigation. Also, the synthesis of the trifluoromethyl analog of norephedrine, *i.e.*, 2-amino-3-hydroxy-3-phenyl-1,1,1-trifluoropropane (II) has been performed.

Compound I was synthesized by reduction of the oxime III with $LiAlH_4$ rather than the previously used method (11) of reductive alkylation of ammonia by the ketone IV. Compound I was also obtained from 2-amino-3-(4-chlorophenyl)-1,1,1-trifluoropropane by dehalogenation (12). The norephedrine analog (II) was obtained by reduction of the oxime of the α-hydroxy ketone (V). The parent ketone, phenyl trifluoroacetyl carbinol (VII), is unstable and undergoes spontaneous enolization to the enediol (VIII), which may further ketonize to the stable benzoyl trifluoromethyl carbinol (IX) (11). The oxime (V) was therefore prepared from the oxime of the bromoketone (VI), by hydrolysis of the bromine atom with ethanolic KOH. Reduction to the amine (II) was effected by catalytic hydrogenation. (Scheme I.)

Reduction with $LiAlH_4$ gave a complex mixture of products, with several runs having varying compositions. Compound II was obtained in a maximum yield of 18%, the other major products being benzylamine, benzyl alcohol, and trifluoroethylamine. Rearrangement and fragmentation of oximes under the conditions of the $LiAlH_4$ reduction are well known (13), and α-hydroxyoximes are particularly susceptible in this respect (14, 15). Benzylamine presumably arises



Scheme II

by a rearrangement of the oxime to an α-hydroxyamide (16), $C_6H_5CHOHNHCOCF_3$, with subsequent reduction and elimination of the trifluoroacetyl group (17). The formation of benzyl alcohol and trifluoroethylamine is somewhat easier to rationalize; a concurrent electron transfer (15) will give benzaldehyde and trifluoroacetonitrile, which will be further reduced to benzyl alcohol and trifluoroethylamine, respectively. (Scheme II.)

The amphetamine analog (I), in standard tests (18),[1] showed no anorectic activity at 25 mg./Kg. (p.o.) in the rat and 10 mg./Kg. in the dog, no antiemetic activity in the dog at 25 mg./Kg., no conditioned escape response blocking action in the rat at 50 and 200 mg./Kg., no tryptamine potentiation in the rat at 100 mg./Kg., and no depletion of catecholamines in the brain and heart of the rat at 100 mg./Kg. (i.p.). The *p*-chloroamphetamine analog showed no anorectic activity in the rat at 29 mg./Kg. (p.o.) and did not deplete heart or brain catecholamines in the rat at 100 mg./Kg. (i.p.). The norephedrine analog (II) showed only 1/300th of the pressor activity of norephedrine itself in the pentobarbitalized rat, and did not deplete brain or heart catecholamines in the rat at 100 mg./Kg. (i.p.).

[1] The authors thank Smith Kline & French Laboratories for the pharmacological data.

EXPERIMENTAL

Benzyl trifluoromethyl ketone, *p*-chlorobenzyl trifluoromethyl ketone, and 3-bromo-3-phenyl-1,1,1-trifluoropropanone were prepared according to Nes and Burger (11).

α-p-Chlorophenyltrifluoroacetylacetonitrile had m.p. 79.5–80.5° (benzene).

Anal.—Calcd. for $C_{10}H_5ClF_3NO$: C, 48.50; H, 2.04; N, 5.66. Found: C, 48.42; H, 2.14; N, 5.70.

p-Chlorobenzyl trifluoromethyl ketone had b.p. 65–66° (0.2 mm.).

Anal.—Calcd. for $C_9H_6ClF_3O$: C, 48.55; H, 2.72. Found: C, 48.66; H, 3.09.

The 2,4-dinitrophenylhydrazone, prepared by mixing ethanolic solutions of the ketone and 2,4-dinitrophenylhydrazine with shaking was recrystallized as needles from ethanol, m.p. 111–112°.

Anal.—Calcd. for $C_{15}H_{10}ClF_3N_4O_4$: C, 44.73; H, 2.50; N, 13.91. Found: C, 45.16; H, 2.50; N, 13.90.

The semicarbazone, prepared by refluxing the ketone, sodium acetate, and semicarbazide hydrochloride in ethanol, was recrystallized as plates from dilute ethanol, m.p. 135–136°.

Anal.—Calcd. for $C_{10}H_9ClF_3N_3O$: C, 42.94; H, 3.24; N, 15.03. Found: C, 42.92; H, 3.19; N, 15.28.

The oxime, prepared by refluxing the ketone and $NH_2OH \cdot HCl$ in ethanol and pyridine (1:1), was recrystallized as needles from petroleum ether (b.p. 30–60°), m.p. 60.5–61.5°.

Anal.—Calcd. for $C_9H_7ClF_3NO$: C, 45.57; H, 2.98; N, 5.90. Found: C, 45.56; H, 3.18; N, 5.84.

2-Amino-3-(4-chlorophenyl)-1,1,1-trifluoropropane—To a stirred suspension of $LiAlH_4$ (5.7 Gm., 0.15 mole) in dry ether (100 ml.) was added dropwise a solution of *p*-chlorobenzyl trifluoromethyl ketoxime (23.5 Gm., 0.1 mole) in dry ether (100 ml.). The mixture was heated under reflux for 5 hr., and excess $LiAlH_4$ was destroyed by careful addition of water. Then 10% NaOH (100 ml.) was added, the solid material was filtered off, and the clear yellow filtrate dried ($MgSO_4$). Removal of ether gave a semisolid. The colorless hydrochloride was prepared in ether–petroleum ether, and was purified by sublimation at 150° (1 mm.), m.p. 209–211°, yield 19.0 Gm. (86%).

Anal.—Calcd. for $C_9H_9ClF_3N \cdot HCl$: C, 41.56; H, 3.87; N, 5.39. Found: C, 41.32; H, 3.97; N, 5.42.

The *N*-acetyl derivative, obtained by the Schotten-Baumann method using acetic anhydride, crystallized from dilute ethanol as needles, m.p. 171–172°.

Anal.—Calcd. for $C_{11}H_{11}ClF_3NO$: C, 49.74; H, 4.18; N, 5.27. Found: C, 49.84; H, 4.05; N, 5.41.

2-Amino-3-phenyl-1,1,1-trifluoropropane (11) was prepared in 65% yield from the oxime (III) by a similar method, m.p. of hydrochloride 204–205°. [Lit. (11) m.p. 203–206°.] It was also prepared by the following method.

A mixture of 2-amino-3-(4-chlorophenyl)-1,1,1-trifluoropropane (10 Gm.), methanol (120 ml.), 5% Pd/C (4 Gm.), and KOH (10 Gm.) was shaken at room temperature and 2.8 Kg./cm.^{2} for 5 hr. The catalyst was filtered off and methanol removed under reduced pressure. The residue was taken up in ether, washed with water, and dried ($MgSO_4$). The hydrochloride was identical with that prepared above. Yield, 6.2 Gm. (72%).

3-Bromo-3-phenyl-1,1,1-trifluoropropanone Oxime (VI)—To a solution of hydroxylamine hydrochloride to (40 Gm.) and sodium acetate (40 Gm.) in water (300 ml.) was added all at once 3-bromo-3-phenyl-1,1,1-trifluoropropanone (20 Gm.), and the mixture was shaken vigorously for 10 min. Precipitation of the oxime began immediately and was complete after 30 min. Recrystallization from chloroform gave needles, m.p. 100–102°. Yield, 19 Gm. (85%). $\nu_{max.}^{KBr}$ 3305 (OH), 1695 (C=N, weak) cm.$^{-1}$.

Anal.—Calcd. for $C_9H_7BrF_3NO \cdot H_2O$: C, 36.02; H, 3.09; N, 4.67. Found: C, 36.15; H, 3.02; N, 4.51.

3-Hydroxy-3-phenyl-1,1,1-trifluoropropanone Oxime (V)—To a solution of VI (30 Gm., 0.1 mole) in ethanol (100 ml.) was added dropwise, with stirring and cooling, ethanolic KOH (5.6 Gm. of KOH, 0.1 mole), and the mixture was stirred at room temperature for 2 hr. The precipitated KBr was filtered off and washed thoroughly with ethanol. Most of the ethanol was removed by evaporation under reduced pressure, and water (50 ml.) was added to precipitate the oxime as an oil, which was extracted with ether (2 × 150 ml.) and dried ($MgSO_4$). The ether was removed to yield a yellow oil, which was crystallized from benzene–petroleum ether (b.p. 30–60°), m.p. 90–91.5°, yield, 20 Gm. (90%). $\nu_{max.}^{KBr}$ 3505 (OH), 3250 (OH), 1660 (C=N, weak) cm.$^{-1}$.

Anal.—Calcd. for $C_9H_8F_3NO_2$: C, 49.33; H, 3.68; N, 6.39. Found: C, 49.18; H, 3.70; N, 6.47.

2-Amino-3-hydroxy-3-phenyl-1,1,1-trifluoropropane (II)—A mixture of the oxime (V) (8.8 Gm., 0.04 mole) and 5% Pd/C (4.4 Gm.) in glacial acetic acid (100 ml.) and concentrated H_2SO_4 (8.8 Gm., 0.09 mole) was shaken at room temperature under 2.8 Kg./cm.^{2} of hydrogen. Hydrogen absorption began at once and the theoretical uptake was complete within 2 hr. After the catalyst had been removed by filtration, the clear, colorless filtrate was treated with a solution of NaOH (3.6 Gm., 0.09 mole) in water (15 ml.), with cooling, and the precipitated sodium sulfate was removed by filtration. Acetic acid was removed under reduced pressure, and the residue was made basic with 50% aqueous KOH (cooling). The mixture was extracted with ether (3 × 50 ml.) and dried ($MgSO_4$). Dry HCl was passed into the ethereal solution, and the collected solid was recrystallized from ethanol–petroleum ether (b.p. 30–60°), m.p. 212–214°. Yield, 6.2 Gm. (65%). $\nu_{max.}^{KBr}$ 3445 (OH), 2880 (NH_3^+) cm.$^{-1}$.

Anal.—Calcd. for $C_9H_{10}F_3NO \cdot HCl$: C, 44.74; H, 4.59; N, 5.80. Found: C, 44.49; H, 4.81; N, 5.76.

Hydrogenation in AcOH–anhydrous HCl could not be achieved, a situation also observed in the reduction of 2-indanone oxime (19).

The *N*-acetyl derivative, prepared by boiling the amine with acetic anhydride for 30 min. and then pouring into cold water, was recrystallized from dilute ethanol as needles, m.p. 128.5–130°.

Anal.—Calcd. for $C_{11}H_{12}F_3NO_2$: C, 53.65; H,

4.50; N, 5.69. Found: C, 53.48; H, 4.62; N, 5.80.

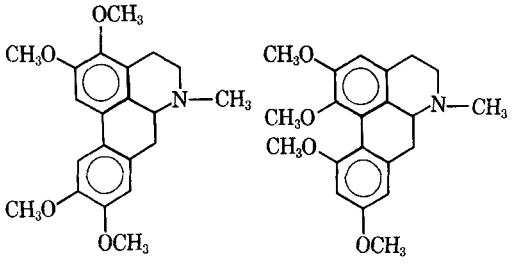
Structure of Argemonine

Identification as (−)-*N*-Methylpavine

By MICHAEL J. MARTELL, JR.*, TAITO O. SOINE, and LEMONT B. KIER†

The structure of argemonine has been shown to be (−)-*N*-methylpavine both by chemical evidence and spectral evidence. Racemic *N*-methylpavine has been deracemized as the bitartrates and the base obtained from the D-bitartrate has been shown to be identical with argemonine. The question of whether argemonine is an artifact obtained by cyclization of *N*-methyl-1,2-dihydropapaverine during isolation procedures has been examined, and there appears to be no basis for such conversion.

EARLIER WORK in these laboratories (1, 2) had led to a tentative aporphine-type structural assignment (I) for the alkaloid, argemonine (3). The proposed structure admittedly was biogenetically unfeasible, and Shamma (4), basing his reasoning on the lower than expected intensity of the ultraviolet absorption maxima, suggested alternate formulations (II and III) imposing a 1:11 methoxyl interaction to accentuate the known twist of the biphenyl moiety in aporphines. The resultant reduction in coplanarity would, of necessity, reduce absorption.



I

Structure of Argemonine

Identification as (−)-*N*-Methylpavine

By MICHAEL J. MARTELL, JR.*, TAITO O. SOINE, and LEMONT B. KIER†

The structure of argemonine has been shown to be (−)-*N*-methylpavine both by chemical evidence and spectral evidence. Racemic *N*-methylpavine has been deracemized as the bitartrates and the base obtained from the D-bitartrate has been shown to be identical with argemonine. The question of whether argemonine is an artifact obtained by cyclization of *N*-methyl-1,2-dihydropapaverine during isolation procedures has been examined, and there appears to be no basis for such conversion.

EARLIER WORK in these laboratories (1, 2) had led to a tentative aporphine-type structural assignment (I) for the alkaloid, argemonine (3). The proposed structure admittedly was biogenetically unfeasible, and Shamma (4), basing his reasoning on the lower than expected intensity of the ultraviolet absorption maxima, suggested alternate formulations (II and III) imposing a 1:11 methoxyl interaction to accentuate the known twist of the biphenyl moiety in aporphines. The resultant reduction in coplanarity would, of necessity, reduce absorption.

IV

To examine the structural problem further and, initially, to determine the validity of structures I, II, or III, an oxidation of norargemonine ethyl

Received March 8, 1967, from the Department of Medicinal Chemistry, College of Pharmacy, University of Minnesota, Minneapolis, MN 55455
Accepted for publication May 4, 1967.
Presented to the Scientific Section, A.PH.A., Miami Beach meeting, May 1963.
A previous communication presenting a portion of this work has appeared in *J. Am. Chem. Soc.*, **85**, 1022(1963). [See also Stermitz, F. R., Lwo, S.-Y., and Kallos, G., *ibid.*, **85**, 1551(1963).]
The authors are grateful to Dr. V. J. Bauer (Lederle Laboratories) for helpful discussions, Mr. W. Fulmor and staff (Lederle Laboratories) for the many absorption spectra, Mr. A. Struck and staff (Central Research Division, American Cyanamid Co., Stamford, Conn.) for the mass spectra, and Dr. J. H. Boothe (Lederle Laboratories) for encouragement. Microanalyses were performed by the Microanalytical Laboratory, School of Chemistry, University of Minnesota, Minneapolis.

ether seemed indicated [as discussed in an earlier communication from these laboratories (3)]. *O*-Ethylnorargemonine, obtained by diazoethylation, was oxidized under mild conditions with manganese dioxide in diluted sulfuric acid, a procedure that previously had yielded 4,5-dimethoxy-*N*-methylphthalimide and 4,5-dimethoxyphthalic acid from argemonine (2). The oxidation yielded four products—namely, 4,5-dimethoxyphthalic acid and its *N*-methylimide as well as 4-ethoxy-5-methoxyphthalic acid and its *N*-methylimide. On this basis, structures I, II, and III were all shown to be untenable (3). Reassurance, however, of the $C_{20}H_{23}NO_4$ molecular formula of norargemonine was obtained by mass spectral analysis, and the molecular formula of argemonine, $C_{21}H_{25}NO_4$, was confirmed as well. The mass spectrum of argemonine showed a large peak at *m/e* 204, corresponding to a *N*-methyl-6,7-dimethoxyisoquinolinium cation (5). For a more extensive treatment of the mass spectra of the pavine type alkaloids, see *Reference 5*.

At this point, nuclear magnetic resonance (NMR) studies were initiated which, aside from showing a far more symmetrical absorption pattern than expected, indicated the presence of *two pairs* of identical aromatic protons, rather than the *three* nonidentical protons expected in an aporphine formulation. This rendered untenable any aporphine formulation and a review of all previously known naturally-occurring alkaloidal types based on the isoquinoline moiety indicated that none of them could be entertained as structural candidates. The high degree of symmetry of the NMR spectrum suggested a symmetrical molecule, and yet the optical activity suggested asymmetry. Both of these requirements could be sustained in the *N*-methylpavine (IV, R = CH_3) structure, since, in spite of the obvious symmetry of the molecule, the asymmetric bridgehead carbons would have the same relative configuration and thus contribute optical activity. The NMR spectrum was explicable in light of the structure of IV (R = CH_3) and is, in part, an ABX system (6) in which protons H_a couple only with H_b[1] and appear as a doublet centering at 5.92 τ (J_{ab} = 6 c.p.s.).

Protons H_c couple only with protons H_b and are a doublet centering at 7.38 τ (J_{bc} = 17 c.p.s.). Protons H_b are split by H_a and H_c and are a pair of doublets centering at 6.47 and 6.58 τ. The aromatic protons are singlets of intensity two each at 3.24 and 3.41 τ and the methoxyl groups are singlets at 6.08 and 6.16 τ. The *N*-methyl group is a singlet at 7.43 τ. Comparison of the spectrum with that of (±)-pavine[2] (IV, R = H) indicated a remarkable similarity, except that the bridgehead protons are shifted downfield to a doublet centering at 5.55 τ and protons H_c occur as a doublet shifted downfield to 7.25 τ. The *N*-methyl group is absent, of course, and the NH appears as a singlet at 7.87 τ.

In order to permit direct comparison with authentic *N*-methylpavine it was synthesized by the usual procedure (7) from *N*-methyl-1,2-dihydropapaverine to provide the racemic base. The NMR spectrum of the synthetic base was superimposable on that of argemonine, indicating structural identity. The racemic base was then deracemized by conversion to the bitartrate salts of (+)-L- and (−)-D-tartaric acid. The levorotatory form, obtained from the (−)-D-bitartrate salt, was identical to natural argemonine in every respect.

The possibility that argemonine, isolated from plant material, was an artifact arising from the cyclization of *N*-methyl-1,2-dihydropapaverine due to acid treatment during isolation was considered. It seemed unlikely in view of the work of Knabe *et al.* (8), who showed that dilute acid treatment of this compound results in migration of the 1-homoveratryl group to the 3-position, rather than ring closure. Furthermore, Schermerhorn and Soine (1) had isolated argemonine earlier in a procedure scrupulously avoiding mineral acids. However, to eliminate any doubt on this point, a sample of *N*-methyl-1,2-dihydropapaverine was dissolved in 10% tartaric acid and the ultraviolet spectra of samples withdrawn at various times over a period of 72 hr. were observed. No conversion to *N* methylpavine was noted.

Argemonine, therefore, is the naturally-occurring form of *N*-methylpavine, and this is the first instance of this tetracyclic system being observed in a plant alkaloid. Further examples of the pavine types of alkaloids have been recently described in the literature (5, 9).

In addition, the absolute configuration of argemonine has been determined (10).

[1] This phenomenon has been investigated by Anet, F. A. L. [*Can. J. Chem.*, 39, 789(1961), and references contained therein] as applied to the bicyclo[2.2.1]heptane system. Thus, 2-exo,3-exo-camphane-2,3-diol (*i*) exhibits a bridgehead coupling constant of zero ($J_{3,4}$ = 0) with the adjacent proton, as predicted by the Karplus equation [Karplus, M., *J. Chem. Phys.*, 30, 11(1959)] where the dihedral angle is 79°.

EXPERIMENTAL

Oxidation of O-Ethylnorargemonine—Norargemonine (1 Gm., 0.003 mole) was dissolved in a mixture of 200 ml. of dichloromethane and 50 ml. of absolute methanol. The solution was cooled in an ice bath to 5° and to it was added an excess of diazoethane[3] (1.68 Gm., 0.03 mole) in ether. The mixture was then allowed to come to room temperature gradually over a period of several hours, after which the solvent was stripped off on a steam bath. The residue was dissolved in 100 ml. of 2% (w/v) hydrochloric acid and then alkalinized with enough 10% (w/v) sodium hydroxide solution to make the final solution about 4% (w/v) in sodium hydroxide. The alkaline solution was extracted with several 50-ml. portions of ether until the extracts were negative to Valser's reagent. The combined ethereal extracts were washed twice with 50-ml. portions of distilled water, dried over anhydrous sodium sulfate, and then stripped of solvent under reduced pressure to leave an amorphous yellow residue. The crude ethylated product, without further purification, was dissolved in 100 ml. of 2.5% (w/v) sulfuric acid and refluxed with 1 Gm. of manganese dioxide for 5 hr. The reaction mixture was filtered while hot, cooled, and then extracted for 3 days continuously with ether in a liquid–liquid extractor. The ethereal extract was dried over anhydrous magnesium sulfate and then stripped of solvent to leave a yellowish residue. The residue was warmed with 5% (w/v) sodium carbonate solution (20 ml.) upon which a portion of the residue dissolved, the remaining residue being termed the "neutral fraction" and the dissolved portion the "acidic fraction."

Acidic Fraction—The sodium carbonate solution was acidified with 5% (w/v) hydrochloric acid and then extracted continuously with ether in a liquid–liquid extractor for 2 days. The ethereal extract was dried and stripped of solvent, the residue was dissolved in 5 ml. of 33% aqueous ethylamine, and the solution was concentrated to dryness. The residue was heated at 180° for 10 min. and then sublimed at 170–185°/1 mm. to yield 50 mg. of sublimate. The sublimate was crystallized from methanol to yield 20 mg. of white needles, m.p. 223–224°, which failed to depress the melting point of authentic 4,5-dimethoxy-*N*-ethylphthalimide. The mother liquor from the first crystallization was allowed to stand and slowly concentrate, upon which a white crystalline residue, m.p. 189–195°, separated (14 mg.). Recrystallization of this residue yielded 5 mg. of product, m.p. 200–202°, which failed to depress the melting point of authentic 4-ethoxy-5-methoxy-*N*-ethylphthalimide.[4]

Neutral Fraction—This residue was washed with water, dried, and sublimed at 170–185°/0.1 mm. to give a yellowish-white sublimate with a melting range of 200–256°. Crystallization from ethanol yielded 10 mg. of white crystals, m.p. 263–264°, which failed to depress the melting point of authentic 4,5-dimethoxy-*N*-methylphthalimide. The mother liquor, on slow concentration, yielded a white crystalline residue, m.p. 180–200°, which on continued recrystallization yielded 6 mg. of white crystals, m.p. 189–191°. A mixed melting point determination with authentic 4-ethoxy-5-methoxy-*N*-methylphthalimide[5] failed to depress the melting point.

N-Methyl-1,2-dihydropapaverine—Prepared according to the method of Schopf and Thierfelder (11), m.p. 128–130°. [Lit. (11) m.p. 129–130°.]

(±)-N-Methylpavine—This was prepared from *N*-methyl-1,2-dihydropapaverine by the method of Battersby and Binks (7), m.p. 138–140°. [Lit. (7) m.p. 135–140°.]

(+)-N-Methylpavine-(+)-L-bitartrate—(+)-L-Tartaric acid (1.5 Gm., 0.01 mole) was dissolved with heat in 35 ml. of ethanol and added while hot to a hot solution of (±)-*N*-methylpavine (3.55 Gm., 0.01 mole) in ethanol (40 ml.). On cooling, copious crystallization occurred to yield 3.1 Gm. of white crystals. These were recrystallized several times from ethanol to yield 0.4 Gm. of white crystals, m.p. 228–230° (with effervescence and previous softening at 221°); $[\alpha]_D^{29}$ +174.8° (c 2.0, H_2O).

Anal.—Calcd. for $C_{25}H_{31}NO_{10}$: C, 59.40; H, 6.18. Found: C, 59.12; H, 6.31.

(+)-N-Methylpavine—(+)-*N*-Methylpavine-(+)-L-bitartrate (0.3 Gm.) was dissolved in about 25 ml. of water and then alkalinized with 5 ml. of 5% (w/v) aqueous sodium hydroxide. The alkaline solution was then extracted with three portions (15 ml.) of dichloromethane and the combined extracts washed once in a separator with 15 ml. of water. The dichloromethane extract was then dried over anhydrous magnesium sulfate and stripped of solvent to leave a clear glassy, noncrystalline residue. This residue was recrystallized from a dilute ethanolic solution to yield prisms (60 mg.), m.p. 133–145° (with effervescence), $[\alpha]_D^{25}$ +207.8° (c 2.0, C_2H_5OH). When these crystals were powdered and dried in vacuum over phosphorus pentoxide at 100° the melting point changed to 151–153°. Argemonine (20 mg.) and (+)-*N*-methylpavine (20 mg.), both in the dried form, were each dissolved in sufficient dichloromethane to effect complete solution and the solutions combined. The solvent was stripped from the combined solution to leave a colorless gum which solidified and crystallized when rubbed with a small amount of ether, m.p. 136–139°. The melting point was not depressed on admixture with authentic (±)-*N*-methylpavine.

(−)-N-Methylpavine-(−)-D-bitartrate—*From (±)-N-Methylpavine*—This salt was prepared in exactly the same manner as described for (+)-*N*-methylpavine-(+)-L-bitartrate except for the use of (−)-D-tartaric acid ("unnatural") instead of the natural (+)-L-tartaric acid, m.p. 227–230°, $[\alpha]_D^{25}$ −176.5° (c 2.0, H_2O).

From Argemonine—Argemonine (0.355 Gm., 0.001 mole) was dissolved in ethanol, and to this solution, while hot, was added 10 ml. of a hot ethanolic solution containing 0.150 Gm. (0.001 mole) of (−)-D-tartaric acid. On cooling, a copious gelatinous residue formed which became crystalline on agitation and warming. Recrystallization of the white crystalline residue from ethanol yielded 350 mg. of crystalline rosettes, m.p. 230–232° (with effervescence and softening at 225°); $[\alpha]_D^{23}$ −188.8°

[3] Prepared from Ethyl Diazald, Aldrich Chemical Co., Milwaukee, Wis.

[4] Prepared by permanganate oxidation of *O*-ethylated boldine and subsequent conversion of the acidic fraction to the *N*-ethylimide.

[5] Prepared by permanganate oxidation of *O*-ethylated boldine and subsequent conversion of the acidic fraction to the *N*-methylimide.

(c 2.5, H_2O). A mixed melting point determination with the same salt prepared by the first method showed no depression of melting point.

Anal.—Calcd. for $C_{25}H_{31}NO_{10}$: C, 59.40; H, 6.18. Found: C, 59.26; H, 6.28.

(−)-N-Methylpavine—The preparation of this base was carried out in exactly the same manner as for (+)-*N*-methylpavine from its bitartrate salt. The product, after recrystallization from aqueous ethanol, possessed a melting point of 130–140° (with effervescence); $[\alpha]_D^{25}$ −209° (c 1.0, C_2H_5OH). On drying the crystals in the same way as for the (+)-rotatory base, the white powder melted at 152–153°. A mixed melting point determination as well as infrared comparison with authentic dried argemonine base showed them to be completely identical.

Spectra

Nuclear Magnetic Resonance—Spectra were obtained in $CDCl_3$ on a Varian A-60 spectrometer using tetramethylsilane as the internal standard.

Mass—Spectra were obtained on a C.E.C.-103-C instrument at 200° using a metal inlet at 70 e.v.

Ultraviolet—*N* - Methyl - 1,2 - dihydropapaverine (100 mg.) was dissolved in 100 ml. of 10% (w/v) aqueous tartaric acid. At various time intervals over a 72-hr. period the spectrum of the solution was examined over the wavelength range of 220–370 mμ to determine whether the characteristic absorption bands for argemonine were appearing in the 275–295-mμ region. The analysis was carried out by diluting 1 ml. of the sample solution to 100 ml. with water and placing this solution in the sample cell. The reference cell was filled with a solution obtained by diluting 1 ml. of the 10% aqueous tartaric acid solution (without sample) to 100 ml. The measurements were carried out on a Bausch & Lomb model 505 recording spectrophotometer and showed no absorption in the region mentioned although maxima developed at 250 and 312 mμ.

Structures of Some Degradation Products of (±)-*N*-Methylpavine

By MAHMOUD M. ABDEL-MONEM* and TAITO O. SOINE

The structures of three products encountered during structural studies on argemonine and (±)-*N*-methylpavine (I) have been determined. The first of these, obtained by hydrochloric acid treatment of 3-hydroxy-2′:3′:2″:3″-tetramethoxy-1:2-5:6-dibenzoöcta-1:5:7-triene (II), has been determined to be 3-chloromethyl-2′:3′:2″:3″-tetramethoxy-1:2-4:5-dibenzocyclohepta-1:4:6-triene. The second, known as argemoninic acid and resulting from permanganate oxidation of II, has been shown to be 2:2′-dicarboxy-4:5:4′:5′-tetramethoxybenzil. The third product, resulting from alkaline ethyl chloroformate treatment of I, has been shown to be the corresponding *N*-carbethoxy derivative of pavine.

THE ISOLATION of three new alkaloids from *Argemone* species was accomplished in these laboratories (1–3), these alkaloids being named argemonine, norargemonine, and bisnorargemonine. Diazomethylation of the latter two showed them to be the mono- and diphenolic precursors, respectively, of argemonine. After initial studies which led to an erroneous tentative structural postulation for argemonine as an aporphine (3, 4), the correct structure was reported by Martell, Soine, and Kier (5) as being (−)-*N*-methylpavine. The structure of synthetic (±)-*N*-methylpavine (I) had been elucidated in 1955 by Battersby and Binks (6) and the natural product proved to be identical to the synthetic product except for rotatory differences and melting point.

In the course of the early structural work on argemonine a number of degradation products were obtained as shown in Scheme I.

Received February 3, 1967, from the Department of Medicinal Chemistry, College of Pharmacy, University of Minnesota, Minneapolis, MN 55455
Accepted for publication May 4, 1967.
Presented to the Scientific Section, A.PH.A., Detroit meeting, March 1965.
* Present address: Research Department, The Nile Company for Pharmaceuticals and Chemicals Industries, Cairo, Egypt, U.A.R.

(c 2.5, H_2O). A mixed melting point determination with the same salt prepared by the first method showed no depression of melting point.

Anal.—Calcd. for $C_{25}H_{31}NO_{10}$: C, 59.40; H, 6.18. Found: C, 59.26; H, 6.28.

(−)-N-Methylpavine—The preparation of this base was carried out in exactly the same manner as for (+)-*N*-methylpavine from its bitartrate salt. The product, after recrystallization from aqueous ethanol, possessed a melting point of 130–140° (with effervescence); $[\alpha]_D^{25}$ −209° (c 1.0, C_2H_5OH). On drying the crystals in the same way as for the (+)-rotatory base, the white powder melted at 152–153°. A mixed melting point determination as well as infrared comparison with authentic dried argemonine base showed them to be completely identical.

Structures of Some Degradation Products of (±)-*N*-Methylpavine

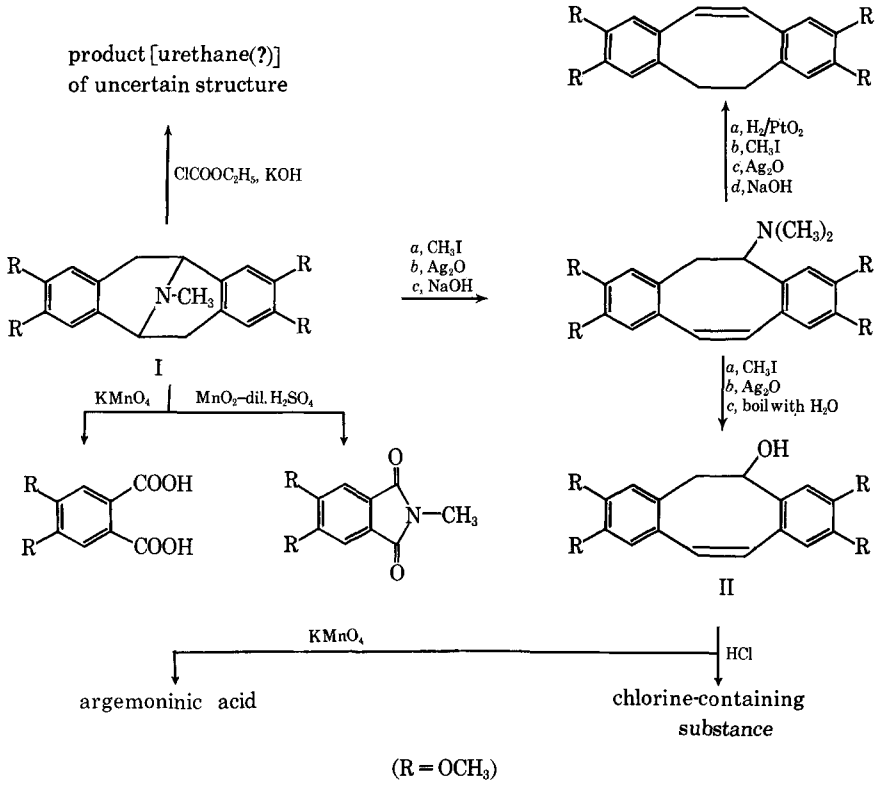
By MAHMOUD M. ABDEL-MONEM* and TAITO O. SOINE

The structures of three products encountered during structural studies on argemonine and (±)-*N*-methylpavine (I) have been determined. The first of these, obtained by hydrochloric acid treatment of 3-hydroxy-2′:3′:2″:3″-tetramethoxy-1:2-5:6-dibenzoöcta-1:5:7-triene (II), has been determined to be 3-chloromethyl-2′:3′:2″:3″-tetramethoxy-1:2-4:5-dibenzocyclohepta-1:4:6-triene. The second, known as argemoninic acid and resulting from permanganate oxidation of II, has been shown to be 2:2′-dicarboxy-4:5:4′:5′-tetramethoxybenzil. The third product, resulting from alkaline ethyl chloroformate treatment of I, has been shown to be the corresponding *N*-carbethoxy derivative of pavine.

THE ISOLATION of three new alkaloids from *Argemone* species was accomplished in these laboratories (1–3), these alkaloids being named argemonine, norargemonine, and bisnorargemonine. Diazomethylation of the latter two showed them to be the mono- and diphenolic precursors, respectively, of argemonine. After initial studies which led to an erroneous tentative structural postulation for argemonine as an aporphine (3, 4), the correct structure was reported by Martell, Soine, and Kier (5) as being (−)-*N*-methylpavine. The structure of synthetic (±)-*N*-methylpavine (I) had been elucidated in 1955 by Battersby and Binks (6) and the natural product proved to be identical to the synthetic product except for rotatory differences and melting point.

In the course of the early structural work on argemonine a number of degradation products were obtained as shown in Scheme I.

Received February 3, 1967, from the Department of Medicinal Chemistry, College of Pharmacy, University of Minnesota, Minneapolis, MN 55455
Accepted for publication May 4, 1967.
Presented to the Scientific Section, A.PH.A., Detroit meeting, March 1965.
* Present address: Research Department, The Nile Company for Pharmaceuticals and Chemicals Industries, Cairo, Egypt, U.A.R.



Scheme I

Some of these had been reported earlier by Pyman (7) as well as by Battersby and Binks from their somewhat parallel studies on racemic *N*-methylpavine. In considering the possible structural assignments to the degradation products it appeared that some of them needed additional structural definition. The present work describes the structural elucidation of the three principal degradation products: (*a*) the chlorine-containing substance, (*b*) argemoninic acid, and (*c*) the ethyl chloroformate reaction product.

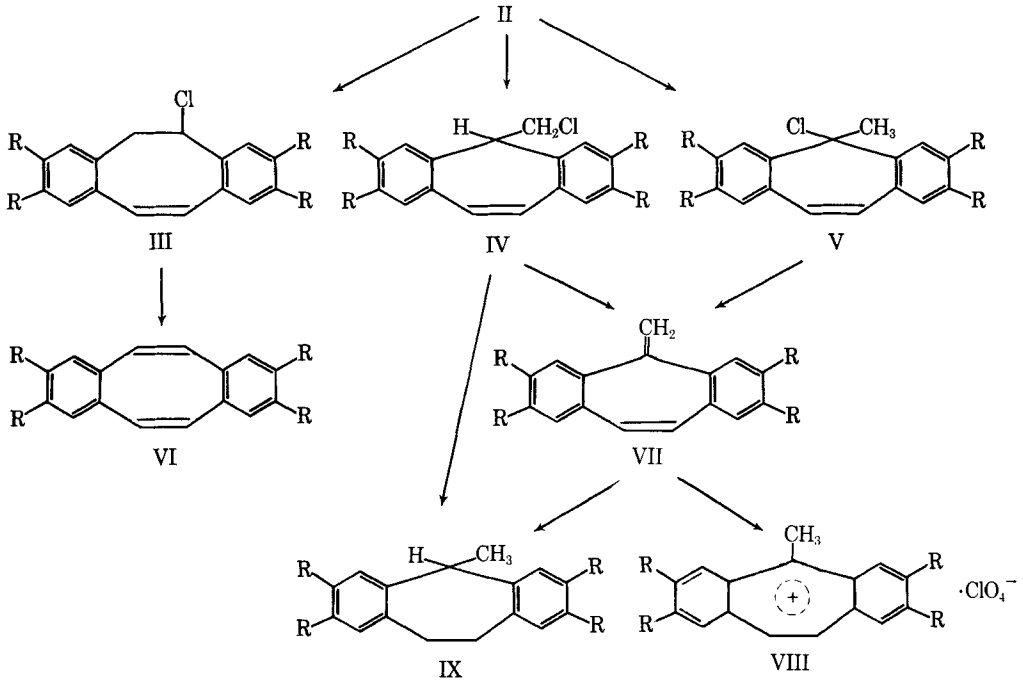
DISCUSSION

The Chlorine-Containing Substance—(±)-*N*-Methylpavine (I), when subjected to two steps of the Hofmann exhaustive methylation procedure, produced a nitrogen-free alcohol (II). The structure of II had been determined unambiguously (6) by Battersby and Binks as 3-hydroxy-2′:3′:-2″:3″-tetramethoxy-1:2-5:6-dibenzocycloöcta-1:5:7-triene. When II was treated with acetyl chloride by Pyman (7) a chlorine-containing compound, $C_{20}H_{21}ClO_4$, was produced which was assigned the structure III by Battersby and Binks. (Scheme II.)

(−)-*N*-Methylpavine (*i.e.*, argemonine), when subjected to a similar degradation, produced trimethylamine and a dextrorotatory nitrogen-free substance which was evidently an optically-active isomer of II (4). Treatment of an ethanolic solution of the latter with concentrated hydrochloric acid produced a chlorine-containing substance which had identical properties with the chlorine-containing substance reported by Pyman and to which Battersby and Binks had assigned structure III.

In considering the possible reactions of hydrochloric acid with II there appeared to be three possible structures (III, IV, and V) for the chlorine-containing compound. From a comparison of the ultraviolet spectra of the two compounds, *i.e.*, the alcohol (II) and the chloro-compound, it was obvious that there had been a bathochromic shift in the maxima of the latter compared to II, a shift that suggested a more significant change in the nature of the chromophore than would be expected in passing from II to III. In contrast, structures IV and V were both more reasonable on the basis of the ultraviolet data because the rearrangement of the middle ring from a cycloöctatriene to a cycloheptatriene system would be expected to cause the two aromatic rings to become more coplanar.

The chloro-compound, when refluxed in 2-picoline or alcoholic sodium hydroxide, provided a halogen-free substance analyzing for $C_{20}H_{20}O_4$, indicating that dehydrohalogenation had taken place. Structure III, on dehydrohalogenation, could be expected to produce a tetramethoxydibenzocycloöctatetraëne (VI). The latter, however, is a known compound (7) and was not the product of the reaction. On the other hand, structures IV and V under the conditions of the reaction would give the same product, namely VII. In order to gain more information about the dehydrohalogenated product, it was subjected to nuclear magnetic resonance (NMR) study.



Scheme II

The NMR spectrum of this compound showed six distinct singlets integrating for a total of 20 protons. Aromatic protons with an intensity of two each were found as singlets at 3.26 and 3.32 τ. The singlets for the methoxyl protons integrating for six each were found at 6.06 and 6.10 τ. A singlet at 3.06 τ, integrating for two protons, was assigned to a pair of olefinic protons conjugated to aromatic rings. The difference in the chemical shift of this pair of protons, compared to the almost equivalent pair of olefinic protons in *cis*-stilbene (3.45 τ), was attributed to the greater coplanarity of the benzene rings and the consequent deshielding effect. A singlet at 4.47 τ integrated for two protons and was assigned to a pair of terminal methylene protons. The NMR data, therefore, excluded structure VI but was compatible with structure VII.

Structure VII would be expected to form a tropylium salt on treatment with acids and it was found that the dehydrohalogenation product did, indeed, form a stable perchlorate with the correct analysis (VIII).

Hydrogenation of the dehydrohalogenation product provided a tetrahydro derivative, $C_{20}H_{24}O_4$, a product that would be expected from VII and which would be represented by structure IX. This derivative, on C-methyl analysis, showed one terminal methyl group as expected. The NMR spectrum showed the aromatic protons as singlets integrating for two each at 3.23 and 3.36 τ. The methoxyl protons gave singlets integrating for six each at 6.13 and 6.17 τ. A singlet at 6.90 τ, integrating for four protons, was assigned to the four equivalent benzylic protons of the ethylene bridge. The protons of the terminal methyl group appeared as a doublet centered at 8.32 τ with an integration of three protons (J = 7.5 c.p.s.). A quartet centered at 5.80 τ, integrating for one proton, was assigned to the benzylic proton (J = 7.5 c.p.s.) adjacent to the methyl group.

Compound IX had been synthesized unequivocally by Battersby and Binks (8) and the reported melting point coincided with that of the substance obtained in the present study by hydrogenation of VII. From the above data it appears that the dehydrohalogenation product can be assigned structure VII and its hydrogenation product, structure IX.

Although the structures of VII and IX appear unequivocal at this point, the structure of the chlorine-containing substance had not necessarily been proven since the possibility of rearrangement of III during dehydrohalogenation, although seemingly remote, could not be ignored. This possibility was dismissed by hydrogenolysis of the chloro-compound to yield IX. Since no rearrangement would be anticipated under these conditions, the chloro-compound would of necessity have structure IV or V. Because it was sparingly soluble in virtually all solvents which could be used for NMR analysis except pyridine, it was studied in the latter solvent. The methoxyl protons appeared as singlets at 6.15 and 6.17 τ. The chloromethyl group appeared as a doublet centered at 5.96 τ (J = 8 c.p.s.). A triplet centered at 5.40 τ (J = 8 c.p.s.) was assigned for the benzylic proton coupled to the protons of the chloromethyl group. The spectrum, in general, was not very clear and integration was not possible. Nevertheless, it appeared certain that the chloro-compound did not have structure V since its NMR spectrum should have

shown a singlet corresponding to the terminal methyl, this singlet together with the methoxyl proton peaks being the only ones expected in the region of 4.00 to 10.00 τ. Such absorption was not observed and, coupled with the observation (4) that C-methyl was not found by analysis, the evidence appears conclusive that the chlorine-containing substance may be represented by structure IV rather than III as suggested earlier by Battersby and Binks.

Argemoninic Acid—When II was oxidized with potassium permanganate, an optically inactive acid was obtained which was named argemoninic acid. The acid was tentatively identified in the earlier studies as a tetramethoxybiphenyltricarboxylic acid, based on an erroneous aporphine formulation of argemonine (4). Following elucidation of the correct structure (5), it became obvious that the proposed structure for the acid was incorrect. Furthermore, additional analyses suggested $C_{20}H_{18-20}O_{10}$ as a more reasonable empirical formula, in keeping with neutral equivalent determinations which gave values of 215 and 219 (theory, 209 and 210).

Likely structures for argemoninic acid, based on the known structure of II, would be X and XI with the structure XII, which conceivably could arise from X by benzilic acid rearrangement, being untenable on the basis of analytical and neutral equivalent data. The indophenine test for 1,2-diketones (9) proved to be positive and was substantiated by hydrogen peroxide oxidation of argemoninic acid to yield the expected *m*-hemipinic acid (XIV) isolated as its *N*-methylimide (XV). These results suggested X as the most likely structural possibility.

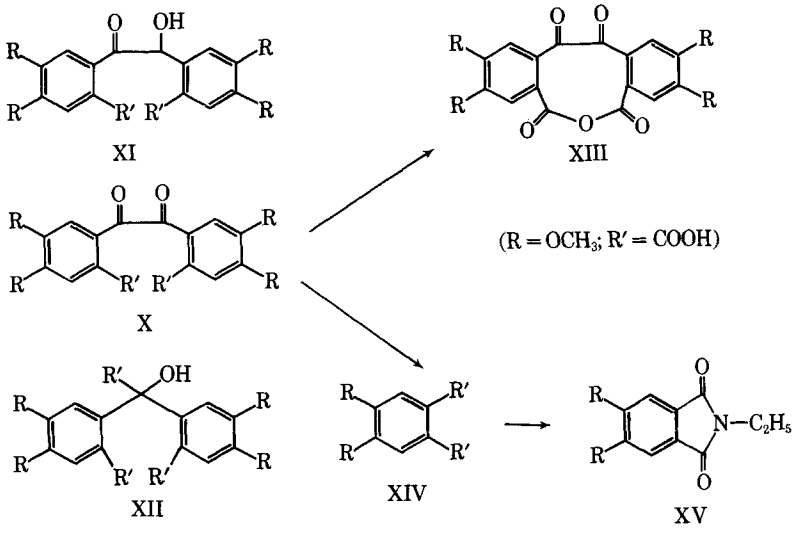
To further eliminate the possibility of a benzoin structure such as in XI, the infrared spectra of the acid and its triethylamine salt were examined. In the case of the acid, a broad band due to carboxylic group hydroxyl at about 3400 cm.$^{-1}$ precluded making a decision, but the triethylamine salt, on the other hand, while showing carbonyl absorption at 1690 cm.$^{-1}$ (α-diketone) and 1750 cm.$^{-1}$ (carboxylate) failed to show absorption in the hydroxyl region.

The NMR spectrum of argemoninic acid was determined in two solvent systems: (*a*) sodium bicarbonate in deuterium oxide and (*b*) sodium methoxide in dimethylsulfoxide. The spectrum of the acid in the first system was quite simple, showing only three distinct peaks corresponding to aromatic protons, methoxyl protons, and water. The aromatic protons appeared as a singlet at 2.90τ with an intensity of four protons, whereas the methoxyl protons were singlets at 6.04 and 6.18 τ with an intensity of six protons each. A large peak at 5.3τ was attributed to water. However, the possibility that the acid had still other spectral features that were masked by the water peak could not be ruled out. Inspection of the NMR spectrum in the second system showed the aromatic protons as a pair of singlets at 2.75 and 2.90τ. The methoxyl peaks at 6.13τ were complex due to interference of the methoxyl peak from sodium methoxide but, nevertheless, the spectrum failed to show peaks in the 3.0 to 6.0τ region and, therefore, strongly pointed to structure X.

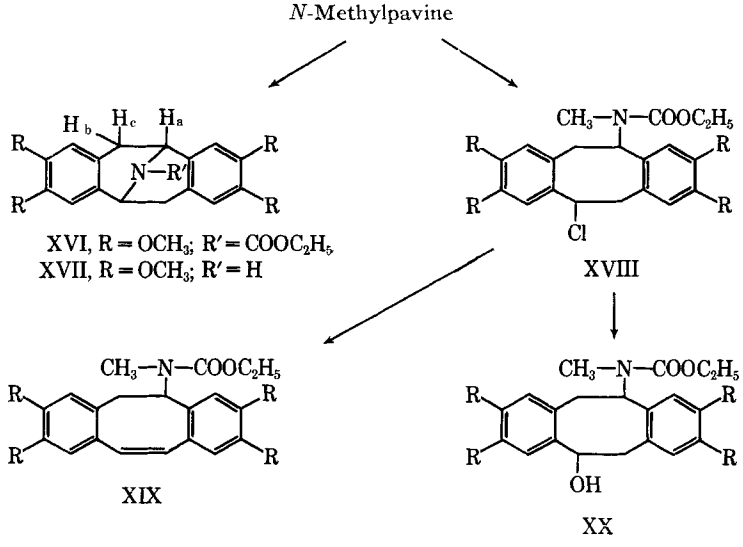
An interesting confirmation of structure X was also achieved by taking advantage of the fact that Kier and Soine (4) had previously shown that the acid, at its melting point, effervesced and liberated a mole of water. The most likely possibilities would have been formation of an anhydride from X or an anhydride or lactone from XI. The solid residue from such a melt analyzed for $C_{20}H_{16}O_9$. Its infrared spectrum showed no hydroxyl absorption but did show carbonyl absorptions at 1690 cm.$^{-1}$ (α-diketone) and at 1750 and 1790 cm.$^{-1}$ (anhydride). If argemoninic acid had structure XI it would have been impossible for it to form an anhydride *or* a lactone without leaving one hydroxyl group. The structure of the compound resulting from the melting of argemoninic acid can, therefore, be assigned as XIII and the structure of argemoninic acid is X. (Scheme III.)

The Ethyl Chloroformate Reaction Product—Subjection of *N*-methylpavine to the action of ethyl chloroformate in the presence of alkali according to the method of Gadamer and Knoch (10) yielded a neutral product (11). This reaction, which specifically cleaves benzylic carbon-to-nitrogen bonds (12), ordinarily provides a urethane as the end product and the reaction has been used to some extent in alkaloidal structural work. It fails occasionally, as in the case of tetrahydroberberine (12) but with aporphines, for example, the reaction proceeds with facility. Since earlier tentative conclusions as to the structure of argemonine indicated that it might be an aporphine (4) this reaction was employed during the structural studies. In light of the now known structure of argemonine as (−)-*N*-methylpavine, it is apparent that there are *two* benzylic carbon-to-nitrogen bonds in the molecule, and therefore the fact that a neutral product was obtained was of considerable interest from the standpoint of its structure.

Analysis of the product, resulting in a probable formula of $C_{23}H_{27}NO_6$, rendered untenable the product that might have resulted from a simple cleavage of a benzylic carbon-to-nitrogen bond such as XVIII or structures XIX and XX which could result from XVIII. The ultraviolet spectrum of the compound further supported the assumption that no cleavage had occurred, since the spectrum was virtually identical with that of *N*-methylpavine and unlike that of II, and further, the infrared spectrum failed to show hydroxyl absorption. The loss of —CH_3 during the reaction together with gain of —$COOC_2H_5$ appeared compatible with the analytical data and the neutral character of the product and thus suggested structure XVI as the most likely possibility. On this basis, the compound was subjected to lithium aluminum hydride reduction, since such reductions of urethanes have been reported by Knabe (13) and others (14) to yield an *N*-methyl group. The reduction process yielded a basic compound which was isolated as the methiodide and which proved to be identical in melting point and mixed melting point with *N*-methylpavine methiodide. Unfortunately, the methiodide melts with decomposition, and therefore further evidence of the identity of the two products seemed desirable. The infrared spectrum of the methiodide of reduced XVI was found to be identical with the spectrum of *N*-methylpavine methiodide, as were the X-ray powder diffraction patterns. In addition, alkaline hydrolysis of the suspected



Scheme III



Scheme IV

urethane yielded a new basic substance which was identical in all respects to (±)-pavine. The NMR spectrum of this new basic substance was also identical in all respects to that of (±)-pavine (5). (Scheme IV.)

Examination of the NMR spectrum of the ethyl chloroformate reaction product was entirely compatible with structure XVI. The aromatic protons were singlets at 3.28 and 3.47τ with an intensity of two each, whereas the methoxyl protons were singlets at 6.12 and 6.20τ with an intensity of six each. The protons of the methyl group of the ethoxy moiety appeared as a triplet centering at 8.72τ (J = 7 c.p.s.) with an intensity of three protons and the methylene protons of this group were found as a quartet centering at 5.79τ (J = 7 c.p.s.) with an intensity of two protons. The bridgehead protons appeared as a broad peak at 4.47τ with an intensity of two protons. As in the case of (−)-*N*-methylpavine (5), protons H_c coupled only with protons H_b and were seen as a doublet centering at 7.24τ (J_{bc} = 17 c.p.s.). Protons H_b were split by H_a and H_c and were observed as a pair of doublets at 6.41 and 6.68τ.

On the basis of the above evidence, structure XVI can be assigned to the product of the ethyl chloroformate reaction.

EXPERIMENTAL

Melting points were determined on a Thomas-Hoover capillary melting point apparatus. Microanalyses were determined by the Microanalytical Laboratory, School of Chemistry, University of Minnesota, or by the Schwarzkopf Microanalytical Laboratory, Woodside, N. Y. The infrared spectra were determined as Nujol and halocarbon mulls by the Infrared Laboratory, School of Chemistry,

University of Minnesota, using a Perkin-Elmer 521 grating infrared spectrophotometer. Ultraviolet spectra were determined in ethanolic solution using a Bausch & Lomb Spectronic 505 recording spectrophotometer. Nuclear magnetic resonance spectra were determined through the courtesy of Dr. William Schwabacher, School of Chemistry, University of Minnesota, using a Varian Associates A-60 instrument.

N-Methylpavine (I)—This substance was prepared essentially following the method of Battersby and Binks (6), m.p. 139–140°. [Lit. m.p. 135–140° (6).]

N-Methylpavinemethine Methiodide—This derivative of I was prepared according to the procedure of Kier and Soine (4) and was used without further purification.

3-Hydroxy-2′:3′:2″:3″-tetramethoxy-1:2-5:6-dibenzocyclooöcta-1:5:7-triene (II)—A suspension of *N*-methylpavinemethine methiodide (10 Gm.) in water (200 ml.) was treated with freshly prepared silver oxide (from 5 Gm. of silver nitrate). The reaction mixture was kept in an ice bath and stirred until a filtered portion failed to give a test for iodide ion with silver nitrate T.S. The precipitated silver iodide and excess silver oxide were removed by filtration and the filtrate was then boiled for 30 min., during which time a white crystalline precipitate formed. This precipitate was separated by filtration and recrystallized from a methanol–water mixture. The dried crystals (4.97 Gm.) melted at 142–147°. [Lit. (5) m.p. 145–146°.] $\lambda_{min.}$ 267.5 mμ (log ε 3.97); $\lambda_{max.}$ 220 (4.49), 292 mμ (4.05) in ethanol.

3-Chloromethyl-2′:3′:2″:3″-tetramethoxy-1:2-4:5-dibenzocyclohepta-1:4:6-triene (IV)—A solution of II (300 mg.) in ethanol (30 ml.) was cooled in an ice bath and then concentrated hydrochloric acid (15 ml.) was added dropwise. The solution acquired a transient pink to violet color which disappeared on shaking. The solution was then refluxed for 20 min. on a steam bath. On cooling, a white crystalline material separated which was removed by filtration (270 mg.) and recrystallized from hot glacial acetic acid. The dried crystals melted at 219–220°. [Lit. (4) m.p. 219–220°.] $\lambda_{min.}$ 265 mμ (log ε 4.54); $\lambda_{max.}$ 238 (4.54), 316 mμ (4.15) in ethanol.

Anal.—Calcd. for $C_{20}H_{21}ClO_4$: C, 66.57; H, 5.87; Cl, 9.83. Found: C, 66.65; H, 5.77; Cl, 9.55.

3-Methylene-2′:3′:2″:3″-tetramethoxy-1:2-4:5-dibenzocyclohepta-1:4:6-triene (VIII)—This substance was obtained from IV by two different methods.

Dehydrohalogenation Using 2-Picoline—A solution of IV (250 mg.) in 2-picoline (25 ml.) was refluxed under a nitrogen atmosphere for 7 days. The solution was then treated with 1% hydrochloric acid (80 ml.) and extracted with three successive portions (50 ml.) of ether. The combined ethereal extracts were washed successively with 1% hydrochloric acid (20 ml.) and distilled water (20 ml.). The ether extract was then dried with anhydrous sodium sulfate and, following removal of the drying agent by filtration, was evaporated to dryness to yield a crystalline residue. Recrystallization from ethanol yielded 126 mg. of yellowish plates, m.p. 226–229°. Further recrystallization from the same solvent provided faintly yellow crystals, m.p. 233.5–234.5°, which gave a negative halogen test.

Anal.—Calcd. for $C_{20}H_{20}O_4$: C, 74.06; H, 6.35. Found: C, 73.81; H, 6.34.

Dehydrohalogenation with Alcoholic Sodium Hydroxide—A solution of IV (300 mg.) in ethanol (300 ml.) was treated with sodium hydroxide pellets (3 Gm.) and refluxed for 24 hr. The ethanol was evaporated and the residue was treated with 100 ml. of boiling water, allowed to cool, and then filtered. The precipitate was then recrystallized from the least amount of boiling ethanol and colorless platelets (258 mg.), m.p. 234–236°, were obtained. The product gave no depression in melting point with the material obtained through the use of 2-picoline.

3-Methyl-2′:3′:2″:3″-tetramethoxy-1:2-4:5-dibenzocyclohepta-1:4-diene (IX) from VII—Palladium-on-carbon catalyst (10%, 400 mg.) was added to a solution of VII (200 mg.) in ethanol (200 ml.), and the mixture was then shaken with hydrogen under atmospheric pressure until the uptake of hydrogen stopped. The hydrogenated mixture was then heated to boiling and filtered to remove the catalyst. The filtrate was evaporated to dryness under reduced pressure and the residue recrystallized from the least amount of hot ethanol to obtain a crystalline precipitate (82.5 mg.), m.p. 128–129°. [Lit. (6) m.p. 126–128°.]

Anal.—Calcd. for $C_{20}H_{24}O_4$: C, 73.14; H, 7.36; C-methyl, 4.37. Found: C, 73.37; H, 7.13; C-methyl, 5.34.

3-Methyl-2′:3′:2″:3″-tetramethoxy-1:2-4:5-dibenzocyclohepta-1:4-diene (IX) from IV—Palladium-on-carbon catalyst (10%, 1.0 Gm.) was added to a solution of IV (400 mg.) in ethanol (300 ml.) and the mixture was then shaken with hydrogen under atmospheric pressure until the uptake of hydrogen stopped. The hydrogenated mixture was heated to boiling and filtered to remove the catalyst. The filtrate was evaporated to dryness and the residue recrystallized from the least amount of ethanol to yield a crystalline precipitate (79 mg.), m.p. 128–129°, which gave no depression of melting point with the product from the previous experiment.

3-Methylene-2′:3′:2″:3″-tetramethoxy-1:2-4:5-dibenzocyclohepta-1:4:6-triene Perchlorate (VIII)—Perchloric acid (60%, 2 ml.) was added dropwise to a hot solution of VII (100 mg.) in glacial acetic acid (200 ml.). The solution was boiled, filtered, and allowed to stand overnight in the refrigerator to yield a brown crystalline precipitate (75 mg.). This material was recrystallized from glacial acetic acid to yield 10 mg. of product, m.p. 350°.

Anal.—Calcd. for $C_{20}H_{21}ClO_8$: C, 56.54; H, 4.98. Found: C, 56.47; H, 4.96.

Argemoninic Acid (X)—A suspension of II (1.0 Gm.) in distilled water (75 ml.) was warmed and potassium permanganate solution (5%, 75 ml.) was added slowly. The mixture was heated on a steam bath with occasional stirring for 1 hr., cooled, and the excess permanganate reduced with methanol. The suspension was cooled, acidified with 30 ml. of 50% sulfuric acid, and the dark color of manganese dioxide discharged by the careful addition of solid sodium bisulfite. A fine white

precipitate remained which was removed by filtration (899 mg.). The precipitate was recrystallized from methanol to give white crystals, m.p. 254–255.5°, with effervescence. $\lambda_{min.}$ 246 mμ (log ε 4.03), 281 (3.91); $\lambda_{max.}$ 229 (4.71), 264 (4.21), and 295 (4.06).

Anal.—Calcd. for $C_{20}H_{18}O_{10}$: C, 57.41; H, 4.33; neut. equiv. (for 2 COOH), 209.18. Found: C, 57.12; H, 4.51; neut. equiv. 215, 219.

Argemoninic Acid Anhydride (XIII)—X (300 mg.) was heated under a nitrogen atmosphere to the melting point, when effervescence was observed followed by solidification of the melt. The residue was cooled and recrystallized from ethyl acetate several times to obtain white needles, m.p. 280–281°.

Anal.—Calcd. for $C_{20}H_{16}O_9$: C, 60.00; H, 4.02. Found: C, 59.76; H, 4.00.

N-Ethyl-m-hemipinimide (XV)—A solution of X (100 mg.) in glacial acetic acid (20 ml.) was treated with 30% hydrogen peroxide (10 ml.) and refluxed for 4 hr. The cooled solution was finally evaporated to dryness. The residue was treated with ethylamine solution (33%, 4 ml.) and again taken to dryness, heated at 180° for 10 min., and then sublimed at 180°/5 mm. The white sublimate was recrystallized from ethanol to yield 10 mg. of white needles, m.p. 227–229°, which failed to depress the melting point of an authentic sample of *N*-ethyl-*m*-hemipinimide.

N-Carbethoxypavine (XVI)—A solution of I (1.5 Gm.) in chloroform (30 ml.) was treated at room temperature with ethyl chloroformate (4 ml.) and aqueous potassium hydroxide solution (15%, 40 ml.). The reaction mixture was shaken for 10 min., additional ethyl chloroformate (5 ml.) added, and shaking continued for 30 min. The addition of ethyl chloroformate (5 ml.) and aqueous potassium hydroxide (40 ml.) was repeated three times at 30-min. intervals, after which the reaction mixture was allowed to stand overnight. The chloroformic layer was separated, the aqueous layer was washed with a little chloroform, and the washing added to the original chloroformic solution. On shaking the chloroformic solution with 20 ml. of dilute (3.7%) hydrochloric acid, the acid extract was found to be positive to Valser's reagent. The chloroform layer, therefore, was extracted with successive portions of hydrochloric acid until the acid extract failed to give a turbidity with the reagent. The chloroform solution was then washed with distilled water dried over anhydrous sodium sulfate, and evaporated to dryness. Crystallization was effected from ethanol to obtain large cubical crystals which were recrystallized from the same solvent, m.p. 191–192°. The yield was 1.18 Gm. (68% of theory).

Anal.—Calcd. for $C_{23}H_{27}NO_6$: C, 66.81; H, 6.58; N, 3.38. Found: C, 66.92; H, 6.41; N, 3.61.

Pavine (XVII)—A solution of XVI (400 mg.) in ethanol (100 ml.) was treated with potassium hydroxide pellets (10 Gm.) and the solution then refluxed for 48 hr. The mixture was then concentrated and, finally, evaporated to dryness following which water (10 ml.) was added and distilled off to remove any residual ethanol. The residue was suspended in water and extracted with three successive portions (50 ml.) of chloroform. The combined chloroformic extract was washed with water and then extracted with successive 50-ml. portions of 3.7% hydrochloric acid until the acid extracts gave a negative test with Valser's reagent. The combined acid extracts were washed with chloroform (20 ml.) and rendered alkaline by the careful addition of 20% sodium hydroxide solution following which the alkaline solution was extracted with successive 50-ml. portions of chloroform until the chloroform extracts gave a negative test with Valser's reagent. The combined chloroformic extracts were washed with water, filtered, and dried over anhydrous sodium sulfate. The dried extract was evaporated to dryness and the residue treated with absolute ethanol (10 ml.) and the ethanol then evaporated to remove traces of moisture. The dry residue was crystallized from xylene and then recrystallized from ethanol to provide 20 mg. of product, m.p. 198–199°. [Lit. (6) m.p. 199–200°.]

N-Methylpavine Methiodide from XVI—A solution of XVI (232 mg.) in dry tetrahydrofuran (40 ml.) was added dropwise to a suspension of lithium aluminum hydride (290 mg.) in dry tetrahydrofuran (50 ml.). After the addition was complete, the reaction mixture was refluxed for 10 hr., following which the excess lithium aluminum hydride was decomposed by the careful addition of moist ether. After filtering the reaction mixture, the precipitate was washed with tetrahydrofuran and the washings added to the filtrate. The filtrate was treated with enough ether (50 ml.) to complete the separation of an aqueous layer which was removed, washed with ether, and the ether washings added to the original ether layer. The ethereal solution was dried with anhydrous sodium sulfate, the drying agent removed by filtration, and the solvent removed by distillation. The dry residue was then dissolved in ethyl acetate, filtered, and treated with methyl iodide (1 ml.). The methiodide salt which separated was filtered off and recrystallized from ethanol, m.p. 265–266°. The yield of product was 214 mg. (61.4% of theory) and failed to depress the melting point of authentic *N*-methylpavine methiodide.

Hydrolysis of Solubilized Esters

By P. B. SHETH* and E. L. PARROTT

The solubilizing ability of four nonionic surface-active agents is quantitatively compared. The critical micelle concentration (CMC) of the surface-active agents was evaluated from the solubility curves. The effect of the surface-active agents on the rate of hydrolysis of benzocaine and homatropine was investigated. At a concentration of surface-active agent less than the CMC, the surface-active agents do not significantly affect the rate of hydrolysis of the esters. At a concentration exceeding the CMC, the surface-active agents enhance the stability, due to micellar interaction.

THE PHENOMENON of micellar solubilization in aqueous systems and its applications to pharmaceuticals has received considerable attention (1–5). The nonionic surface-active agents have been most frequently used in the solubilization of drugs which possess a low water solubility (6, 7). Their use has been presumably due to their lower toxicity and irritation in comparison to ionic surface-active agents (8–10).

Studies of several readily oxidizable materials solubilized by ionic and nonionic surface-active agents have shown the solubilized preparation to be less easily oxidized than emulsions or simple aqueous dispersions (11–13). Riegelman reported that ionic and nonionic surface-active agents provide a different degree of protection from base hydrolysis (14).

This investigation was undertaken to determine the effectiveness of several nonionic surface-active agents in solubilizing and in retarding the alkaline hydrolysis of benzocaine and homatropine. As several mechanisms for increasing the stability of benzocaine to hydrolytic degradation have been studied, benzocaine was chosen for this investigation with the thought that a comparison with previous reports would be of interest (14–16). In pharmaceuticals, basic nitrogen-containing drugs, *i.e.*, amines and alkaloids, are generally used in the salt form in order to enhance the water solubility and/or stability of the drug. In product development it may occasionally be necessary to prepare a clear liquid pharmaceutical in a pH range at which these drugs exist in the base form. In such products the utilization of the phenomenon of micellar formation could possibly increase the apparent solubility and stability of the drug; to study this possibility homatropine was chosen.

EXPERIMENTAL

Materials—The surface-active agents were commercial lots which were used without further purification: polyoxyethylene lauryl ether[1] (PLE); oxyethylene polymer containing 80% polyoxyethylene[2] (POE), approximate mol. wt. 8700; a product formed by the addition of propylene oxide to ethylenediamine followed by the addition of ethylene oxide[3] (POEEO); a condensation product of *tert*-octylphenol with ethylene oxide[4] (OPEO), average mol. wt. 2800; homatropine;[5] and benzocaine N.F.

Solubility Studies—An excess of benzocaine and aqueous solutions of the surface-active agents were rotated in 50-ml. amber bottles in a constant-temperature bath at 30 ± 0.1° for 24 hr. A portion was withdrawn from each bottle with a pipet fitted with a cotton filter. After dilution with distilled water, the absorbance was measured with a Beckman DU spectrophotometer, and the solubility of the benzocaine was determined by means of a calibration curve.

In the analysis of samples containing surface-active agents, with the exception of OPEO solutions, water was used as a blank, since the samples were diluted at least 500-fold and there was no absorption by the surface-active agents. OPEO absorbs strongly in the region of 280 mμ near the maximum for benzocaine. In the assay of solutions containing OPEO, a blank of the OPEO solution, diluted in the same manner as the sample, was used to compensate for absorption by the surface-active agent.

The concentration of a surface-active agent at which micelles are formed is known as the critical micelle concentration. As shown in Figs. 1–4, the apparent solubility of benzocaine was plotted against the concentration of the surface-active agent. The inflection in the solubility curve indicates micelle formation (17).

Hydrolysis of Benzocaine—For studies in 3% POE, 75 ml. of an aqueous 4% POE solution was pipeted into a 6-oz. bottle containing 1 mg. of benzocaine in 5 ml. of solution. For studies in 0.005% POE, 5 ml. of an aqueous 0.1% POE solution was pipeted into a 6-oz. bottle containing 70 ml. of distilled water and 5 ml. of a solution containing 1 mg. of benzocaine. The solution was placed in a 30° constant-temperature bath, and

when thermal equilibrium was attained, 20 ml. of 0.2 *N* sodium hydroxide solution at 30° was added to give a 0.04 *N* hydroxyl ion concentration. At definite intervals of time, samples were withdrawn from the solution which was maintained at 30°. The absorbance of the sample was measured immediately at 284 and 265 mμ, and the concentration of benzocaine was determined by use of simultaneous equations obtained from standard absorption curves (14). With samples containing 3% POE, a blank of a solution of 3% POE and 0.04 *N* hydroxyl ion concentration was used; with samples containing 0.005% POE, a blank of a solution containing 0.005% POE and 0.04 *N* hydroxyl ion concentration was used.

The hydrolysis of benzocaine in water, PLE, and POEEO was followed in a similar manner. With OPEO, a direct ultraviolet method was not satisfactory due to strong absorbance of the surface-active agent at 284 mμ (6). A chloroform extraction procedure was used. The absorption maximum of benzocaine in chloroform was 279 mμ.

Hydrolysis of Homatropine—One hundred milligrams of homatropine was dissolved in 100 ml. of solvent medium, *i.e.*, water, 0.005 or 3% solution of surface-active agent, at 30°. The first 30-ml. sample was withdrawn, designated as the zero time, and analyzed for homatropine. The solution was maintained at 30°, and subsequent 10-ml. samples were withdrawn at definite intervals of time and were analyzed by the procedure of Patel and Lemberger (18).

RESULTS AND DISCUSSION

In dilute aqueous solutions in which the surface-active agent is molecularly dispersed, compounds of low water solubility, such as benzocaine, do not dissolve to a greater extent than they would in water; however, at concentrations of the surface-active agent in excess of the CMC, the apparent solubility is increased. When the CMC is exceeded, the apparent solubility of benzocaine is linearly dependent on the concentration of the surface-active agent. As shown in Figs. 1–4, the point of inflection in the solubility curve indicates the CMC.

The amount of benzocaine solubilized by micellar interaction is represented by the difference between the apparent solubility in a solution of a surface-active agent and the solubility of benzocaine in water. The difference between the concentration of the surface-active agent and its CMC represents the amount of surface-active agent in the micellar form. This relationship may be expressed by the equation:

$$S = S_0 + K\,(C_{\text{surfactant}} - C_{\text{CMC}}) \quad \text{(Eq. 1)}$$

in which S is the apparent solubility of a compound in the aqueous solution of a surface-active agent, S_0 is the solubility of the compound in water, $C_{\text{surfactant}}$ is the concentration of the surface-active agent, C_{CMC} is the critical micelle concentration, and K is a constant, *i.e.*, the slope of the solubility curve.

For the solubilization of benzocaine, the K values in Table I show the order of solubilizing ability of the surface-active agents to be OPEO > PLE > POEEO > POE.

The conditions of 30° and 0.04 *N* hydroxyl ion concentration for the hydrolysis of benzocaine were essentially the same as those used by previous investigators (14, 15). The initial concentration

	3.00	0.00238	291
OPEO	0.005	0.00908	76
	3.00	0.00234	295
POEEO	0.005	0.01012	69
	3.00	0.00644	107
POE	0.005	0.00989	70
	3.00	0.00759	91

of benzocaine was either 1 mg./100 ml. or 1 mg./ml. of solution. The hydrolysis of homatropine was carried out in distilled water at 30°. The experimental conditions for the hydrolysis of the esters produced an insignificant change in hydrogen ion concentration, and consequently the observed hydrolysis was pseudo first-order.

Hydrolysis of Benzocaine in the Presence of Nonionic Surface-Active Agents—The rate of hydrolysis of benzocaine was followed at 30° in the presence of four nonionic surface-active agents. As shown in Figs. 5 and 6, a plot of the logarithm of concentration of benzocaine against time is linear, designating a pseudo first-order reaction. The specific rate constant was determined by multiplying the slope of the curve by 2.303. As the hydrolysis is a pseudo first-order reaction, the half-life period was determined by dividing 0.693 by the specific rate constant (19). The specific rate constants and the half-life periods are given in Table II.

The alkaline hydrolysis was carried out in water and in a 0.005% solution of the surface-active agent, which was a concentration less than the CMC. A comparison of the half-life periods of benzocaine at 0.04 *N* hydroxyl ion concentration in water and in 0.005% surface-active agent shows that the surface-active agent *per se* does not significantly affect the stability. In Figs. 5 and 6 the points on the 0.005% curve are experimental values showing the rate of hydrolysis of benzocaine in the presence of 0.005% surface-active agent; the line upon which these points fall is drawn to show the rate of hydrolysis of benzocaine in water at 0.04 *N* hydroxyl ion concentration.

In 3% concentration of surface-active agents, the half-life periods were increased. For example, with PLE and OPEO the half-life of benzocaine was increased fourfold. As the surface-active agents exhibited no effect on the stability below their CMC, the increased stability at a concentration exceeding the CMC is attributed to micellar interaction.

This is further suggested by the stability of benzocaine in other surface-active agents. POE, which forms micelles of a low aggregation number, would theoretically provide less opportunity for micellar interaction with benzocaine; therefore, it would only slightly increase the stability of benzocaine. The experimental results concur, as the half-life of benzocaine in the presence of 3% POE is increased only 30%.

Hydrolysis of Homatropine in the Presence of Nonionic Surface-Active Agents—The rate of hydrolysis of homatropine was followed at 30° in the presence of four nonionic surface-active agents. As shown in Figs. 7 and 8 the rate of hydrolysis is first order with respect to homatropine. The observed specific rate constants and the half-life periods are given in Table III.

When the hydrolysis was carried out at a concentration of 0.005% surface-active agent, the rate of degradation was the same as that in distilled water. In Figs. 7 and 8, the points on the 0.005% curve are experimental values showing the rate of hydrolysis of homatropine in the presence of 0.005% surface-active agent; the line upon which these points fall is drawn to show the rate of hydrolysis of homatropine in water.

In 3% concentrations of OPEO and PLE, the half-life periods were increased approximately twofold. In 3% concentrations of POE and

POEEO, the half-life periods are increased approximately 60%.

It has been suggested that solubilization occurs by (*a*) solution of the solubilizate within the interior of the micelle, (*b*) adsorption on the surface of the micelle, and (*c*) penetration into the palisade layer of the micelle (14). When a nonpolar compound is solubilized within the lipophilic interior of the micelle, the system is presumably more stable because the attacking species cannot readily contact the solubilized compound. If a compound is solubilized by penetration into the palisade layer of the micelle, it is generally susceptible to attack and degradation, although to a lesser extent than a compound solubilized by surface adsorption on the micelle.

In comparing the effect of the nonionic surface-active agents on the hydrolysis of benzocaine and homatropine, the greater stabilization of benzocaine may be attributed to the deeper penetration of the less polar benzocaine into the palisade layer of the micelles. The more polar homatropine only superficially penetrates the palisade layer, or is adsorbed onto the surface of the micelle; thus, homatropine is exposed to the hydroxyl ions and its stability is not markedly enhanced by solubilization.

A comparison of the effect of the four nonionic surface-active agents on the solubilization and the stability of benzocaine, as given in Table I, indicates that the stability increase by solubilization reflects the solubilizing ability of the surface-active agent. PLE and OPEO have the same solubilizing ability, and at 3% concentration both increase the half-life of benzocaine approximately fourfold. POE, which has the least solubilizing ability, only slightly increases the half-life of benzocaine. POEEO is intermediate in its solubilizing ability and enhancement of stability.

The limited solubilization of benzocaine by POE mirrors its low aggregation number and limited incorporation of benzocaine in the micelle. POE does not appreciably retard the hydrolysis of benzocaine, which is adsorbed on the surface of the micelle and is exposed to the attacking hydroxyl ions.

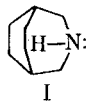
Potential Anti-Infective Agents I

Quinoline, Phenolic, and β-Aminoketone Derivatives

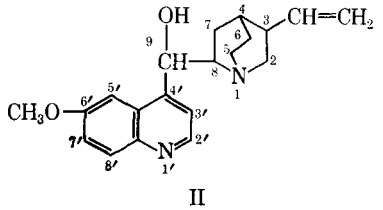
By ROBERT ARMEN MAGARIAN* and W. LEWIS NOBLES

Mannich bases were prepared from quinolinols, isoquinolinols, phenols, biphenols, and ketones in order to have their antimicrobial properties evaluated.

THE USE OF 3-azabicyclo[3.2.2]nonane (I), also known as AZBN, in the Mannich reaction was reported by Blanton and Nobles in 1962 (1). In biological screening, some of these Mannich bases were found to possess marked antimicrobial activity (2). As an extension of this study, AZBN, along with other bicyclic and heterocyclic amines, was condensed with moieties of known anti-infective agents utilizing the Mannich reaction (3) in order to study their antimicrobial properties, *i.e.*, antimalarial, antiamebic, and related effects. Quinine (II), a quinolylcarbinolamine containing a methoxy group on the quinoline nucleus linked by a secondary carbinol to a quinuclidine ring bearing a vinyl group, is an antimalarial that has been utilized since the year 1630 (4). This structure (II) served to provide the fountainhead of ideas for this work when a search of the literature revealed that many known anti-infectives have resulted from condensation of quinoline and phenolic compounds with aminomethyl moieties. Since AZBN is a bicyclic amine, it is conceivable that this amine can be useful—along with other bicyclic and heterocyclic amines—in place of the quinuclidine moiety in quinine. With this in mind, a number of substituted phenols and compounds structurally related to quinine were synthesized; more specifically, the products were prepared by the condensation of quinolinols, isoquinolinols, phenols, biphenols, and ketones with 37% aqueous formaldehyde (formalin), and cyclic amines.



I



II

Quinine (6′-methoxy-3-vinyl-9-rubanol)

DISCUSSION

The *o*- and *p*-hydrogens in phenols are sufficiently active to react in the Mannich reaction (5). From 8-quinolinol and 5-isoquinolinol (Table I), mono- and disubstituted products are expected, while only a mono-substituted product is obtainable with 5-chloro-8-quinolinol. Bruson (6), Burckhalter and associates (7), and Burke (8) have carried out Mannich reactions with phenols in which an *ortho* or *para* position was blocked by a chloro or bromo group. From the reaction of equimolar amounts of 2-phenylphenol, formaldehyde, and diethylamine, Burckhalter (9) was able to prove that the Mannich condensation takes place preferentially in the *ortho* position as compared to the *para* position.

It is interesting to note that the disubstituted Mannich product of 8-quinolinol (compound *2*, Table I) was not obtainable when 8-quinolinol was refluxed in absolute ethanol with 2 moles each of formaldehyde and AZBN. This disubstituted compound could only be obtained when equimolar amounts of formaldehyde and AZBN were reacted with the monosubstituted Mannich product III in absolute ethanol.

The solubility of aminomethylphenols in dilute alkali has served also as an aid in the confirmation of structure. Burckhalter and co-workers (7, 9), reported that 4-phenyl, 4-alkyl, or 4-halo-substituted 2-(dialkylaminomethyl) phenols are insoluble in 5% sodium hydroxide solution at room temperature, whereas the isomeric and analogous 4-(dialkylaminomethyl) phenols are soluble. The work of Julia and Tchernoff (10) is in agreement with that of Burckhalter and associates. They concluded that solubility in alkali apparently depends on the position of the amino group; the phenolic properties of the compound are possibly masked by the amino groups.

Millon's test has been utilized to identify an unsubstituted *ortho* position in phenolic derivatives (9). This test is used with monohydroxy phenols, tyrosine, tyrosine-containing proteins, phenolic acids, and other compounds that have a phenolic group with an open *ortho* position (11). The procedure involves the addition of 50 mg. of the phenolic derivative to 1 ml. of Millon's reagent. The test tube is placed in a beaker of water and heated to boiling. A red color indicates an open *ortho* position. (See Table II.)

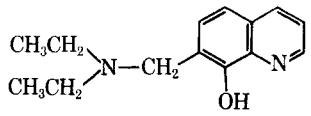
8-Quinolinols have been found to be effective against bacteria (12, 13), and considerable evidence points to direct antiamebic activity by compounds of this type (13). One such compound is shown in structure III (14).

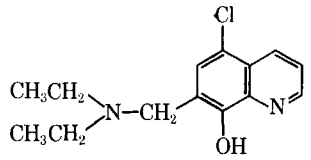
Various 7-(mono- and di-alkylaminomethyl)-8-quinolinols have also been prepared and evaluated by others as amebicides in the hope that the introduction of this solubilizing group would confer promising activity against amebic hepatitis (13–19). Although this new type of 8-quinolinol conferred only partial suppression of the hepatic lesion in hamsters (13), the activity of many of these compounds *in vitro* and in experimental intestinal amebiasis is equivalent to or exceeds that of the clinically-used iodinated 8-quinolinols (13, 18). One of the most promising members of this series is 5-chloro-7-diethylaminomethyl-8-quinolinol (IV) which was synthesized by Burckhalter and co-workers (14) and was found to be effective in human intestinal amebiasis (13).

There is a possibility that such derivatives could also be antifungal, since quinoline derivatives frequently possess such a property. This fact led to the preparation of the compounds in Table I. The effectiveness of diallylbiphenols, biphenols, and phenolic derivatives as medicinal agents was established by Burckhalter (7) when he found that certain α-dialkylamino-*o*-cresols (V, VI) possessed antimalarial activity. This work aroused interest in the synthesis of derivatives using various amine components along with the phenolic-types mentioned above in the Mannich reaction.

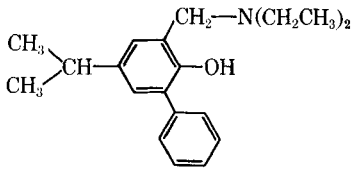
The products shown in Tables III, IV, V, and VI possibly offer the basis for a good study in structure–activity relationship, since they can be viewed as compounds that resemble 2,2′-diallyl-4,4′-biphenol (VII) with or without all the functional groups. The antibacterial activity of the Mannich bases derived from *p*-nitroacetophenone (20) led to the preparation of four β-aminoketones (Table VII) to be tested for possible anti-infective activity.



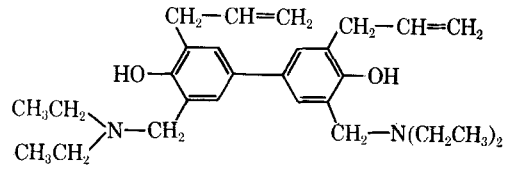
III



IV



V



VI

Also, there was interest in seeing what activity the 3-azaspiro[5.5]undecane may possess, since Grogan (21) and co-workers have prepared a number of different azaspirane derivatives that were found to be of interest in medicinal chemistry.

and Nobles (1) was essentially followed, except that 37% aqueous formaldehyde (formalin) was employed rather than paraformaldehyde and the amine hydrochloride was used only in the synthesis of the β-aminoketones. The starting materials were available commercially.[1]

RESULTS AND DISCUSSION

Conclusions regarding the reactants used were drawn from this study based on the reaction conditions employed. The phenolic and quinolinolic derivatives reacted with facility when the free amine was used; however, Mannich products were virtually impossible to obtain when the amine hydrochloride was used. For example, 4,4′-biphenol and 3-azabicyclo[3.2.1]octane hydrochloride were refluxed together with 37% aqueous formaldehyde; instead of isolating the Mannich product, the starting materials were obtained. The results were similar with 4-phenylphenol. Conversely, the Mannich ketones were relatively easy to obtain when the amine hydrochloride was used. If the free base were used, however, the ketonic product was not isolated; when AZBN, as the free base, was refluxed with *p*-nitroacetophenone and formalin, a novel di-substituted substance was isolated (22).

Aqueous formaldehyde (37%) was employed in all reactions and it was found to be as effective as paraformaldehyde; the latter appears more often in the literature when the Mannich reaction is discussed. The reason that paraformaldehyde is used more often may be attributed to its use with organic solvents, whereas a condensation reaction involving 37% aqueous formaldehyde is ordinarily carried out by shaking or stirring the reactants in the absence of an organic solvent (3). When aqueous formaldehyde was used with 2-allyl-4-methylphenol and 1-(*p*-chlorophenyl)-2-methylpiperazine in only 10 ml. of absolute ethanol as solvent, the desired Mannich base was not isolated in spite of shaking, stirring, and finally refluxing for 2.5 hr. Instead, a bis-amine (VIII) was isolated as the product. The white crystalline solid was thus obtained in 70% yield and had a melting point of 162–164° (corrected). Recrystallization from acetone–water resulted in a product melting at 164–166° (corrected). The conclusion that the product was a bis-amine was based on elemental analyses and infrared spectral data. The following analytical values were obtained.

Anal.—Calcd. for CHN: C, 63.79; H, 6.98; N, 12.93. Found: C, 63.94; H, 6.91; N, 12.12.

It is not uncommon to find bis-amines as products in the Mannich reaction (3). Other bis-type Mannich products have also been reported. The isolation of a methylene-bis-indanedione (IX) involving indanedione, amine, and formaldehyde has been accomplished in this laboratory by Blanton, Magarian, and Varma with secondary amines of varying strength (23). Also, Sam and Thompson (24) isolated a methylene-bis-thiaindanone (X).

Absolute ethanol was employed in all the reactions with aqueous formaldehyde, and the latter did not appear to encumber the reaction. Also paraformaldehyde is normally used in the synthesis of ketonic Mannich bases (Table VII); however, aqueous formaldehyde was used and the yields were relatively good.

The Mannich products in most cases were easy to obtain, but, in nearly all instances exclusive of the ketonic Mannich bases, the products were difficult to recrystallize. Perhaps this could be attributed to a complex mixture of many products. In some cases, the reaction products (compounds *15* and *17*) obtained from these phenolic compounds were difficult to crystallize. They were dissolved in ethyl ether and extracted with 10% aqueous hydrochloric acid solution. The aqueous solution was neutralized with 10% sodium carbonate solution which was then extracted with ethyl ether and the extract dried over anhydrous magnesium sulfate. The drying agent was removed by filtration and anhydrous hydrogen chloride was bubbled through the anhydrous ether solution to yield a solid. In other instances (compound *19*), 20% aqueous hydrochloric acid provided the right environment to form

[1] The biphenol, 2,2′-diallyl-4,4′-biphenol, was supplied through the courtesy of Dow Chemical Co., Midland, Mich., and the amine, 3-azabicyclo[3.2.1]octane hydrochloride, was prepared by N. D. Potti of this laboratory.

a crystalline hydrochloride from a sticky residue. In another situation a viscous residue (compound *23*) was dissolved in ethyl ether and anhydrous hydrogen chloride bubbled through the solution. This precipitated an oil that crystallized from acetone when placed in the refrigerator overnight.

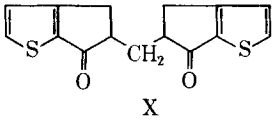
IX



X

evaporator and the product was recrystallized from absolute ethanol. The reactions proceeded smoothly and the yields were consistently good. These Mannich products were easy to recrystallize in comparison with the phenolic derivatives.

Although the condensations in the Mannich reaction proceed much faster in the higher-boiling solvents, and the formation of certain by-products, obtained by prolonged heating in ethanol, is avoided (3), it is believed that the condensation in ethanol is less subject to side reactions associated with the instability of the aminoketone salts at the higher temperatures (25). The time required for a Mannich reaction depends, among other things, upon the nature of the starting materials and upon the boiling point of the solvent (3); it was found that these reactions in absolute ethanolic solution yielded the desired products after the mixtures had been refluxed for 2–3 hr. An increase in reflux time was of no avail in producing better yields.

Biological Evaluation—When the results of the antibacterial screening tests are available, they will be presented in connection with a subsequent article in this series.

Antibacterial and Antifungal Properties of β-Naphthol Derivatives VI

By M. L. KHORANA*, S. Y. PANDIT†, and A. D. PISHAWIKAR‡

The bacteriostatic and fungistatic activities of a number of β-naphthol, 2-hydroxy-6-naphthoic acid, and 2-hydroxy-3-naphthoic acid derivatives are reported against *Staphylococcus aureus, Salmonella typhosa,* and *Aspergillus niger.* Selected compounds from the initial screening have been further tested for their activity against *Staphylococcus albus, Salmonella paratyphi* A, *S. paratyphi* B, *Escherichia coli, Shigella dysenteriae, Trichophyton rubrum, Trichophyton gypseum, Candida albicans,* and *Candida tropicalis.* Few compounds exhibited activity against the selected Gram-negative organisms at concentrations below 50 mcg./ml. For *S. aureus* and *S. albus,* the bacteriostatic concentrations of 6-alkyl-, 3-alkyl-, and 1,6-dialkyl-β-naphthols, esters of 2-hydroxy-6-naphthoic acid, and substituted anilides of 1,6-dibromo-, 1-nitro-, and 1-nitro-6-bromo-2-hydroxy-3-naphthoic acid are between 1 and 10 mcg./ml. Marked inhibition of the few fungus pathogens tested is shown by 3-propyl, 3-butyl, 1-methyl-6-ethyl-, 1-methyl-6-propyl- and 1,6-diethyl-β-naphthol, and alkyl esters of 2-hydroxy-6-naphthoic acid.

ANTI-INFECTIVE ACTIVITY of a number of β-naphthol derivatives has been reported previously (1–5) from this laboratory. As a further extension of this work another 200 derivatives have been prepared and tested. The syntheses of these compounds have already been published (6–11).

In the preliminary screening all the compounds were tested against *S. aureus*, *S. typhosa*, and *A. niger*. Various derivatives of 3-keto- (9), 6-keto- β-naphthols (7), 6-naphthyl-alkyl acids (8, 11), dinaphthols (7), *etc.*, are not included in this publication as they showed little activity in the screening.

EXPERIMENTAL

Bacteriostatic Activity

The serial broth dilution method of McKee, Rake, and Menzel (12) was followed, using the organisms *S. aureus* (FDA 209) and *S. typhosa* (Lister). Different concentrations of the test compounds were prepared by adding the requisite quantities of alcoholic (95%) stock solutions to double strength broth to make up the volume to 5 ml. Stock solutions were so prepared that in no case did the quantity of the alcoholic solution added to broth exceed 0.1 ml. A similar quantity of alcohol alone added to the broth did not show bacteriostasis. The results were observed after incubation at 37° for 24 hr. and further confirmed after 48 hr. The minimum inhibition concentrations, in mcg./ml., are recorded in Table I.

Fungistatic Activity

Screening for fungistatic activity against *A. niger* was done following the agar cup-plate (13) as well as the agar-streak (14) methods. The results of the former method gave an idea of the power of diffusion of the substances; that of the latter gave the minimum inhibition concentrations.

Agar Cup-Plate Method (13)—One per cent alcoholic solutions of the compounds were added to prepared cups and the plates were incubated for 48 hr. at 25–27°. The average diameters of the zones of complete inhibition have been recorded in Table I. Alcohol alone gave no zone of inhibition.

Agar Streak Method (14)—Spore suspensions of test organisms were streaked on Sabouraud's agar plates containing the test substances in concentrations of 200, 100, 50, 10, and 5 mcg./ml. Control plates containing alcohol exhibited no inhibition. Results were noted after incubation for 5 days at 25–27° and these have been recorded in Table I.

Antimicrobial Spectra—Compounds which were fairly active in the preliminary screening were next tested against organisms such as *S. aureus, S. albus, S. typhosa, S. paratyphi* A, *S. paratyphi* B, *S. dysenteriae,* and *E. coli.* The results of these tests are presented in Table II.

Similarly, the antifungal activity of these compounds was determined against *T. rubrum* and *T. gypseum* by the agar-streak method, and against *C. tropicalis* and three strains of *C. albicans* by both the serial broth dilution and the agar-streak methods. The methods used were essentially the same as described above except that Sabouraud's glucose broth and glucose agar were used as the culture media.

DISCUSSION

Alkylation increases the bacteriostatic activity of β-naphthol. Compared to 6-alkyl derivatives reported in a previous publication (4), the corresponding 1,6-dialkyl derivatives now tested are more active. The lower members of 1,6-dialkyl derivatives, such as 1-methyl-6-ethyl-, 1,6-diethyl-, and

[a] Minimum inhibition concentration (MIC) in mcg./ml. [b] Average diameter of zone of inhibition in mm. with 1% w/v solution. [c] MIC more than 200 mcg./ml. [d] No zone of inhibition. [e] Not tested.

1-ethyl-6-propyl-β-naphthol (compounds *13*, *18*, *19*) are active against all the microorganisms tested, while the higher homologs, such as 1-methyl-6-hexyl-, 1-ethyl-6-pentyl-, and 1-ethyl-6-hexyl-β-naphthol (compounds *17*, *21*, *22*) show specific activity against *S. aureus* and *S. albus* only. The position of the alkyl group has a marked influence. The 3-alkyl derivatives possess activity against a wider microbial spectra than the 1-alkyl-, 6-alkyl-, or 1,6-dialkyl derivatives. Of all the alkyl derivatives screened, 3-butyl-β-naphthol (compound *8*), is the most active compound.

Introduction of bromine in 6-alkyl-β-naphthols shows variable effects. The activity increases as the chain-length is increased to butyl (compound *25*) and then drops down. In general, bromination does not appear to enhance considerably the antimicrobial activity of the parent alkyl compounds.

Conversion of β-naphthol to alkyl ethers has been reported (4) to depress the activity. However, the ethers of 1-alkyl-β-naphthols now tested show enhanced activity especially against *S. aureus* and *S. albus* (compounds *29*, *30*, *31*).

All the ketonaphthols, their methyl ethers, and bromo derivatives tested show poor activity; the only exception is 3-propionyl-2-methoxy-naphthalene (compound *32*) and this compound is bacteriostatic at a concentration of 5 mcg./ml. against *S. aureus* and *S. albus* and some Gram-negative organisms.

2-Hydroxy-3-naphthaldehyde (compound *33*) is much more active than 2-naphthol, itself, against the few Gram-positive and Gram-negative organisms tested. However, introduction of an additional nitro group, conversion of the aldehydes to anils or chalkones depresses the activity considerably.

Introduction of a carboxyl group in β-naphthol has been reported (3) to reduce its bacteriostatic activity. The activity of 1-methyl-2-naphthol (compound *9*) is similarly reduced by the introduction of a carboxyl group (compound *56*). However, esterification of the carboxyl group appears to enhance the antimicrobial activity. Among the straight-chain alkyl esters of 2-hydroxy-6-naphthoic acid studied, the bacteriostatic activity increases until the propyl (compound *41*) derivative is reached, and then it drops. The branched-chain esters are as active as the straight-chain esters against *S. aureus* and *S. albus* (Table II).

The anilides of 2-hydroxy-3-naphthoic acid have been reported (4) to be bacteriostatic at low concentrations against Gram-positive organisms. Various substituted anilides of 1,6-dibromo-, 1-nitro-, and 1-nitro-6-bromo-2-hydroxy-3-naphthoic acids, now studied, exhibit marked activity against *S. aureus* and *S. albus*. The activity varies considerably with the position and nature of the substituent on the aniline ring; in general, the *para*-substituted

18	20	50	50	50	50	5	[c]
19	50	50	50	20	50	5	[c]

[a] Minimum inhibition concentration (MIC) in mcg./ml. [b] Numbers refer to compounds listed in Table I. [c] MIC more than 50 mcg./ml.

derivatives show the highest and the *ortho*-substituted ones the lowest activity. Of the *para*-substituted compounds, the chloro and nitro derivatives (compounds *61*, *62*, *71*) are bacteriostatic at 1 mcg./ml.

Table II, which records the activity of the selected compounds against some other microorganisms, shows that while very few compounds are bacteriostatic against the four Gram-negative microorganisms used for the study below the concentration of 20 mcg./ml., several of them are active against *S. aureus* and *S. albus* at fairly low concentrations. The specificity of activity shown by the alkyl derivatives is noteworthy and further data on these compounds will be reported separately.

The fungistatic activity reported in Table I indicates that as the length of the alkyl chain in alkyl naphthols increases, the zone of inhibition against *A. niger* first increases and then decreases, the ethyl derivatives being the most active.

Of the dialkyl derivatives, 1-methyl-6-ethyl-, 1-methyl-6-propyl-, and 1,6-diethyl-β-naphthol (compounds *13*, *14*, *18*) exhibit good activity against *A. niger* and a few other fungi. Of the esters of 2-hydroxy-6-naphthoic acid, the methyl ester (compound *39*) shows the highest activity and the

ethyl and propyl esters (compounds *40*, *41*) come next. However, in general they have lower fungistatic activity than the alkyl naphthols.

Comparing the activities against all the fungi included in the tests (Table III), it is observed that while compounds *8* and *14*, 3-butyl- and 1-methyl-6-propyl-β-naphthol, are fungistatic at 20 mcg./ml., all others are fungistatic only at 50 mcg./ml.

Effects of Adrenochrome Semicarbazone on Blood Loss in the Mouse

By JACK H. KEITH, WILLIAM W. KEITH, and MARY H. NELSON

A method for determining the blood loss and bleeding time of a standardized wound is described, and it is applied in examining the activities of a clinically-used hemostatic agent—adrenochrome semicarbazone. It is shown that adrenochrome semicarbazone has an effect in decreasing blood loss at doses as low as 0.1 mg./Kg., and is effective in the presence of anticoagulants. A mechanism of action is suggested.

THE DIFFICULTY in showing a decrease in blood loss, clinically or experimentally, is apparent when one attempts to produce a standard wound. Variations of up to 1000% may occur on the same animal with the same size wound.

Roskam (1) measured blood loss from rabbit ears, achieving reproducible results, but the authors found that his method gave insufficient information. The major deficiency in his procedure was the measurement of bleeding times rather than blood loss. Blood loss was assumed to parallel bleeding time, and the authors have found that this is not always true.

After many attempts at determining blood loss, with and without adrenochrome semicarbazone, it was found that blood loss could be most accurately and reproducibly measured in mice. The clipping of 1.5 cm. from the tips of the tails of animals of the same size and sex gives an easily measurable method of determining blood loss.

The mouse tail was used because the vessels are large enough to produce a bleeding condition that could be classified as traumatic hemorrhage. The major vessels in the mouse tail vary from 0.05 mm. to 0.25 mm. in diameter. During the peak period of hemorrhage, the first 30 sec., the blood loss may be as great as 0.2 ml., which would represent 10% of total blood volume.

This paper concerns the effect of adrenochrome semicarbazone upon initial blood loss from the clipped tail of the mouse, and an indication of its mechanism of action. We emphasize the term "initial blood loss," since anticoagulant-treated animals stop bleeding only for a short period, and then begin again.

METHOD

Determination of Blood Loss and Bleeding Time—Male mice[1] weighing 18–22 Gm. were used. The tail was severed 1.5 cm. from the tip with a frequently changed razor blade to ensure keenness. The animals were placed in a holder at least 5 min. before cutting. This holder consisted of a plastic vial 1 in. × 2.5 in. (Fig. 1) with holes for ventilation. In some of the experiments the tails were bled into a beaker containing 100 ml. of deionized water at 37°; 3–5 mice were bled into the same 100 ml. of water containing disodium ethylendiaminetetraacetate, 2 mg./100 ml., as an anticoagulant. The tail was observed until bleeding stopped and was then removed immediately from the water. The

Effects of Adrenochrome Semicarbazone on Blood Loss in the Mouse

By JACK H. KEITH, WILLIAM W. KEITH, and MARY H. NELSON

A method for determining the blood loss and bleeding time of a standardized wound is described, and it is applied in examining the activities of a clinically-used hemostatic agent—adrenochrome semicarbazone. It is shown that adrenochrome semicarbazone has an effect in decreasing blood loss at doses as low as 0.1 mg./Kg., and is effective in the presence of anticoagulants. A mechanism of action is suggested.

THE DIFFICULTY in showing a decrease in blood loss, clinically or experimentally, is apparent when one attempts to produce a standard wound. Variations of up to 1000% may occur on the same animal with the same size wound.

Roskam (1) measured blood loss from rabbit ears, achieving reproducible results, but the authors found that his method gave insufficient information. The major deficiency in his procedure was the measurement of bleeding times rather than blood loss. Blood loss was assumed to parallel bleeding time, and the authors have found that this is not always true.

After many attempts at determining blood loss, with and without adrenochrome semicarbazone, it was found that blood loss could be most accurately and reproducibly measured in mice. The clipping of 1.5 cm. from the tips of the tails of animals of the same size and sex gives an easily measurable method of determining blood loss.

The mouse tail was used because the vessels are large enough to produce a bleeding condition that could be classified as traumatic hemorrhage. The major vessels in the mouse tail vary from 0.05 mm. to 0.25 mm. in diameter. During the peak period of hemorrhage, the first 30 sec., the blood loss may be as great as 0.2 ml., which would represent 10% of total blood volume.

This paper concerns the effect of adrenochrome semicarbazone upon initial blood loss from the clipped tail of the mouse, and an indication of its mechanism of action. We emphasize the term "initial blood loss," since anticoagulant-treated animals stop bleeding only for a short period, and then begin again.

METHOD

Determination of Blood Loss and Bleeding Time—Male mice[1] weighing 18–22 Gm. were used. The tail was severed 1.5 cm. from the tip with a frequently changed razor blade to ensure keenness. The animals were placed in a holder at least 5 min. before cutting. This holder consisted of a plastic vial 1 in. × 2.5 in. (Fig. 1) with holes for ventilation. In some of the experiments the tails were bled into a beaker containing 100 ml. of deionized water at 37°; 3–5 mice were bled into the same 100 ml. of water containing disodium ethylendiaminetetraacetate, 2 mg./100 ml., as an anticoagulant. The tail was observed until bleeding stopped and was then removed immediately from the water. The

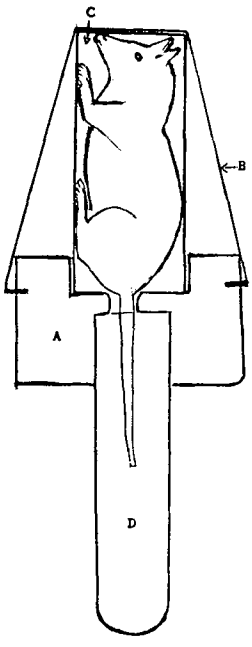

Fig. 1—Holder and tube arrangement for bleeding-time determinations. Key: A, Plexiglas block 5.5 cm.² and 3 cm. thick. When used with a 100-ml. beaker the block is 1.5 cm. thick; B, wire holder, 19 mm. for test tube and 29 mm. for mouse holder; C, plastic vial, 64 mm. × 28 mm.; D, 25-ml. test tube.

dose response experiment varied from this procedure in that the tail was left in the water for 3 min. After bleeding, 1 ml. of concentrated hydrochloric acid was added to the beaker to change the hemoglobin to acid hematin for quantitative measurement. The blood loss was determined from a curve made from a pooled sample of known quantities of blood which was read at 540 mμ on a Bausch & Lomb spectrophotometer (Spectronic 20).

In some of these tests a 25-ml. tube was used in place of the 100-ml. beaker, and only one mouse was bled into each 25 ml. of water.

The mean values in all tests were compared, using the Fisher *t* test for significance (2).

Dose Response—The drug was administered subcutaneously at 0.1, 1, and 5 mg./Kg. Fifteen minutes were allowed for drug action. The mouse tail remained in the water for 3 min.

Adrenochrome Semicarbazone and Heparin Administration—The mice were given 6 mg./Kg. sodium heparin intraperitoneally (119 units/mg.) and 30 min. was allowed for drug action. Adrenochrome semicarbazone was used at a 5 mg./Kg. dosage subcutaneously, allowing 30 min. for drug action.

Adrenochrome Semicarbazone and Bishydroxycoumarin Administration—The effects of bishydroxycoumarin in mice were investigated by administering the drug orally or intraperitoneally daily for 2 to 8 days. One group (A) was given the bishydroxycoumarin in the diet at a level of 0.015% for 8 days. In two of the groups (B), bishydroxycoumarin was given intraperitoneally, 20 mg./Kg. at 0 hr. and 10 mg./Kg. at 24 hr. The mice were bled 24 hr. after the second dose. In three other groups (C), a 10-mg. dose intraperitoneally was given at 0, 24, and 48 hr.; the mice were bled at 72 hr. Adrenochrome semicarbazone, 0.5 mg./ml., was added to the drinking water and 3 mg./Kg. was injected subcutaneously 30 min. before bleeding.

Each group—controls, bishydroxycoumarin, and bishydroxycoumarin–adrenochrome semicarbazone—contained 21 mice. Three mice were bled into the same 100 ml. of water.

Adenosine Diphosphate and Adenosine Administration—These drugs were given at 1 and 30 mg./Kg. intraperitoneally in 2% gelatin solution. Thirty minutes was allowed for drug action. Forty animals were used at each dosage level and compared with 40 controls receiving an equal volume of 2% gelatin solution.

Bishydroxycoumarin Toxicity—One hundred male mice, 22–25 Gm., were given their normal diet *ad libitum* with bishydroxycoumarin 80 mg./100 Gm. of food. Another group of 100 mice received bishydroxycoumarin, 80 mg., and adrenochrome semicarbazone, 60 mg./100 Gm. of food. The number of deaths were recorded daily for 8 days. The drug was removed from the food on the 6th day. These animals were caged in groups of 10. (See Table IV.)

In another test the mice were caged individually and fed the regular diet plus bishydroxycoumarin, 35 mg./100 Gm. of food. One group was given adrenochrome semicarbazone at a level of 20 mg./100 Gm. of food. The drugs were administered for 12 days. Each of the two groups contained 75 animals. (See Table V.)

The daily accumulative deaths were graphed using the Litchfield–Wilcoxon (3) method to analyze the LD effects for possible difference. The day of death rather than the drug consumption was used as the abscissa. The LD_{50} is based on the number of days after beginning drug administration.

Heparin Toxicity—Male mice, 22–25 Gm., were injected with adrenochrome semicarbazone subcutaneously, 5 mg./Kg. in a volume of 0.5 ml./100 Gm. body weight. The adrenochrome semicarbazone was given 5–10 min. before intravenous administration of sodium heparin. The tails were cut with a razor blade 2.5–3 cm. from the base immediately after the injection of the heparin. Those animals given only heparin were given a volume of physiological saline, 0.5 ml./100 Gm., subcutaneously. The sodium heparin was dissolved in 0.85% sodium chloride solution and administered at a volume of 1 ml./100 Gm. of body weight. The dosage levels of heparin were 500, 1000, 1500, 2000, and 3000 units/Kg. The animals, in groups of 10, were placed in plastic boxes 5 × 6 × 10 in. with shavings on the floor. The results were graphed, and the Litchfield-Wilcoxon (3) method of comparison was used to determine significance of difference in the two treatments.

RESULTS AND DISCUSSION

The end point in these experiments is easily determined, but accounting for the wide variations in blood loss is a complex, unsolved problem. The day-by-day differences in groups often reaches a multiple of three in treated and untreated alike.

Dose Response—Table I shows a dose response obtained with adrenochrome semicarbazone as seen in the mouse tail experiment. To make this test more objective, the blood from each mouse was collected for a period of 3 min. at which time the

tail was removed from the water. The 3-min. time period is considerably longer than the normal bleeding time. The dosage of 0.1 mg./Kg. is in the same range as that used clinically.

With a drop in blood loss of 45% at 0.1 mg./Kg., it might be concluded that a lower dose would have effected a dose response. Constantinescu (4) *et al.* have found activity at much lower doses in rats. They compared blood loss from the tail in anesthetized rats, 6 groups of 40 each, and found a 64% reduction in blood loss at 5 mcg./Kg. adrenochrome semicarbazone.

Heparin—Table II shows that adrenochrome semicarbazone decreases blood loss in heparin-treated mice. Bleeding time is significantly increased by heparin, but the initial blood loss is less than that of the controls. The blood pressure is lowered by doses of heparin larger than those used in this experiment, which in itself will reduce initial blood flow. The authors have observed in previous experiments that a dose of 25 mg./Kg. of heparin will cause initial blood loss to fall to a very low level. Care was exercised in all the experiments to rule out an effect due to a drop in blood pressure. Mice given 6 mg./Kg. doses of heparin occasionally bleed to death after the tail is severed. The blood stops flowing, but a clot does not form and the bleeding resumes. If the tail is observed for long periods, there are numerous periods of spontaneous bleeding. Although there is a decrease in the initial blood loss, the LD_{50} of heparin in mice is not changed when adrenochrome semicarbazone is administered. In addition to the anticoagulant effect of heparin, which exceeds 1 hr. in these experiments, Zucker (5) and Solandt and Best (6) have shown that the activity of platelets is greatly decreased.

To determine an LD_{50} with heparin, a standard wound is produced by severing the tail 2.5–3 cm. from the base. Those animals that succumb do so in a period of 2–12 hr. The wound greatly reduces the amount of heparin necessary for a lethal dose. The authors had previously noted that doses of heparin, 4000–12,000 units/Kg., do not produce death, but often a semishock state is produced. In many mice there is a massive fluid exudate in the peritoneal cavity. Because of this fluid loss, the dosage was kept below 4000 units/Kg. and a trauma severe enough to cause death was used.

The LD_{50} for the heparin–adrenochrome combination was 1150 units/Kg., and 1400 units/Kg. for the heparin only group. (See Table III.) The difference of 350 units/Kg. in toxicity was not significant at the 95% confidence limits.

Bishydroxycoumarin—When bleeding time and blood loss is examined in groups of mice given bishydroxycoumarin and adrenochrome semicarbazone (Table VI), there is a significant decrease in blood loss in these animals as compared with bishydroxycoumarin-treated animals, with the bleeding time returned to normal. An exception was noted in group A: some of these animals had died and the remainder were in severely hemorrhagic condition. Hemorrhagic areas were present around the shoulders and testicles, and in the peritoneal cavity. The bleeding time increased significantly with bishydroxycoumarin, but blood loss did not reflect this increase. The results seen here with bishydroxycoumarin agree with those seen by Chen and Tsai (7). They state that in their animals (frogs and rabbits) given bishydroxycoumarin the initial bleeding was stopped by vasoconstriction, but bleeding started again when the constricted vessels relaxed. Without intervention death often resulted.

As indicated in Tables II and III, the failure of bishydroxycoumarin and heparin to increase the initial blood loss is a convincing demonstration of the importance of factors other than clotting mechanisms in the initial retardation of blood flow.

The ability of adrenochrome semicarbazone to reduce initial blood loss in heparin- or bishydroxycoumarin-treated animals clearly indicates activity in the absence of effective clotting components.

[a] Number of days of drug administration. [b] Accumulative per cent deaths.

The toxicity of bishydroxycoumarin requires several days to be manifest. (See Tables IV and V.) Thus the drug was administered in the diet. Food consumption was normal the first 3 days with a sharp drop after that. There was no difference in quantity of food consumed by the 2 groups. The animals receiving bishydroxycoumarin, 35 mg./100 Gm. of food, were not less affected than those given 80 mg./100 Gm. of food. This was not expected, since the animals at 35 mg. were caged individually. The authors anticipated that individual contact would intensify hemorrhage, causing a more rapid death. It may be that grouping together helps the animals to maintain normal temperature. The time required for bishydroxycoumarin to produce death in 50% of the mice was not reduced by adrenochrome semicarbazone.

Since adrenochrome semicarbazone fails to reduce mortality in heparin- or bishydroxycoumarin-treated animals, the activity would have to be other than an antiheparin or increased coagulation effect. The mechanism left to consider would be an effect on increasing the efficiency of the platelet plug formation or potentiation of the local vasoconstrictor effect.

Adenosine and Adenosine Diphosphate—Stewart and Brooks (8) presented information suggesting that adrenochrome semicarbazone produced a hemostatic effect in irradiated rats by increasing the activity of platelets. In the authors' test, the effects appeared to be separate from the platelet plug effect. This is not to infer that adrenochrome semicarbazone does or does not have an effect on or in conjunction with platelets, but that adrenochrome semicarbazone will promote hemostasis in the absence of the platelet plug.

Johnson (9) *et al.* have recently observed the mechanism of hemostasis in vessels of 50–160 μ by sectioning the hemostatic plug. Their plug was composed of red cells enmeshed in fibrin. Platelet aggregation did not occur until after this plug formed.

Other evidence which helps us rule out more efficient plug formation as the basic method of adrenochrome semicarbazone activity was obtained with adenosine and adenosine diphosphate. Adenosine diphosphate, a physiological substance known to produce *in vivo* clumping of platelets (10–12) and the subsequent platelet plug, was used to test the effect of increased platelet activity. With adenosine diphosphate, the initial blood loss was not decreased. Adenosine is a competitive inhibitor (12) of adenosine diphosphate and thereby blocks the formation of the platelet plug. Adenosine did not increase the initial blood loss. These results strongly suggest that the hemostatic effect of adrenochrome semicarbazone in the experiments was not in the more rapid building of the platelet plug but on the local vascular contraction at the area of the trauma.

Received bishydroxycoumarin for 8 days. [b] Bishydroxycoumarin 20 mg./Kg. at 0 hr., 10 mg./Kg. at 24 hr.; bled at 48 hr. [c] 10 mg. at 0, 24, 48 hr.; bled at 72 hr.

SUMMARY

Adrenochrome semicarbazone has been shown to decrease blood loss in normal mice whose tails have been clipped. The decrease in blood loss does not correlate with bleeding time. The bleeding times increased with anticoagulants but initial blood loss did not change significantly.

Heparin and bishydroxycoumarin have been used to deplete or block the blood stream of necessary clotting components and in these animals adrenochrome semicarbazone can be shown to decrease the blood loss when measured to cessation of the initial blood flow. Adrenochrome semicarbazone will not increase rate of survival in animals lacking a necessary amount of clotting components.

The failure of adenosine and adenosine diphosphate, heparin, and bishydroxycoumarin to influence initial blood loss indicates that in the tail vessel of the mouse the primary hemostatic consideration is that of local vasoconstriction. Adrenochrome semicarbazone appears to augment this constrictor effect.

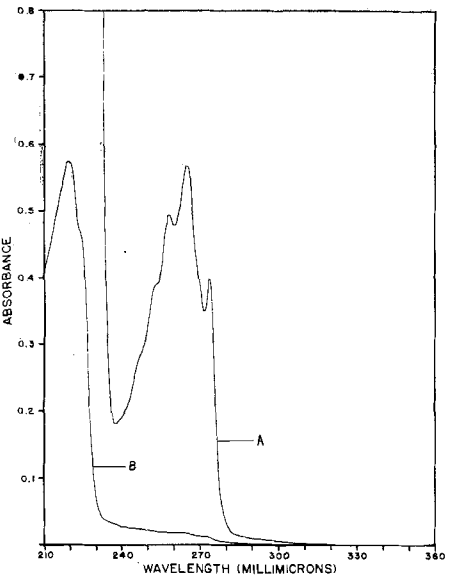

Fig. 1—Ultraviolet absorption spectra of chlorphentermine hydrochloride in water; Beckman model DK-2A spectrophotometer. Key: A, *500 mcg./ml.;* B, *10 mcg./ml.*

Identity Tests—Dissolve about 50 mg. of chlorphentermine hydrochloride in 3 ml. of water, add ammonia T.S. until basic, and filter. Acidify the filtrate with diluted nitric acid and add 1 ml. of silver nitrate T.S.: a white precipitate forms, which is insoluble in diluted nitric acid but soluble in ammonia T.S. (presence of chloride).

A 1 in 2000 solution of chlorphentermine hydrochloride in water exhibits ultraviolet maxima at about 259, 268, and 278 mμ, and absorbance minima at about 239, 261, and 275 mμ. A 1 to 50 dilution of this solution exhibits an absorbance maximum at about 220 mμ [absorptivity (a) about 52]. The spectrum at each concentration is shown in Fig. 1.

The infrared spectrum of a chlorphentermine hydrochloride dispersion in liquid petrolatum is shown in Fig. 2.

Purity Tests—Dry about 1 Gm. of chlorphentermine hydrochloride, accurately weighed, at 105° for 4 hr.: it loses not more than 1% of its weight.

Char about 1 Gm. of chlorphentermine hydrochloride, accurately weighed, ignite, cool, and weigh: the residue does not exceed 0.1%.

Determine the heavy metals content of chlorphentermine hydrochloride by the U.S.P. heavy metals test, method II: the heavy metals limit for chlorphentermine hydrochloride is 20 p.p.m.

Assay—Transfer about 400 mg. of chlorphentermine hydrochloride, accurately weighed, to a tall-form 200-ml. beaker, and add 25 ml. of glacial acetic acid and 10 ml. of mercuric acetate T.S. Warm slightly to effect solution, cool, add 2 drops of crystal violet T.S., and titrate with 0.1 N acetous perchloric acid to a blue-green end point. Perform a blank determination, and make any necessary correction. Each milliliter of 0.1 N perchloric acid is equivalent to 22.01 mg. of $C_{10}H_{14}ClN.HCl$.

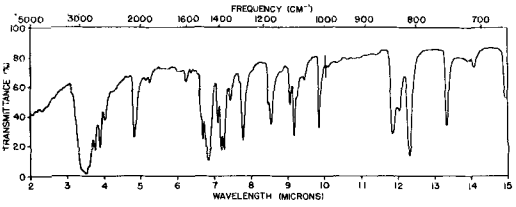

Fig. 2—Infrared spectrum of chlorphentermine hydrochloride dispersion in liquid petrolatum; Perkin-Elmer model 21 spectrophotometer, sodium chloride prism.

The amount of chlorphentermine hydrochloride found is not less than 98.0% and not more than 102.0%.

DOSAGE FORMS OF HYDROCHLORIDE CHLORPHENTERMINE

Chlorphentermine Hydrochloride Tablets

Identity Test—The filtrate from the original tablet solution obtained in the *Assay* exhibits absorbance maxima and minima at the same wavelengths as a solution of chlorphentermine hydrochloride standard in 0.01 N hydrochloric acid at a concentration of about 500 mcg./ml.

Assay—Weigh and finely powder not less than 10 chlorphentermine hydrochloride tablets. Weigh accurately a portion of the powder, equivalent to about 500 mg. of chlorphentermine hydrochloride, and transfer to a 1000-ml. volumetric flask. Add about 500 ml. of 0.01 N hydrochloric acid and warm on a steam bath for about 15 min. with intermittent agitation. Cool, dilute to volume with 0.01 N hydrochloric acid, and mix. Filter the solution through paper discarding the first 50 ml. of filtrate. Transfer 20.0 ml. of clear filtrate into a 125-ml. separator, add 1 ml. of sodium hydroxide T.S., and extract with four 20-ml. portions of ether, collecting the ether extracts in a second separator. Extract the ether phase with two 40-ml. portions of 0.01 N hydrochloric acid, combine the acid extracts in a 100-ml. volumetric flask, dilute with the acid to volume, and mix. Dilute 10.0 ml. of this solution to 100.0 ml. with the acid, and mix. Concomitantly determine the absorbance of this solution and of a standard solution of chlorphentermine hydrochloride, in the same medium, at a concentration of about 10 mcg./ml., in 1-cm. cells, at the maximum at about 220 mμ, with a suitable spectrophotometer, using 0.01 N hydrochloric acid as the blank. Calculate the quantity, in milligrams, of $C_{10}H_{14}ClN$ in the portion of tablets taken by the formula $50\ C\ (A_u/A_s) \times 0.834$, in which C is the exact concentration of the standard solution, in mcg./ml., A_u is the absorbance of the sample solution, A_s is the absorbance of the chlorphentermine hydrochloride standard solution, and 0.834 is the conversion factor relating chlorphentermine base to chlorphentermine hydrochloride. The amount of chlorphentermine base found is not less than 95.0% and not more than 105.0% of the labeled amount.

DISCUSSION

U.S.P. and N.F. terminology for solubility,

melting range, reagents, *etc.*, has been used wherever feasible.

Chlorphentermine hydrochloride,[1] an anorectic agent indicated for treatment of obesity, is distinguished by a selective pattern of pharmacologic action. This pattern of activity differs qualitatively and quantitatively from the amphetamines, whose indiscriminate effects at anorectic doses on the cardiovascular system and central nervous system are well known. Unlike the amphetamines, chlorphentermine hydrochloride exhibits no adverse effect on blood pressure, heart rate, or blood sugar.

The tablet formulation is a sustained action product so prepared that the medication is released gradually and without interruption over an 8-hr. period. The tablets are labeled to contain 65 mg. of chlorphentermine base which is equivalent to 78 mg. of the hydrochloride salt.

Identity Tests—The chloride test and ultraviolet absorption spectrum are not sufficient for differentiation of chlorphentermine hydrochloride from other sympathomimetic amine hydrochlorides. However, this information together with the infrared spectrum and melting range for chlorphentermine hydrochloride does provide a satisfactory identification. Mason *et al.* (1) have published a comprehensive report dealing with the physical properties of the drug.

Quantitative Methods—The nonaqueous titration for chlorphentermine hydrochloride with perchloric acid using crystal violet T.S. gave an average value of 99.9 ± 0.2%.[2] Analysis of commercial chlorphentermine hydrochloride tablets by the spectrophotometric method gave an average value of 100.5 ± 1.5%.[2] The suitability of the procedure was verified by an average recovery of 100.2 ± 0.3%[2] for a standard chlorphentermine hydrochloride solution carried through the extractive steps as included for the tablets.

Notes

Novel Disubstituted Mannich Product as a Potential Anti-Infective Agent

By ROBERT A. MAGARIAN and W. LEWIS NOBLES

Identification of α,α′-di-{3-(3-azabicyclo[3.2.2]-nonyl)-methyl}-*p*-nitroacetophenone is reported.

THE ISOLATION of a new disubstituted Mannich product was mentioned in a previous publication (1). The Mannich reaction, involving the reactive hydrogen compound acetophenone (I), is shown and illustrates the replacement of one of the active hydrogen atoms by an aminomethyl group which may arise from formaldehyde and the amine.

The Mannich product from a methyl ketone (II) contains labile hydrogens, and, in some cases, it is possible to proceed a step further yielding a compound with two basic groups (III) (2).

The amine hydrochloride is usually employed to provide the proper acidic environment. Cummings and Shelton (3) and Hellmann and Opitz (4) have carried out kinetic studies of the Mannich reaction and have concluded that the active aminomethylating agent is the electrophilic carbonium-immonium ion ($R_2\overset{+}{N}{-}\overset{+}{C}H_2 \leftrightarrow R_2\overset{+}{N}{=}CH_2$) which arises only under acidic conditions from the aminomethylol (*N*-hydroxymethylamine) derivative R_2NCH_2OH. The nucleophile is thought to be the enolic tautomer of the ketone which condenses with the aminomethylating agent.

When the free amine is used in equimolar amounts with the other reactants, a dibasic Mannich product may be isolated. The mechanism of the Mannich reaction has not been completely elucidated; it is considered unlikely that a single mechanism can be postulated which will include all known cases involving this reaction. In these studies, the Mannich condensation involving equimolar amounts of *p*-nitroacetophenone, 37% aqueous formaldehyde, and 3-azabicyclo[3.2.2]nonane was first conducted by modifying the conditions set forth by Blanton and Nobles (5); that is, the free base rather than the hydrochloride salt of the amine was employed.

Received December 29, 1967, from the Department of Pharmaceutical Chemistry, School of Pharmacy, The University of Mississippi, University, MS 38677

Unlike the amphetamines, chlorphentermine hydrochloride exhibits no adverse effect on blood pressure, heart rate, or blood sugar.

The tablet formulation is a sustained action product so prepared that the medication is released gradually and without interruption over an 8-hr. period. The tablets are labeled to contain 65 mg. of chlorphentermine base which is equivalent to 78 mg. of the hydrochloride salt.

Identity Tests—The chloride test and ultraviolet absorption spectrum are not sufficient for differentiation of chlorphentermine hydrochloride from other sympathomimetic amine hydrochlorides. However, this information together with the infrared spectrum and melting range for chlorphentermine hydrochloride does provide a satisfactory identification. Mason *et al.* (1) have published a comprehensive report dealing with the physical properties of the drug.

Quantitative Methods—The nonaqueous titration for chlorphentermine hydrochloride with perchloric acid using crystal violet T.S. gave an average value of 99.9 ± 0.2%.[2] Analysis of commercial chlorphentermine hydrochloride tablets by the spectrophotometric method gave an average value of 100.5 ± 1.5%.[2] The suitability of the procedure was verified by an average recovery of 100.2 ± 0.3%[2] for a standard chlorphentermine hydrochloride solution carried through the extractive steps as included for the tablets.

Notes

Novel Disubstituted Mannich Product as a Potential Anti-Infective Agent

By ROBERT A. MAGARIAN and W. LEWIS NOBLES

Identification of α,α′-di-{3-(3-azabicyclo[3.2.2]-nonyl)-methyl}-*p*-nitroacetophenone is reported.

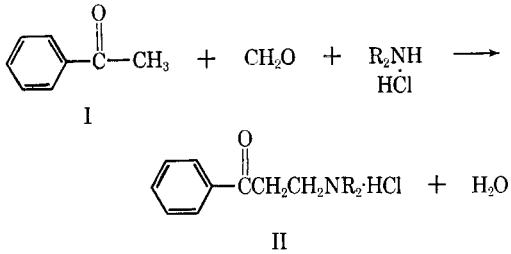
THE ISOLATION of a new disubstituted Mannich product was mentioned in a previous publication (1). The Mannich reaction, involving the reactive hydrogen compound acetophenone (I), is shown and illustrates the replacement of one of the active hydrogen atoms by an aminomethyl group which may arise from formaldehyde and the amine.

The Mannich product from a methyl ketone (II) contains labile hydrogens, and, in some cases, it is possible to proceed a step further yielding a compound with two basic groups (III) (2).

The amine hydrochloride is usually employed to provide the proper acidic environment. Cummings and Shelton (3) and Hellmann and Opitz (4) have carried out kinetic studies of the Mannich reaction and have concluded that the active aminomethylating agent is the electrophilic carbonium-immonium ion ($R_2\overset{+}{N}{-}\overset{+}{C}H_2 \leftrightarrow R_2\overset{+}{N}{=}CH_2$) which arises only under acidic conditions from the aminomethylol (*N*-hydroxymethylamine) derivative R_2NCH_2OH. The nucleophile is thought to be the enolic tautomer of the ketone which condenses with the aminomethylating agent.

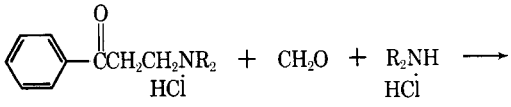
When the free amine is used in equimolar amounts with the other reactants, a dibasic Mannich product may be isolated. The mechanism of the Mannich reaction has not been completely elucidated; it is considered unlikely that a single mechanism can be postulated which will include all known cases involving this reaction. In these studies, the Mannich condensation involving equimolar amounts of *p*-nitroacetophenone, 37% aqueous formaldehyde, and 3-azabicyclo[3.2.2]nonane was first conducted by modifying the conditions set forth by Blanton and Nobles (5); that is, the free base rather than the hydrochloride salt of the amine was employed.

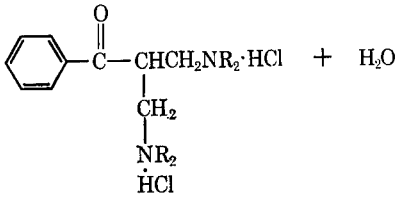
Received December 29, 1967, from the Department of Pharmaceutical Chemistry, School of Pharmacy, The University of Mississippi, University, MS 38677
Accepted for publication May 17, 1967.



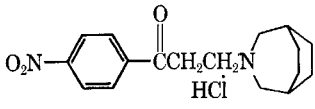
I

II

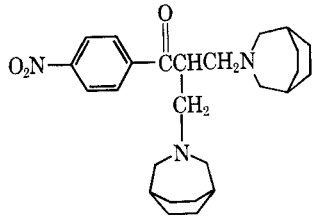




III



IV



V

Consequently, the product (IV) as reported by Blanton and Nobles was not isolated. Instead, a bright yellow solid was obtained in 41% yield with a melting point of 148–152° (corrected). Recrystallization several times from absolute ethanol–acetone resulted in a product melting at 158–160° (corrected). The starting ketone melted at 79–82° (corrected) and the melting point of a mixture of the above product and the ketone was 76–79° (corrected). The product was shown to be the disubstituted derivative (V) as evidenced by elemental, infared, and nuclear magnetic resonance analyses.[1]

Anal.—Calcd. for $C_{26}H_{37}N_3O_3$ (mol. wt. 439.6): C, 71.04; H, 8.48; N, 9.56. Found: C, 70.87; H, 8.55; N, 9.46.

[1] Microanalyses were conducted by Alfred Bernhardt, Microanalytisches Laboratorium, Max-Planck-Institut fur Kohlenforschung, Mulheim (Ruhr), Germany. Infrared spectra were determined on a Perkin-Elmer model 137G Infracord spectrophotometer using potassium bromide disks. The Varian A-60(mc) was employed in obtaining the nuclear magnetic resonance spectra.

The infrared spectrum showed two strong nitro bands at 1520 cm.$^{-1}$ and 1350 cm.$^{-1}$. There was a strong carbonyl band at 1675 cm.$^{-1}$. The relative proton absorption of the NMR spectrum in deuterochloroform was in agreement with the proposed structure. Neither the ketonic nor enolic tautomers seemed to predominate. The phenyl proton pattern might have been partially collapsed by this tautomeric exchange. The NMR spectrum in trifluoroacetic acid showed the low resolution expected from the Stark effect due to a doubly charged ion.

Subsequent to the discovery of the antibacterial activity of the Mannich bases derived from *p*-nitroacetophenone (6), interest was aroused in the reduction of this compound to the corresponding carbinol in order to study the effect of this variation in structure on the biological activity of such a compound when appearing as a side chain in quinoline and acridine derivatives. Consequently, product V was reduced to the corresponding carbinol by the method of Chaikin and Brown (7) as modified by Nobles (8) using sodium borohydride. The reaction proceeded smoothly, and a light yellow solid was isolated in 67% yield with a melting point of 163–165° (corrected). Recrystallization from absolute ethanol resulted in a very light yellow, almost cream-colored, solid with a melting point of 163–164° (corrected). Two additional recrystallizations yielded a white solid with a melting point of 163–164° (corrected). A 2,4-dinitrophenylhydrazine test performed on the product was negative. The melting point of a mixture of the above product and the ketone was 140–144° (corrected).

Anal.—Calcd. for $C_{26}H_{39}N_3O_3$ (mol. wt. 441.6): C, 70.71; H, 8.90; N, 9.52. Found: C, 70.19; H, 8.90; N, 9.19.

Inspection of the infrared spectrum revealed that carbonyl absorption at 1675 cm.$^{-1}$ was absent, and a hydroxy band was present at 3400 cm.$^{-1}$. Also, there were two strong nitro bands at 1520 cm.$^{-1}$ and 1350 cm.$^{-1}$. The relative proton absorption in the NMR spectrum performed in deuterochloroform showed that the disubstituted alcohol was the product. Also, the NMR spectrum indicated a reduction from two electron-withdrawing groups on a benzene ring to only one; *i.e.*, the keto and nitro groups were present in the keto compound, but after keto reduction the only electron-withdrawing group on the benzene ring was the nitro group. The NMR spectrum in trifluoroacetic acid showed low resolution due to the Stark effect from two protonated nitrogens. Due to the optically active carbinol carbon atom, the cyclohexyl ring peaks are separated farther part—103 and 113 c.p.s.

The Mannich reaction involving equimolar amounts of *p*-nitroacetophenone, 37% aqueous formaldehyde, and 3-azabicyclo[3.2.2]nonane was repeated; however, this time the hydrochloride salt of the amine was used and the desired product IV was isolated as reported by Blanton and Nobles (5).

Estimation of Amphetamine in Urine of Race Horses

By M. S. KARAWYA, M. A. EL-KIEY, S. K. WAHBA, and A. R. KOZMAN

Separation of amphetamine from urine of doped horses was achieved on anion-exchange resin (Na^+) and Silica Gel G plates. A micro method for the estimation of the free base was performed by measuring the violet color developed after nitration of the amphetamine eluted from either an ion-exchange resin column or Silica Gel G plates.

In Egypt in 1961, the menace of doping with amphetamine hovered over the horseraces and seriously threatened the results of the race. Since then, the race authorities have decided to stand against this new doping invader.

The method of analysis of amphetamine adopted by the B.P. (1) depends on steam distillation, while that of the E.P. (2) makes use of the direct extraction with ether.

The biological fluids contain normally some steam volatile and ether extractable bases (3) which may interfere in the determination of amphetamine. This fact renders the official methods not applicable for the separation and determination of amphetamine in urine of doped animals.

In an attempt to eliminate these interfering substances, ion-exchange and thin-layer chromatographic techniques were adopted.

Tampsett (4) was able to elute amphetamine on a cationic ion-exchange resin[1] column. He used 400 ml. of 8.0 *N* hydrochloric acid to achieve complete recovery. However, on trying this method, the eluate was found to be highly colored, and the colorimetric assay of the eluted amphetamine was almost impossible.

Materials—The materials used in this experiment were horse urine containing amphetamine (100 mcg./100 ml.); a column of ion-exchange resin[2] (Na^+) (1 × 15 cm.); and eluents used in the following succession: (*a*) 0.5% ammonium hydroxide, (*b*) acetone–water (3:7), (*c*) distilled water, (*d*) 10% aqueous solution of potassium chloride–1 *N* hydrochloric acid (1:1).

EXPERIMENTAL

Separation of Amphetamine on Ion-Exchange Resin (Na^+)

In the present work an anion-exchange resin[2] (Na^+) was chosen for the quantitative elution of amphetamine from horse urine.

Procedure—Add the urine sample to the resin column. Remove the impurities by washing successively with 50 ml. of each of the above-mentioned eluents (*a*), (*b*), and (*c*), and then elute the amphetamine with 150 ml. of eluent (*d*). Render the eluate alkaline with ammonium hydroxide T.S., extract the free base with chloroform (4 × 25 ml.), evaporate the chloroform, and keep the residue for the colorimetric estimation as described later. The results in Table I show the following observations.

A—The successive washing of the column with 0.5% ammonium hydroxide, acetone–water (3:7), and distilled water achieves the removal of most of the urine pigments and other impurities but not amphetamine.

B—Complete recovery of amphetamine is effected by washing the ion-exchange resin column with 150 ml. of 10% potassium chloride–1 *N* hydrochloric acid (1:1).

Separation of Amphetamine on Silica Gel G Plates

Separation of amphetamine from the saliva on silica gel plates was performed by Baeumler *et al.* (5) using triethanolamine–acetone–methanol (0.03:1:1). However, it was found difficult to separate amphetamine from urine on adopting the same procedure.

Other systems were tried and the system *n*-butanol–glacial acetic acid–water (4:1:5) proved to effect good separation of amphetamine from urine pigments, R_f values being 0.65 and 0.95, respectively.

Amphetamine is located with bromocresol blue T.S. when a blue color is obtained.

Procedure—Amphetamine is first extracted from urine before its application on the plate as follows.

Table I—Recovery of Amphetamine from Horse Urine by Columns of Ion-Exchange Resin (Na^+)

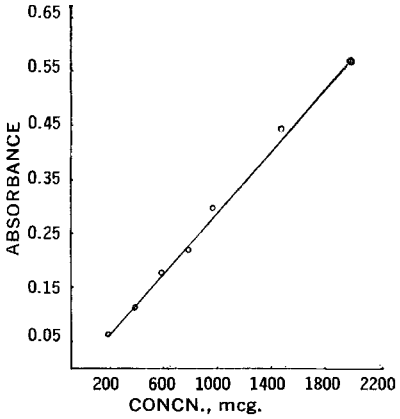

Fig. 1—Absorbance/concentration curve of amphetamine.

Introduce 50 ml. of urine to a separator and render it alkaline to litmus by the gradual addition of ammonium hydroxide T.S. solution. Extract the liberated base with chloroform (4 × 20 ml.), washing each portion with the same 5 ml. of water. Dehydrate the combined chloroformic extract with anhydrous sodium sulfate, washing the sodium sulfate with fresh chloroform and add the washing to the mother extract. Adjust the combined chloroformic extract to a suitable known volume according to the concentration of amphetamine. Another sample of urine free of amphetamine was treated and extracted as described above to be used as a blank.

By means of an Agla micrometer syringe apply the chloroform extracts of both experiment and blank on the starting line of a Silica Gel G plate, 2 cm. apart. Apply on each side of the starting line a pilot spot of a chloroformic solution of authentic amphetamine. The amphetamine content of any spot lies between 50–250 mcg. Insert the plate in the chromatographic jar and develop by the organic layer of the solvent system. In order to locate the amphetamine, spray the two peripheral pilot spots with bromocresol T.S. after covering the central part of the plate with a sheet of glass. Scrape the nonsprayed areas enclosed between and at the level of the located pilot spots with a thin spatula. Collect the powder obtained from each area on a glazed paper and transfer it quantitatively to a micro column (0.4 × 10 cm.). Wash each column with 10 ml. of ethanol.

Evaporate the ethanol cautiously, and keep the residues corresponding to experiment and blank for the colorimetric estimation.

Colorimetric Determination of the Eluted Amphetamine from Resin Columns and Silica Gel Plates

The nitration test (6) is used as the basis of the colorimetric estimation of amphetamine after making the following modification.

A 0.5% amount of potassium hydroxide in methanol–acetone (97:3) is used instead of 10% aqueous sodium hydroxide which does not allow stability of color. The procedure is run as follows.

To the residue in a test tube, add 0.1 Gm. of potassium nitrate and 2 ml. of sulfuric acid. Heat in a boiling water bath for 15 min., then cool. Transfer the liquid quantitatively with distilled water to a separator, wash the liquid with chloroform, reject the chloroform, make the aqueous solution alkaline with the gradual addition of ammonium hydroxide, and extract with chloroform. Evaporate the chloroformic extract in an evaporating dish and dissolve the residue in 10 ml. of acetone. Transfer the acetone solution to a test tube, add 2 drops of 0.5% potassium hydroxide in methanol–acetone (97:3), and allow to stand for 10 min. Measure the developed purple color in a Unicam SP 1300 colorimeter using No. 1 filter (370–515 mμ) against the blank experiment. The results are deduced from an absorbance/concentration curve (Fig. 1), from which it is clear that the color obeys Beer's law in the range of 50–250 mcg. of amphetamine.

The color reaches its maximum after 10 min. and remains stable for another 15 min.

The colorimetric method was applied to residues obtained from both ion-exchange column and chromatoplates using urine samples containing variable amounts of amphetamine. The results are shown in Table II.

From Table II, it is clear that amphetamine can be recovered quantitatively from either the ion-exchange resin (Na^+) column or Silica Gel G plate, with an error of +3.6 to +5.0 and −0.8 to +2.5%, respectively.

Tracing of Amphetamine in Urine of Doped Horses

horses three horses weighing between 250 and 300 Kg. were chosen. The animals were kept in a clean stable under veterinary medical observation[3] for 3 days before the administration of the drug and were examined constantly to ascertain their normal state of health. During the 24 hr. prior to administration of amphetamine, urine was collected from the three horses in leather bags tied under their bodies. Each animal was then injected subcutaneously with 100 mg. amphetamine sulfate. The urine of each animal was collected periodically after 3, 12, 24, 48, and 72 hr. by means of a sterile catheter. In addition, a clean leather bag was tied under each horse to collect any urine which might pass off between the specified collection times. The urine samples were pale yellow, turbid, and possessed a pH 5.9–6.3.

The urine samples were made alkaline with ammonium hydroxide T.S., shaken with chloroform, the extract chromatographed by TLC, and the separated amphetamine was colorimetrically assayed as described above.

The urine collected before the administration of amphetamine was used as a blank. The results are shown in Table III, from which it is clear that about 55.6% of the administered amphetamine was excreted in the urine of horses within 48 hr. after the administration of amphetamine. During this period, amphetamine could be detected by thin-layer chromatography; after 48 hr. it was hardly detectable and had almost disappeared after 72 hr.

[3] The authors thank Dr. A. Hanna, Faculty of Veterinary Medicine, Cairo University, for his valuable help.

Antibacterial Activity of Some Substituted Benzofurans. Preliminary Study of Structure Activity Relationship

By P. K. SHARMA, KALA MEHTA, O. P. GUPTA, M. M. MAHAWAR, and S. K. MUKERJI

Sensitivity of three substituted nitrobenzofurans, 4-methyl-6-phenylbenzofuran, 2(*p*-nitrophenyl)benzofuran, and 2-aceto-5-methyl-7-nitrophenylbenzofuran, against *Staphylococci, Pyocyanea,* and *B. coli* was studied. A possible structure activity relationship has been worked out, which suggested that the sensitivity of benzofurans is due to nitro substitution. Sensitivity is reduced by substitution of aceto and methyl groups.

NITROFURANS have been widely studied for their antibacterial activity (1–3). A series of substituted benzofurans and nitrobenzofurans were synthesized and tested for their antibacterial activity.

The reaction of *p*-nitrobenzyl bromide with an *O*-hydroxy carbonyl compound in presence of anhydrous potassium carbonate in methanol yields a 2-(*p*-nitrophenyl) benzofuran (4, 5). This reaction was utilized to prepare a few benzofurans required for pharmacological studies.

The reaction of benzyl bromide with hydroxymethyl propiophenone and *p*-nitrobenzyl bromide with 2-hydroxypropiophenone and 2-hydroxy-3-aceto-6-methylpropiophenone in methanol, in the presence of anhydrous potassium carbonate from 45 min. to 1 hr., furnishes the respective benzyloxy and *p*-nitrobenzyloxy derivatives. When allowed to react further with anhydrous potassium carbonate in methanol under reflux (time varying from 6–9 hr.), they yield the respective benzofurans—*viz.*, 4-methyl-6-phenylbenzofuran (a pasty substance) (I), 2-(*p*-nitrophenyl) benzofuran (m.p. 193°) (II), and 2-aceto-5-methyl-7-nitrophenylbenzofuran (m.p. 68°) (III). All the three compounds are completely soluble in alcohol, acetone, and ether.

Received August 4, 1966, from R. N. T. Medical College, Udaipur, Rajasthan, India.
Accepted for publication November 7, 1966.

EXPERIMENTAL

Aqueous suspensions of these compounds were prepared in 1% polysorbate 80,[1] the wetting agent being used to compensate for low aqueous solubility. Control experiments were also performed with the same solvent.

The bactericidal property of the test agents (I, II, and III) was studied against *Staphylococci, Pyocyanea,* using nutrient agar media and *B. coli* on MacConkey's agar media, by the use of impregnated filter paper disks to determine the bacterial sensitivity for the compounds under study.

The disks were soaked in the solutions, the activity of which was to be tested, placed on the media, and incubated overnight at 37°. The diameters of the circular areas of inhibited growth were observed and percentage of inhibition was calculated.

RESULTS AND DISCUSSION

The results of these observations are presented in Table I. From the results it is evident that compound II is the most active against all three test

[1] Marketed as Tween 80 by Atlas Chemical Industries, Inc., Wilmington, Del.

horses three horses weighing between 250 and 300 Kg. were chosen. Antibacterial Activity of Some Substituted Benzofurans. Preliminary Study of Structure Activity Relationship

By P. K. SHARMA, KALA MEHTA, O. P. GUPTA, M. M. MAHAWAR, and S. K. MUKERJI

Sensitivity of three substituted nitrobenzofurans, 4-methyl-6-phenylbenzofuran, 2(*p*-nitrophenyl)benzofuran, and 2-aceto-5-methyl-7-nitrophenylbenzofuran, against *Staphylococci, Pyocyanea,* and *B. coli* was studied. A possible structure activity relationship has been worked out, which suggested that the sensitivity of benzofurans is due to nitro substitution. Sensitivity is reduced by substitution of aceto and methyl groups.

NITROFURANS have been widely studied for their antibacterial activity (1–3). A series of substituted benzofurans and nitrobenzofurans were synthesized and tested for their antibacterial activity.

The reaction of *p*-nitrobenzyl bromide with an *O*-hydroxy carbonyl compound in presence of anhydrous potassium carbonate in methanol yields a 2-(*p*-nitrophenyl) benzofuran (4, 5). This reaction was utilized to prepare a few benzofurans required for pharmacological studies.

The reaction of benzyl bromide with hydroxymethyl propiophenone and *p*-nitrobenzyl bromide with 2-hydroxypropiophenone and 2-hydroxy-3-aceto-6-methylpropiophenone in methanol, in the presence of anhydrous potassium carbonate from 45 min. to 1 hr., furnishes the respective benzyloxy and *p*-nitrobenzyloxy derivatives. When allowed to react further with anhydrous potassium carbonate in methanol under reflux (time varying from 6–9 hr.), they yield the respective benzofurans—*viz.*, 4-methyl-6-phenylbenzofuran (a pasty substance) (I), 2-(*p*-nitrophenyl) benzofuran (m.p. 193°) (II), and 2-aceto-5-methyl-7-nitrophenylbenzofuran (m.p. 68°) (III). All the three compounds are completely soluble in alcohol, acetone, and ether.

Received August 4, 1966, from R. N. T. Medical College, Udaipur, Rajasthan, India.
Accepted for publication November 7, 1966.

EXPERIMENTAL

Aqueous suspensions of these compounds were prepared in 1% polysorbate 80,[1] the wetting agent being used to compensate for low aqueous solubility. Control experiments were also performed with the same solvent.

The bactericidal property of the test agents (I, II, and III) was studied against *Staphylococci, Pyocyanea,* using nutrient agar media and *B. coli* on MacConkey's agar media, by the use of impregnated filter paper disks to determine the bacterial sensitivity for the compounds under study.

The disks were soaked in the solutions, the activity of which was to be tested, placed on the media, and incubated overnight at 37°. The diameters of the circular areas of inhibited growth were observed and percentage of inhibition was calculated.

RESULTS AND DISCUSSION

The results of these observations are presented in Table I. From the results it is evident that compound II is the most active against all three test

[1] Marketed as Tween 80 by Atlas Chemical Industries, Inc., Wilmington, Del.

TABLE I—RESULTS OF ANTIBACTERIAL ACTIVITY OF COMPOUNDS

No.	Compd.	Chemical Structure	Bacteria	Concn., mcg./ml.	% Inhibition of Growth[a]
I	4-Methyl-6-phenyl-benzofuran		*Staphylococci*	0.25	0
				0.50	0
				1.00	0
			Pyocyanea	0.25	0
				0.50	0
				1.00	10
			B. coli	0.25	0
				0.50	0
				1.00	0
II	2-(*p*-Nitrophenyl) benzofuran		*Staphylococci*	0.25	80
				0.50	100
				1.00	100
			Pyocyanea	0.25	50
				0.50	80
				1.00	100
			B. coli	0.25	100
				0.50	100
				1.00	100
III	2-Aceto-5-methyl-7-nitrophenyl-benzofuran		*Staphylococci*	0.25	50
				0.50	50
				1.00	100
			Pyocyanea	0.25	0
				0.50	0
				1.00	100
			B. coli	0.25	0
				0.50	50
				1.00	100

[a] No inhibition of growth was observed with control.

species of bacteria. Compound III is active against *Staphylococci* but inactive against *Pyocyanea* and *B. coli* in low concentrations (0.25 and 0.50 mcg./ml.) and sensitive in higher concentration (1.0 mcg./ml.). Compound I is practically resistant to all the three types of bacteria. This suggests that the nitro group is essential for antibacterial activity of the benzofurans (compound II) while the sensitivity is reduced by the substitution of methyl and aceto groups (compound III).

Solubilization of Lecithin in Antibiotic Preparations by a Nonionic Surfactant

By FRANCES W. BOWMAN, EVERETT W. KNOLL, and MIRIAM P. CALHOUN

A nonionic surfactant (alkyl phenoxy polyethoxy ethanol) solubilizes antibiotic preparations containing up to 1 per cent lecithin. Toxicity studies showed that the surfactant at a concentration of 0.1 per cent (v/v) in 0.1 per cent peptone solution (w/v) permits recovery from a low inoculum of vegetative cells when membrane filtration sterility tests are performed. The addition of the surfactant to peptone diluting fluid makes it possible to perform membrane filtration tests on many antibiotic preparations that otherwise could only be tested by the direct method. The use of surfactant–peptone diluting fluid also makes it possible to use 300 mg. from each of 20 vials instead of 50 mg. when testing oxytetracycline, chlortetracycline, or tetracycline for sterility.

In 1964, the Antibiotic Regulations were amended (1) to permit the testing of the sterility of antibiotics by membrane filtration (2), in addition to the direct test. Membrane filtration is now specified in 51 of the 121 monographs, the direct method in 41, and either in 29.

In the direct method, the antibiotic must be inactivated so that it does not interfere in the test, *e.g.*, penicillin is inactivated by the addition of the enzyme penicillinase. Thus the direct method is unsuitable for preparations containing penicillin combined with streptomycin or dihydrostreptomycin for which there are no suitable inactivators.

The membrane filtration technique, on the other hand, requires that the test material be soluble enough to pass through the pores of the membrane filter without clogging them; therefore, its use is limited to materials that are soluble or can be solubilized in some way. For example, in combination with streptomycin or dihydrostreptomycin, mentioned above, the slightly soluble procaine penicillin G is converted by the addition of penicillinase to soluble penicilloic acid until its concentration is reduced to about 5 mg./ml. At this concentration the antibiotic is dissolved (3). Since streptomycin and dihydrostreptomycin are both in solution, the formulation may then be filtered without difficulty.

However, problems are presented by formulations containing emulsifying agents, such as sodium carboxymethylcellulose or lecithin, a water-dispersible phospholipid with strongly polar groups. These compounds are used as suspending and/or homogenizing agents to produce oil-in-water emulsions of antibiotics that are rather insoluble in water. Although these agents improve the resuspendability and syringeability of the aqueous suspensions of antibiotics, the resulting suspensions are not completely soluble at the concentrations used in the membrane filtration test, and they tend to clog the filter. The clogged membrane will either stop the filtration or greatly extend the filtration time. In either case, a filtration sterility test cannot be performed.

Because of these difficulties, a study was undertaken to devise a reliable method for solubilizing injectable preparations containing lecithin. The first approach involved the use of lecithinase to hydrolyze lecithin, in analogy with the use of penicillinase to convert procaine penicillin G to a soluble substance. However, this approach was unsuccessful.

The authors then explored the use of a polyoxyethylene nonionic surfactant (alkyl phenoxy polyethoxy ethanol).[1] Russomanno and Wollish (4) reported using this surfactant to wash and remove oil from the membrane following a filtration sterility test for oils. Since lecithin is used to produce oil-in-water emulsions of antibiotics, it seemed feasible that the surfactant could be used to solubilize these emulsions so that they would be suitable for membrane filtration sterility testing. This approach proved more successful.

EXPERIMENTAL

In the usual membrane filtration sterility test, the sample is added to a sterile 500-ml. conical flask containing approximately 200 ml. of a 0.1% peptone (w/v) solution. The flask is stoppered and swirled to dissolve the drug. The solution is then filtered aseptically.

Ten different antibiotic formulations containing varying amounts of lecithin were used in the tests with the surfactant (see Table I). When 0.1% peptone alone was used as the diluting fluid, the preparations were insoluble and could not be filtered. Adding the surfactant at 0.1% (v/v) to the peptone diluting fluid solubilized each of the preparations so that they could be filtered through a 0.45-μ membrane filter. The total time required to filter the antibiotic preparation and make the three washings did not exceed 20 min.

The solubility of lecithin in 0.1% surfactant–peptone solution was determined on samples of commercial grade lecithin used by two antibiotic manufacturers. Lecithin was added to the surfactant–peptone diluting fluid at 25° until the fluid became turbid. Additional surfactant–peptone diluting fluid was added until the turbidity disappeared. This titration procedure established that 0.5 mg./ml. of lecithin is completely soluble in 0.1% peptone solution containing the surfactant at a concentration of 0.1%. Apparently the successful use of filtration sterility tests for preparations containing lecithin depends on the final concentration of lecithin in the diluting fluid after the preparation has been pooled as directed in the Antibiotic Regulations (1). If this final concentration of lecithin in surfactant–peptone diluting fluid does not exceed

TABLE I—ANTIBIOTIC PREPARATIONS CONTAINING VARYING AMOUNTS OF LECITHIN SOLUBILIZED BY THE SURFACTANT FOR THE FILTRATION STERILITY TEST

Preparation	% Lecithin in Formulation
Procaine penicillin G in streptomycin sulfate soln. (1.0% monothioglycerol)	0.5
Procaine penicillin G and buffered sodium penicillin G for aqueous suspension	0.1
Procaine penicillin G in dihydrostreptomycin soln.	0.1
Procaine penicillin G in dihydrostreptomycin soln.	0.25
Procaine penicillin G, potassium penicillin G, and streptomycin sulfate for aqueous injection	1.0
Procaine penicillin G and buffered potassium penicillin G for aqueous injection	0.3
Procaine penicillin G, potassium penicillin G, and streptomycin sulfate for aqueous injection	0.2
Procaine penicillin in dihydrostreptomycin with prednisolone	0.28
Procaine penicillin G in aqueous suspension	1.0
Chloroprocaine penicillin O for aqueous injection	1.5

0.5 mg./ml., the solutions filter rapidly through a 0.45-μ membrane, whereas the same amount of lecithin is insoluble in peptone diluting fluid alone, and cannot be filtered satisfactorily. Furthermore, when up to 2 mg./ml. of lecithin is added to surfactant–peptone diluting fluid alone, the solution can be filtered, even though it is cloudy; yet when this concentration of lecithin is combined with actual samples containing antibiotics and other components, results are variable: sometimes the solutions can be filtered, sometimes they cannot.

The surfactant was also found to be useful in the filtration procedures for antibiotics that do not contain lecithin. In the standard filtration procedure, a total of 6 Gm. (300 mg. from each of 20 containers) of the antibiotic is added to 200 ml. of the peptone diluting fluid, resulting in a 3% solution. Some antibiotics, such as the tetracyclines, cannot be filtered at this concentration; only 50 mg. can be taken from each container instead of 300 mg., and therefore only 1 Gm., a 0.5% solution, can be tested. When surfactant was added to the peptone diluting fluid, the usual 3% solution could be filtered and the standard amount of the antibiotic could be tested for sterility.

When the filtration procedures for sterility testing were developed, 0.1% peptone was selected as the diluting fluid because it protected the vulnerable vegetative cells in an antibiotic milieu. Before proposing that the surfactant be added to this diluting fluid, it was necessary to investigate its toxicity to microorganisms. Russomanno and Wollish (4) reported that it was nontoxic when in contact with vegetative forms of bacteria for several hours. Dowben and Koehler (5), in a study on the interaction of the surfactant with bovine plasma, found that no gross structural changes occur in the protein, *i.e.*, proteins are not denatured. The following study on the survival of eight microorganisms in surfactant–peptone solution confirms these findings.

TABLE II—SURVIVAL OF ORGANISMS IN SURFACTANT–PEPTONE SOLUTIONS FOR 30 min. AT 25° AS DETERMINED BY MEMBRANE FILTRATION STERILITY TESTS

Organism	Estimated No. Cells of Inoculum	Day Showing Growth After Incubation: Thioglycollate at 32°	Day Showing Growth After Incubation: Sabouraud at 25°

Bacillus cereus ATCC 11778	52	2	3
Staphylococcus aureus ATCC 6538P	132	3	6
Sarcina lutea ATCC 9341	66	3	4
Streptococcus faecalis	160	2	3
Klebsiella pneumoniae ATCC 10031	88	1	3
Pseudomonas sp. ATCC 19146	154	3	3[a]
Saccharomyces cerevisiae ATCC 9763	64	3	2

[a] pH was adjusted to 7.0 since this organism will not grow at pH 5.7 ± 0.1.

Eight organisms representing Gram-positive and negative bacilli, Gram-positive cocci, and yeasts were used. A stock suspension of each organism was prepared, and a viable cell count was made by the plate method. The stock suspensions were further diluted with 0.1% peptone so that 1 ml. contained from 40 to 160 cells. One milliliter of the dilute suspension was added to each of 10 flasks containing 200 ml. of surfactant–peptone solution, and the flasks were held at room temperature. After a 30-min. contact period, the viability of the organisms added to the surfactant–peptone was determined by the membrane filtration sterility tests (1). Table II shows that all microorganisms were recovered from small inocula in both thioglycollate and Sabouraud liquid media after incubation for 1–5 days.

Determination of Impurities in Phenacetin by Thin-Layer Chromatography

By PAUL TURI and JERRY POLESUK

A rapid and sensitive method has been devised to detect acetanilid, *p*-chloroacetanilid, and *p*-phenetidin contaminations in phenacetin by a single test, simplifying the U.S.P. technique which involves three separate procedures. The TLC method is not only faster, but also more sensitive than the official procedures.

PHENACETIN, one of the most popular constituents in analgesic combinations,[1] may contain impurities which increase toxicity. In U.S.P. XVII, requirements have been established for three of these impurities: acetanilid and *p*-phenetidin should be absent, and the *p*-chloroacetanilid content should not exceed 0.03%. The toxic properties of these contaminants are well described in the literature.

Several useful methods (1–5) have been published on the detection of the possible impurities in phenacetin. However, some of the methods do not consider all of the above-listed significant contaminants, and others apply laborious procedures and sophisticated equipment. The authors' objective was to develop a simple, rapid, and sensitive technique for the detection of the three impurities.

EXPERIMENTAL

Apparatus—Desaga-Brinkmann TLC equipment, 8 × 4 and 8 × 8 in. glass plates coated with a 250 μ layer of fluorescent Silica Gel (GF). Short-wave U.V. lamp, Mineralight,[2] model UVS-12. Long-wave U.V. lamp, Blak-Ray,[2] model UVL-22.

Reagents—Solvents (Table I): reagent grade. Phenacetin: U.S.P. grade. Acetanilid, *p*-chloroacetanilid, *p*-phenetidin: commercially available samples were used, without further purification.

Procedure—One gram of phenacetin was shaken with 5.0 ml. of ether for 5 min. in a small glass-stoppered flask. The suspension was allowed to settle, and 50 μl. of the supernatant was spotted on a Silica Gel GF plate. As a control, ethereal solutions of acetanilid, *p*-chloroacetanilid, and *p*-phenetidin were applied, containing 0.15, 0.30, and 3.0 mcg. of each. A partial list of solvents and solvent mixtures that were utilized to develop the chromatograms is included in Table I. The solvent front was allowed to ascend 10 to 15 cm. above the spot points.

The plate was then removed from the tank and dried in air. The dried plate was exposed to iodine vapor in an appropriate tank for 20 sec., and subsequently inspected under a short-wave (253.7 mμ) U.V. lamp. The substances appeared as dark spots against a bright green fluorescent background. (Fig. 1.)

As a corroborative estimation of the *p*-chloroacetanilid, the U.S.P. detection method was also applied (6). After exposing the plate to the short-wave U.V. radiation for about 5 min., the chromatogram was inspected under a long-wave (366.0 mμ) U.V. lamp: only the *p*-chloroacetanilid spots exhibited a bright blue fluoresence. This additional testing was more selective, but the range of sensitivity was the same as that of the first observation.

DISCUSSION AND RESULTS

In attempting to develop an improved procedure for detecting certain possible impurities in phenacetin, there were basically two problems to be solved: selecting the most suitable technique, and finding the optimal conditions for both the separation and identification of the substances.

Thin-layer chromatography was selected because of its easy availability, speed, and high degree of sensitivity. Unlike gas chromatography, the TLC method can be used without lengthy preliminary steps such as column preparation and equilibration. It facilitates the estimation of as little as 0.003% *p*-chloroacetanilid (the U.S.P. sets a limit of 0.03%). Furthermore, in proving the absence of acetanilid, it is much more accurate than the official method. Koshy and his co-workers (3) found that the U.S.P. test is sensitive only to concentrations greater than 1.2%. The same authors estimated that the sensitivity of the color reaction of iodine T.S. with *p*-phenetidin was in the range of 0.003%. It was found that by the described TLC method, a *p*-phenetidin contamination corresponding to a concentration of 0.0015% is safely detectable.

In selecting the optimal solvent system, it was obvious that the major difficulty was the separation of the acetanilid and *p*-chloroacetanilid, because the solubility properties of these compounds are very similar. Strongly polar solvents (methanol, acetone) moved all the compounds too fast and resulted in practically no separation. On the other hand, a solvent containing 90% petroleum ether left all substances at the starting line. It was found that ethyl ether mixed with a small volume (0.5–1.0%) of nonpolar solvent yielded a safe and reproducible separation of the four compounds. An ether–hexane (99:1) mixture proved suitable because of the comparatively speedy development (about 30 min.), and because of the availability of these solvents in reagent grade purity.

The detection of the phenacetin and its impurities can be achieved by alternate methods. Szász and his co-workers (1) exposed the plates to freshly generated nitrogen monoxide gas and subsequently sprayed the chromatogram with a 1% solution of β-naphthol in 2 *N* sodium hydroxide. The products (acetanilid was not included) appear in different colors; nevertheless, the limit of detection for *p*-chloroacetanilid is 0.1%. Other papers refer to the use of a spray reagent consisting of 3% potassium permanganate in strong sulfuric acid, or, in the

Received February 6, 1967, from the Analytical Laboratories, Sandoz Pharmaceuticals, Hanover, NJ 07936

case of *p*-chloroacetanilid only, to the exposure to short-wave U.V. radiation followed by an examination under long-wave U.V. radiation (5, 6). It was found that by utilizing the fluorescent silica gel plate, no spray is necessary in order to detect the spots, and the use of the U.V. irradiation technique is not limited to the *p*-chloroacetanilid identification, but also facilitates the rapid and simultaneous examination of all four compounds. (The 20-sec. iodine exposure is necessary in order to make the *p*-phenetidin spot visible.)

SUMMARY

The separation, identification, and estimation of possible phenacetin impurities listed in the U.S.P. XVII monograph have been investigated.

A thin-layer chromatographic technique has been developed which offers a rapid identification of acetanilid, *p*-chloroacetanilid, and *p*-phenetidin impurities, and facilitates the near quantitative evaluation of their amounts. Limits of detection are 0.003% for acetanilid and *p*-chloroacetanilid, and 0.0015% for *p*-phenetidin.

The method presents a favorable alternative for the official limit test and two additional qualitative assays, by replacing them with a single, rapid, and highly sensitive procedure.

Atropine Antagonism of Carbachol-Induced Hyperglycemia

By A. E. WADE

Hyperglycemia was induced with carbachol in rats, rabbits, and dogs, and the effect in rabbits was shown to be dose related. In albino rabbits with negligible plasma esterase activity, atropine sulfate effectively prevented hyperglycemia following 25 mcg./Kg. of carbachol, and the effect appeared to be dose dependent. In rabbits with moderate esterase levels, atropine sulfate dosage as high as 0.8 mg./Kg. had little inhibitory effect on carbachol hyperglycemic or cholinomimetic responses. This plasma esterase was not effectively blocked *in vivo* with 20 mg./Kg. of 2-(diethylamino)ethyl-2,2-diphenylvalerate (proadifen) HCl (SKF 525-A). However, this dose of proadifen HCl did block carbachol hyperglycemia in rabbits with negligible esterase activity. Carbachol hyperglycemia was similarly prevented by atropine in rats and dogs.

HEPATIC PHOSPHORYLASE ACTIVITY glycogenolysis, and the hyperglycemia resulting from the administration of exogenous epinephrine are reduced by certain adrenergic blocking agents (1–8) and certain indirectly acting sympathomimetics (2). The biochemical site of action of these dissimilar agents appears to be different (9), some suppressing synthesis of adenosine-3′,5′-monophosphate and others affecting reactions subsequent to this.

Catecholamines may be liberated from the adrenal medulla as a result of hypoglycemia (10) or by drugs such as acetylcholine, carbachol, histamine, nicotine, physostigmine, or reserpine (11, 12). Suppression of catecholamine mobilization from adrenal stores by these stimuli has been accomplished with chronic administration of reserpine and monoamine oxidase inhibitors, by ganglionic blocking agents, and in certain instances by atropine, chlorpromazine, guanethidine, and tetracaine (12).

Atropine has been shown to reduce blood levels of catecholamines (13), block the pressor response of neostigmine (14–16) and other ganglionic stimulants (16, 17), and depress the response of the nictitating membrane to nerve stimulation (18). The site of action is presumably at the ganglion. Atropine in large doses has adrenolytic activity, reducing many effects of exogenous epinephrine and sympathetic nerve stimulation (19, 20).

The effects of atropine on carbachol hyperglycemia in rabbits, rats, and dogs are enumerated in this report.

EXPERIMENTAL

The animals used in this study included female albino rabbits of the California strain, weighing 1.2 to 5.3 Kg.; female Sprague-Dawley rats, weighing 170–251 Gm.; and mongrel dogs of both sexes, weighing 8–14.5 Kg.

Serum esterase levels of the rabbits were determined by the method outlined previously (21). The serum esterase level was considered negligible if, under the conditions of this assay, less than 0.06 μ-mole procaine was hydrolyzed per ml. serum per hour at 26 ± 1°. Following an 18–24-hr. fast, rabbits were anesthetized with i.p. injections of a solution of Na phenobarbital (100 mg./Kg.) and Na pentobarbital (15 mg./Kg.) dissolved in 50% propylene glycol. Approximately 1 hr. after anesthesia was established, 0.9% NaCl solution, atropine sulfate, or 2-(diethylaminoethyl)-2,2-diphenylvalerate (proadifen) HCl (SKF 525-A)[1] was administered i.v. Blood samples of 0.6 to 1.0 ml. were removed by cardiac puncture 10 min. after such pretreatment and 10 min. prior to the intravenous carbachol.[2] Additional blood samples were obtained at 15, 30, and 60 min. following carbachol. The samples were mixed with dry sodium citrate and immediately placed in an ice–salt bath until deproteinized.

Rats were fasted overnight and anesthetized with i.p. injections of 25 mg./Kg. Na pentobarbital and 75 mg./Kg. Na phenobarbital in 50% propylene glycol. Blood samples (0.5 ml.) were removed by cardiac puncture 20 min. prior to the subcutaneous administration of 0.9% NaCl or atropine $SO_4^=$ and 35 min. following the subcutaneous administration of 25 mcg. of carbachol per Kg. body weight.

Dogs were fed 18–20 hr. prior to i.p. anesthesia with a solution of Na pentobarbital (10 mg./Kg.) and Na phenobarbital (120 mg./Kg.) in 50% propylene glycol, and 3 hr. later atropine $SO_4^=$ (0.4 mg./Kg.) was administered subcutaneously to the experimental group. Blood samples were withdrawn from the cephalic vein 20 min. prior to subcutaneous carbachol (25 mcg./Kg.) administration, and at 10, 20, and 50 min. after carbachol. In some experiments epinephrine HCl (10 mcg./Kg.) was administered 120 min. following carbachol in order to validate the animals' ability to mobilize hepatic glycogen.

Glucose content of 0.1-ml. samples of deproteinized blood was determined in duplicate by the method of Washko and Rice (22) using a prepared enzyme reagent.[3]

Drug effects were based on the quantitative change in mg. per cent of glucose from pre-carbachol injection values. Each point on the dose-response curves representing total measured response to a given treatment was derived by calculating the area under the graph produced by plotting change in glucose content (mg. %) during the 60 min. post-carbachol. One factor analysis of variance was conducted on all data using standard electronic data processing equipment by the University of Georgia Bureau of Statistics. Differences between groups were calculated at the 5% level using the Duncan multiple range test.

Received March 1, 1967, from the School of Pharmacy, University of Georgia, Athens, GA 30601

Accepted for publication May 17, 1967.

Presented to the Pharmacology and Biochemistry Section, A.PH.A. Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

This investigation was supported in part by the University of Georgia General Research Budget.

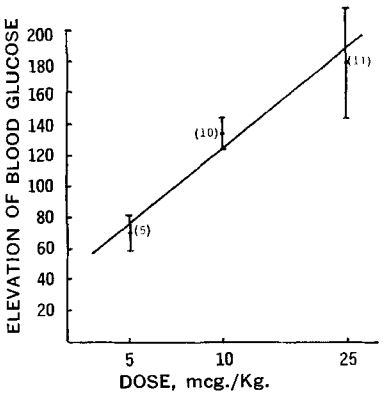

Fig. 1—Total blood glucose elevation during 60-min. post-carbachol in rabbits. Values and bars indicate mean ± S.E. Numbers in parentheses indicate number of animals per dose.

RESULTS

Carbachol Hyperglycemia—The log dose-response curve for carbachol-induced hyperglycemia over the 60-min. period following i.v. carbachol administration in rabbits is il ustrated in Fig. 1. The response is clearly dose dependent, and although 25 mcg./Kg. of carbachol appeared to be supramaximal in some animals, this dose produced hyperglycemia significantly greater than that resulting from 5 mcg./Kg. The hyperglycemia was significant for all doses of carbachol at 15 and 30 min. post-injection, but at the 60-min. period the blood glucose concentration had returned to a level not significantly higher than the controls administered 0.9% NaCl solution. All doses produced profound parasympathomimetic actions, but seldom produced death if infused over a 60–90-sec. period.

Atropine Inhibition of Carbachol Hyperglycemia—The inhibitory effect of atropine sulfate on the hyperglycemia induced by carbachol in rabbits exhibiting negligible serum esterase activity is recorded in Table I. This effect of atropine appeared to be dose related, since 0.05 mg./Kg. produced 70.8% inhibition of the carbachol hyperglycemia and 0.10 mg./Kg. resulted in a 92% inhibition. Doses of 0.2 and 0.4 mg./Kg. produced inhibition statistically indistinguishable from that produced by 0.1 mg./Kg. All doses of atropine sulfate above 0.05 mg./Kg. maintained blood glucose levels in the presence of carbachol that were not statistically different from the nontreated (saline injected) controls.

The mean hyperglycemic response to carbachol was less pronounced in atropinized rabbits having innately high serum esterase levels than in nonatropinized controls; however, this effect was not significant (Fig. 2). Data are also presented in Fig. 2 which suggest that proadifen HCl produces an effect resembling that of atropine but that it does not effectively block the esterase responsible for atropine hydrolysis. This ineffectiveness as a blocking agent was explained, at least in part, by *in vitro* experiments which demonstrated that proadifen HCl is inactivated by rabbit serums having atropinesterase activity. *In vivo* studies in rabbits with negligible esterase levels demonstrated the atropine-like effect of proadifen HCl on carbachol-induced hyperglycemia (Fig. 3).

In the rat, atropine sulfate (0.05 to 0.4 mg./Kg.) produced complete blockade of the hyperglycemia of carbachol. This blockade, measured at 50–55 min. following subcutaneously administered atropine, was not evident at 80 min. post-atropine.

The effect of atropine sulfate in the dog is depicted in Fig. 4. Complete blockade of carbachol hyperglycemia with this dose of atropine sulfate seems evident, although statistically significant changes in blood glucose concentrations were not measured until 50 min. post-carbachol. It became evident early in this study with dogs that glycogen reserves are quickly depleted and that heavy feeding 14–16 hr. prior to the experiments supplied insufficient glycogen reserves to allow consistent hyperglycemia following carbachol injections. Priming doses of orally administered dextrose (3 Gm./Kg.) approximately 3 hr. prior to the experiments alleviated this difficulty and provided sufficient hepatic glycogen to allow measurable hyperglycemia in response to epinephrine in both atropinized and control animals.

DISCUSSION

Carbachol induces hyperglycemia in rabbits, rats, and dogs which is probably due to the liberation of epinephrine from adrenal medullary stores. The data reported here indicate that the mechanism by which atropine inhibits this hyperglycemia is similar in these animals. Although the site of action was not specifically located, it seems reasonable to assume that atropine blocks at a point preceding the release of epinephrine, since it was shown that atropine did not prevent the hyperglycemia caused by a dose of 10 mcg./Kg. of epinephrine in dogs that had failed to respond to carbachol.

TABLE I—EFFECT OF ATROPINE $SO_4^=$ ON CARBACHOL (25 mcg./Kg. i.v.) HYPERGLYCEMIA IN RABBITS WITH NEGLIGIBLE SERUM ESTERASE ACTIVITY

No. of Animals in Group	Pretreatment	Change in Blood Glucose (mg. %) from Pre-Carbachol Levels— 15 min.	30 min.	60 min.
11	Saline	59.43 ± 9.70	55.89 ± 13.58	36.68 ± 8.88
8	Atropine $SO_4^=$ 0.05 mg./Kg.	12.46 ± 5.51[a]	12.31 ± 4.66[a]	21.89 ± 8.98

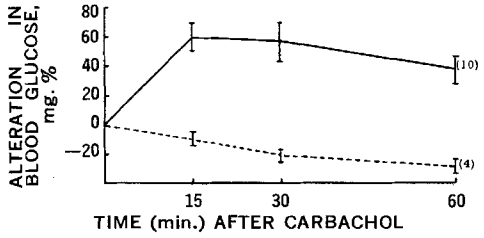

Fig. 3.—The effect of proadifen HCl (20 mg./Kg. i. v.) on carbachol (10 mcg./Kg.) hyperglycemia in rabbits with negligible serum esterase. Numbers in parentheses indicate number of animals per group. Key: ————, *control;* – – – – – –, *proadifen HCl pretreated.*

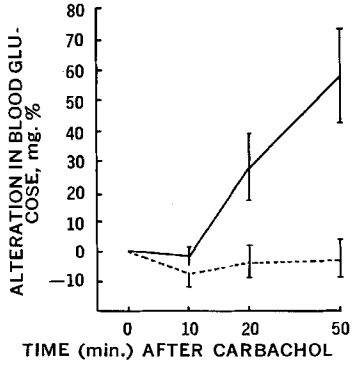

Fig. 4—The effect of atropine SO_4^- (0.4 mg./Kg. s. c.) on carbachol (25 mcg./Kg. s. c.) in the dog. The values and bars represent mean ± S. E. of 4 experiments. Key: ————, *control;* – – – – – –, *atropine pretreatment.*

The enzyme inhibitor proadifen HCl has been reported to inhibit human serum procainesterase activity (23). This inhibition was verified during an *in vitro* study which demonstrated that 1×10^{-4} *M* proadifen HCl reduced procaine hydrolysis by human serum by about 61%. *In vitro* experiments indicated, however, that proadifen HCl at concentrations of 1.4×10^{-3} *M* does not inhibit hydrolysis of atropine by esterase of rabbit serum, and in fact serves as a substrate for this enzyme. The fact that proadifen HCl does not effectively block atropinesterase activity was verified in the *in vivo* experiments in rabbits with high serum esterase levels. The anticholinergic activity of proadifen HCl is well known and its atropine-like activity in blocking carbachol hyperglycemia was demonstrated in these studies. Thus, the antihyperglycemic activity of atropine and proadifen HCl in rabbits with high esterase activity appears to be no more than an additive effect of the two drugs.

If the antihyperglycemic action of atropine is present in man, and if it is capable of inhibiting epinephrine release from the adrenal medulla by stimuli other than carbachol (*i.e.*, hypoglycemia), then two distinct possibilities of clinical importance appear likely. Cholinergic blocking drugs may find use (*a*) in controlling the hyperglycemia of the select group of patients having normal insulin levels but transiently high concentrations of circulating catecholamines, the release of which is triggered by an oversensitive sympathetic hyperglycemic reaction, and (*b*) as insulin-sparing agents for diabetics receiving oral hypoglycemics, by reducing the antagonistic effect of the adrenal medulla. This second point may be doubly important in view of the fact that certain of the oral hypoglycemic agents stimulate epinephrine release from the adrenal medulla (24).

SUMMARY

Carbachol in doses of 5, 10, and 25 mcg./Kg. i.v. produced peak elevations in blood glucose concentration in rabbits within 15 min.

This hyperglycemia was effectively blocked by doses of atropine sulfate as low as 0.05 mg./Kg. in both rabbits with negligible serum esterase activity and in rats. Atropine antagonism of carbachol hyperglycemia was also evident in dogs.

The enzyme inhibitor proadifen HCl (20 mg./Kg. i.v.) completely antagonized the hyperglycemia of carbachol (10 mcg./Kg. i.v.) in rabbits with negligible serum esterase activity, but was ineffective in blocking the esterase of rabbit serum responsible for atropine hydrolysis.

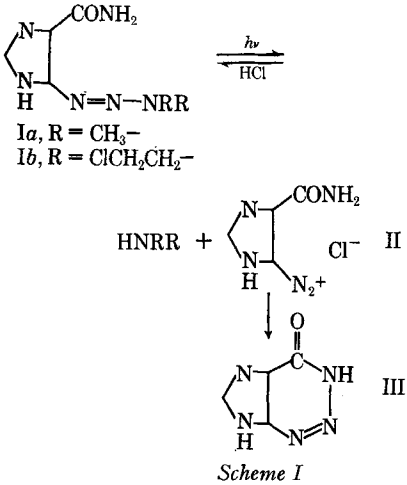
Colorimetric Determination of Dialkyltriazenoimidazoles

By TI LI LOO and ELIZABETH A. STASSWENDER

A colorimetric method has been developed for the determination of dialkyltriazenoimidazoles in plasma and urine.

RECENTLY a series of dialkyltriazenoimidazoles (I) has been synthesized as potential antitumor agents (1). Several of these have shown promise as useful drugs in cancer chemotherapy, notably 5-(dimethyltriazeno)-imidazole-4-carboxamide (I*a*) (DIC, NSC-45388) and 5-[di(β-chloroethyl) triazeno]-imidazole-4-carboxamide (I*b*) (NSC-82196) (2,3). The former is presently under clinical trial. Concurrently, pharmacologic studies on these new agents in man and animals are also in progress in our laboratories. For such studies a simple, sensitive, and specific method for the quantitative determination of the dialkyltriazenoimidazoles is desirable. The method described below appears to meet this demand.

The dialkyltriazenoimidazoles undergo photodecomposition in dilute acid to 5-diazoimidazole-4-carboxamide (II) and a corresponding dialkylamine according to Scheme I.



Scheme I

In aqueous solutions II readily cyclizes by intramolecular coupling to 2-azahypoxanthine (III), imidazo-[4,5-*d*]-*v*-triazin-4(3*H*)-one (1). However, in the presence of an aromatic amine such as *N*-(1-naphthyl)ethylenediamine (Bratton-Marshall reagent) (4), coupling takes place with the formation of an intensely colored azo-dye. Under rigidly controlled experimental conditions with an excess of the coupling amine, the competing intramolecular coupling to III could be held to a constant minimum; thus the intensity of the color adequately measures the concentration of I. Because the photodecomposition is a general reaction of I, the colorimetric method is expected to be applicable to all dialkyltriazenoimidazoles, although the present work concerns mainly I*a* and I*b*.

EXPERIMENTAL

Apparatus

A standard colorimeter (for example, Bausch & Lomb Spectronic 20) is required for measurement of absorbance of 0.4 ml. to 2 ml. of solution.

The light source is a long-wave (maximal radiation at 366 mμ) ultraviolet lamp (Blak-Ray lamp, model XX-15, supplied by Ultraviolet Products, Inc., San Gabriel, Calif., equipped with two General Electric F15 T8-BLB 15-w. bulbs).

A wooden rack holds the test tubes (Pyrex 75 × 10 mm.) containing drug solutions rigidly vertical and at a fixed distance of 2 cm. from the light bulbs. The lamp is positioned so that an entire row of test tubes may receive the same maximal exposure to ultraviolet radiation.

Reagents

Bratton-Marshall Reagent—Aqueous solutions of *N*-(1-naphthyl)ethylenediamine dihydrochloride, 0.2% for aqueous and plasma assays, but 1% for urine assays.

DIC Standards—A stock solution of DIC, 10.0 mg./ml. in 0.1 *N* hydrochloric acid is prepared and stored in the dark under refrigeration. It is stable for at least 1 month. Dilutions are made of stock with 0.1 *N* hydrochloric acid, plasma, or urine.

Trichloroacetic Acid—A 10% solution of trichloroacetic acid in 6 *N* sulfuric acid.

PROCEDURES

Determination in Aqueous Solutions—A mixture of 2.0 ml. of DIC solution, ranging from 0.1 mcg./

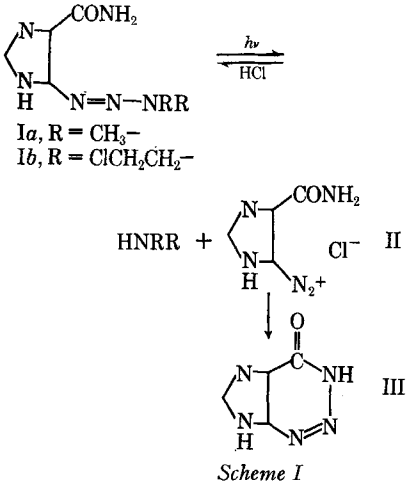
Colorimetric Determination of Dialkyltriazenoimidazoles

By TI LI LOO and ELIZABETH A. STASSWENDER

A colorimetric method has been developed for the determination of dialkyltriazenoimidazoles in plasma and urine.

RECENTLY a series of dialkyltriazenoimidazoles (I) has been synthesized as potential antitumor agents (1). Several of these have shown promise as useful drugs in cancer chemotherapy, notably 5-(dimethyltriazeno)-imidazole-4-carboxamide (I*a*) (DIC, NSC-45388) and 5-[di(β-chloroethyl) triazeno]-imidazole-4-carboxamide (I*b*) (NSC-82196) (2,3). The former is presently under clinical trial. Concurrently, pharmacologic studies on these new agents in man and animals are also in progress in our laboratories. For such studies a simple, sensitive, and specific method for the quantitative determination of the dialkyltriazenoimidazoles is desirable. The method described below appears to meet this demand.

The dialkyltriazenoimidazoles undergo photodecomposition in dilute acid to 5-diazoimidazole-4-carboxamide (II) and a corresponding dialkylamine according to Scheme I.



Scheme I

In aqueous solutions II readily cyclizes by intramolecular coupling to 2-azahypoxanthine (III), imidazo-[4,5-*d*]-*v*-triazin-4(3*H*)-one (1). However, in the presence of an aromatic amine such as *N*-(1-naphthyl)ethylenediamine (Bratton-Marshall reagent) (4), coupling takes place with the formation of an intensely colored azo-dye. Under rigidly controlled experimental conditions with an excess of the coupling amine, the competing intramolecular coupling to III could be held to a constant minimum; thus the intensity of the color adequately measures the concentration of I. Because the photodecomposition is a general reaction of I, the colorimetric method is expected to be applicable to all dialkyltriazenoimidazoles, although the present work concerns mainly I*a* and I*b*.

EXPERIMENTAL

Apparatus

A standard colorimeter (for example, Bausch & Lomb Spectronic 20) is required for measurement of absorbance of 0.4 ml. to 2 ml. of solution.

The light source is a long-wave (maximal radiation at 366 mμ) ultraviolet lamp (Blak-Ray lamp, model XX-15, supplied by Ultraviolet Products, Inc., San Gabriel, Calif., equipped with two General Electric F15 T8-BLB 15-w. bulbs).

A wooden rack holds the test tubes (Pyrex 75 × 10 mm.) containing drug solutions rigidly vertical and at a fixed distance of 2 cm. from the light bulbs. The lamp is positioned so that an entire row of test tubes may receive the same maximal exposure to ultraviolet radiation.

Reagents

Bratton-Marshall Reagent—Aqueous solutions of *N*-(1-naphthyl)ethylenediamine dihydrochloride, 0.2% for aqueous and plasma assays, but 1% for urine assays.

DIC Standards—A stock solution of DIC, 10.0 mg./ml. in 0.1 *N* hydrochloric acid is prepared and stored in the dark under refrigeration. It is stable for at least 1 month. Dilutions are made of stock with 0.1 *N* hydrochloric acid, plasma, or urine.

Trichloroacetic Acid—A 10% solution of trichloroacetic acid in 6 *N* sulfuric acid.

PROCEDURES

Determination in Aqueous Solutions—A mixture of 2.0 ml. of DIC solution, ranging from 0.1 mcg./

Received February 6, 1967, from the University of Texas M. D. Anderson Hospital and Tumor Institute, Houston, TX 77025
Accepted for publication April 3, 1967.
This work was supported by contract PH 43-66-1156 with the National Cancer Institute, U.S. Public Health Service, Bethesda, Md.
The authors thank the Cancer Chemotherapy National Service Center, National Cancer Institute, for the drugs NSC-45388 and NSC-82196.

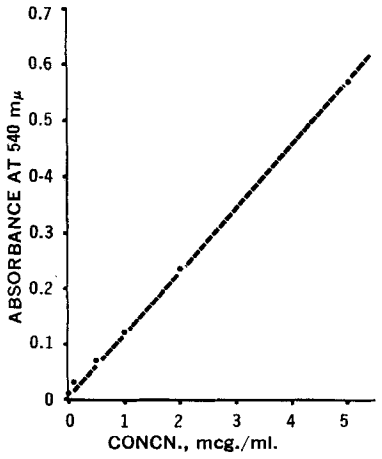


Fig. 1—Linearity between absorbance and concentration of DIC, 5-(dimethyltriazeno)-imidazole-4-carboxamide, NSC-45388.

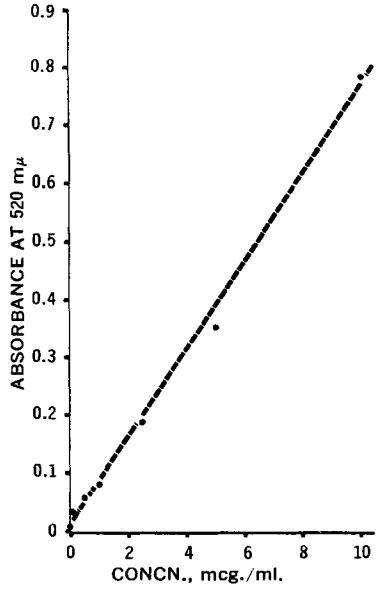

Fig. 2—Linearity between absorbance and concentration of NSC-82196, 5-[di(β-chloroethyl)triazeno-imidazole-4-carboxamide.

ml. to 5.0 mcg./ml., and 0.1 ml. of 0.2% Bratton-Marshall reagent is thoroughly shaken and placed in front of the ultraviolet light. After a 30-min. exposure, the absorbance (540 mμ for DIC and 520 mμ for NSC-82196) is measured against water. A blank is similarly run with 2.0 ml. of 0.1 *N* hydrochloric acid.

Plasma Recovery—A 3.0-ml. plasma solution of the drug is thoroughly mixed with 1.5 ml. of trichloroacetic acid. The protein precipitate is removed by centrifugation at about 2,000 r.p.m. (top speed of International clinical centrifuge, model CL) for 20 min. An aliquot of 2.0 ml. of the supernatant is withdrawn and assayed as for aqueous solutions. A blank containing no drug is likewise run. As a rule, in every experiment standards are established by adding given amounts of the drug to the pretreatment plasma collected from the subject and assayed in accordance with the above procedure. Whenever possible, three concentrations are arbitrarily chosen and run in triplicates.

The above procedure is slightly modified as follows for smaller amounts of plasma. To 1.0 ml. of a plasma solution is added 0.5 ml. of trichloroacetic acid solution. The mixture is thoroughly shaken and centrifuged. An aliquot of 0.4 ml. of the supernatant is removed and mixed with 0.02 ml. of 0.2% Bratton-Marshall reagent and assayed as before.

Urinary Recovery—All urine samples are diluted before assay because, first of all, the presence of natural pigments in urine makes direct determination impractical. Second, in actual clinical pharmacological work, the rapid excretion of the drug causes very high initial urinary concentration. For these reasons, the standard curve is constructed with urine solutions ranging from 250 mcg./ml. to 2000 mcg./ml. These are then appropriately diluted to 5.0 mcg./ml. with 0.1 *N* hydrochloric acid. Except that the Bratton-Marshall reagent used is 1% instead of 0.2%, the assay procedure is the same as described for aqueous solutions. The observed absorbance multiplied by the dilution factor gives the true value corresponding to each original concentration. Again, as in plasma recovery, urine standards are run with pretreatment urine in every experiment.

Table I—Concentration and Absorbance (± Standard Error) of NSC-45388 and NSC-82196

Concn., mcg./ml.	NSC-45388	NSC-82196
0	0.012 ± 0.0019	0.012 ± 0.0010
0.1	0.032 ± 0.0003	0.032 ± 0.0010
0.5	0.073 ± 0.0006	0.056 ± 0.0003
1	0.121 ± 0.0012	0.080 ± 0.0015
2	0.237 ± 0.0022	
5	0.569 ± 0.0063	0.353 ± 0.0041
10		0.783 ± 0.0104

RESULTS AND DISCUSSION

The excellent linearity between absorbance and concentration for both NSC-45388 and NSC-82196 in aqueous solutions is shown in Figs. 1 and 2, respectively, each point representing 10 replicates. The standard errors are illustrated in Table I. Obviously, the reproducibility is good. It appears the method is less sensitive with NSC-82196 than with NSC-45388. This is hardly surprising because the ratio of their molecular weights is about 3:2. Theoretically, the wavelength of maximal absorption should be the same for all dialkyltriazeno-imidazoles. In practice, however, there was a slight variation from drug to drug and hence the $\lambda_{max.}$ should be determined individually: it was 540 mμ for NSC-45388 and 520 mμ for NSC-82196.

After 30 min. the photodecomposition is complete and further exposure to ultraviolet light is of no

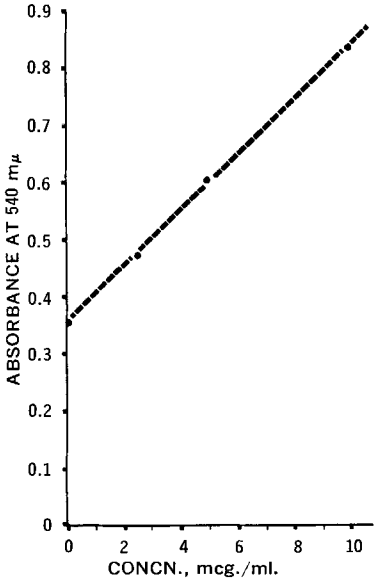

Fig. 3—Plasma standard curve of DIC, NSC-45388.

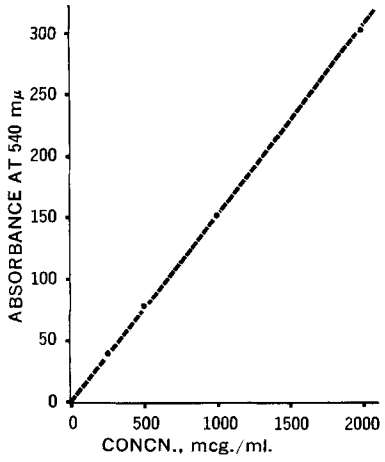

Fig. 4—Urinary standard curve of DIC (high concentration), NSC-45388.

advantage. If the Bratton-Marshall reagent is not added prior to irradiation, no color is produced, probably because the diazo compound has cyclized.

A typical plasma standard curve of DIC is represented by Fig. 3. Bratton-Marshall reagent of 1% is not used in plasma assay because it gives a higher blank than the 0.2% reagent. The results of urinary determination of the same drug are illustrated in Fig. 4. It is readily seen that the method applies well to all these determinations.

No naturally occurring material in either plasma or urine is known to give rise to a diazo compound upon illumination under ultraviolet light. Consequently, this method is specific for dialkyltriazenoimidazoles. Moreover, it is reasonable to expect the method to be applicable equally well to other dialkyltriazenoimidazoles.

The very small absorbance of the aqueous blank is accounted for by the slight brown tint produced by the Bratton-Marshall reagent after exposure to ultraviolet light. However, with plasma and especially with undiluted urine the brown tint becomes very much enhanced to afford high blanks which vary from one subject to another. This is one of the reasons why plasma and urine standards are always prepared and assayed in every experiment. The high blanks are not caused by azo dyes but by the end absorption due to certain brown pigment resulting from the interaction of Bratton-Marshall reagent and some unidentified constituents of plasma and urine after ultraviolet irradiation. Both plasma and urine blanks are assumed to remain constant throughout the experiment. This is a reasonable assumption since an experiment rarely lasts longer than 4–5 hr.

Tumor Localizing Agents I. Synthesis and Tissue Distribution of ^{14}C-Labeled and Radioiodinated 5,6-Diacetoxyindole

By R. E. COUNSELL, T. D. SMITH, J. DOELLE, D. MEIER, and W. H. BEIERWALTES

Interest in the development of radiopharmaceuticals suitable for the diagnosis and treatment of malignant melanoma prompted the present study. One of the first approaches to this problem has involved the synthesis of suitably labeled precursors of melanin with the hope that these substances would be selectively taken up by the pigmented tumor and rapidly converted to a radiolabeled melanin within the tumor. Since 5,6-dihydroxyindole is a late precursor of melanin, the synthesis of this material labeled with ^{14}C was undertaken. This substance, however, proved to be too unstable and was therefore converted to the diacetate for animal studies. The radioiodine-labeled analog was prepared by iodine exchange of 5,6-diacetoxy-7-iodoindole with sodium iodide-^{126}I. Neither 5,6-diacetoxyindole-2-^{14}C nor the ^{126}I analog showed a predilection for melanomas in mice.

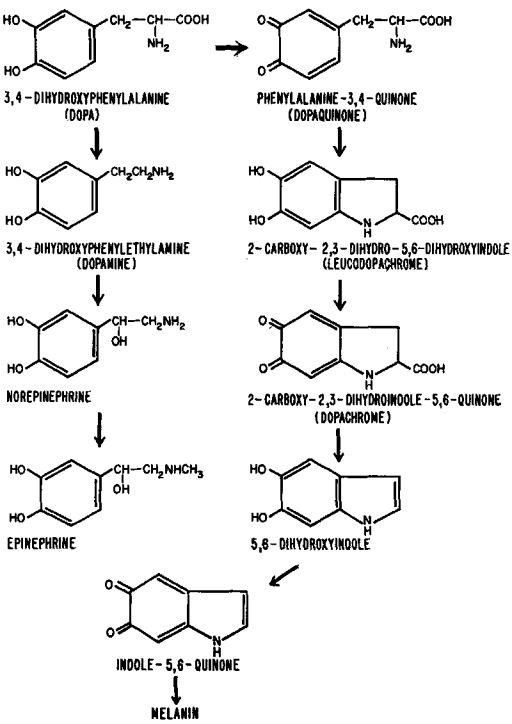
IN A RECENT REVIEW on the clinicopathological status of malignant melanoma, Raven (1) emphasized the need for new diagnostic and therapeutic agents for this disease. For several years now, the authors have been involved in a broad program aimed at the synthesis of substances which will localize in various tumors or organs. One objective of this program has been to find compounds that will selectively concentrate in melanotic tissues. Such compounds, when labeled with γ-emitting radionuclides, can be readily detected by external photoscanning techniques and thus afford a means for determining the location and metastatic nature of melanotic tumors.

One approach to the development of radiopharmaceuticals having a predilection for melanomas has involved an investigation of radio-labeled precursors of melanin. Since melanin appears to be an end product of tyrosine metabolism, it seemed possible that suitably labeled precursors of melanin could be selectively taken up by the pigmented tumor and rapidly converted to a labeled melanin which would remain within the tumor. Recent publications by several investigators have served to support the validity of this hypothesis. Blois and Kallman (2) studied the uptake of *dl*-dihydroxyphenylalanine-2-^{14}C (dopa-2-^{14}C) in mice with deeply pigmented melanomas and found the radioactivity of the different tissues to be in the order: melanoma > adrenal $\gg$ kidney > liver > spleen. Similarly, Fimiam and Dowd (3) noted that when *dl*-tyrosine-2-^{14}C was administered to melanotic mice significantly greater radioactivity was associated with melanoma than with any other tissue studied.

On the basis of this information, the authors elected to synthesize radiolabeled compounds structurally similar to biological precursors of melanin. As indicated in the proposed pathway of melanin biosynthesis (Scheme I), tyrosine and dopa serve as precursors for not only melanin but also catecholamines (4). Since a high target–nontarget ratio in melanomas compared to surrounding tissues was desired, it seemed advisable to select precursors formed in the later stages of melanogenesis for the studies. The synthesis and preliminary tissue distribution data for two radiolabeled derivatives of 5,6-dihydroxyindole are reported here.

In the preliminary experiments, 5,6-dihydroxyindole proved to be too unstable for use in the tissue distribution experiments. The protected *O*-acetylated product, however, proved to be much more stable and suitable for the animal studies.

Among the various methods previously reported for the synthesis of 5,6-dihydroxyindole and its derivatives, the approach of Beer and co-workers



Biosynthesis of Melanin and Epinephrine

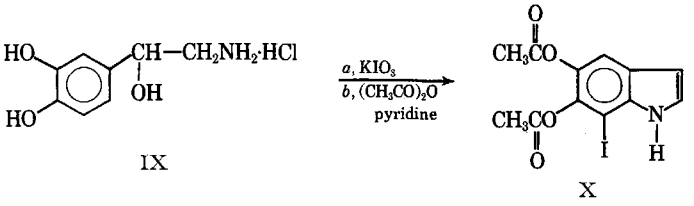
Synthesis of 5,6-Diacetoxyindole-2-^{14}C

Scheme II



Synthesis of 5,6-Diacetoxy-7-iodoindole

Scheme III

(5) seemed the most amenable for preparation of ^{14}C-labeled 5,6-diacetoxyindole. As outlined in Scheme II, piperonal (I) served as the starting material and was readily converted to 6-nitropiperonal (II). This product was then converted to acylal (III) and demethylenated according to the method of Parijs (6).

The radiolabel was introduced at this stage by condensation of IV with nitromethane-^{14}C. The subsequent steps were studied in detail in preliminary experiments so that the authors could proceed directly to the final product without isolating intermediates and thus minimize losses of radioactivity. Accordingly, the nitroalcohol V was immediately acetylated to give the triacetate (VI). Dehydroacetylation and reductive ring closure with iron in acetic acid afforded, after chromatography, 5,6-diacetoxyindole-2-^{14}C (VIII) in 43% over-all yield from IV.

The radioiodine-labeled product was prepared by isotope exchange of 5,6-diacetoxy-7-iodoindole (X) with sodium iodide-^{125}I. The iodinated indole was readily obtained by potassium iodate oxidation of *dl*-norepinephrine hydrochloride (IX) according to the procedure of Heacock *et al.* (7) (Scheme III). Glacial acetic acid proved to be the most suitable solvent for the iodine exchange, and the rate of exchange could be readily followed by radioscanning of thin-layer chromatograms (TLC).

Tissue Distribution Studies[1]—Table I compares the distribution of radioactivity in various tissues after administration of *dl*-dopa-2-^{14}C and the radiolabeled indole derivatives to mice with deeply pigmented melanomas. In contrast with Blois and Kallman's results (2), the *dl*-dopa-2-^{14}C showed a greater concentration of radioactivity in adrenal than in melanoma. At 24 hr., for example, the concentration in adrenal was almost 15 times that in melanoma. Similar results were obtained by Hempel and Deimel (9) with tritiated *dl*-dopa in mice with Harding-Passey melanoma.

[1] A more detailed description of these findings and related material has been reported elsewhere (8).

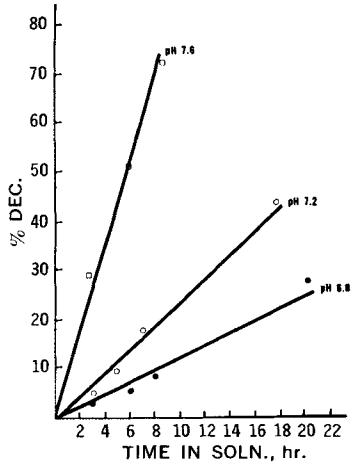

Fig. 1—Decomposition of 5,6-diacetoxyindole in aqueous solution at three pH values.

Neither 5,6-diacetoxyindole-2-^{14}C nor the ^{125}I analog showed selective uptake by the tumor. The site of injection, however, blackened rapidly after administration, suggesting that the diacetoxyindoles hydrolyzed to the dihydroxyindoles and rapidly polymerized to melanin-like materials. This undoubtedly accounted for the high levels of radioactivity at this site. The kidneys also became dark and the urine brown-black in color following administration of these compounds.[2] Presumably the concentration of radioactivity in the kidney represents renal excretion of these products or their metabolites. The rapid formation of dark melanin-like products at these sites indicates that a metabolic precursor of melanin preceding dihydroxyindole must enter the melanocyte prior to oxidative polymerization to melanin. Other potential precursors of melanin are currently under investigation.

Stability Studies—The high concentration of radioactivity at these sites prompted the authors to determine the effect of pH on the stability of 5,6-diacetoxyindole. The rate of decomposition at pH 6.8, 7.2, and 7.6 was ascertained by measurement of the absorbance of buffered aqueous solutions at 218 mμ. As shown in Fig. 1, decomposition of 5,6-diacetoxyindole increased with increasing pH. The high concentration of activity at the site of injection could therefore be related to the slightly basic pH at this site (10) or to the presence of an esterase. With regard to the latter possibility, Riley (11) recently demonstrated that 5,6-diacetoxyindole is rapidly converted to melanin in sections of human skin and presented evidence to support the presence of an indole-5,6-acetyl esterase.

EXPERIMENTAL[3]

5,6-Diacetoxyindole-2-^{14}C (VIII)—A solution of 6-nitro-protocatechuic aldehyde (5, 6) (IV, 2.5 Gm., 13.6 mmole) and nitromethane-^{14}C (0.84 Gm., 13.8 mmoles, 1.13 mc.)[4] in ethanol (25 ml.) was cooled to 0°. To this solution was added dropwise with stirring a solution of potassium hydroxide (1.8 Gm.) in 95% ethanol (25 ml.) while maintaining the reaction temperature at 0°. Following the addition period of about 1 hr., the reaction mixture was stored at 0° for 24 hr. and diluted with water (30 ml.). The mixture was acidified with 10% HCl

[2] Radiochromatogram analysis of the solutions used in the animal experiments indicated that no decomposition of the compounds had taken place prior to the tissue localization studies

[3] Melting points were taken on a Fisher-Johns melting point apparatus and are corrected. Ultraviolet spectra were recorded on a Beckman DK2A spectrophotometer in phosphate buffer system (pKa 6.8). Thin-layer chromatograms of radiolabeled materials were run with 1-in. wide Eastman chromatograms, type K301R with fluorescence indicator, and the compounds were detected with ultraviolet light. The distribution of radioactivity on the developed chromatograms was determined by scanning each strip with an Atomic Associates RCS-363 radiochromatogram scanner. The specific activities were determined with an Atomic Associates well scintillation counter model 810C and scintillation spectrometer model 530. The silicic acid used in the column chromatography was Baker and Adamson reagent grade.

[4] Purchased from New England Nuclear Corp., Boston, Mass.

and extracted with ether (6 × 25 ml.). The extract was washed with 10% sodium bisulfite solution (100 ml.) and dried over a mixture of anhydrous sodium sulfate and a decolorizing agent.[5] Removal of the solvent gave a solid (crude V) which was acetylated directly with acetic anhydride (10 ml.) containing a few drops of 70% perchloric acid. The acetylation mixture was allowed to stand at room temperature for 30 min. Water (25 ml.) was then added and the product was extracted with chloroform (5 × 25 ml.). Evaporation of the dried chloroform solution (anhydrous sodium sulfate) furnished the solid triacetate (VI).

This triacetate (VI), without further purification, was treated with acetic anhydride (12 ml.) and anhydrous sodium acetate (6.0 Gm.) at 140° for 2 min. The cooled reaction mixture was diluted with water (25 ml.) and extracted with chloroform (5 × 40 ml.). The extract was washed with 5% sodium bicarbonate solution (100 ml.), dried (anhydrous sodium sulfate), and evaporated to afford the solid, dinitrostyrene derivative (VII).

Crude VII was suspended in glacial acetic acid (65 ml.) and added dropwise over a 3-hr. period to a stirred mixture of glacial acetic acid (50 ml.) and iron powder (18.6 Gm.). No external heat was applied. The reaction mixture was stirred for an additional 3 hr. at room temperature. The solid residue was removed by filtration and washed well with hot ethanol. The resulting filtrate was diluted with water (50 ml.), neutralized with solid $KHCO_3$, and extracted with ether (7 × 50 ml.). The extract was treated with anhydrous sodium sulfate and the decolorizing agent and the solvent were removed *in vacuo*. The resulting solid brown residue was dissolved in a minimum of benzene, and adsorbed onto silica gel (25 Gm.), and the column was eluted with benzene. The solvent was removed from the combined indole-containing fractions[6] under reduced pressure to give pure VIII (1.37 Gm., 43%) m.p. 131–133° [lit. (5) m.p. 134–136°] with a specific activity of 90 μc./mmole.

Purity of the final product was checked by mixed melting point with an authentic sample, and by ascending paper chromatography using benzene as the solvent. Chemical and radiochemical purity were confirmed when the radiochromatogram scan of the developed chromatogram showed only one peak, corresponding to the same position as the indole compound.

5,6-Diacetoxy-7-iodoindole-^{125}I (X)—An aqueous solution of $Na^{125}I$ (1 ml., 350 μc.)[7] was evaporated under nitrogen (45°), and a solution of 5,6-diacetoxy-7-iodoindole (7) (101.2 mg.) in acetic acid (5 ml.) was added. The solution was refluxed for 30 min. and diluted with water (20 ml.), and solid sodium bicarbonate was added in small portions to neutralize the acetic acid. The resulting mixture was extracted with benzene (5 × 10 ml.), and the extract was washed with 5% sodium bicarbonate solution and dried (anhydrous sodium sulfate). Removal of the solvent *in vacuo* gave a residue which was purified by column chromatography over silica gel (5 Gm.) and elution with chloroform–benzene (1:1). The indole-containing fractions were combined and concentrated under nitrogen. Petroleum ether (b.p. 30–40°) was added periodically until a white crystalline material appeared. Removal of the supernatant afforded pure X (93 mg.), m.p. 125.7–127.1° [lit. (7) m.p. 125–126.5°], with a specific activity of 484 μc./mmole. Exchange occurred to the extent of 35.6%. Purity of the final product was established by TLC using ethyl ether as the eluant. The developed chromatogram was subsequently subjected to a radiochromatogram scan in which only one area of radioactivity was found which was superimposable with the developed indole spot.

Spectrophotometric Analysis of 5,6-Diacetoxyindole Solutions—Standard phosphate buffer solutions (pKa 6.8) were prepared for pH values of 6.8, 7.2, and 7.6, and their lack of absorbance in the ultraviolet region (210–360 mμ) was established. The buffered stock solutions of 5,6-diacetoxyindole were prepared by dissolving the indole in a minimum volume of methanol and diluting to volume with the respective standard phosphate buffer solutions. Subsequent dilutions of the indole stock solutions for U.V. determinations were made with the corresponding phosphate buffer. The pH of each solution was checked experimentally before and after spectrophotometric determination. Data from these experiments provided standard linear curves of concentration of indole *versus* absorbance for each pH value. The rates of decomposition for these dilute solutions of 5,6-diacetoxyindole were determined from the standard linear curves. Results are shown in Fig. 1.

Evaluation of the Stormer Viscosimeter in the Measurement of Certain Pharmaceutical Systems

By OSCAR E. ARAUJO

The performance of the Stormer viscosimeter was analyzed in detail by the study of the rheological properties of natural gums (acacia and tragacanth) and of synthetic gums (methylcellulose, sodium carboxymethylcellulose, and hydroxyethylcellulose). Two Newtonian systems (glycerin and sucrose solutions) were also investigated. Several different concentrations of each material were studied. There appeared to be an increase in viscosity with increasing rate of shear for most of the systems at the lower concentrations; a level of concentration was eventually reached where all the gum systems exhibited pseudoplastic characteristics and the Newtonian systems true linearity.

THE STORMER viscosimeter is a commercially available Searle type of viscometer described and modified for application to non-Newtonian systems by Fischer (1). The operational features and suggested useful ranges are outlined in several other references (2–5). The instrument has been widely used by investigators in the pharmaceutical sciences for well over a decade (6–12). Durability, ease of operation, and reproducibility of results are largely the strong points of the Stormer which led to its use by the above investigators.

None of the workers reported inconsistencies in the rheological data obtained. The following study was performed largely because of certain unusual results obtained in the measurement of some dilute solutions of hydrocolloids with the Stormer viscosimeter.

The initial inclination to attribute these discrepancies to experimental error was abandoned because of the recurring pattern of the results. Consequently, it was decided to carry out an extensive analysis of the performance of the Stormer viscosimeter in the measurement of various rheological systems.

EXPERIMENTAL

Preparation of Solutions—The substances used in the study, along with the range of concentration of their solutions, are given in Table I. From 7 to 10 solutions of different concentrations were prepared for each substance within the indicated range.

The solutions were prepared in the conventional manner. A Waring blender was used to disperse the gums after they had been moderately hydrated. Heat was employed to speed up solubility in the more concentrated solutions.

Rheological Measurements—A Stormer viscosimeter equipped with the modified cup and bob, as suggested by Fischer (1), was used. A weight hanger with various slotted weights provided the shearing stress. The appropriate instrumental constants, K_v, were determined from calibration data collected using standard oils, and were applied to each point on the rheograms. The apparent viscosity of the various solutions were then calculated from the expression:

$$\eta = K_v \frac{\text{Gm.}}{\text{r.p.m.}}$$

where Gm. represents the shearing stress and r.p.m. the rate of shear. All viscosity measurements were carried out at 20 ± 0.1°.

TABLE I—RANGE OF CONCENTRATION FOR EACH SUBSTANCE USED

Substance	% w/w
Acacia	7.5–45
Tragacanth	0.1–2.0
Methylcellulose	0.4–3.5
Sodium CMC	0.2–4.0
Hydroxyethylcellulose	0.5–2.0
Glycerin	35–90
Sucrose	35–70

RESULTS AND DISCUSSION

Rheograms were constructed for all the solutions by plotting r.p.m. as the ordinate and Gm. as the abscissa. Representative plots at three levels of concentration for each substance are shown in Figs. 1, 3, and 5.

The rheograms in Figs. 1 and 3 were redrawn to show the change in viscosity with rate of shear so that a more thorough analysis of the data could be performed. Figures 2 and 4 show the result of this representation.

The first series of rheograms obtained were those for the acacia solutions. As a result of the data collected, several other systems of known pseudoplastic nature were prepared as indicated in Table I; two Newtonian systems (glycerin and sucrose solutions) were also prepared to provide the basis for a complete comparison of the results.

Figure 1 shows rheograms of each solution at a low level of concentration. Each substance exhibits the same "dilatant" type curve, whereby there is an increase in viscosity with increasing rate of shear. These results can hardly be attributed to isolated experimental discrepancies, since, as can be clearly seen in Fig. 2, a definite pattern is consistent throughout. The instrument was checked as to proper alignment of the cup and bob and for any mechanical defects which might cause discrepancies in the data. No apparent mechanical anomalies were found to exist.

As the concentration of the solutions is increased, the rheograms indicate an over-all decrease and eventual disappearance of this dilatant effect. Figure 4 shows the plots for that level of concentration of each substance above which the so-called dilatant effect no longer exists.

Figure 5 shows the rheograms depicting the performance of the Stormer viscosimeter in the measure-

ment of the gum systems at the highest level of concentration of each, as indicated in Table I. All the

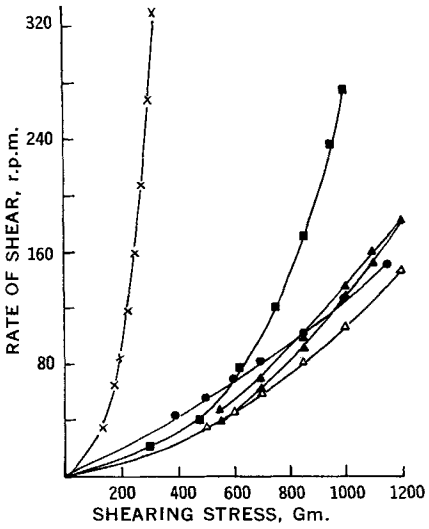

Fig. 5—Rheograms of aqueous gum solutions of high concentration. Key: ×, 1.8% tragacanth; ●, 45% acacia; ▲, 4.0% sodium carboxymethylcellulose; △, 3.5% methylcellulose; ■, 2.0% hydroxyethylcellulose

systems are cleary pseudoplastic in nature, except for sodium carboxymethylcellulose which exhibits a slight degree of thixotropy. No apparent problems are evident at this level of concentration with the instrument used.

From all of the results obtained, unless one cares to argue the case for actual dilatancy of all the systems at low concentrations, there are some interesting inferences which can be made.

It is conceivable that all gums used are pseudoplastic throughout the entire range of shear at all concentrations, and that there is an inherent "dilatant" producing effect with the Stormer which shifts all systems in that direction at lower concentrations. This effect then becomes less pronounced as the concentrations are increased and the true pseudoplastic nature of all the hydrocolloids eventually becomes predominant rendering the dilatant appearance imperceptible.

The other possibility is that these hydrocolloids are Newtonian in nature at the lower concentrations and the dilatant behavior simply indicates that the Stormer cannot be used effectively for systems having a viscosity lower than 20 cps. As the concentration is increased the systems become truly pseudoplastic and the Stormer performance is satisfactory at all rates of shear. This approach would explain the glycerin rheograms, since they exhibit Newtonian behavior only after a certain concentration is reached. Glycerin solutions, incidentally, should not be used to calibrate the Stormer viscosimeter in order to obtain the instrumental constants, K_v, because of their hygroscopic nature.

SUMMARY

1. Various hydrocolloids at several concentrations were studied using the Stormer viscosimeter.

2. Two Newtonian systems (glycerin and sucrose solutions) at various concentrations were also studied rheologically.

3. Results showed some interesting features not usually attributed to these systems: (*a*) there appeared to be a dilatant effect for all systems at low concentrations; (*b*) there seemed to be a minimum concentration for all gum systems, above which pseudoplastic behavior is observed throughout the entire range of shear rate.

4. The Stormer viscosimeter appeared to perform well in the rheological measurements of the more concentrated gum systems.

Acetylsalicylic Acid Hydrolysis in Aqueous Solutions of Polysorbate 80

By K. S. MURTHY and E. G. RIPPIE

The hydrolysis of acetylsalicylic acid (ASA) has been shown to occur at a measurable rate within polysorbate 80 micelles in an aqueous environment at pH 1.8. An estimate of the apparent pseudo first-order rate constant for the micellar degradation is made on the basis of the distribution of the undissociated ASA between the aqueous and the micellar pseudophase.

HYDROLYTIC SUSCEPTIBILITY of various drug species, in aqueous systems containing surfactants at concentrations above their CMC, has been the subject of several studies. Generally, it has been found that hydrolysis occurs within the micellar pseudophase as well as in the aqueous phase. Riegelman (1) demonstrated that benzocaine, solubilized in the polyoxyethylene palisade layer of certain cetyl alcohol polyoxyethylene ethers, is subject to hydroxyl-ion catalyzed hydrolysis. However, recent studies (2) indicate that no hydroxyl-ion catalyzed hydrolysis of chlorobutanol occurs within micelles formed by lauromacrogal or polysorbate 20. It has been suggested by Nogami (3) that the observed suppression by surfactants of the hydrolysis, below pH 5, of undissociated acetylsalicylic acid is due to partitioning of a part of the ASA into the micelles, where it becomes less hydrolyzable. The present study was undertaken to determine quantitatively the degree of protection afforded by polysorbate 80 to aqueous solutions of ASA.

EXPERIMENTAL

Reagents—Acetylsalicylic acid U.S.P. (Mallinckrodt) and polysorbate 80 (Atlas Chemical Industries, Inc.) were used as received. All other chemicals used were reagent grade.

Apparatus—All studies were performed using a Sargent constant-temperature water bath held at 30° ± 0.01°, Burrell wrist action shaker, Beckman model GS pH meter, and Beckman model DU spectrophotometer.

Experimental Procedure—Since solutions of relatively high buffer capacity were required in many cases, all solutions were adjusted to an ionic strength of 1.00. Analysis of salicylic acid and ASA was accomplished spectrophotometrically by the method of Edwards (4).

Solubility studies were conducted in vials of 20-ml. capacity. Excess solid ASA was added to vials containing 20 ml. of 0, 1, 2.5, and 4% solutions of polysorbate 80 at various pH's in the range 2.63–4.43. The solutions were agitated until successive assays indicated a state of equilibration. In general, three separate equilibrations were run at each combination of pH and polysorbate 80 concentration. Samples were forced through Millipore G.S. 0.22-μ filters prior to assay and the pH of the filtrate noted at this time. Buffers were as follows: pH 2.63, phosphate; pH 3.63, 4.10, 4.21, and 4.43, citrate.

Kinetic studies were carried out with saturated suspensions as well as with saturated and half-saturated solutions of ASA at a pH of 1.8. The suspensions and solutions were sampled periodically, and the samples filtered and analyzed as before. Kinetics were followed at 0, 2, and 4% polysorbate 80 levels for periods of 48 hr. Phosphate buffer (1.69 M) was used, and duplicate runs were conducted at each polysorbate concentration.

RESULTS AND DISCUSSION

The apparent pKa of acetylsalicylic acid under the conditions of these studies was obtained from

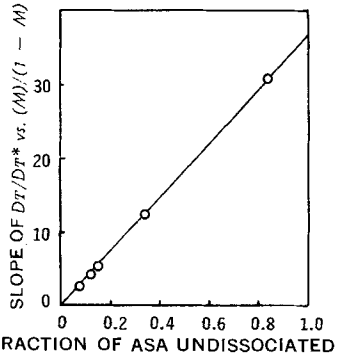

Fig. 1—Graph showing the slopes of $(D)_t/(D)_t^*$ vs. $(M)/(1 - M)$ *plotted* vs. *the fraction of ASA undissociated. The intercepts are the partition coefficients of the undissociated and dissociated acid.*

2[d]	5.7	1.9
4[d]	4.4	1.8

[a] Conditions: pH = 1.80; ionic strength = 1.00; temperature = 30° C. [b] Constants are calculated on the basis of the micellar pseudophase, assuming its volume in ml. is equal to the weight of polysorbate 80 in Gm., and assuming a partition coefficient of 51.9. [c] Saturated solutions of ASA. [d] Half-saturated solutions of ASA.

solubility data and found to be 3.35. The usual literature value cited is 3.49.

Hydrolysis of polysorbate 80 at pH 1.8 and unit ionic strength was found to be approximately 3% after an elapsed time of 48 hr. This degree of degradation did not have a measurable effect on either the solubility or the stability of ASA.

Partitioning of ASA into the Micellar Pseudophase—Results of the solubility determinations were interpreted assuming a linear partition isotherm, as described previously (5). In the present studies, however, the volume occupied by the micelles was not assumed to be negligible. Figure 1 represents a plot of the slope of the ratio $(D)_t/(D)_t^*$ *versus* $(M)/(1 - M)$, against the mole fraction of undissociated ASA. $(D)_t$ and $(D)_t^*$ are the total concentration of ASA in solution, and the concentration of ASA exclusive of that present in the micelles, respectively; (M) is the volume fraction of micellar pseudophase in the system, assuming the micellar volume in ml. is equal to the weight of surfactant in Gm. The curve passes through the origin, indicating the absence of dissociated ASA in the micellar pseudophase of the polysorbate 80 solutions. These findings are in agreement with those of Nogami (3).

The apparent partition coefficient of undissociated ASA, under the conditions of the kinetics studies, was found to be 52. This differs from that (about 37) predicted by Fig. 1. In this case, the high percentage of phosphoric acid (6.7%) present in the medium would change the polarity of the solvent so as to increase the activity coefficient of the undissociated ASA. This was confirmed by solubility determinations of ASA at pH 1.55 and unit ionic strength in aqueous solutions at various phosphoric acid concentrations.

Kinetic Studies—Since from the solubility studies it is inferred that the dissociated form of ASA exists only in the aqueous phase, the observed increase in degradation rate constants in suspensions (pseudo zero-order rate constants) with added polysorbate 80 is due to instability of undissociated ASA in the micellar phase. These constants were calculated from the rate of appearance of salicylic acid in the suspensions as illustrated in Fig. 2. Results are given in Table I.

Rates of hydrolysis were also determined in homogeneous solutions at saturation and half-saturation under conditions similar to the suspensions. The results are presented in Table II, where it can be seen that the rate of hydrolysis of ASA in polysorbate 80 micelles, while lower than in the aqueous phase, is not negligible. The reaction occurring within the micellar pseudophase is presumably hydrogen-ion catalyzed since the hydroxyl and water catalyzed reactions do not occur to a measurable extent at this pH (4).

Salicylic acid, produced during the hydrolysis, has been shown (6) to have no significant effect on the apparent solubility of ASA in aqueous systems.

SUMMARY AND CONCLUSIONS

Hydrolysis of ASA occurs to a significant extent within polysorbate 80 micelles in an aqueous medium at a pH of 1.8. An estimate of the pseudo first-order rate constants for the micellar degradation indicates a rate approximately one fifth that in the corresponding aqueous phase. For this reason, the addition of polysorbate 80 to aqueous suspensions of ASA can be expected to accelerate hydrolytic degradation at pH's below approximately 5.

Phase Transitions I.

Preliminary Study of Theophylline Hydrate–Anhydrate System

By ELI SHEFTER and GERALD KMACK*

The phase transformation of theophylline hydrate to an anhydrous form was measured at a variety of temperatures using X-ray powder diffractometry. The conversion rate appeared to be first order with respect to the amount of hydrate present.

NUMEROUS MEDICINAL AGENTS are capable of existing in the solid state as hydrates and nonhydrated polymorphs. Since the physical chemical properties of many of these modifications of a drug can be markedly different, this may in turn influence its pharmaceutical formulation. In many instances it would therefore be important to understand what factors might influence a solid state transition from a hydrate to an anhydrous form, or *vice versa*, and at what rate this transformation occurs.

The primary purpose of this preliminary study on phase transitions of pharmaceuticals is to demonstrate that by the use of X-ray powder diffractometry, kinetic data for the conversion of a hydrate to its anhydrous state can easily be obtained. The method has the advantage over other techniques in that one is measuring directly the crystal structure transformation. For this study the theophylline system was chosen, since the crystal structure of the hydrate has already been reported (1) and the thermodynamics of dissolution for the system has been investigated (2).

EXPERIMENTAL

Theophylline (U.S.P. grade) was recrystallized from water and then allowed to dry on filter paper at room temperature for a week. The material was then ground in a glass mortar until a fine powder was obtained. Since the particle size was not measured in these experiments, it was necessary to grind all the experimental material at once, so that the particle size distribution from run to run would be fairly constant.

A series of samples weighing approximately 4 Gm. each was distributed evenly on the bottom of Petri dishes by shaking the glass vessels. The dishes were placed in an oven with the temperature previously set. During the experiment, a thermometer recorded the air temperature directly above the sample. Samples were taken from the oven at hourly intervals, without altering the temperature more than a degree or two, and then added to tightly-stoppered vials.

Some of the material was heated at a temperature of 100° for a period of 1 week. Though conversion of the hydrate to the anhydrous form occurred at an extremely rapid rate at this temperature, the week-long heating ensured that all the material was converted to the latter form. X-Ray diffraction powder patterns of the two modifications were measured on a GE XRD-6 diffractometer. There were many diffraction regions in which the two forms had intense peaks which were separated sufficiently to permit quantitative analysis of mixtures of the two, in a manner similar to that described by Azaroff and Buerger (3) and Shell (4). The diffraction peaks utilized were those at 13.2° (2θ) for the hydrate and at 12.6° (2θ) for the anhydrous crystals.

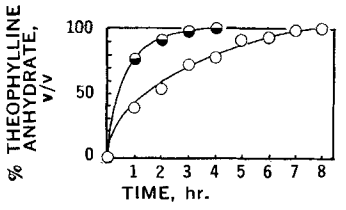

Fig. 1—Anhydrate formation from theophylline hydrate at 40° and 50°. Key: ◒, 50°; O, 40°.

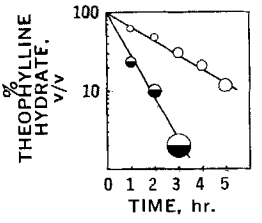

Fig. 2—Conversion of theophylline hydrate to the anhydrate–transformation rates at 40° and 50°. Key: ◒, 50°; O, 40°.

RESULTS AND DISCUSSION

Studies carried out at room temperature (approximately 25°) showed that there was no detectable transformation of the hydrate to the anhydrous form, over a period of 2 months. Above 60° the rate of conversion was so rapid that it was not possible to measure it by the present technique. At 60° the rate was measureable but appeared to be suffering from the lag time necessary for the material to reach the oven temperature. The conversion curves (Figs. 1 and 2) at 40° and 50° gave apparent first-order transformation rates. It is felt that at these temperatures the time necessary for the solid material to reach the oven temperature was probably negligible compared to the initial rate of transformation. Since particle size and humidity were not controlled, it is felt that a detailed analysis of the rate data would be presumptuous. It is interesting to note, however, that the transition temperature for this phase transformation probably lies not too far above room temperature but below 40°. This temperature is considerably lower than that obtained by the solubility method of Shefter and Higuchi (2); where 73° was obtained for the transition temperature in water. This is a direct indication that hu-

midity probably plays a major role in this phase transformation.

The transformation of caffeine hydrate to an anhydrous state was also carried out in the same manner. The results obtained for the two purine systems are quite different. Hydrated caffeine had a fairly rapid rate of transformation at room temperature, and the conversion appeared to go through various hydrate intermediates, as evidenced through certain changes in the X-ray powder patterns with time. This latter phenomenon is in agreement with the findings of Waters and Beal (5). The general differences in the transformation processes for the two purine hydrates are consistent with structural studies on the hydrates of the two compounds (1, 6, 7). The hydrogen bonding schemes in the two hydrate crystal structures are markedly different with respect to the waters. It would be tempting to correlate the semiquantitative rate data with the crystal structures of the hydrates; however, such speculations would be premature at this time in view of the lack of structural data on the anhydrous crystals and more detailed phase transformation data.

Stereospecific Hydrogenations Using Palladium-on-Poly-L-leucine

By ROBERT L. BEAMER, CAROLYN S. FICKLING, and JAMES H. EWING

Studies have been conducted concerning the stereospecific nature of catalysts prepared by depositing palladium upon a poly-L-amino acid. The poly-L-amino acid chosen for this study was poly-L-leucine which was prepared from *N*-carboxy-L-leucine anhydride. The substrates employed in this work were α-methylcinnamic acid and α-acetamidocinnamic acid. Hydrogenation of α-methylcinnamic acid catalyzed by palladium-on-poly-L-leucine produced predominately R(−)-dihydro-α-methylcinnamic acid and hydrogenation of α-acetamidocinnamic acid using the same catalyst produced, after hydrolysis, S(−)-phenylalanine.

THE STEREOSPECIFICITY of catalysts prepared from silica gels precipitated in the presence of cinchona alkaloids has been shown by Padgett and Beamer (1). Beamer and Lawson have presented evidence of substrate specificity with similarly prepared gels (2). The silica gel work was based on prior evidence indicating the existence of stereospecific and substrate-specific centers in palladium-on-charcoal catalysts (3). Also, Akabori *et al.* had demonstrated the stereospecificity of palladium-on-silk fibroin (4) and Beckett *et al.* had shown the stereospecificity of adsorption in specially prepared silica gels (5–7).

The present work concerns the observation of stereospecificity in palladium-on-poly-L-amino acids. The poly-L-amino acid chosen for this study was poly-L-leucine which was prepared by polymerization of the *N*-carboxy-α-amino acid anhydride *in vacuo*.

Stereoselection in these catalysts should occur from asymmetric induction arising from stereoselective adsorption to active sites on the catalyst surface followed by *cis*-addition of hydrogen (3).

EXPERIMENTAL

Reagents—α-Methylcinnamic acid (Aldrich), carbobenzyloxy chloride (Nutritional Biochemicals), L-leucine (Mann Biochemicals).

Poly-L-leucine—This polypeptide was prepared from the *N*-carboxy-α-amino acid anhydride by the Bergman procedure (8) which consisted of preparation of the carbobenzyloxy amino acid (CBZ amino acid) from CBZ chloride and L-leucine. The anhydride was prepared by Leuch's procedure from the CBZ amino acid and thionyl chloride (8). By melting the anhydride under high vacuum (10^{-3} mm. Hg) the polyamino acid was obtained. The yield was 23% of theory (based on L-leucine). Infrared spectra (Nujol mull) of the resulting polyamino acid were identical with those given by Bamford *et al.* (9). Carbon, hydrogen, and nitrogen analyses indicate the product is the hemihydrate and this has been confirmed by drying in an oven. Molecular weight determinations are currently being carried out and will be reported at a later date.

Carbon, hydrogen, and nitrogen analyses indicate the product is the hemihydrate and this has been confirmed by drying in an oven. Molecular weight determinations are currently being carried out and will be reported at a later date.

Anal.—Calcd. for $C_6H_{11}NO \cdot {}^1/_2H_2O$: C, 58.99; H, 9.90; N, 11.47. Found: C, 59.66; H, 9.51; N, 11.55.

α-Acetamidocinnamic Acid—This compound was prepared by hydrolysis of the azlactone, 2-methyl-4-benzilideneoxazolin-5-one (10). The product melted from 190° to 191.5° (uncorrected). [Lit. (10) m.p. 191°–192°.]

Preparation of Catalysts—Two methods were used to prepare the catalysts.

Method A—Sixteen milliliters of a 2.5% palladous

chloride solution (representing 200 mg. of $PdCl_2$ per Gm. of polyamino acid carrier) was added to 2.0 Gm. of poly-L-leucine suspended in 200 ml. of distilled water. The mixture was shaken 1 hr. on a Parr low-pressure hydrogenator prior to the introduction of hydrogen. Following the shaking period, the system was evacuated and hydrogen was introduced. The mixture was shaken for 1 hr. in an atmosphere of hydrogen. The hydrogen pressure was 2.8 Kg./cm.^{2}. The catalyst was collected by suction filtration, washed with a total of 300 ml. of distilled water, and dried for 48 hr. in a vacuum desiccator over sulfuric acid.

Method B—Two grams of poly-L-leucine was suspended in 200 ml. of distilled water in a 500 ml., two-necked, round-bottomed flask equipped with a dropping funnel and a motor-driven stirrer. While the mixture was stirred vigorously, 16 ml. of a 2.5% palladous chloride solution was added dropwise. After the addition of the palladous chloride solution was complete, the mixture was stirred vigorously for 1 hr. The mixture was then transferred to a Parr hydrogenation bottle and hydrogenated for 1 hr. at a hydrogen pressure of 2.8 Kg./cm.^{2}. Following hydrogenation, the catalyst was treated as has been described under *Method A*.

Elutriation Studies—The catalyst prepared by method *A* produced nonreproducible results when used to hydrogenate α-methylcinnamic acid according to the procedure of Padgett and Beamer (1).

Since the lack of reproducibility apparently stemmed from inhomogeneity within the catalyst preparation, an elutriation technique was employed to separate the catalyst into five arbitrarily assigned layers numbered 1 through 5 with 1 representing the bottom layer in the elutriation column. Each layer was then used to catalyze the hydrogenation of α-methylcinnamic acid according to the method of Padgett and Beamer (1) using 2.9 Gm. of the substrate and 0.36 Gm. of catalyst.

Hydrogenation Studies—Two substrates were used for the hydrogenation studies. These substrates were α-methylcinnamic acid and α-acetamidocinnamic acid.

α-Methylcinnamic Acid—Except for the hydrogenations using the catalysts obtained by the elutriation technique noted above, 4.05 Gm. (0.025 mole) of α-methylcinnamic acid and 0.5 Gm. of catalyst (method *B*) were employed. The hydrogenations were carried out in 50 ml. of absolute ethanol with a Parr low-pressure hydrogenation apparatus. The initial pressure was 4.2 Kg./cm.^{2} and a fall in pressure of 2.8×10^{-1} Kg./cm.^{2} was observed (theoretical: 2.9×10^{-1} Kg./cm.^{2}).

Following hydrogenation, the catalyst was removed by filtration and the solvent evaporated. The residue was vacuum distilled. The yield was 2.6 Gm. representing 63.4% of theory. The boiling point was 106°/0.35 mm. Hg (uncorrected). [Lit. (11) m.p. 160°/13 mm. Hg.] The $[\alpha]_D^{25}$ of the distilled product was −0.406 (c = 25 in benzene) was determined using a Rhudolph 200S polarimeter. The specific rotation represents 1.50% of the literature value of −27.06° (11). Infrared spectra of the product were identical with those given by Beamer and Lawson (2). The neutralization equivalent of the product agreed with that calculated for dihydro-α-methylcinnamic acid.

α-Acetamidocinnamic Acid—Hydrogenation of this substrate was carried out in 100 ml. of absolute ethanol with a Parr low-pressure hydrogenator. The weight of α-acetamidocinnamic acid was 4.8 Gm. (0.023 mole). The initial pressure of hydrogen was 4.2 Kg./cm.^{2}. One gram of catalyst was used. The observed fall in pressure was the same as that expected from theory (1.3×10^{-1} Kg./cm.^{2}).

Following hydrogenation, the catalyst was removed by suction filtration and the solvent was evaporated leaving a white, crystalline residue. The residue was treated according to the directions of Akabori (4) by boiling under reflux with 10% hydrochloric acid. Following the acid hydrolysis, the solution was concentrated under vacuum to approximately one-half its volume and treated with acetone to precipitate the amino acid hydrochloride. The phenylalanine was obtained by adjustment of a 50% v/v hydromethanolic solution to the isoelectric point of phenylalanine (pH 5.4) and collecting the resulting precipitate by suction filtration. The product weighed 3.5 Gm. representing a yield which was 92.3% of theory. The product melted with decomposition from 269° to 270° (uncorrected). [Lit. (12) m.p. 271°–273° dec.] Descending filter paper chromatography using butanol–acetic acid showed the R_f value of the product to be identical with that of known phenylalanine determined under identical conditions. The infrared spectra of the product and known phenylalanine were identical.

The phenylalanine was dissolved in 6.4% sodium hydroxide solution, placed in a 100 mm. polarimeter tube, and read in a Rhudolph 200S spectropolarimeter giving an observed rotation of −0.26° representing an $[\alpha]_D^{25}$ of −2.6° (c = 10). The literature value for the specific rotation of phenylalanine is −48.4° (13). From these data an optical yield of 5.4% may be calculated.

Table I—Hydrogenation of α-Methylcinnamic Acid Using Palladium-on-Poly-L-leucine Separated by Elutriation[a]

Layer	HMCA[b] Yield, Gm.	Yield,[c] %	Reduction Time, hr.	$[\alpha]_D^{25}$ [d]	Pressure Drop, Kg./cm.^{2} [e]
1	2.6	90	1	−0.146 ± .01°	7×10^{-2} [f]
2	2.48	85.5	1	−0.536 ± .01°	8.4×10^{-2}
3	2.45	84.5	1	−0.250 ± .01°	5.6×10^{-2}
4	0.00	0.00	1	...	1.4×10^{-2}
5	0.00	0.00	1	...	7×10^{-3}

[a] Weight of catalyst was 0.36 Gm. [b] HMCA = dihydro-α-methlcinnamic acid. [c] Based on 2.9 Gm. of α-methylcinnamic acid. [d] Determined in benzene using a 100-mm. tube (c = 25). The instrument used was the Rhudolph 200S spectropolarimeter. [e] Initial pressure was 4.2 Kg./cm.^{2} (gauge). [f] Hydrogen uptake for complete hydrogenation of 2.9 Gm. of substrate was calculated to be 1.04×10^{-1} Kg./cm.^{2}

RESULTS

The results of the hydrogenation experiments using the elutriated catalyst prepared by method *A* are given in Table I.

The catalyst prepared by method *B* appeared more homogeneous to the eye and in divided catalysts produced uniformly reproducible results. However, the product of the hydrogenation using the method *B* catalyst was not so optically active as that obtained from the second layer of the elu-

triated method *A* catalyst (see Table I). The hydrogenation product using method *B* catalyst was more optically active than the hydrogenation product using layers one and three of the elutriated method *A* catalyst.

The results of the other hydrogenations are given under *Experimental*. Hydrogenation of α-acetamidocinnamic acid, followed by hydrolysis, produced predominately (−)-phenylalanine.

The results of the hydrogenations using the elutriated catalyst are reproducible.

DISCUSSION

While it is too early in the studies involving these catalysts to form definite conclusions regarding the experimental evidence already gathered, one can form some preliminary ideas concerning these catalysts.

The similarities between proteins and polypeptides and the catalytic action of certain proteins (enzymes) prompted the investigation in this area. Does the stereospecificity observed from enzymes stem from the asymmetry of their individual amino acid residues or from the secondary, tertiary, or even quaternary structures of the proteins involved? Recent reports (14–16) indicate that synthetic polyamino acids, far from being random, may coil in either a righthanded or a lefthanded manner, and the direction of coiling is dependent in part on the amino acid involved. These reports are in sharp contrast to earlier data showing a more random arrangement (17).

Since these hydrogenation catalysts have been developed as models of enzymes, it might be well to critically examine our studies in the light of current concepts of enzyme specificity. The well-known theory of Koshland (18), which has been applied by Belleau (19) to include drug receptors, involves the assumption of a conformational perturbation occurring in the protein as a result of the forces of interaction between the substrate (or drug) and the enzyme (or drug-receptor). One particular interaction involved stems from the hydrophobic nature of the substrate molecule and the hydration of the protein. Other forces can also contribute to the induced perturbation (20).

It would be speculation to conceive of such a mechanism operating in the catalysts described in this paper. However, the similarities involved between synthetic polypeptides and proteins and the recent observations of Scheraga *et al.* (15) indicate something in this regard. Certain groups within the peptide chain do influence the synthetic peptide's secondary structure.

More definite conclusions may be obtained from a consideration of the absolute configurations of the products of the hydrogenations using palladium-on-polyleucine. As noted above, hydrogenations of both α-methylcinnamic acid and α-acetamidocinnamic acid yield levorotatory products. The absolute configurations of (−)-dihydro-α-methylcinnamic acid and (−)-phenylalanine have been determined (21–23). (−)-Dihydro-α-methylcinnamic acid has been shown to have the R configuration as shown in Fig. 1. (−)-Phenylalanine, however, possesses the S configuration.

Obviously the two substrates must be interacting—at least, in part—at two different sites on the catalyst surface. Analysis of the structure of α-methylcinnamic acid indicates four points which could bind with the catalytic surface: the olefinic group (C=C) at which reduction takes place, the carboxyl group which could form a salt bond with a cationic group or could form a hydrogen bond with a suitable group on the catalyst, a phenyl group which could bind by van der Waal's forces, and a methyl group which also could bind by van der Waal's forces. The methyl group is replaced by an acetamido group in α-acetamidocinnamic acid, but all the other groups are common to the two substrates. The methyl group is nonpolar but can bind to the catalyst by van der Waal's forces. The acetamido group can bind to the catalyst by hydrogen bonds or by induced dipole interaction. If the respective points of attachment are suitably situated and if two active centers or sites of reaction are envisioned, the production of the configurations described above can be explained. Schemes I and II illustrate possible mechanisms explaining the observed results. The hydrogen in these figures is shown enter-

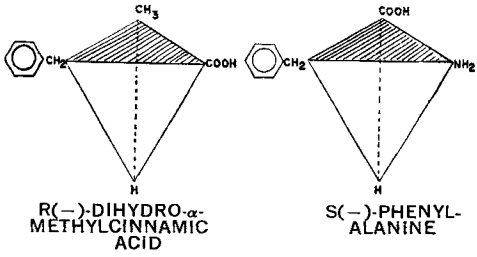

Fig. 1—Absolute configurations of (—)-dihydro-α-methylcinnamic acid as reported by Schrecker (21) and (—)-phenylalanine as reported by Karrer et al. *(22, 23).*

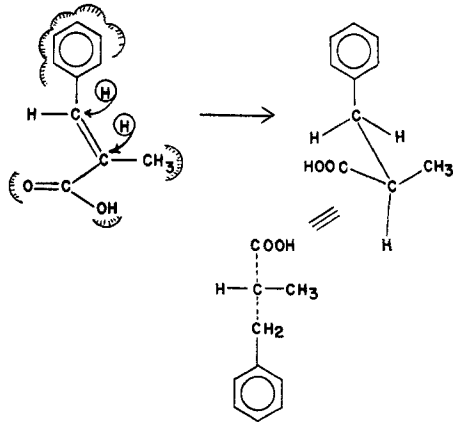

Proposed Scheme for the Stereospecific Hydrogenation of α-Methylcinnamic Acid Catalyzed by Palladium-on-Poly-L-leucine. Scheme II

ing the α-methylcinnamic and acid *cis* and from the catalytic side, *i.e.*, beneath the molecule or toward the side of the molecule away from the viewer. Stereoselective adsorption apparently occurs prior to addition of hydrogen and stereospecific hydrogenation is the result.

Later work with palladium-on-synthetic polypeptides may provide answers to the questions raised in this paper and indicate the fidelity of this model in explaining the complex phenomena of enzymatic catalysis.

SUMMARY

Hydrogenations using palladium-on-poly-L-leucine with α-methylcinnamic acid and α-acetamidocinnamic acid as substrates gave optically active products. The absolute configurations of the hydrogenation products indicate the two substrates fit—at least, in part—different active sites.

Isolation of a Potential Antitumor Fraction from *Rumex hymenosepalus* (*Polygonaceae*) II. Identification of the Active Fraction

By LEONARD BUCHALTER and JACK R. COLE

Continued investigation into the character of the antitumor fraction of *Rumex hymenosepalus* has resulted in the identification of leucodelphinidin and leucopelargonidin as components of this fraction. The activity was shown to reside in the polymeric fraction. The monomeric fraction was shown to be inactive.

In a previous communication (1) the authors have reported that the roots and tubers of *Rumex hymenosepalus* yielded a tannin extract which demonstrated antitumor activity. The active extract was subsequently fractionated into two components, A and B. The presence of leucoanthocyanidin units in fraction B was confirmed by the conversion of leucocyanidin to cyanidin.

Further investigation of fraction B has led to the characterization of this fraction as consisting of polymeric leucoanthocyanidin units consisting of leucopelargonidin, leucodelphinidin, as well as the leucocyanidin previously reported. In subsequent tests for antitumor activity, it was found that the activity resided in the polymeric fraction, and attempts at purification of the polymeric material did not enhance the antitumor activity.

The identification of the polymeric nature of fraction B was carried out by paper chromatographic analysis, visible spectra analysis, and degradation by potassium fusion of the anthocyanidins produced from the polymeric leucoanthocyanidins.

Subsequent investigation of fraction A has shown that this fraction consisted of monomeric leucoanthocyanidin units of the same type as was found in the polymeric condensed unit. The leucoanthocyanidins—leucocyanidin, leucodelphinidin, and leucopelargonidin—were identified by conversion to their corresponding anthocyanidins and identification was again made by means of paper chromatography, visible spectra analysis, and degradation by potassium fusion. The results of the antitumor testing of this fraction indicated that the monomeric leucoanthocyanidins were inactive.

EXPERIMENTAL

Conversion of Fractions A and B from Leucoanthocyanidins to Anthocyanidins—Both fractions A (water-soluble ethyl acetate extractable fraction of the tannin extract) and B (water-soluble ethyl acetate nonextractable fraction of the tannin extract), when boiled for 15 to 30 min. in ethanolic 10% hydrochloric acid, gave red solutions, indicating that both fractions consisted of leucoanthocyanidins which were convertible to anthocyanidins.

Paper Chromatography of Anthocyanidins—The anthocyanidins were applied to Whatman No. 1 filter paper for chromatographic analysis. Descending chromatography was used. The chromatogram was developed for 6 hr. and travelled 18 in. The following three solvent systems were utilized as they have proved effective for identifying anthocyanidins on paper (2, 3): (*a*) formic acid–3 *N* HCl (1:1), (*b*) water–acetic acid–concentrated HCl (10:30:3), (*c*) acetic acid–concentrated HCl–water (5:1:5).

All three solvent systems indicated the presence of three anthocyanidin pigments. The R_f values in solvent system (*a*) matched those described in references for delphinidin, cyanidin, and pelargonidin. The R_f values obtained in solvent systems (*b*) and (*c*) verified the presence of these three anthocyanidins. The same anthocyanidins were produced from both fractions A and B. (See Table I.)

Visible Spectra Analysis of Anthocyanidins—Although anthocyanidins characteristically exhibit intense absorption in the 500–550 mμ, addition of a few drops of aluminum chloride solution produces a bathochromic shift (15–50 mμ) of the principal $\lambda_{max.}$ of those anthocyanidin derivatives which contain adjacent hydroxyl groups.

Papers containing the three pigments corresponding to the anthocyanidins were extracted with methanol–0.1% HCl and subjected to visible light analysis in a Beckman DB spectrophotometer. The results of this visible analysis were compared with the values obtained by Harborne (4). Each material was also analyzed after the addition of 3 drops of aluminum chloride solution to the methanolic 0.1% HCl in which they were originally extracted.

The results of this analysis (Table II) verified the pigments that had been previously identified on paper. Delphinidin showed a maximum absorption at 546 mμ and a bathochromic shift of 23 mμ when aluminum chloride solution was added. Pelargonidin showed a maximum absorption in the visible region at 520 mμ and no bathochromic shift occurred on the addition of the aluminum chloride. Cyanidin showed a maximum absorption of 535 mμ, and a bathochromic shift of 20 mμ when aluminum chloride was added.

Degradation by Potassium Fusion of Anthocyanidins—In order to substantiate further chemically the structure of the anthocyanidins, the anthocyanidins were degradated by fusion with potassium hydroxide (5). This procedure resulted in phenolic and acidic portions which were then subjected to paper chromatography.

Paper Chromatography Identification of Fragments—Commercial samples of gallic acid, protocatechuic acid, *p*-hydroxybenzoic acid, and phloroglucinol were obtained, and chromatography of the degradation products of potassium fusion and commercial samples was carried out in the follow-

ing three solvent systems: (*1*) butanol–acetic acid–water (4:1:5) (upper phase only), (*2*) phenol–water (9:1), (*3*) 5% glacial acetic acid.

Five per cent ferric chloride solution was used as the chromogenic spray to identify the fragments produced on Whatman No. 1 filter paper. The results of the paper chromatography of the products of potassium fusion are shown in Table III. These results further verified the identity of the anthocyanidins produced from fractions A and B.

SUMMARY AND CONCLUSIONS

It has been determined that the active antitumor fraction of ground roots and tubers of *R. hymenosepalus* consists of polymeric leucoanthocyanidin units. These units are leucocyanidin, leucodelphinidin, and leucopelargonidin. The exact method of polymerization of these units in the active fraction has not yet been determined.

Monomeric flavanoidal units of the same type contained in the polymer were investigated and found to be devoid of antitumor activity.

Cation Radius and Deoxycholic Acid Polymer-Like Structure Stability

By C. BOTRÉ, P. A. CICCONETTI, G. LIONETTI, and M. MARCHETTI

The stability of the polymer-like structure displayed by deoxycholic acid gels under certain conditions has been investigated. The influence of cation dimensions, hydration, and hydrogen bonds is shown. A peculiar behavior of deoxycholic acid quaternary ammonium salts is discussed. Some biological implications are mentioned briefly.

Deoxycholic acid (DCA) is a unique molecule from its physical, chemical, and biological aspects. The physicochemical properties of DCA have been reported by Giacomello (1, 2), and more recently by Rich (3, 4). It has been found that under appropriate conditions sodium deoxycholate aggregates in solution to form a gelatinous complex of macromolecular dimensions. X-Ray diffraction studies of fibers of this complex showed that the molecules had assumed an elongated helical configuration 36 Å. in diameter (3, 4). The formation of a helical complex of macromolecular dimension from sodium deoxycholate is highly specific since closely related compounds do not exhibit this effect.

In previous work the influence of counterions on the conformation of either synthetic or natural polyelectrolytes (5, 6) has been shown. Therefore, it seemed worthwhile to study DCA gels in order to acquire further information on the many factors which influence the stability of these structures. It was the objective of the present study to determine if the formation of gels of macromolecular dimensions was in some way affected when deoxycholic acid salts other than sodium deoxycholate were used. The effects of cation dimensions, hydration, and hydrogen bonds on the stability of the structure were also investigated.

The importance of DCA and related structures to the physicochemical properties of biological membranes, as well as the interactions between these polymer-like structures and drugs, must not be overlooked. The study of the variation of the ionic activity of quaternary ammonium ions in a polyelectrolyte solution and the resulting influence on the conformation of the structure is of basic importance in order to interpret, on physicochemical grounds, biological problems such as nerve transmission.

EXPERIMENTAL

Material—DCA (Merck) was recrystallized from alcohol before use.

Solutions of different DCA salts were prepared by neutralizing DCA solution with the hydroxides of different cations. The DCA salt solutions thus obtained were then lyophilized.

Stock solutions of Li^+, Na^+, K^+, Rb^+, Cs^+, NH_4^+, and quaternary ammonium bases were freshly prepared and standardized with a solution of 0.1 *N* HCl.

Lithium hydroxide solution was prepared from Li_2SO_4 and $Ba(OH)_2$. A small excess of Li_2SO_4 was employed so as to have a minimum of Ba^{2+} in the LiOH solution. The $BaSO_4$ was separated by filtration, and the LiOH solution free of sulfate and carbonate was obtained by passing the solution through an anion exchange column.[1]

Rubidium hydroxide and CsOH solutions were prepared by exchanging RbCl and CsCl solutions through the above-mentioned ion exchanger.

In a similar way quaternary ammonium bases were prepared by exchanging the corresponding iodides. The absence of halogens (Cl^- or I^-) from these solutions was checked.

All reagents used were of analytical grade.

PROCEDURE

The different DCA salts were prepared by dissolving DCA with an amount, slightly less than that required, of hydroxide solutions of the corresponding cations. The excess of acid was removed by filtration. The solution was evaporated and the DCA salt recovered.

DCA gels were obtained by dissolving known amounts of the DCA salts in water and then adjusting the pH to a value of 6.8–6.9 by adding very small amounts of HCl under continuous and constant stirring. All gels obtained were stored at a temperature of about 5°.

Conductivity measurements were carried out in a constant-temperature bath regulated within 0.01° for temperatures from 20° to 30° and within 0.3° for higher or lower temperatures. The complete filling and closing of the cell prevented evaporation of the solution. A WTW bridge (model LF_2) was employed for such measurements.

RESULTS AND DISCUSSION

In Fig. 1 specific conductivity data recorded in a solution of NaDCA are plotted against temperatures. The break in the trend, corresponding to a particular value of temperature, indicates a transition which is a function of the concentration of DCA in solution and of the radius of the cation which neutralizes DCA. As shown in Fig. 1, graphs of different monovalent cations (Li, Na, K, Rb, Cs, and NH_4) have the same general shape but are shifted toward higher or lower temperatures.

In Fig. 2 data obtained from solutions of different concentrations (0.05 and 0.10 *M*) of the above-mentioned DCA salts are reported. The transitional temperatures are plotted against the crystallographic radius of the different cations. The thermal stability of the helical complex decreases with the increasing crystallographic radius following the cation sequence.

In the case of NaDCA the influence of concentration on the transitional temperatures is shown in Fig. 3. The trend of the plot shows that the stability of the complex is temperature-dependent below a concentration of about 6×10^{-2} *M*. Above

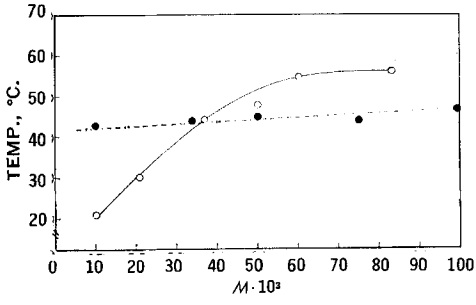

Fig. 3—Transitional temperatures dependence upon concentration of NaDCA (○) and NH_4DCA (●) solutions.

this value, the transitional temperatures are no longer affected by DCA concentration in solution.

In Fig. 2 the anomalous position in the plot of NH_4^+ which seems to have almost the same transitional temperature for the two different concentrations, 0.05 and 0.10 *M*, is evident. This is due to the fact that, in the case of NH_4DCA, the trend of the plot of transitional temperature *versus* concentration differs from those of the other cations. In a range of concentration between 0.01 and 0.10 *M*, the transitional temperatures of NH_4DCA go from 43° to 47°, while in the same range of concentration of NaDCA, as well as the other monovalent cations, there is a shift of about 35° (see Fig. 3).

Furthermore, the plot of specific conductivity against temperature of an NH_4DCA solution shows a different trend. Below and above the transitional temperature the plot differs in slope (see Fig. 4). In addition, viscosity measurements in an NH_4DCA solution show a deviation toward higher values than those obtained from solutions of other salts. This suggests that the presence of ammonium ions, through hydrogen bond formation, affects the complexity of these structures, which will grow in all directions forming a matted matrix of high viscosity. In fact, addition of urea to a solution of NH_4DCA brings the plot back to the shape common to the other cations (see Fig. 5).

To further investigate the role played by ionic dimensions in these polymer-like structures, solutions of some organic quaternary nitrogen salts have been studied. They are monomethylammonium (MMA), dimethylammonium (DMA), tetramethylammonium (TMA), tetraethylammonium (TEA), and tetrabutylammonium (TBA) deoxycholate.

In Fig. 6 the transitional temperatures of the above-mentioned DCA salts are plotted against the

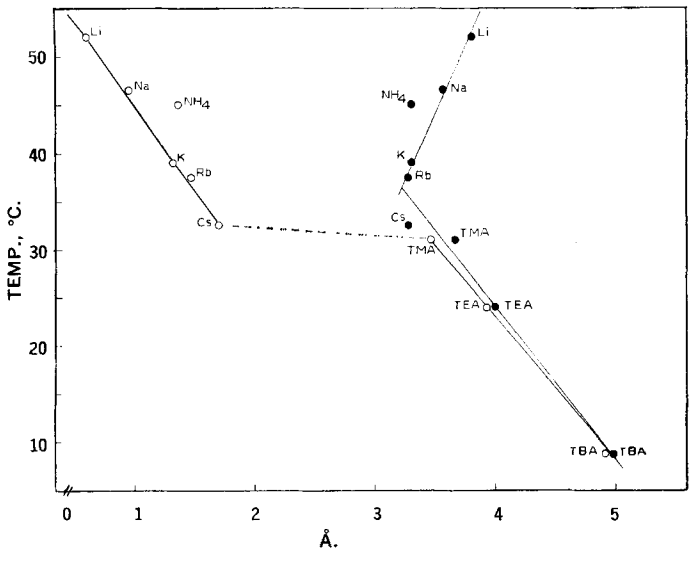

Fig. 6—Transitional temperatures of different DCA salts as a function of the crystallographic radius (○) and the hydrated radius (●).

crystallographic radius and against the hydrated radius (7). If the increment of crystallographic radius were the only reason for the increase of transitional temperatures, we should find much higher values in that part of the plot where Li, Na, K, Rb, and Cs are placed. In other words, the plot of transitional temperature as a function of crystallographic radius should be represented by the same straight line. When the hydrated radii are taken into consideration, the resulting plot shows a completely different trend. In fact, whenever there is a slight difference between crystallographic and ionic radii, that is, whenever the amount of water bound to cations is negligible, as in the case of organic cations, the resulting plots are almost identical. Instead, when the amount of structuralized or iceberg-like water bound to cations begins to be relevant, that part of the plot referring to inorganic cations exhibits a marked change in the slope and shows a discontinuity.

The experimental data summarized in Fig. 6 prove that structuralized or iceberg-like water bound to cations increases the thermal stability of the helical complex.

Water, therefore, proves to be of fundamental importance to the structural stability of such polymer-like compounds.

In conclusion, three factors were found to influence the stability of the structure: cation dimension, hydration, and hydrogen bonds.

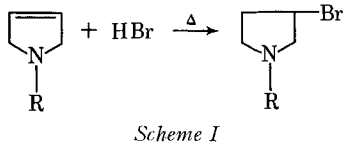
Synthesis of 1-Substituted-3-bromopyrrolidines

By D. C. RUOPP, F. A. E. SCHILLING, and B. B. BROWN

Considerable interest has been shown in 3-substituted pyrrolidines because of their physiological activity on the central nervous system. The preparation of several 1-substituted-3-bromopyrrolidines is described. In addition, a unique technique of halopyrrolidine synthesis, virtually eliminating self-quaternization, is presented.

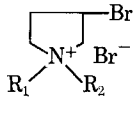
INTEREST in 1-alkyl-3-halopyrrolidines has been stimulated by their usefulness as intermediates for the preparation of central nervous system stimulants, antispasmodics, ganglionic stimulants, anticholinergics, and parasympathetic depressants (1–5). Many theoretical routes to 1-alkyl-3-halopyrrolidines are possible; however, most are quite costly and involve several steps. Preparation of 1-alkyl-3-halopyrrolidines by hydrohalogenation of 1-alkyl-Δ^3-pyrrolines offers an inexpensive and direct approach to this type of compound. Extensive information regarding the addition of hydrogen halides to straight chain olefins is present in the literature (6–8). Some work has been reported using cyclic olefins (9, 10); however, no reference was found disclosing the addition of hydrogen halides to Δ^3-pyrrolines.

1-Alkyl-Δ^3-pyrrolines were prepared by cyclization of *cis*-1,4-dichlorobutene-2 with the appropriate primary amines (11, 12). Low reaction temperature conditions favorable for hydrobrominating butene-1 (8) and pentene-1 (6) were not successful with the 1-substituted-Δ^3-pyrrolines in aqueous or nonaqueous media. Successful hydrobromination was achieved using 60% aqueous HBr at 120–125°. No reaction was obtained with the commercially available 48% HBr at the same conditions. Although hydrobromination of 1-substituted-Δ^3-pyrrolines obviously does not occur with the facility of the olefin systems, here too, the rate of HBr addition was found to far exceed hydrochlorination under the necessary temperature conditions. (Scheme I.)



Scheme I

The 1-substituted-3-bromopyrrolidines were subsequently converted to their amine and quaternary salts. (I–VI.)



R_1	R_2
I, H	CH_3
II, CH_3	CH_3
III, H	C_2H_5
IV, CH_3	C_2H_5
V, H	$C_6H_5CH_2$—
VI, CH_3	$C_6H_5CH_2$—

The preparation of the above pyrrolidine salts, with the exception of V, afforded no difficulty. Some dissociation of the pyrroline salt occurs during the hydrobromination reaction as shown by the resultant formation of a mixture of 1-ethyl-3-chloropyrrolidine and 1-ethyl-3-bromopyrrolidine when starting with 1-ethyl-Δ^3-pyrroline hydrochloride. Self-quaternization occurs to a significant degree also during the hydrobromination reaction, especially with I, forming presumably 1-alkyl-1-(1′-alkyl-3′-pyrrolidyl)-3-bromopyrrolidinium bromides. The authors have found that by first forming the quaternary salt of the 1-substituted-Δ^3-pyrrolines, self-quaternization during the hydrobromination reaction is minimized. For example, hydrobromination of 1-methyl-Δ^3-pyrroline methobromide produced 57% of II and a 32% recovery of the starting quaternary, whereas hydrobromination of 1-methyl-Δ^3-pyrroline gave only 22% of I and a 10% recovery of the starting amine.

EXPERIMENTAL

The hydrobromination reaction was conducted in a 500-ml. pressure bottle mounted on a Parr shaker apparatus equipped for heating. Since bromopyrrolidines tend to self-quaternize even under refrigeration, the products were converted immediately after isolation to their amine or quaternary salts with hydrogen bromide or methyl bromide. Benzene was used as the reaction medium and afforded a quantitative recovery of the respective pyrrolidine salts.

1-Methyl-3-bromopyrrolidine—A solution of 16.39 Gm. (0.1 mole) of 1-methyl-Δ^3-pyrroline hydrobromide in 67.5 Gm. (0.5 mole) of 60% HBr was heated at 120–125° for 24 hr. After cooling to 25°, the reaction mixture was adjusted to pH 11 by the addition of 25% NaOH (100 Gm.). The oil layer was extracted with benzene (2 × 25 ml.), washed with water (10 ml.), and azeotroped dry at atmospheric pressure while charcoaling for 15 min. Filtration of the charcoal resulted in a light yellow benzene solution which was analyzed by vapor phase chromatography; yield 3.6 Gm. of 1-methyl-3-bromopyrrolidine (22% of theory). This benzene solution was carefully gassed with dry hydrogen bromide to pH 7. The amine salt was filtered and recrystallized from acetone to yield I, m.p. 92–93°.

Anal.—Calcd. for $C_5H_{11}Br_2N$: N, 5.72; Br^-, 32.6; Br, 65.2. Found: N, 5.79; Br^-, 33.4; Br, 64.6.

1-Ethyl-3-bromopyrrolidine—This compound was prepared as described above in 60% of theory yield and was converted to III, m.p. 89–90°.

Anal.—Calcd. for $C_6H_{13}Br_2N$: N, 5.4; Br^-, 30.9; Br, 61.8. Found: N, 5.5; Br^-, 31.8; Br, 62.1.

1-Benzyl-3-bromopyrrolidine—This substance was prepared in the same manner in 52% of theory yield and converted by the addition of methyl bromide gas to VI, m.p. 134–135°.

Received March 22, 1967, from the S. B. Penick Research Laboratory, Orange, N J 07050

Accepted for publication May 19, 1967.

The authors thank J. Swidinsky for synthesizing the substituted pyrrolines and Mr. Russo and his staff, S. B. Penick and Company Control Laboratory, for the analyses reported in this paper.

Anal.—Calcd. for $C_{12}H_{17}Br_2N$: N, 4.2; Br^-, 23.9; Br, 47.8. Found: N, 4.9; Br^-, 24.8; Br, 48.9.

1-Methyl-Δ^3-pyrroline Methobromide—A solution of 8.3 Gm. (0.1 mole) of 1-methyl-Δ^3-pyrroline in 100 ml. of methyl ethyl ketone was treated with 9.5 Gm. of methyl bromide gas. The resulting solid was filtered to yield 17.79 Gm., 100% of theory, 1-methyl-Δ^3-pyrroline methobromide, m.p. 303–304°.

Anal.—Calcd. for $C_6H_{12}BrN$: N, 7.88; Br^-, 44.9; Br, 44.9. Found: N, 8.58; Br^-, 45.37; Br, 45.40.

1-Methyl-3-bromopyrrolidine Methobromide (II)—A solution of 17.79 Gm. (0.1 mole) of 1-methyl-Δ^3-pyrroline methobromide in 67.5 Gm. of 60% HBr was reacted as described above. The excess hydrobromic acid was distilled and the residue crystallized from 2 B ethyl alcohol (90 ml.) to yield 57% of theory II, m.p. 190–191°.

Anal.—Calcd. for $C_6H_{13}Br_2N$: N, 5.4; Br^-, 30.9; Br, 61.8. Found: N, 5.3; Br^-, 32.1; Br, 62.9.

1-Ethyl-3-bromopyrrolidine Methobromide (IV)—This compound, similarly prepared from 1-ethyl-Δ^3-pyrroline methobromide, m.p. 265–266°, was extremely hygroscopic and required rapid crystallization from a mixture of methyl ethyl ketone (50 ml.) and 2 B ethyl alcohol (10 ml.), m.p. 134–135°.

Communications

Synthesis of the *Veratrum* Alkaloid Verazine from Tomatid-5-en-3β-ol

Sir:

Recently, several new minor alkaloids have been isolated from *Veratrum album* subsp. *lobelianum* (Bernh.) Suessenguth (1). In a preceding communication (2) we described the structural elucidation of one of these new alkaloids, verazine, which according to chemical transformations and physical measurements possesses the structure 25*S*-22,26-epimino-cholesta-5,22(*N*)-dien-3β-ol (I). In this paper the establishment of this structure by a nine-step synthesis of compound I starting from the spirosolane alkaloid tomatid-5-en-3β-ol (II) (3) is reported.

Reduction of II with sodium borohydride in methanol afforded (22*S*:25*S*)-22,26-epimino-cholest-5-ene-3β,16β-diol (III), m.p. 165–167°, 189–191°, and $[\alpha]_D$ −69.1°[1] in 70% yield. Acetylation of III with acetic anhydride/pyridine at 20° for 14 hr. gave nearly quantitatively the amorphous *O,O,N*-triacetate (IV) with $[\alpha]_D$ −10.3°. Hydrolysis of this compound by refluxing with 5% potassium hydroxide in methanol for 2 hr. furnished (22*S*:25*S*)-22,26-acetylepimino-cholest-5-ene-3β, 16β-diol (V), m.p. 248–250°, $[\alpha]_D$ −35° (yield 81%). The *N*-acetyl-diol (V) through partial oxidation with 1 equivalent chromium trioxide in acetic acid–sodium acetate yields 80% (22*S*:25*S*)-22,26-acetylepimino-3β-hydroxy-cholest-5-en-16-one (VI), m.p. 213–215°, $[\alpha]_D$ −121.1°. Treatment of this ketone (VI) with ethanedithiol–hydrochloric acid followed by desulfurization of the obtained thioketal (VII) with Raney nickel in ethanol gave (22*S*:25*S*)-22,26-acetylepimino-cholest-5-en-3β-ol (VIII), m.p. 256–258°, and $[\alpha]_D$ −19.4° (74%).

[1] Melting points are corrected. All rotations in chloroform (c = 0.5). The infrared and molecular mass spectra of all new compounds described in this communication are in agreement with the proposed structure. The authors are indebted to Dr. R. Tummler, Dresden, for the molecular mass spectra.

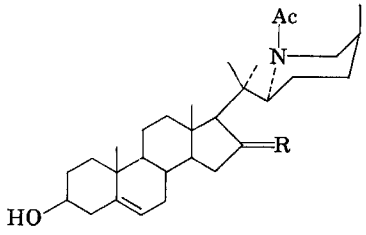
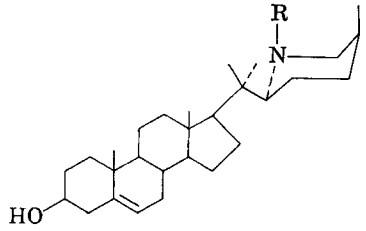
III, R, R_1 = H
IV, R, R_1 = Ac
V, R = H, R_1 = Ac



VI, R = O
VII, R = S
S



VIII, R = Ac
IX, R = H
X, R = Cl

Saponification of the amide (VIII) furnished the amine (IX) in only 11% yield even after employing the drastic Schmidt-Thome conditions [refluxing with potassium hydroxide in ethylene glycol for 8 hr. (4)]. The amine (IX) was separated from unchanged starting amide (VIII) by preparative thin-layer chromatography on Silica Gel G (development five times with chloroform) and has m.p. 167–171°, $[\alpha]_D$ −39.0°. *N*-Chlorination of IX with *N*-chloro succinimide in methylene dichloride at −5° and subsequent treatment of the unisolated *N*-chloro derivative (X) with sodium methoxide in methanol led to compound I with 24% yield, m.p. 173–176°, and $[\alpha]_D$ −83.4°, which was identical in every respect (mixed m.p., infrared spectrum, thin-layer chromatography) with authentic verazine, isolated from *V. album*. Since the starting tomatid-5-en-3β-ol (II) is already total synthetically obtainable (3,5) the above reported sequence of reactions also represents the total synthesis of verazine (I).

Assignment of Absolute Configurations to Receptor Sites and Drugs

Sir:

Based on the facts that racemic 9-(1′-[2′-dimethylamino]propyl) - 10 - thia - 1,9 - diazaanthracene, isothipendyl (I) is antihistaminically active and that the antihistaminically more active geometric isomer of 1-(2′-pyridyl)-1-(*p*-methylphenyl)-3-pyrrolidinoprop-1-ene, triprolidine (II) has the *trans*-configuration and exhibits an ultraviolet spectrum characteristic of vinyl pyridine and not styrene, Barlow (1) proposed *A* as the hypothetical antihistaminic receptor to which II, in the conformation written (1) presents its lower face. However, the equally probable mirror image receptor configuration (*B*) may be deduced upon adsorption by the opposite face of II.

Nevertheless, assuming that *A* is the receptor configuration, Barlow's conclusion (1) that (+)-1 - (2′ - pyridyl) - 1 - (*p* - chlorophenyl) - 3 - dimethylaminopropane, (+)-chlorpheniramine, the antihistaminically more active antipode, has the (R)-configuration (III) is unwarranted since III

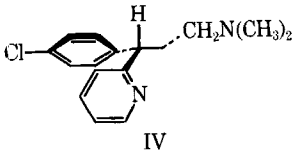
III

(S)



IV

(complementary to *A*) with the methine hydrogen toward the receptor surface, presents the same receptor pattern (*A*) as IV, the (S)-configuration with the hydrogen away from the receptor surface. The adsorption of (+)-chlorpheniramine with the hydrogen toward the receptor is clearly arbitrary. Thus, even if one knew the absolute configuration of the (+)-pheniramines to be (R) there would be no justification for assigning *A* as the absolute configuration of the hypothetical antihistaminic receptor since presentation of the upper face of III (methine hydrogen away from the receptor surface) affords the receptor pattern *B*.

Any argument based upon steric considerations, for example, that the receptor should adsorb to the bottom face of III since this represents the sterically less hindered approach to the molecule, is equally arbitrary and is not in keeping with current concepts regarding the conformational mobility and adaptability of proteins (2, 3) or with the related duality of conformational (4) and configurational (5) requirements of analogs of model drugs presumably acting on the same receptors.

The topography and configuration of the receptor, or more likely, the drug-bound receptor, may be deduced only for the selected case where one face of a conformationally rigid molecule, presenting the requisite configuration and pharmacophoric array, is accessible for binding. Indeed, conclusions based upon such models need not be valid for conformationally less restrained systems or for systems exhibiting chemical and spatial differences in peripheral groups. Assuming involvement of the same receptor and possible accessory binding or hindering moieties, these peripheral groups may modify the receptor–drug interaction and result not only in different modes of attachment to the receptor (4) but also in inversion of optical specificity (5). Since the

topography of the hypothetical antihistaminic receptor and/or drug-bound receptor is unknown, *A* and *B* should only be looked upon as highly schematized two-dimensional representations of a three-dimensional pattern for the bound receptor. In addition, the structures presented here are not necessarily uniformly representative of the conformations of the bound drug. There is no evidence to suggest that the conformationally mobile antihistamines are bound in their most stable conformations nor is there any evidence to suggest that I, II, and IV bind to the hypothetical receptor in the same way.

Finally, it is clear that Barlow's (1) rationalization leading to assignment of the (S)-configuration for the antihistaminically more active antipode of isothipendyl (I) is subject to the same objections already discussed. Accordingly, this assignment of configuration, if correct, is only fortuitously so. While the α-methyl may sterically inhibit the drug receptor binding as apparently suggested (1), it may instead contribute to and thus re-enforce the other drug–receptor interactions through hydrophobic and more highly distant specific van der Waals interactions with the receptor. The latter possibility would lead to selection of the (R)-configuration as the more active antipode. Neither observation is necessarily productive of sound configuration-activity relationships without data on the desmethyl analog as well.

The finding (6) that the absolute configuration of all the (+)-pheniramines is (S) and not (R) as proposed by Barlow (1) does not affect this critique, and we obviously defer assignment of configuration to the hypothetical antihistaminic receptor until more definitive experiments, now in progress, are completed.

Tumor Localizing Agents III. Radioiodinated Quinoline Derivatives

Sir:

For several years we have been interested in developing an agent which would be useful for the diagnostic localization and treatment of melanotic tumors. Our approach to this problem has involved the synthesis of radiolabeled compounds which would selectively localize in these tumors much like radioiodine localizes in the thyroid. In order to achieve this tumor selectivity, the initial selection of compounds for radiolabeling has fallen into two categories, namely: (*a*) precursors of melanin and (*b*) compounds which are known to interact with melanin. Previous publications (1, 2) from this laboratory described the results with several radiolabeled melanin precursors.

In recent years, several reports have appeared indicating that chloroquine has a marked affinity for melanin and is only slowly released from pigmented tissues (3–5). This information prompted us to synthesize a number of radioiodinated analogs of chloroquine and study their distribution in mice with transplanted melanomas. This report describes initial results with one of these radioiodinated analogs.

The general procedure of Price and Roberts (6) was employed to obtain the key intermediate 4-chloro-7-iodoquinoline (V). (Scheme I.)

Ethoxymethylenemalonic ester was condensed with 3-iodoaniline to give ethyl α-carbethoxy-β-(3-iodophenylamino)acrylate (I) in 77% yield, m.p. 88–89°.

Anal.—Calcd. for $C_{14}H_{16}INO_4$: C, 43.21; H, 4.14. Found: C, 43.34; H, 4.11.

The addition of I to refluxing diphenylether afforded 3-carbethoxy-4-hydroxy-7-iodoquinoline (II) in 94% yield. Recrystallization from pyridine gave an analytical sample which starts to sublime at 255°.

topography of the hypothetical antihistaminic receptor and/or drug-bound receptor is unknown, *A* and *B* should only be looked upon as highly schematized two-dimensional representations of a three-dimensional pattern for the bound receptor. In addition, the structures presented here are not necessarily uniformly representative of the conformations of the bound drug. This information prompted us to synthesize a number of radioiodinated analogs of chloroquine and study their distribution in mice with transplanted melanomas. This report describes initial results with one of these radioiodinated analogs.

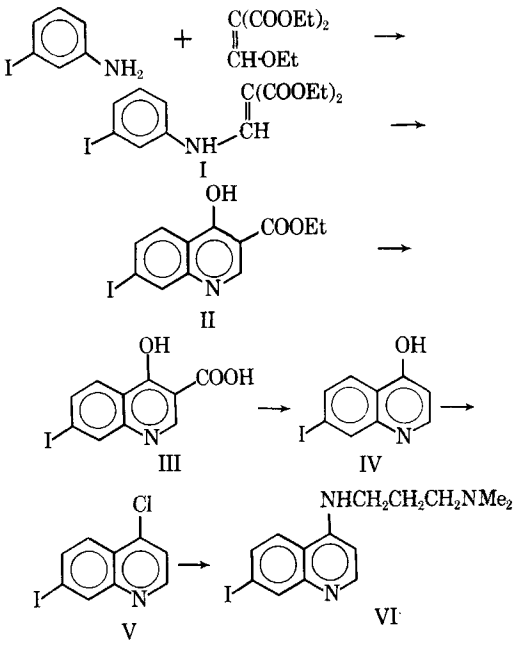
The general procedure of Price and Roberts (6) was employed to obtain the key intermediate 4-chloro-7-iodoquinoline (V). (Scheme I.)

Ethoxymethylenemalonic ester was condensed with 3-iodoaniline to give ethyl α-carbethoxy-β-(3-iodophenylamino)acrylate (I) in 77% yield, m.p. 88–89°.

Anal.—Calcd. for $C_{14}H_{16}INO_4$: C, 43.21; H, 4.14. Found: C, 43.34; H, 4.11.

The addition of I to refluxing diphenylether afforded 3-carbethoxy-4-hydroxy-7-iodoquinoline (II) in 94% yield. Recrystallization from pyridine gave an analytical sample which starts to sublime at 255°.



Scheme I

Anal.—Calcd. for $C_{12}H_{10}INO_3$: C, 42.02; H, 2.94. Found: C, 42.11; H, 2.83.

Saponification in aqueous ethanol followed by acidification furnished the carboxylic acid (III) in 98% yield, melting with decarboxylation at 278°.

Anal.—Calcd. for $C_{10}H_6INO_3$: C, 38.13; H, 1.92. Found: C, 38.18; H, 1.88.

When III was recrystallized from dimethysulfoxide a crystalline solvate was obtained which sublimed at 280–290°, $\gamma_{max.}$ 1720 (C=O) and 1030–1010 cm.$^{-1}$ (S=O).

Anal.—Calcd. for $C_{10}H_6INO_3 \cdot C_2H_6SO$: C, 36.66; H, 3.08. Found: C, 36.58; H, 2.96.

Decarboxylation of III in refluxing diphenylether afforded crude 4-hydroxy-7-iodoquinoline (IV) which, without further purification, was treated with phosphorous oxychloride. Recrystallization of the resulting product from chloroform furnished 4-chloro-7-iodoquinoline (V) in 70% yield, m.p. 97–98°. [Reported m.p. 95.5–97° (7).] Treatment of V with refluxing 3-dimethylaminopropylamine gave the desired chloroquine analog, 4-(3-dimethylaminopropylamino)-7-iodoquinoline (VI) in 65% yield, m.p. 101–103°. The NMR spectrum ($CDCl_3$) showed a singlet at 7.64 δ (NCH_3), a triplet at 7.43 δ ($-CH_2N$) (J = 6.0 c.p.s.), and a multiplet centered at 6.67 δ (CH_2NH—) which became a triplet upon deuteration (J = 6.0 c.p.s.).

Anal.—Calcd. for $C_{14}H_{18}IN_3$: C, 47.35; H, 5.11. Found: C, 47.36; H, 5.17.

Iodine-125 or ^{131}I was introduced into VI by isotope exchange with radioactive sodium iodide in ethylene glycol at 170–175°. By this procedure the ^{125}I and ^{131}I-labeled compounds were obtained with specific activities of 2.03 and 1.42 mc./mmoles, respectively. The radiolabeled compounds were purified by recrystallization and analyzed by thin-layer chromatography (TLC). In both cases, a radiochromatogram scan showed a single radioactive area coincident with the single TLC spot seen under ultraviolet light.

Four to five-week-old male, black mice of the BL6J strain were injected intraperitoneally with 10 μc. of 4-(3-dimethylaminopropylamino)-7-iodoquinoline-^{125}I and sacrificed at 12, 24, and 48 hr. Control mice were injected *via* the same route with 10 μc. of sodium iodide-^{125}I and sacrificed at the same time intervals. Counting was done in a commercial well counter. Table I shows the concentrations in six tissues, two of

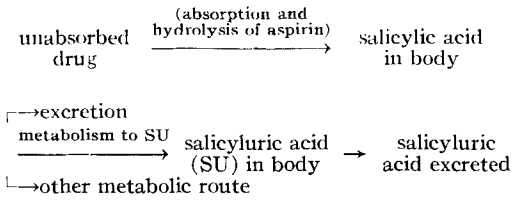
Evidence for Nonfirst-Order Kinetics of Salicylate Elimination—A Rebuttal

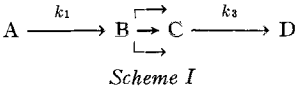
Sir:

Wagner's recent article (1) relating to the pharmacokinetics of salicylate elimination contains unwarranted conclusions and therefore requires an early rebuttal.

He claims that our pharmacokinetic model for salicylate elimination in man, which assumes capacity-limited formation of salicyluric acid at doses of 1 Gm. aspirin and above (2), is unjustified, and that all processes are likely to be apparent first-order. He bases his reasoning on a model involving a catenary chain of the type shown in Scheme I.

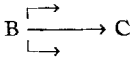


i.e.,



Scheme I

where all processes are first-order and the over-all rate constant for decline of B is defined as k. A direct and unambiguous test of this model is available by using experimental conditions which reduce the model to that shown in Scheme II.



Scheme II

This is accomplished by injecting B intravenously and following its concentration in the plasma as a function of time.[1]

Wagner's model requires that the half-life for the decline of salicylate concentrations in the plasma after intravenous injection of sodium salicylate be independent of dose. In fact, the average half-life [or the apparent half-life, since we do not consider the kinetics at higher doses to be first-order (2)] is 2.4 hr. with 0.25-Gm. doses (4), 6.1 hr. with 1.3-Gm. doses (5), and 19 hr. with 10–20-Gm. doses (6). In all instances, the drug was injected intravenously as salicylate.[2] These data, which were cited in our original paper, provide direct evidence that Wagner's contention is incorrect.

Wagner's pharmacokinetic model consists entirely of first-order rate processes. As a consequence (and in addition to the requirement stated in the preceding paragraph), the time course of urinary excretion of drug in all forms,

[1] Salicylate distribution is so rapid relative to elimination (3) that blood level data are not distorted by the distributive process beyond a very short time following intravenous injection.

[2] Only with the lowest dose was the half-life determined from urinary excretion data (which is acceptable in the context of the present discussion since it yielded the shortest half-life).

which are known to contain large amounts of melanin (eye, skin). The distribution of activity of the radioiodinated analog of chloroquine was similar to that seen with chloroquine in rats (8) and chloroquine-^{14}C in mice (9). Evidence for Nonfirst-Order Kinetics of Salicylate Elimination—A Rebuttal

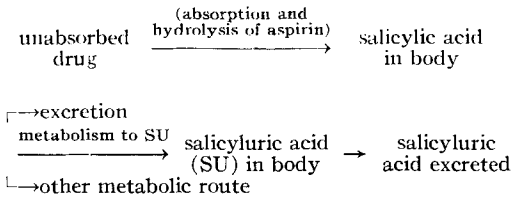
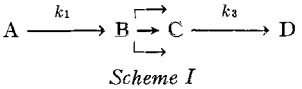
Sir:

Wagner's recent article (1) relating to the pharmacokinetics of salicylate elimination contains unwarranted conclusions and therefore requires an early rebuttal.

He claims that our pharmacokinetic model for salicylate elimination in man, which assumes capacity-limited formation of salicyluric acid at doses of 1 Gm. aspirin and above (2), is unjustified, and that all processes are likely to be apparent first-order. He bases his reasoning on a model involving a catenary chain of the type shown in Scheme I.

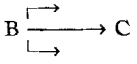


i.e.,



Scheme I

where all processes are first-order and the over-all rate constant for decline of B is defined as k. A direct and unambiguous test of this model is available by using experimental conditions which reduce the model to that shown in Scheme II.



Scheme II

This is accomplished by injecting B intravenously and following its concentration in the plasma as a function of time.[1]

Wagner's model requires that the half-life for the decline of salicylate concentrations in the plasma after intravenous injection of sodium salicylate be independent of dose. In fact, the average half-life [or the apparent half-life, since we do not consider the kinetics at higher doses to be first-order (2)] is 2.4 hr. with 0.25-Gm. doses (4), 6.1 hr. with 1.3-Gm. doses (5), and 19 hr. with 10–20-Gm. doses (6). In all instances, the drug was injected intravenously as salicylate.[2] These data, which were cited in our original paper, provide direct evidence that Wagner's contention is incorrect.

Wagner's pharmacokinetic model consists entirely of first-order rate processes. As a consequence (and in addition to the requirement stated in the preceding paragraph), the time course of urinary excretion of drug in all forms,

[1] Salicylate distribution is so rapid relative to elimination (3) that blood level data are not distorted by the distributive process beyond a very short time following intravenous injection.

[2] Only with the lowest dose was the half-life determined from urinary excretion data (which is acceptable in the context of the present discussion since it yielded the shortest half-life).

the shape of a cumulative plot of salicylurate excretion *versus* time, and the composition of urinary metabolites must be independent of dose (*i.e.*, superimposable) when expressed in per cent (or fraction of dose) terms.[3] Here are the actual facts:

(*a*) *All* published data on the urinary excretion of salicylates of which this author is aware show that the urinary excretion rate of total salicylates (*i.e.*, fraction of dose excreted after t hours, where t is less than the time required for total excretion) decreases with increasing dose. Appropriate data may be found in *References 2, 7, 8,* and *9*.

(*b*) The composition of urinary metabolites of salicylate changes with dose when the doses exceed about 0.5 Gm. in adults. Specifically, the fraction excreted as salicylurate decreases with increasing dose (2,10).

(*c*) Cumulative plots of salicylurate excretion as a function of time after salicylate administration are curved with low doses (10, 11) and linear over an appreciable period of time after higher doses (10, 12). An example of this is shown in Fig. 1. Wagner's kinetic model predicts that the two curves in the figure should be superimposable, *i.e.*, that all data points (regardless of dose) should fall on the same line!

(*d*) Semilogarithmic plots of total drug remaining to be excreted *versus* time after drug administration become linear, independent of dose, when the drug in the body has declined to a certain *amount* (2) rather than to a certain *fraction* of the dose, as would be the case with Wagner's model.

(*e*) Figure 2, based on the work of Salassa *et al.* (13), shows that a semilogarithmic plot of salicylate concentration in the plasma following a 3-Gm. dose of sodium salicylate *curves downward* for almost 30 hr. It is practically a straight line when plotted on linear coordinates, reflecting the constant rate of formation of salicylurate and the fact that this process is still the predominant one in the elimination of salicylate in the range of drug levels encountered in the study. When the salicylurate formation process is effectively blocked by co-administration of *para*-aminobenzoate, the decline of salicylate concentration in the plasma becomes exponential. This evidence is discussed in greater detail in previous publications from this laboratory (2, 14).

All of the evidence cited so far (except for the specific data in Fig. 1) is taken from papers which

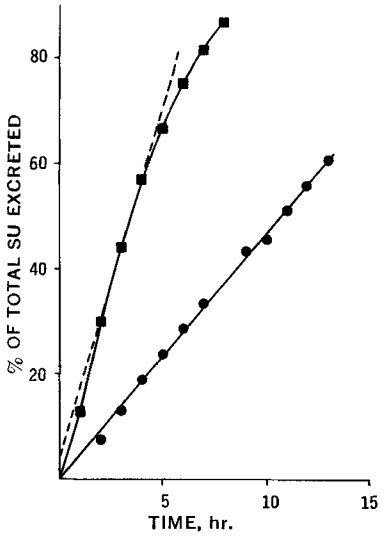


Fig 1—Cumulative excretion of salicyluric acid after 300 mg. (■) and 2 Gm. sodium salicylate (●) given orally in solution to a healthy adult. More than 98% of the dose was recovered in each case. Seventy-five per cent of the low dose and 62% of the high dose were transformed to salicyluric acid. The stippled line is straight and shows that the experimental points for the low dose do not fit a straight line. First-order kinetic models predict that the two curves would be superimposable.

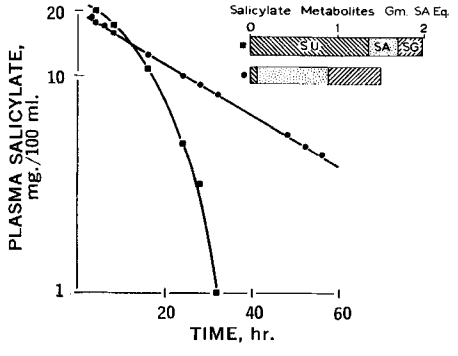

Fig. 2—Plasma concentration of salicylate following a 3-Gm. oral dose of sodium salicylate alone (■) and with para*-aminobenzoate (●) which blocks the salicylurate formation process. Bar graph shows output of salicylate (SA), salicylic glucuronides (SG), and salicyluric acid (SU) in the urine during the time when plasma concentrations were measured. Data from* Reference 13. *The curvature of the plot for salicylate alone reflects the capacity-limited formation of salicylurate and the nonfirst-order elimination of salicylate.*

appeared in the literature prior to the submission of Wagner's article but none of it was mentioned in that article. The impression was given (1) that our own conclusions concerning the elimination kinetics of salicylate in man (2) were based entirely on the time course of urinary excretion data. A review of our paper will show that our

[3] This is shown readily by dividing Wagner's Eq. 8 by X_A°, thus yielding X_D/X_A° (*i.e.*, fraction of dose) on one side and only k's and t on the other.

conclusions were based on much more extensive evidence. While additional reports from our laboratory concerning the elimination kinetics of salicylate as a function of age, dose, route of administration, co-administration of other drugs, *etc.*, will be forthcoming, this rebuttal is limited intentionally to presently published data to show that Wagner's "fallacy" is the result of his disregard for the totality of the evidence available and of his sole reliance on hypothetical models.

Organisch-Chemische Arzneimittel und Ihre Synonyma (Organic Chemical Medicaments and Their Synonyms). By MARTIN NEGWER. Published by the Akademie-Verlag, Berlin, Germany. Distributed by Pergamon Press, Inc. 44–01 21st Street, Long Island City, New York, N. Y. 11101, 1966. vii + 1224 pp. 17.5 × 24 cm. Price $35.00.

In tabular fashion, this book lists approximately 3,500 compounds with more than 26,000 synonyms. The book is written in German, but because of the organization, it can be used by those not able to read German. Compounds are presented by their molecular formulas in order of the number of carbon atoms and are numbered individually. For example compound No. *1* is CCl_4, No. *2* is $CHBr_3$, No. *3* is $CHCl_3$, *etc.*, through No. *3567* which is $C_{254}H_{377}N_{65}O_{75}S_6$ (insulin). The information given for each compound includes its structural formula, chemical name, salt form, its synonyms including trade names from many countries, and therapeutic use or pharmacologic category. All of the synonyms and names appearing throughout the book are listed in the index, with cross-references to the compound number. Completeness of coverage and accuracy can be judged only upon continued use.

A Systematic Approach to the Interpretation of Infrared Spectra. By HERMAN A. SZYMANSKI. Hertillon Press, Box 1677, Buffalo, NY 14216, 1967. vi + 150 pp. 22 × 28 cm. Price $2.00. Paperbound.

The major purpose of this text is to acquaint the reader with the methods used in correlating the observed infrared absorption bands with the structure of the compound being examined. Each absorption band, appearing at a fixed position, can be related to a specific structural group in a molecule. The position, shape, and intensity of the bands are three parameters that are associated with the structure of the compound.

The subject matter is arranged according to the general types of groupings that occur in organic molecules and the important group frequencies that appear as infrared bands. Spectra of several representative compounds are included to illustrate each grouping and to note shifts from the expected frequencies due to the influence of adjacent groups. Over 100 interpreted spectra are included to encompass the groups usually associated with organic compounds.

The book is intended as an introductory text but a working knowledge of infrared fundamentals is necessary to utilize this volume to the fullest advantage.

Organisch-Chemische Arzneimittel und Ihre Synonyma (Organic Chemical Medicaments and Their Synonyms). By MARTIN NEGWER. Published by the Akademie-Verlag, Berlin, Germany. Distributed by Pergamon Press, Inc. 44–01 21st Street, Long Island City, New York, N. Y. 11101, 1966. vii + 1224 pp. 17.5 × 24 cm. Price $35.00.

In tabular fashion, this book lists approximately 3,500 compounds with more than 26,000 synonyms. The book is written in German, but because of the organization, it can be used by those not able to read German. Compounds are presented by their molecular formulas in order of the number of carbon atoms and are numbered individually. For example compound No. *1* is CCl_4, No. *2* is $CHBr_3$, No. *3* is $CHCl_3$, *etc.*, through No. *3567* which is $C_{254}H_{377}N_{65}O_{75}S_6$ (insulin). The information given for each compound includes its structural formula, chemical name, salt form, its synonyms including trade names from many countries, and therapeutic use or pharmacologic category. All of the synonyms and names appearing throughout the book are listed in the index, with cross-references to the compound number. Completeness of coverage and accuracy can be judged only upon continued use.

A Systematic Approach to the Interpretation of Infrared Spectra. By HERMAN A. SZYMANSKI. Hertillon Press, Box 1677, Buffalo, NY 14216, 1967. vi + 150 pp. 22 × 28 cm. Price $2.00. Paperbound.

The major purpose of this text is to acquaint the reader with the methods used in correlating the observed infrared absorption bands with the structure of the compound being examined. Each absorption band, appearing at a fixed position, can be related to a specific structural group in a molecule. The position, shape, and intensity of the bands are three parameters that are associated with the structure of the compound.

The subject matter is arranged according to the general types of groupings that occur in organic molecules and the important group frequencies that appear as infrared bands. Spectra of several representative compounds are included to illustrate each grouping and to note shifts from the expected frequencies due to the influence of adjacent groups. Over 100 interpreted spectra are included to encompass the groups usually associated with organic compounds.

The book is intended as an introductory text but a working knowledge of infrared fundamentals is necessary to utilize this volume to the fullest advantage.

Staff review

Advances in Chromatography. Volumes II and III. Edited by J. C. GIDDINGS and R. A. KELLER. Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10016, 1966. 15.5 × 23 cm. Vol. II, xvi + 377 pp. Price $14.50. Vol. III, xii + 271 pp. Price $11.50.

Those who are actively interested in a particular phase of chromatography will maintain a continuous acquaintanceship with the developments in that realm. This series, as noted in the review of Vol. I [*J. Pharm. Sci.*, **55**, 863(1966)] is intended to enable the reader who cannot keep up with the explosive growth in the entire field to maintain an over-all view of the progress of chromatography.

Since the reader will have a greater interest in the fields allied to his own, it is inevitable that any one chapter of the series will be regarded with varying degrees of interest by an individual reader. From the point of view of the pharmaceutical chemist, Volumes II and III succeed in fulfilling the aims of the Editors to about the same extent as did Volume I. Two chapters in each volume, devoted primarily to highly technical aspects of a limited area of chromatography, are perhaps too narrow and deep to provide the desired broad picture. It is recognized that without rigorous theoretical investigation of each aspect of chromatography we would be dependent upon empirical findings alone. Many readers whose interest lie in the applications of chromatography would, however, prefer less detailed, but broader, expositions of this theoretical groundwork as background for helping to evaluate the potentialities of a particular technique. At the other extreme are two chapters, one in each volume, which may be considered to be too shallow for a series of this type.

The remaining chapters do, for the most part, succeed in providing convenient and facile access to many facets of chromatography. Notable among the latter are chapters devoted to the chromatographic support, to ionization detectors, to gradient techniques, and to programmed temperature gas chromatography. Two chapters cover the chromatography of families of compounds—amino acids and carbohydrates—which are closely related to drugs, and are therefore of particular interest to the pharmaceutical chemist.

The topics covered in the two volumes are as follows. *Vol. II:* "Ion Exchange Chromatography of Amino Acids: Recent Advances in Analytical Determinations" by Paul B. Hamilton; "Ion Mobilities in Electrochromatography" by John T. Edwards; "Partition Paper Chromatography and Chemical Structure" by J. Green and D. McHale; "Gradient Techniques in Thin-Layer Chromatography" by A. Niederwieser and C. C. Honegger; "Geology—An Inviting Field to Chromatographers" by Arthur S. Ritchie; "Extracolumn Contributions to Chromatographic Band Broadening" by James C. Sternberg; "Gas Chromatography of Carbohydrates" by James W. Berry; "Ionization Detectors for Gas Chromatography" by Arthur Karmen; "Advances in Programmed Temperature Gas Chromatography" by Louis Mikkelsen.

Vol. III: "The Occurrence and Significance of Isotope Fractionation During Analytical Separations of Large Molecules" by Peter D. Klein; "Adsorption Chromatography" by C. H. Giles and I. A. Easton; "The History of Thin-Layer Chromatography" by N. Pelick, H. R. Bolliger, and H. K. Mangold; "Chromatography as a Natural Process in Geology" by Arthur S. Ritchie; "The Chromatographic Support" by D. M. Ottenstein; "Electrolytic Conductivity Detection in Gas Chromatography" by Dale M. Coulson; "Preparative-Scale Gas Chromatography" by G. W. A. Rijnders.

Atomic Absorption Spectroscopy. By JAMES W. ROBINSON. Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10016, 1966. xi + 204 pp. 15 × 23 cm. Price $9.75.

As has been true of so many new analytical techniques, the development of atomic absorption spectroscopy into a practical laboratory tool has largely awaited the development of simple, reliable, and relatively inexpensive instrumentation. To a large extent this has now been accomplished. There are now a number of well-designed instruments on the market that meet these requirements rather adequately. So it is only fitting that a simplified text be made available to explain the theory and practice of atomic absorption spectroscopy in terms that the average analytical or pharmaceutical chemist, too rushed to delve deeply into the subject, can understand and use. Dr. Robinson has written just such a text.

Atomic absorption spectroscopy is an efficient procedure for assaying large numbers of samples for small amounts of metals. While it cannot entirely replace polarography, colorimetry, X-ray fluorescence, or arc, spark, or flame emission spectroscopy, it can, under appropriate conditions, be more rapid, more accurate, more reproducible, and more convenient than any of these. Selecting the appropriate conditions can, however, require considerable background, understanding, and experience. Dr. Robinson's book would certainly be an excellent place for a person unacquainted with the subject to start.

Addressed, according to the author, to the graduate student, to the research worker not well-versed in analytical chemistry, and to the analytical chemist interested in rapid and accurate analyses for research and industry, the book was apparently not designed to provide comprehensive coverage of the subject. Indeed, a more apt title for the book might be "An Introduction to Atomic Absorption Spectroscopy," for that is what it is. It is a short book, consisting of little more than 200 pages. Written in a simple straightforward style, it can be read in a few hours without unduly taxing the eye or the mind.

This is not to indicate that it is a superficial book. In fact, it covers the subject matter quite well for a book of this size. Among the more important subjects included are a brief description of the sources of atomic absorption spectra, a short discussion of advantages and disadvantages of atomic absorption, an extensive discussion of instrument components and parameters, a fairly comprehensive discussion of analytical parameters such as atomizer effects, effects of anions and other cations, solvents, sensitivity,

Atomic Absorption Spectroscopy. By JAMES W. ROBINSON. Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10016, 1966. xi + 204 pp. 15 × 23 cm. Price $9.75.

As has been true of so many new analytical techniques, the development of atomic absorption spectroscopy into a practical laboratory tool has largely awaited the development of simple, reliable, and relatively inexpensive instrumentation. To a large extent this has now been accomplished. There are now a number of well-designed instruments on the market that meet these requirements rather adequately. So it is only fitting that a simplified text be made available to explain the theory and practice of atomic absorption spectroscopy in terms that the average analytical or pharmaceutical chemist, too rushed to delve deeply into the subject, can understand and use. Dr. Robinson has written just such a text.

Atomic absorption spectroscopy is an efficient procedure for assaying large numbers of samples for small amounts of metals. While it cannot entirely replace polarography, colorimetry, X-ray fluorescence, or arc, spark, or flame emission spectroscopy, it can, under appropriate conditions, be more rapid, more accurate, more reproducible, and more convenient than any of these. Selecting the appropriate conditions can, however, require considerable background, understanding, and experience. Dr. Robinson's book would certainly be an excellent place for a person unacquainted with the subject to start.

Addressed, according to the author, to the graduate student, to the research worker not well-versed in analytical chemistry, and to the analytical chemist interested in rapid and accurate analyses for research and industry, the book was apparently not designed to provide comprehensive coverage of the subject. Indeed, a more apt title for the book might be "An Introduction to Atomic Absorption Spectroscopy," for that is what it is. It is a short book, consisting of little more than 200 pages. Written in a simple straightforward style, it can be read in a few hours without unduly taxing the eye or the mind.

This is not to indicate that it is a superficial book. In fact, it covers the subject matter quite well for a book of this size. Among the more important subjects included are a brief description of the sources of atomic absorption spectra, a short discussion of advantages and disadvantages of atomic absorption, an extensive discussion of instrument components and parameters, a fairly comprehensive discussion of analytical parameters such as atomizer effects, effects of anions and other cations, solvents, sensitivity,

interferences, *etc.* Most of the second half of the book is devoted to a listing of analytical procedures metal-by-metal for some 49 common metals. The last section of the book includes a description of most of the commercially produced instruments now on the market with some discussion of advantages and disadvantages of each. It also includes a brief discussion of special topics related to atomic absorption spectroscopy such as atomic fluorescence, vacuum ultraviolet techniques, *etc.*

While the important aspects of the subject appear to have been covered quite adequately, one gets the impression that the author has leaned rather too heavily on a few well-known sources for his information and so has not given his work a broad enough base. Certainly, his discussion of currently available instruments more strongly reflects information gleaned from instrument manufacturers than from personal experience either of the author or of other workers in the field. Incidently, much of this section is already outdated since it does not mention the rapidly growing field of automated atomic absorption analysis and the many partially or completely automated instruments now on the market.

Notwithstanding its deficiencies, the book can be highly recommended to almost any beginner in the field who would like to know what atomic absorption spectroscopy will do for him, how and when to use it, what equipment is available, what pitfalls to avoid, and how to get the most out of equipment already purchased. It should serve most analysts well, at least until they have gotten their bearings in the field. After that they are on their own.

Quantitative Pharmaceutical Chemistry. Sixth Edition. By GLENN L. JENKINS, ADELBERT M. KNEVEL, and FRANK E. DIGANGI. Blakiston Div., McGraw-Hill Book Co., 330 West 42nd St., New York, NY 10036, 1967. xxi + 519 pp. 16 × 23.5 cm. Price $12.

The latest revision of this reference and instruction text reflects significant trends which are evident in the methods of analysis included in "The United States Pharmacopeia XVII" and in "The National Formulary XII." The presentation remains relatively unchanged with an introductory discussion for each topic and a classification of U.S.P. and N.F. monographs according to general assay methods. However, specialized areas including potentiometry and pH and hydronium ion concentration are noted for expanded coverage. The addition of new sections on nonaqueous titrations and complexation methods is indicative of the extensive use accorded such procedures. There are approximately 150 official assays which employ nonaqueous titration and about 50 monographs involving complexation techniques. The reagent of choice for the latter group is disodium ethylenediaminetetraacetate (EDTA). Increased emphasis toward instrumental methods is shown by new entries on infrared spectroscopy, polarography, and gas chromatography. The general section of chromatography has been extended to include thin-layer chromatography.

The book is recommended as a companion volume for information pertaining to U.S.P. and N.F. articles, especially in view of the physical impossibility of incorporating complete instructional background material in the compendia.

Applications of Nuclear Magnetic Resonance Spectroscopy in Medicinal and Pharmaceutical Chemistry

By A. F. CASY

NUCLEAR MAGNETIC RESONANCE (NMR) spectroscopy is a physical method which enables chemists to study certain atomic nuclei within molecules. One phase of this area, proton magnetic resonance (PMR) spectroscopy, is of particular interest to the organic chemist. The spectroscopic technique was first applied to organic compounds soon after 1950 and its use has grown enormously over the last decade. It is probable that most medicinal and pharmaceutical chemists have encountered the method and are aware of its physical basis. Several textbooks written with the requirements of the organic chemist in mind have been published (1–5) since the pioneer account of Jackman (6). One of the more recent publications is a comprehensive two-volume work by Emsley, Feeney, and Sutcliffe (7).

Numerous reviews are available dealing with the application of NMR spectroscopy to specific topics, such as the structure elucidation of natural products (8, 9) and biochemistry (10). (Other reviews are mentioned throughout this paper.) However, no particular emphasis has been given to the potentialities for application of the NMR technique to problems of interest to medicinal chemists, and the present review has been written to this end. A comprehensive account is not intended—rather, a selection of the literature has been made, and the topics therein outlined and discussed in some detail so that the value and versatility of NMR spectroscopy in the field of medicinal chemistry may be demonstrated.

A general outline of the basic principles of NMR spectroscopy is not included here because of space limitations and the large number of introductory accounts now available. Apart from the textbooks referred to previously, several texts describing the use of physical methods in organic chemistry include useful chapters on NMR spectroscopy (11–13).

The interpretation of NMR spectra is based on three sets of parameters which characterize the absorption of radiofrequency radiation by atomic nuclei placed in a magnetic field (H): (a) the frequencies of the absorbed radiation (ν) expressed as the *chemical shift* relative to an arbitrary standard absorption line; (b) the multiplicity of the lines originating from a given group of nuclei and described by the appropriate *coupling constants* (J values); and (c) the decay times characterizing the return of the nuclei excited by the absorption of radiation to a lower energy state referred to as *relaxation times*.

Additional information is derived from the integration curve which enables the relative number of protons within each absorption band to be determined. Of the above parameters, the first two are the most widely applied to chemical

problems, although more attention is now being given to relaxation times because of their value in the study of molecular interactions (14). NMR spectra are displayed as plots of a detector signal (ordinate) against a magnetic field (abscissas) calibrated in cycles per second (c.p.s.) since H is proportional to ν. In many cases chemical shifts and coupling constants may be read directly from a spectrum (first-order treatment);[1] an example is the spectrum of 4-ethoxybenzyl chloride (Fig. 1). In this spectrum chemical shifts are measured relative to tetramethylsilane (TMS), the most commonly employed internal standard [in deuterium oxide solutions the water-soluble analog, sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) may be employed (16)]. Three scales are used to express the chemical shift: (*a*) a frequency scale (ν) given in c.p.s. for TMS set at zero (coupling constants are also measured in these units); (*b*) parts per million (δ), obtained from the expression:

$$\delta = \frac{\text{c.p.s.} \times 10^6}{\text{oscillator frequency in c.p.s.}}$$

TMS at zero; and (*c*) the τ (or tor) scale where:

$$\tau = 10 - \delta(\text{TMS at } 10)$$

The last two scales are dimensionless, while the first depends on the operating frequency and must always be used in conjunction with the frequency value. (This is not the serious drawback it first appears because the great majority of reported spectra are recorded at a frequency of 60 Mc./sec.) All three systems are in common use [their relative merits have been discussed by Bible (4)]; therefore, in studying NMR literature, care must be taken to ascertain the chemical shift scale and the standard employed. In this review, no attempt has been made to standardize chemical shift values, and examples of all three scales are included.

[1] Sometimes nonmagnetically equivalent nuclei give rise to spectra that appear to be susceptible to first-order treatment, but are really not; such "deceptively simple" spectra are considered in a review by Becker (15).

USE IN ANALYSIS

Integral data may be used for the analysis of mixtures when overlap between signals due to individual components does not occur (or may be corrected for), and NMR methods for the quantitative assay of mixtures of aspirin, phenacetin, and caffeine (17) and of barbiturates (18) have been described. The spectrum of an APC tablet in $CDCl_3$ (binders such as starch and lactose are insoluble and do not interfere) is shown in Fig. 2. The signal at 2.3 p.p.m. is due to OCO*Me* of aspirin, and its integral value (compared with that of Me in a standard solution of caffeine) enables the aspirin content of the mixture to be determined. The signals at 3.4 and 3.6 p.p.m. (both due to Me) give the caffeine content, and the integral of the quartet centered near 4 p.p.m., due to OCH_2Me (and corrected for the overlapping N^7-Me signal of caffeine), gives the phenacetin content. The method is claimed to have the advantage of speed and to be of an accuracy sufficient for quality control. An example in the field of organic synthesis is the determination of isomeric ratios obtained in alkylations employing 2-chloro-1-dimethylaminopropane (these proceed *via* ethyleniminium ions and hence lead to mixtures of products). Thus, it is found that alkylation of diphenylacetonitrile leads to an approximately 1:1 mixture of the cyanide precursors of methadone and isomethadone (Fig. 3), while that of 2-benzylbenzimidazole gives a mixture in which one isomer shows a marked preponderance (19) (Fig. 4). A molecular weight

determination method based on PMR integrals has been described (20). It consists of comparing the integrated intensities of an added standard and a recognizable peak or group of peaks of the unknown in a solution containing known weights of standard and unknown. Molyneux, Rhodes, and Swarbrick (21) used a PMR method to check the homogeneity of the alkyl chain in some betaines (I). With D_2O as solvent, distinct signals for the proton groups a–e were observed and, using the integral of the Me signal (a) as standard, the number of protons in the other groups were calculated.

$$\underset{a}{Me}\ \underset{b}{(CH_2)_{n-2}}\underset{c}{CH_2}\overset{+}{N}\underset{d}{Me_2}\underset{e}{CH_2}C\bar{O}_2$$

I

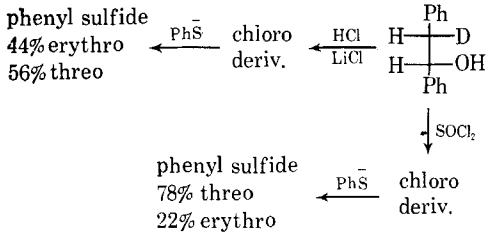
Diastereoisomeric mixtures may be analyzed by NMR spectroscopy provided the spectrum exhibits one or more signals, due to each isomer, which do not overlap. Raban and Mislow (22) have pointed out the principles involved but give, as an example, a case in which a clear separation of isomer signals is not observed. We have used this method to analyze isomeric 4-phenyl-3-methyl-4-piperidinols obtained by treating a 3-methyl-4-piperidone with lithium phenyl, and find that mixtures of two parts of the *trans* (3-Me/4-Ph) and one part of the *cis* isomer result (23); the analyses were based on the secondary Me signals which do not overlap and are particularly well separated in the base hydrochlorides, as discussed later. The isomeric mixture of alcohols (II)—the propionate ester of the α-isomer is propoxyphene—may be analyzed similarly.[2]

$$Me_2NCH_2CHMeCPh(OH)CH_2Ph$$

II

Chemical shifts of CH*Me* (c.p.s. from TMS in $CDCl_3$) are: α-(base) 50, β-(base) 66, α-(HCl) 75, and β-(HCl) 97.

Kingsbury and Thornton (25) have obtained evidence of the stereochemistry of displacement reactions using diastereoisomeric substrates, reaction mixtures being analyzed by measurement of NMR integrals (Scheme I). The advantage of the method is that the amount of retention and displacement product can be directly observed in favorable cases.



Scheme I

Mixtures of structurally isomeric alkenes are also amenable to assay by the integration technique. Figure 5 shows the spectrum of the product of dehydration of 3-methyl-4-phenyl-4-piperidinol. The 3-methyltetrahydropyridine content of the mixture is obtained from the 3-Me integral (broad singlet at 92 c.p.s.), and the 5-methyl isomer from integrals of the secondary Me (doublet at 59 c.p.s.) and vinylic proton (triplet at 357 c.p.s.) signals (26). By this analytical procedure, a study of the relative stabilities of isomeric 3- and 5-methyltetrahydropyridines and of the influence of structure and stereochemistry upon the direction of elimina-

tion of 4-aryl-3-methyl-4-piperidinols has been made (27).

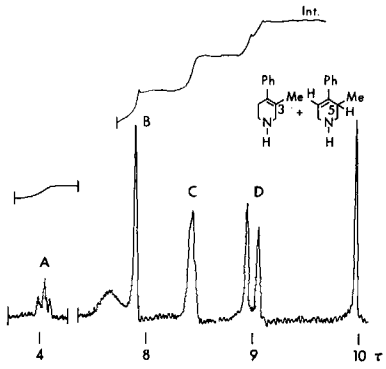

Fig. 5—Part of the PMR spectrum of the dehydration product of 3-methyl-4-phenyl-4-piperidinol in $CDCl_3$. C (tert Me) is due to 3-methyl-4-phenyl-1,2,5,6-tetrahydropyridine, and A (vinylic) and D (sec Me) to the 5-methyl isomer; B (N-H) is due to both isomers.

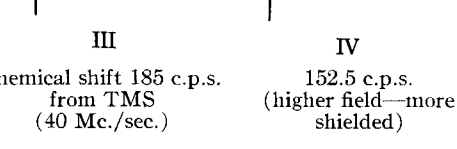
CONFIGURATIONAL AND CONFORMATIONAL STUDIES IN CYCLIC MOLECULES

In cyclohexane derivatives, an equatorial proton is generally less shielded than the corresponding axial one [*e.g.*, 4-H in *cis*(III) and *trans*(IV) 4-bromo-*tert*-butylcyclohexane (28)] and much use has been made of this observation



III — chemical shift 185 c.p.s. from TMS (40 Mc./sec.)

IV — 152.5 c.p.s. (higher field—more shielded)

in calculating the conformational preferences of substituent groups (29). A valuable relationship for assigning configuration and conformation in rigid systems is the dependence of coupling constants between protons on adajcent carbon atoms (vicinal coupling) upon the dihedral angle (ϕ) between the protons. A number of formulas have been developed to express this relationship (30, 31), and the plot of J_{vic} against ϕ for Williamson and Johnson's formula (31) is shown in Fig. 6. From this, J_{vic} should have a value of about 16 c.p.s. when $\phi = 180°$ (as in axially related protons) and 2.5 c.p.s. when $\phi = 60°$ (as in a/e or e/e related protons). In practice, J_{aa}, J_{ae}, and J_{ee} values deviate from these values as a result of distortion of the ideal dihedral angles

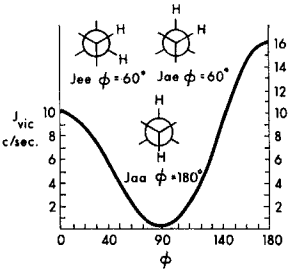


Fig. 6—Plot showing the dihedral angle dependence of vicinal coupling constants from Williamson and Johnson (31).

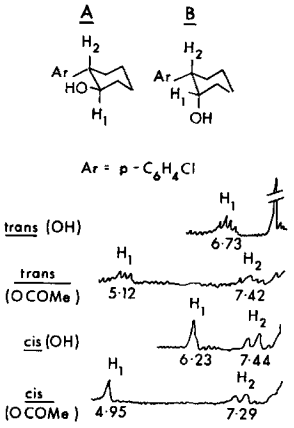

Fig. 7—Part of the PMR spectra of trans *and* cis *2-(p-chlorophenyl) cyclohexanol and corresponding acetate esters; chemical shifts in τ values from TMS, solvent CCl_4. [Adapted with permission from* J. Org. Chem., **27**, *715(1962).]*

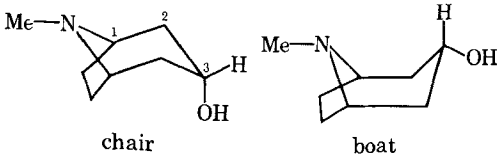
and the influence of substituent electronegativities upon J values, but it is clear that J_{aa} coupling constants exceed J_{ae} and J_{ee} values. Thus, large J_{vic} coupling constants between protons in a cyclic structure may be associated with an approximately diaxial orientation of atoms, and smaller separations with a–e or e–e interactions. Much use has been made of these principles in establishing the stereochemistry of biologically active cyclic compounds. A typical example, taken from Huitric's extensive study of aryl substituted cyclohexanols (32), is the investigation of *cis*- and *trans*-2-(chlorophenyl)cyclohexanol (33). Signals of the 1- and 2-protons are shown in Fig. 7; these are readily differentiated by the large downfield shift of the 1-hydrogen upon acetylation (6, 34). [Use of the upfield shift of the methine proton which follows methylation of *sec* alcohols has recently been proposed as an alternative method of identifying protons on carbon bearing a hydroxyl group (35).] The broad unresolved multiplets for the 1 and 2-hydrogens in A (OH and acetate) are consistent with their *trans* configuration; in the geometry depicted in A, both are axial and each is adjacent to two nonidentical axial hydrogens. In the *cis* geometry, B, the 1-hydrogen is equatorial and has little spin–spin coupling with adjacent hydrogens (hence an approximate singlet results), while the

2-hydrogen is axial and adjacent to only one other axial hydrogen giving rise to what is essentially a doublet with $J_{2,3}$ of about 11.5 c.p.s. PMR evidence of the same nature has been used to settle the controversial problem of whether the piperidine ring of tropane derivatives exists in a chair or a boat conformation (36, 37). The most valuable information in this respect derives from the approximate triplet due to the 3-proton of tropine (V)—the small value of its base width shows that it cannot involve a *trans* (or near *trans*) coupling (as in the boat form) and establishes that the 3-proton must be attached equatorially to a six-membered ring. Furthermore, the characteristics of this signal are very similar to those of the 4-proton in the β-isomer of 1-methyl-2,6-diphenylpiperidin-4-ol (VI) of known conformation (38).



V

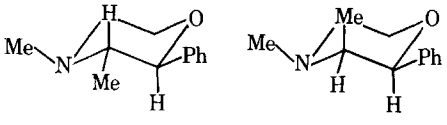
4-H, 16.0 c.p.s.



VII VIII

Acid-catalyzed cyclization of *N*-(β-hydroxyethyl)-(−)-ephedrine (erythro configuration) yields the appetite depressing drug (+)-3,4-dimethyl-2-phenylmorpholine (VII, phendimetrazine) while cyclization of *N*-chloroacetyl ephedrine and reduction of the product with lithium aluminium hydride gives the corresponding diastereoisomer (VIII) (without influence upon appetite). From the $J_{2,3}$ coupling constants, phendimetrazine is assigned a threo ($J_{2,3}$ 8.8 c.p.s., a value indicative of *trans* coupling) and its isomer an erythro ($J_{2,3}$ 2.7 c.p.s.) configuration (39). Hence, the acid-catalyzed process must proceed with inversion of configuration.

Knowledge of the stereochemistry of the α- and β-2-ethyl-5-methyl-3,3-diphenyltetrahydrofurans (IX) derived from the diastereoisomeric analgesics α- and β-methadol, respectively (40, 41), is of importance in that it provides evidence of the configurations of the precursor amino alcohols themselves (41). The PMR spectra of the isomeric cyclic ethers differ markedly in the respect to the 4-methylene signals (40), which form the AB part of an ABX system (Fig. 8). Assignments to H_α and H_β (*cis* and *trans* to the methine proton, H_x) may be made by use of the dihedral angle dependence of coupling constants [the reasonable assumption is made that the C-4 and C-5 substituents are staggered (29) with the $H_\alpha H_x$ and $H_\beta H_x$ dihedral angles intermediate between 0° and 60°, and 120° and 180°, respectively, leading to the conclusion that $J_{\beta x}$ should exceed $J_{\alpha x}$], and it is apparent, from comparisons with the AB signals of a series of related 5-methyl-3,3-diphenyltetrahydrofurans, that the H_α proton has an abnormally high field position in the α-isomer (IX). This is a result to be expected if the same isomer has *cis*-2-Et/5-Me geometry, since a consideration of the probable conformations of the *gem* diphenyl groups in this molecule (that of phenyl *trans* to 2-Et will be determined largely by the orientation of the *cis*-phenyl group, itself influenced by the bulky 2-Et substituent) leads to a conformer in which the α-C-4 methylene proton falls within the screening zone of the adjacent phenyl group (B in Fig. 9). In the β-isomer (*trans*-2-Et/5-Me) interactions between 2-Et and a flanking phenyl group will likewise be an important factor in determining the preferred conformation of phenyl *trans* to Et. Here, however, the methylene proton *cis* to 5-methyl (H_β) will be screened and, as a result, the H_α-H_β chemical shift difference will increase because H has the higher field position in the absence of differential screening effects; these arguments account for the well separated H_α and H_β signals and the unusually high field position of H_β in the β-isomer,

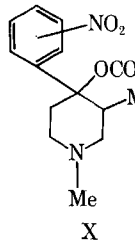
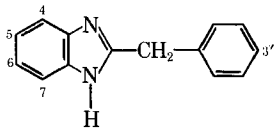
PROBLEMS OF AROMATIC SUBSTITUTION

The position taken by an aromatic substituent can often be identified by PMR spectroscopy from considerations based upon a combination of chemical shift, spin–spin couplings (*ortho* 5–9, *meta* 2–3, and *para* coupling 0–1 c.p.s.), and integration data. A simple example is provided by the nitration product of alphaprodine (X) (42). If the nitro group enters the *para* position,

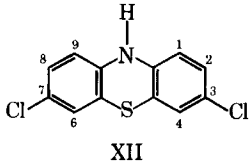


X



XI

the aromatic protons will comprise an A_2X_2 (or A_2B_2) system, and their signal will be a pair of superimposed doublets with J values typical of *ortho* coupling. If the nitro group enters the *ortho* or *meta* positions, the aromatic protons will comprise nonsymmetrical groups, and their resonance signal will be correspondingly more complex. In fact, the aromatic signal of nitro alphaprodine consists of two doublets that both integrate for two protons and have a J value of 9 c.p.s.; hence X is a *p*-nitro derivative. Orientation in the case of the dinitro product obtained from 2-benzylbenzimidazole (XI) was assisted by comparison of its PMR spectrum with that of 3′- and 5-nitro-2-benzylbenzimidazole (Fig. 10) (43). The A_2B_2-4 proton quartet of the 3′-nitro derivative and signals due to protons of the benzimidazole nucleus of the 5-nitro isomer may both be discerned (in spite of the signal overlap) in the spectrum of the dinitro derivative. In the 5-nitro isomer, assignment of the lowest field doublet (511 c.p.s.) to the 4-proton (on the basis of its being flanked by electronegative, deshielding groups) is confirmed by the fact that it exhibits a coupling constant (2 c.p.s.) typical of *meta* placed protons. The doublet of doublets (center 490 c.p.s. J 2 and 9) must arise from the 6-proton since this is *meta* coupled to the 4- and *ortho* coupled to the 7-proton, the latter giving a signal of the expected multiplicity and J value (doublet at 464.5 c.p.s. J 9 c.p.s.), *ortho* coupling alone being involved in this case. Craig and others (44) have reported chemical shift data for a series of mono- and di- derivatives (mostly chloro and methoxy) of phenothiazine and have demonstrated the feasibility of deducing orientation in substituted phenothiazines by analysis of the aromatic proton resonance signals. When substitution is 3,7, for example, two doublets, both having J = 9 and one further split by *meta* coupling [due to the 1 (9) and 2 (8) protons, respectively], should be differentiated —as in the spectrum of 3,7-dichlorophenothiazine



XII

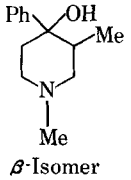
(XII). The problem of orientation has particular significance in characterizing hydroxylated phenothiazines (formed in the metabolism of pharmacologically active derivatives) since the necessary synthetic reference compounds are not yet available. Warren *et al.* (45) have published the PMR spectra of a collection of commercially available phenothiazines for use in their identification.

HYDROGEN BONDING STUDIES

The resonance position of a hydroxylic proton moves to lower fields when it is hydrogen bonded

(2, 6, 7, 46), a phenomenon which has made PMR spectroscopy a valuable tool for the study of hydrogen bond formation. The dependence of the OH resonance position (a time average of a weighted average of the various hydrogen-bonded species present) upon the extent of hydrogen bonding accounts for the changes in the OH chemical shift which result when the concentration of the hydroxyl compound or the temperature are varied. Concentration independent (or largely so) OH resonance signals are obtained when solvents capable of forming strong hydrogen bonds such as dimethylsulfoxide and pyridine (47, 48) are employed; solvent–substrate bonding (unaffected by substrate concentration) then becomes the predominant hydrogen-bonded species because of the large excess of solvent over solute molecules. $CDCl_3$ is also a solvent of this nature as seen from the OH chemical shifts of β-1,3-dimethyl-4-phenylpiperidin-4-ol, which are far more sensitive to concentration changes in CCl_4 than in $CDCl_3$ (49) as the data in Table I demonstrate.

TABLE I—CHEMICAL SHIFTS OF



β-Isomer

Solvent	Concn., mg./ml.	Chemical Shift (from TMS), c.p.s.
CCl_4	70	122
CCl_4	23	95.5
$CDCl_3$	70	133
$CDCl_3$	23	122

The chemical shift of the hydroxyl proton has been shown to be linearly related to concentration in CCl_4 in the 0.015 to 0.002 mole fraction range and, by extrapolating to infinite dilution, the chemical shift of the monomeric OH proton can be determined (48). Comparisons of such values in triads of compounds such as those shown in Fig. 11 have enabled the conformation preferences of cyclohexane substituents to be calculated (48). It is probable (on steric grounds) that an axial OH group is less hydrogen bonded than one in the equatorial positon; hence, the OH chemical shift of an axial alcohol should be less concentration-dependent than that of the epimer. From these arguments evidence of stereochemistry may be derived from the limiting slopes of chemical shift–concentration plots (48). Thus, from the data of Fig. 11, the slope for *cis*-4-*tert*-butylcyclo-

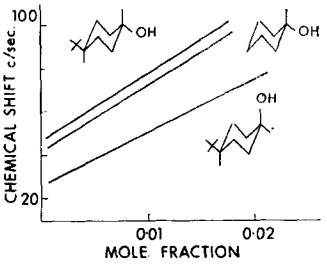


Fig. 11—Chemical shift dependence of hydroxyl proton with concentration at 40°. Solvent CCl_4. [Adapted with permission from J. Am. Chem. Soc., **86**, *4378 (1964).]*

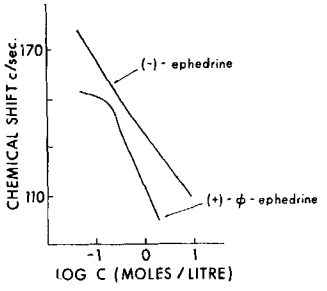

Fig. 12—Chemical shift dependence of NH/OH protons with concentration in $CHCl_3$. [Adapted with permission from Can. J. Chem., **38**, *125 (1960).]*

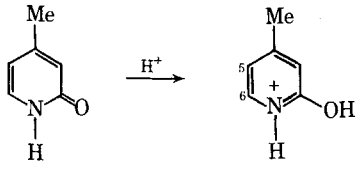
hexanol (axial OH) is less than that of the *trans* isomer (equatorial OH). A more subtle use of PMR spectroscopy in these studies is the detection of intra- in distinction from intermolecular hydrogen bonding, as may occur in diols and amino alcohols. Inter- is more sensitive than intramolecular hydrogen bonding to dilution, and this difference should be reflected in OH chemical shift–concentration plots. It is found, for example, that the concentration dependence of the *o*-chlorophenol OH resonance frequency reaches a maximum at low concentrations, while that of the *m*- and *p*-isomers continues to increase throughout the dilution range studied (intramolecular hydrogen bonding is only possible in the *o*-chloroisomer) (50). Figure 12 shows the concentration dependence of resonance frequencies of the NH and OH protons of ephedrine and pseudoephedrine (these appear as a single line because of rapid exchange). At low concentrations the pseudoephedrine signals are less sensitive to concentration changes and Hyne (51) advances this fact as evidence for intramolecular hydrogen bonding (N---H—O—) in the pseudoisomer. The position of the OH resonance lines in chloramphenicol and its isomers in acetone at low fields compared with those of the OH of simple monohydric alcohols at infinite dilution in CCl_4, indicates that both OH groups of the antibiotic are involved in hydrogen bonds. These bonds are considered to be of an intra- rather than intermolecular nature because of the comparative concentration independence of the OH chemical shifts, while bonding to the solvent

was thought unlikely on account of evidence that inter- and intramolecular hydrogen bonds are stronger than those formed between hydroxyl groups and acetone (the chemical shifts of monohydric alcohols at infinite dilution in acetone are at higher fields than those of OH in dihydric alcohols capable of intramolecular bonding) (52).

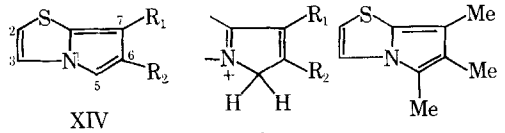
SITE OF PROTONATION

The problem of identifying the site of protonation in a molecule containing more than one basic center, often encountered in medicinal chemistry, may frequently be solved by studying the effect of proton uptake on chemical shifts and the spin–spin coupling patterns of protons in the vicinity of the various possible sites. Some examples follow. The C-6 proton peak of 4-methyl-2-pyridone (XIII) in sulfuric acid appears as a triplet indicating approximately equal coupling with the C-5 proton and *one* proton on the nitrogen atom (53). This result demonstrates the



XIII

O-protonation of the pyridone (XIII); if *N*-protonation had occurred, the C-6 proton signal would have been a quartet (two protons on nitrogen). Similar evidence supports sulfur and ring nitrogen as protonation sites in thiopyridones and aminopyridines, respectively (54). Protonation of the pyrrolo[2,1-*b*]thiazoles (XIV*a–c*) is considered to occur at a carbon atom because



XIV salt XV

a, $R_1 = R_2 = H$
b, $R_1 = H$, $R_2 = Me$
c, $R_1 = R_2 = Me$

PMR spectra of the salts display a two proton singlet that has a position characteristic of a methylene group (55). A low field AB system (two doublets), which is common to spectra of all the salts of XIV*a–c*, and XV can only arise from the C-2 and 3 protons; hence protonation must occur in the pyrrole ring. C-5 must be the site since, in XIV*c*, a methylene group can only develop at this position; the same site is postulated for the other derivatives since the methylene signals of the spectra (XIV*a–c*), all have similar chemical shifts. In the salt of XV, the C-5 proton signal is the anticipated quartet. In the next example evidence for the protonation site is obtained by identifying the proton most deshielded when a base is converted to its salt. The aromatic proton signals of the 2-benzylbenzimidazole shown in Fig. 13 are readily analyzed. The lowest field signal is assigned to the C-4 proton (it is flanked by electronegative groups and exhibits *meta* coupling only), the quartet (center τ 1.8) to the C-5 proton (it exhibits *ortho* and *meta* coupling), and the high field doublet (*ortho* coupled) to the C-6 proton. In the monohydrochloride, this pattern of signals, although disturbed, is maintained, and the downfield shifts may be measured. These are C-4 (7.2 c.p.s.), C-5 (13.2 c.p.s.), and C-6 (24.5 c.p.s.). The fact that the C-6 proton suffers the greatest shift indicates that N-1, rather than N-3, is the protonation site (56).

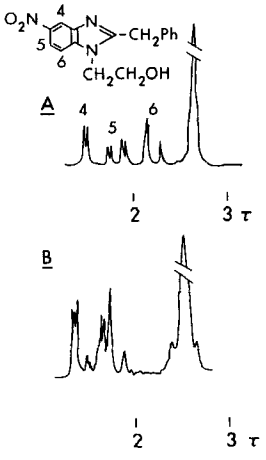


Fig. 13—Aromatic PMR signals of 2-benzyl-1-(2-hydroxyethyl)-5-nitrobenzimidazole in dimethylsulfoxide. Key: A, free base; B, hydrochloride. Chemical shifts in τ values from TMS.

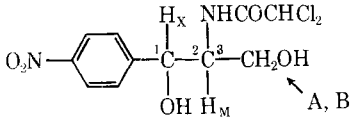
Appropriate to this section is mention of the potentiality of PMR spectroscopy in determining pKa values of acids and bases. When an acid ionizes, the chemical shifts of protons near the acidic function change and if the PMR spectra of the unionized acid (HA) alone, and the anion (A^-) alone are known, the ratio HA/A^- for mixtures may be derived from chemical shift values [the spectral characteristics resulting from two species undergoing rapid chemical exchange depend only upon the PMR parameters of the individual species and their relative amounts (2)]. The same arguments apply in the case of a base and its conjugate acid. These principles have been applied by Birchall and Jolly (57) to the determination of the relative acidities of weak acids in liquid ammonia.

CONFORMATION OF PHARMACOLOGICALLY ACTIVE MOLECULES

Knowledge of the probable conformations of pharmacologically active molecules in solution, particularly as solutes in water, is of great importance to medicinal chemists because of the value of such information in extending the understanding of receptor sites. Some of the relatively few examples in which NMR spectroscopy has been employed in this connection are discussed below.

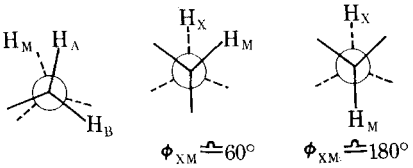
Jardetzky (52) has made a detailed analysis of the PMR spectra of chloramphenicol (XVI) and its erythro isomer. Signals arising from the



J_{AB} = 10–11 c.p.s
$J_{AM} = J_{BM}$ = 5–6 c.p.s
J_{MX} = 2–3 c.p.s

XVI

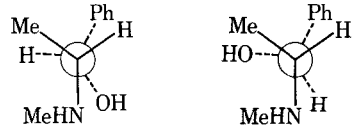
proton group attached to carbons 1, 2, and 3 of chloramphenicol could be analyzed by the ABMX procedure, and it was concluded (*a*) from the smallness of the J_{MX} value (2.6 c.p.s.) and (*b*) the nonequivalence of the two hydrogens on C-3, that rotation about the single C—C bonds of the propanol side chain is restricted. In principle, methylene protons (AB) adjacent to an asymmetric center must be nonequivalent because of differences in the averaging of the A and B shifts by rapid rotation (rotational nonequivalence); however, nonequivalence of this type is not observed in the PMR spectra of many asymmetrically substituted molecules in which "free" rotation can be inferred from the magnitude of the coupling constants [*e.g.*, catecholamines (58)], and for it to be observed, differences in conformation populations are an additional requirement. The preferred conformation (XVII) of the C_2 and C_3 portion of the molecule (with



XVII $\phi_{XM} \simeq 60°$ XVIII $\phi_{XM} \simeq 180°$ XIX

the AM and BM dihedral angles close to 0° and 180°, respectively) is based upon the values and equality of the J_{AM} and J_{BM} coupling constants (see plot of J_{vic}/dihedral angle, Fig. 6), while the low value of the J_{MX} constant (2–3 c.p.s.) shows the X and M protons to have a gauche conformation as in XVIII. In the erythro isomer the larger J_{MX} value (6 c.p.s.) shows the X and M protons to be *trans* as in XIX. A choice of the most likely conformations, influenced also by the assumption of an intramolecular hydrogen bond (evidence discussed elsewhere in this review) led to a structure which bore a striking resemblance to a pyrimidine ribonucleotide. Any alteration of the geometry of the propanol side chain (as in erythro isomers) destroys the similarity to the ribose moiety; hence this relationship is considered to have a possible bearing upon the stereochemical features of structure-activity relationships in the chloramphenicol series (52).

Hyne (59) has studied the conformation of a related diastereoisomeric pair, ephedrine and pseudoephedrine, in chloroform. The preferred "off staggered" conformations he proposes for these molecules (XX and XXI) are based upon



pseudoephedrine XX ephedrine XXI

$Ph^1CH(OH)^2CH(NHMe)Me$

PMR evidence for similar methyl environments in the two isomers and for a greater C_1-H/C_2-H dihedral angle in the case of pseudoephedrine (J_{vic} 8.2 for pseudo- and 4.0 c.p.s. for ephedrine). The occurrence of intramolecular hydrogen bonding in the pseudoisomer (see previous discussion) is also accounted for by conformation XX; in the ephedrine conformation (XXI) the tendency for hydrogen bonding should be less because of the great OH-NH distance. Sasaki *et al.* (60), using similar arguments, have advanced a favored conformation for (−)-*N*,*N*-dimethyl-1,2-diphenylethylamine (XXII), an analgesic one-half to one-third as potent as morphine (61).

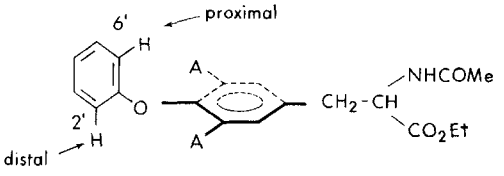
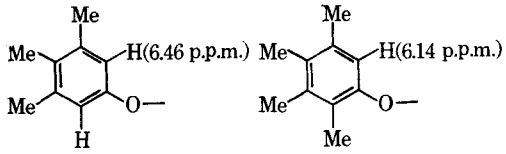
J_{AX} 9.3
(hydrochloride in D_2O)

XXII

Lehman and Jorgensen (62) have presented PMR evidence in support of a preferred skewed conformation for *O*,*O*-disubstituted diphenyl ethers (XXIII) related to thyroxine; this work is

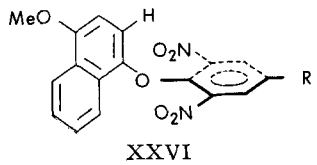


XXIII



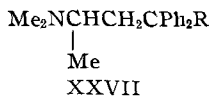
XXIV XXV

related to Jorgensen's proposed receptor for the thyroid hormone (63). Study of models shows that the proximal 6′-proton (but not the distal 2′-proton) lies well within the region in which its magnetic resonance would be shielded by the π-cloud as estimated by Johnson and Bovey (64). In compounds substituted at the 3- and 5-positions (A in XXIII) by iodine or nitro but lacking a 2′-substituent, signals due to the aromatic protons in the outer ring ranged from 6.36 to 8.2 p.p.m. However, in trisubstituted derivatives the 6′-protons resonated at unusually high fields (6.22 p.p.m. in the dinitro- and 6.07 p.p.m. in the diiodo series) as should be the case if the skewed conformation (XXIII) is preferred in these compounds. A consistent difference between the chemical shifts of the 6′-proton and other protons in the same ring was seen throughout the series which included a variety of substituents attached at various points; hence, the possibility of the observed shifts being due to substituent effects is unlikely. Furthermore, the chemical shifts of the 6′-protons in XXIV and XXV may be compared; the upfield shift suffered by this proton when the 2′-proton is replaced by methyl is unlikely to be a substituent effect (the 2′-methyl group is too far removed) and is more reasonably attributed to a steric positioning of the outer ring as in XXIII. Evidence for positioning was found for 2,6-dinitro and diiodo ethers with cyclohexyl, isopropyl, allyl, trifluoromethyl, and methyl C-2′ substituents and also in the case of α-naphthyl derivatives such as XXVI.



XXVI

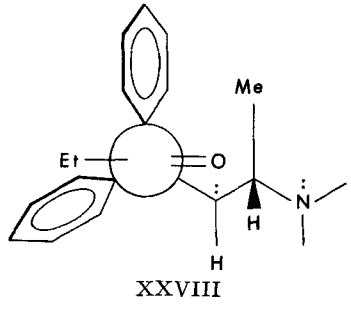
In the case of methadone (XXVII*a*), evidence for probable conformations has been derived by comparing the PMR spectrum of this analgesic with those of related 1-amino-3,3-diphenyl-



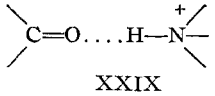
XXVII

R = *a*, COMe; *b*, H; *c*, OH; *d*, CN; *e*, C(NH)Et, *f*, CO_2Et; *g*, CH(OCOMe)Et

propane derivatives (65). It is found that the chemical shift of the secondary methyl group in methadone (XXVII*a*) (29 c.p.s.) is at an abnormally high field position compared with those of the derivatives (XXVII*b*, *c*, and *d*) (all near 60 c.p.s.). Unusually high field *sec* Me signals are also observed in the ketimine (XXVII*e*, 20 c.p.s.) and analogs of methadone bearing different basic groups. When the basic derivatives (XXVII) are protonated, the *sec* Me signals move downfield as a result of the greater deshielding influence of positively charged nitrogen; however, downfield shifts are low (13 compared with 20–25 c.p.s.) in the amino ketones. These results are taken to indicate that in favored conformations of methadone and related ketones, the *sec* Me group lies close to and above the plane of one of the aromatic rings in the molecule, as is the case in crystalline methadone hydrobromide whose conformation has been established by X-ray crystallography (66). The model (XXVIII), based upon the structure of the crystalline salt, is therefore taken to represent a favored conformation for methadone hydrochloride as solute in $CDCl_3$ or water (an unusually high field *sec* Me signal is also observed when D_2O is solvent). The conformation (XXVIII) could be stabilized by an interaction of the type XXIX and the PMR demonstration of the nonequivalence of the two *N*-methyl groups

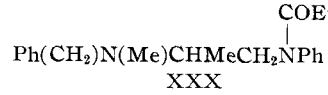


XXVIII



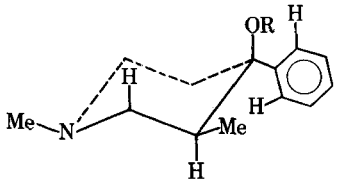
XXIX

(in $CDCl_3$, the NMe_2 signal is a doublet of doublets collapsing to a singlet when D_2O is added) provides evidence for such an interaction; an association involving the protonated basic group may be expected, if sufficiently strong, to lead to restricted rotation about the nitrogen atom (65, 67). High field *sec* Me chemical shifts are also observed in nonketonic analgesically active 3-amino-1,1-diphenylpropane derivatives such as XXVII*f* and *g* (68). In diampromide (XXX,



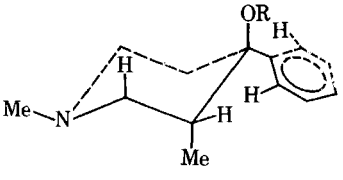
XXX

regarded as a methadone analog in which the quaternary carbon and one phenyl group of the parent are replaced by nitrogen), the *sec* Me group is not especially shielded by the aromatic groups, this and other spectroscopic evidence (69) indicating that the phenyl-*sec* Me-basic groups orientations in the two analgesics differ—a possible reason for their differing stereochemical and basic group features.



XXXI

trans 3-Me/4-Ph



XXXII

cis 3-Me/4-Ph

R = H, COMe, or COEt

The configuration of the two diastereoisomeric propionate esters of 1,3-dimethyl-4-phenylpiperidin-4-ol (α- and β-prodine) has been the subject of several papers (70) and is now firmly established as *trans* (3-Me/4-Ph) for α- and *cis* for β-prodine by X-ray crystallography (71). Differences in the PMR spectra of the two esters and of the alcohols from which they are derived provide evidence of the conformation of these molecules as solutes in $CDCl_3$ and support structures XXXI and XXXII as the most probable conformations for the α- and β-isomers, respectively (49). Signals of greatest value in this

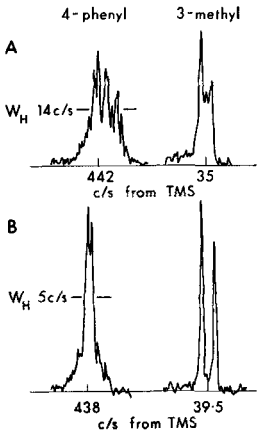


Fig. 14—Part of the PMR spectra of α-1,3-dimethyl-4-phenyl-4-piperidinol (A) *and of the corresponding β-isomer* (B) *in CCl_4. [Reproduced with permission from* Tetrahedron, **22,** *2711 (1966).]*

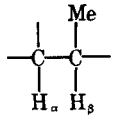
interpretation are those of the 4-aryl and 3-methyl groups. It is postulated that chemical shift differences among the aryl protons should be greater in the α-diastereoisomer with the result that the *trans*- aromatic signal should be more complex than that of the *cis* isomer; this is confirmed experimentally (Fig. 14). Dreiding models of XXXI and XXXII show that both *sec* Me groups fall within the diamagnetic screening zone of the benzene nucleus; this fact accounts for their high field resonance positions (relative to *sec* Me in compounds such as 3,4-dimethyl-1-phenethyl-4-piperidinol, *sec* Me chemical shift 54.5 c.p.s. in $CDCl_3$) but does now allow a stereochemical differentiation to be made (the α/β-*sec* Me chemical shift difference is small with the α-signal at higher field by 5–6 c.p.s.). However, axial Me (in XXXII) is closer than equatorial Me (in XXXI) to the ring nitrogen atom; hence, when the deshielding influence of this atom is enhanced by protonation the β-Me signal should suffer the greater downfield shift. Again this is found to be the case, shifts being 2 c.p.s. for α-Me and 16 c.p.s. for β-Me. The nature of the α- and β-Me signals also provides evidence of conformation. The distorted appearance of the α-signal (Fig. 14) is a typical result of virtual coupling which occurs in the system:



when the coupling constant between H_α and H_β is large and of the same order as the chemical shift difference between the two protons (72). Such conditions are more likely to prevail in XXXI than in XXXII since the former contains an axial proton at C-3 which will be strongly coupled to the C-2 axial proton. In propionate

esters of the piperidinols the $COCH_2Me$ and $CO\mathit{CH_2}Me$ signals are at higher field in the β-isomer. These results are also consistent with the *cis* ester having a preferred conformation akin to XXXII because the acyl portion of the ester group will spend some of its time above the plane of the phenyl group (*i.e.*, well within the aromatic shielding zone) if the planes of the C—O bond and the aromatic ring are approximately perpendicular. The conformation of drug molecules in water is of greater importance from a biological point of view and PMR studies of the prodine esters and alcohols (as hydrochlorides) in D_2O show that replacement of $CDCl_3$ by D_2O brings about significant changes in conformational equilibria. Thus, while the downfield shifts of the aromatic and *N*-methyl signals (resulting from this solvent change) are similar in α- and β-1,3-dimethyl-4-phenylpiperidin-4-ol hydrochlorides, that of the β-*sec*-Me group is almost 11 c.p.s. less than that observed for the corresponding α-signal. In addition, the chemical shift difference between the α- and β-*sec* Me groups is much less in D_2O than in $CDCl_3$. These results indicate an increase in the population of equatorial *sec* Me (chair) and/or skew-boat conformations at the expense of axial-*sec* Me conformers in the β-isomer when $CDCl_3$ is replaced by D_2O. Such an increase would reduce the deshielding influence of protonated nitrogen upon *sec* Me, the chemical shift of this group moving nearer to that of *sec* Me in the α-isomer in consequence. Radical conformational changes through solvent variation must also occur in esters of the piperidinols as is evident from the *sec* Me chemical shifts recorded in Table II. The zero or near-zero chemical shift differences between the α- and β-*sec* Me signals observed with D_2O as solvent are particularly noteworthy in this respect (24). When $CDCl_3$ is replaced by D_2O as solvent, a considerable increase in the degree of solvation of both the protonated basic center and the oxygen function of the piperidinol derivatives is probable and the larger destabilizing Me/H and OR/H 1,3-diaxial interactions obtaining in the solvated molecules are considered responsible for the decrease in the conformational preference for axial 3-Me conformers (49).

TABLE II—SOLVENT EFFECTS UPON *sec* ME CHEMICAL SHIFTS IN ESTERS OF α- AND β-1,3-DIMETHYL-4-PHENYLPIPERIDIN-4-OL HYDROCHLORIDES

RELAXATION TIME STUDIES

The extreme sensitivity of spin–spin (T_2) and spin–lattice (T_1) relaxation processes to variations in the molecular environment of the proton species concerned provide an elegant method for the study of the interactions of drugs with macromolecules of a type liable to be encountered in the body (14). In this technique, relaxation constants are measured for the drug alone and for the drug in the presence of a macromolecule. (T_2 is obtained from measurements of line widths at half the maximum peak height, and T_1 by measuring the recovery time of a signal which has been saturated by the application of a strong R.F. field.) Relative changes in T_1 and T_2 for each proton group that occur in the presence of the added substance are then derived from the data. Differing values indicate that a specific binding mechanism is involved (a non-specific mechanism such as an increase in viscosity would shorten all relaxation times by the same factor), the groups implicated being identified as those which exhibit the greatest decreases in relaxation times. In a study of the binding of sulfonamides to albumin (73), it was found that addition of this protein to the sulfonamide solution generally produced a larger increment in the relaxation rate of the *p*-aminobenzenesulfonamide aromatic protons than for any protons of the N-1 substituent. Results for sulfacetamide (Fig. 15), for example, showed that the aromatic moiety is preferentially stabilized by the interaction of the drug molecule with albumin, whereas the acetyl group retains much greater freedom of motion; in this molecule it is probable, therefore, that the aromatic ring is the primary binding site. A similar study of the binding of benzyl penicillin to serum albumin identifies the benzyl group as the binding site (74), while, in the case of the interaction between epinephrine and adenosine triphosphate (a complex of this nature is thought to be the storage form of catecholamines in the chromaffin granules of the adrenal medulla), results indicate that the propanol side-chain, but not the aromatic ring, is involved in complex formation (14). Chapman and Penkett (75) have studied the interaction of phospholipids with cholesterol by relaxation studies and have obtained evidence for the direct interaction of a portion of the phospholipid (particularly the hydrocarbon chains, the major

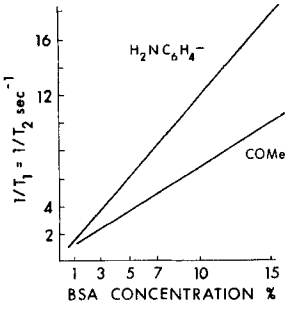

Fig. 15—Relaxation rates of 0.1 M sulfacetamide peaks, pH 8.8, as a function of bovine serum albumin (BSA) concentration. [Adapted with permission from Mol. Pharmacol., **1**, *214 (1965).]*

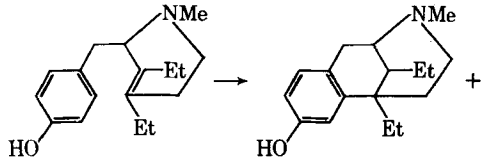
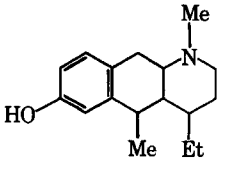
PMR peak arising from protons associated with the hydrocarbon chain of lecithin virtually disappears when an equimolar proportion of cholesterol is present) with the cholesterol molecule. It is obvious that work of this nature has great potentialities in the study of drug–enzyme and drug–receptor interactions.

MISCELLANEOUS

The routine use of PMR data as an aid to structure determination in natural products and in organic synthesis is self-evident. To quote but one example, cyclization of the tetrahydropyridine (XXXIII) by aluminum bromide gives an analgesically active benzo[*g*]quinoline (XXXV) as well as the expected benzomorphan derivatives (XXXIV), the former being characterized



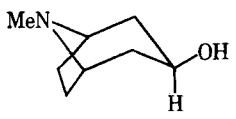
XXXIII *cis* and *trans*-Et/Et XXXIV



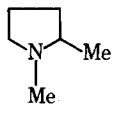
XXXV

by a *sec* Me doublet and a single CH_2Me triplet in its PMR spectrum (76).

Systems in which protons may exchange their environment within the same, or in a different, molecule are also studied conveniently by PMR spectroscopy. If the exchange rate is slow, absorption lines for each environment are seen, fast rates yield single, sharp, lines (corresponding to a weighted average of the separate environmental chemical shifts) while intermediate rates give rise to broad signals. [See Delpuech (77) for a recent review of this topic.] The kinetics of proton exchange in salts of organic bases may be studied in this way. In cyclic bases such as pseudotropine (XXXVI) and 1,2-dimethylpyrrolidine (XXXVII), the separate existence of isomers formed as a result of the protonated basic



XXXVI



XXXVII

HCl N—Me doublets ($J5$)	
130.5 c.p.s. (minor)	6.97 (major)
138.5 c.p.s. (major)	7.27 (minor)
from reference in H_2O, pH 1.0	from TMS in $CHCl_3$

center having two possible configurations is made evident by the appearance of two N-Me signals in the PMR spectra of their salts (78, 79) when solvents unfavorable to proton exchange are employed. The signals differ in intensity, and the more pronounced is assumed to be due to the more stable configuration (equatorial N-Me for XXXVI, *trans* 1,2-diMe for XXXVII). When the rate of proton exchange is accelerated, single N-Me signals are obtained. Protonated N-epimers are also observed in 1,5-dimethyl-4-phenyl-1,2,5,6-tetrahydropyridine (XXXVIII) hydrochloride and related compounds (80).

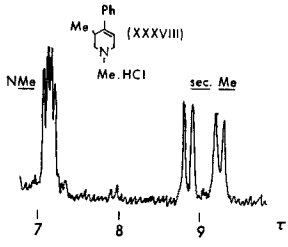


Fig. 16—Part of the PMR spectrum of 1,5-dimethyl-4-phenyl-1, 2, 5, 6-tetrahydropyridine hydrochloride in $CDCl_3$.

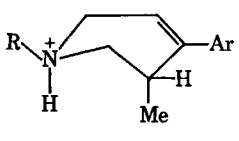
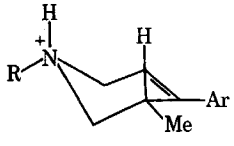
Thus, the spectrum of XXXVIII hydrochloride in $CDCl_3$ displays a doublet of doublets N-Me signal and two well-separated *sec* Me doublets (Fig. 16) which collapse to a singlet and a doublet, respectively, when D_2O is added. In these cases, there is evidence that the epimers differ in their 5-methyl rather than N-methyl configurations, XXXIX and XL being the proposed preferred conformations.



XXXIX



XL

Interesting developments in the differentiation of optical enantiomorphs by PMR spectroscopy

PhCH(OH)CF_3 PhCH(OH)$CHMe_2$
XLI XLII

have recently been reported. Magnetic equivalence of the two methyl groups of isopropanol no longer obtains when the alcohol is esterified with the acid chloride derived from (R)-*O*-methylmandelic acid; the now diastereoisomeric methyl groups in the resultant ester give rise to two doublets which differ in chemical shift by 5 c.p.s. at 60 Mc./sec. (81). The optical purity of propan-2-ol-1-d_3 may then be checked by conversion to the *O*-methylmandelate and examination of the PMR spectrum of the ester; if the material is a single enantiomorph, only one of the *sec* Me doublets of the nondeuterated ester should appear. It has now been shown that optical enantiomorphs themselves may have different PMR characteristics when examined in an optically active solvent as a result of diastereoisomeric interactions (82). Thus, the fluorine resonance signal of racemic 2,2,2-trifluoro-1-phenylethanol (XLI) is a doublet in racemic α-phenethylamine, but a doublet of doublets (of equal intensity) in the levorotatory base. (Each doublet is further split by long-range coupling with aromatic protons.) Partially resolved XLI in the latter solvent gives a doublet pair of unequal intensity. Similarly, the signal of the carbinyl proton of racemic phenylisopropylcarbinol (XLII), a doublet in racemic α-(1-naphthyl)ethylamine, forms two equally intense doublets in the dextrorotatory base (separation 1.6 c.p.s. at 60 Mc. and 2.5 c.p.s. at 100 Mc./sec.).

In conclusion, attention is drawn to some useful reviews. Surveys of the whole field are published periodically in *Analytical Chemistry* (83) and *Annual Reports of the Chemical Society* (for last review, see *Reference 84*). Kinetic studies by NMR (77), NMR of fluorine (85), of ^{13}C (86), of organometallic compounds (87), spin–spin coupling and double resonance (88) [see also Baldeschweiler and Randall (89) for the latter topic], and NMR and electronegativity (90), have all been recently reviewed. Useful accounts of long-range spin–spin coupling (91), geminal coupling constants in methylene groups (92), and conformational analysis of cyclohexane derivatives by NMR spectroscopy (93) are also available.

Effect of Deuterium Oxide on Culturing of *Penicillium janczewskii* I

Growth, Nutritional Factors, and Antibiotic Production

By D. A. NONA, M. I. BLAKE, and J. J. KATZ*

Penicillium janczewskii, **a mold which produces the antifungal antibiotic griseofulvin, was cultured in media containing 50, 75, and 99.6 per cent deuterium oxide. Protio- and deuterio-carbohydrates were used as carbon sources. Griseofulvin production decreased markedly with increase in deuterium content of the medium. There was also a marked reduction in mycelial dry weights with increase in deuterium oxide in the nutrient. The surface culture technique proved more effective than the shake method for both tissue growth and antibiotic formation.**

A VARIETY OF organisms, including bacteria, fungi, and algae, have been successfully cultured in media containing pure heavy water. The growth of the heterotroph *Euglena gracilis* in a fully deuteriated form has also been recently reported (1). Higher plants, including peppermint (2, 3), belladonna (4, 5), and duckweed (6), have been grown in nutrient solutions containing as high as 70% deuterium oxide. These studies have been summarized by Flaumenhaft (7) and by Katz (8), who have reviewed extensively the biological effects of deuterium.

Deuteriated organisms provide a practical source of metabolites containing deuterium in all

molecular positions where hydrogen is normally present. Many compounds of biological importance are not readily prepared by conventional synthetic methods, and for these, biosynthetic procedures are essential. Thus, Blake *et al.* (9) isolated deuteriated mannose, glucose, and several amino acids from *Scenedesmus obliquus* grown in 99% deuterium oxide, and Crespi *et al.* (10) obtained deuterio-DNA from deuteriated algae. Organisms which elaborate pharmacologically active compounds are of particular interest. A clavine alkaloid-yielding strain of *Claviceps purpurea* has been cultured (11) in pure D_2O and a highly deuteriated alkaloid has been prepared (12) by a replacement culture technique. Other molds have also attracted interest. Shaffer *et al.* (13) cultured *Penicillium notatum* and *Aspergillus fonseaceus* in heavy water some years ago, but antibiotic production and isolation were not investigated. The present study concerns the nutritional requirements for culturing the griseofulvin-producing mold, *P. janczewskii*, in a deuterium environment, and reports the effects of deuterium oxide on the production of the antibiotic griseofulvin. Griseofulvin, a systemically active antifungal agent, was originally isolated by Oxford *et al.* (14) and is produced biosynthetically by surface or submerged culture techniques (15–17) with various species of *Penicillia* (14, 18, 19). This constitutes the first report on the detection and isolation of an antibiotic obtained from a deuteriated organism.

EXPERIMENTAL

Preparation of Slant Cultures—The griseofulvin-producing strain, *P. janczewskii* (NRRL 2301), was used throughout this investigation. Slopes of malt extract agar in cylindrical glass tubes were streaked with a wire loopful of mold tissue. The tubes were plugged with cotton and incubated for 7 days at 25 ± 1°. Slants were stored in a refrigerator at 5° where they remained viable for at least 3 months.

Water Culture Techniques—A Czapek-Dox medium modified by addition of 0.5% potassium chloride (Table I) provided a well-defined synthetic medium for this investigation. The pH was adjusted, if necessary, to 4.8. The H_2O culture medium served as a control. The medium was placed in suitable culture flasks and plugged with nonabsorbent cotton. The flasks were sterilized by autoclaving for 15 min. at 15 p.s.i. in a Thermomatic-60 autoclave (Wilmot-Castle). Sugars and nutrient salt solutions were sterilized separately and combined aseptically. Carbohydrates were sterilized either by autoclaving, or by passing a solution through a Swinney adapter equipped with a Millipore filter disk of 0.22 μ porosity. Upon cooling, the medium was inoculated with 1 to 5 ml. (depending upon the medium volume) of a stock spore suspension.

TABLE I—COMPOSITION OF BASIC CULTURE MEDIUM FOR *P. janczewskii* (NRRL 2301)

Culture Medium	
Sodium nitrate	2.3
Potassium dihydrogen phosphate	1.0
Magnesium sulfate · $7H_2O$	0.5
Potassium chloride	0.5
Minor element concentrate	1.0
Dextrose	75.0
Distilled water, dilute to	1000.0
Minor Element Concentrate	
Ferrous sulfate	0.1
Copper sulfate	0.015
Zinc sulfate	0.1
Potassium molybdate	0.01
Distilled water, dilute to	100.00

Fermentation was carried out by employing one of two techniques.

Shake Method—Sixty milliliters of culture medium was placed in 250-ml. conical flasks which provided a liquid depth of approximately 2 cm. The inoculated culture flasks were agitated on an Eberbach rotary shaker at 200 r.p.m., and incubation was allowed to proceed in the dark at 25 ± 2°.

Surface Method—For small scale fermentation studies, 60 ml. of nutrient medium was placed in a 250-ml. conical flask. For preparative cultures, 500 ml. of medium was placed in 3-L. conical flasks, providing a liquid depth of about 2 cm. After inoculation, the cultures were incubated in darkness at 25 ± 2° without agitation.

Preparation of Deuteriated Media—Exchangeable hydrogen of inorganic salts and protio-sugars was replaced with deuterium by dissolution in pure deuterium oxide. The solutions then were evaporated to dryness under reduced pressure. This procedure was repeated to ensure complete exchange. A concentrate of minor elements of the culture medium was prepared with pure deuterium oxide (Table I). Partially deuteriated media composed of the basic nutrients and protio-glucose (7%) were prepared using 50, 75, and 99.6% deuterium oxide. A partially deuteriated medium was also prepared with fully deuteriated sugars (7%) and ordinary water. Fully deuteriated media were prepared using deuterio-sugars (7%) and pure deuterium oxide. The deuteriated monosaccharides were obtained from deuteriated algae according to the procedure of Blake *et al.* (9). Sugars obtained by this method contain 40% deuterio-glucose, 50% deuterio-mannose, and 10% of other hexoses and pentoses. Flasks containing deuteriated media were plugged with cotton and covered with aluminum foil to minimize isotopic dilution by exchange with atmospheric moisture.

Organic Substrates and Additives—A variety of carbon sources were tested for assimilation by the mold in media containing deuterium oxide. Glucose, glycerin, mannose, sodium acetate, and succinic acid were studied in concentrations of 3, 5, 7, and 9%, and dihydroxyacetone was tested in concentrations of 7%. All carbon sources were exchanged with D_2O prior to sterilization. For these experiments 60 ml. of the Czapek-Dox medium was prepared with pure deuterium oxide. Each of the substrates to be evaluated was sterilized separately and then added

TABLE II—COMPOSITION OF VITAMIN SUPPLEMENT ADDED TO FULLY DEUTERIATED MEDIA

Vitamin	Concn., mg./100 ml. D_2O
Biotin	0.5
Calcium pantothenate	0.5
Pyridoxine HCl	5.0
Riboflavin	0.5
Thiamine HCl	5.0

to the sterilized nutrients contained in 250-ml. conical flasks. An analogous series of controls was prepared with H_2O. Culture flasks were inoculated with 1 ml. of a stock spore suspension prepared with D_2O, whereas an H_2O spore suspension was used for the control cultures. The cultures were then incubated as static cultures at room temperature in the dark. Mycelial growth in each case was observed and recorded as a graded response during a 60-day period.

An additive of vitamin B-complex (Table II) was evaluated as a medium supplement in cultures grown in pure deuterium oxide. Concentrations of 1 to 2% were added to the culture medium. Algae extract (1%), bacto-peptone (2%), and corn steep solids (1–2%) were also studied as additives.

Mycelial Dry Weights—Two series of cultures were prepared, each consisting of ten 250-ml. conical flasks. Sixty milliliters of culture medium was prepared with protio-glucose and pure D_2O and placed into each flask of the first series. The same volume of an H_2O medium was placed into a second series of flasks to serve as controls. Each culture was inoculated with 1 ml. of a stock spore suspension in D_2O (H_2O for controls). At varying time intervals, up to a total of 64 days, the mycelium from a culture of each series was separated from its fermentor broth by filtration. The mycelium was dried to a constant weight in a vacuum oven at 100°. Both series were run in duplicate and the dry weights obtained were averaged and plotted as weight *versus* time in days.

Determination of Griseofulvin in Fermentor Broth—A Beckman DU spectrophotometer, model 2400 (Beckman Instruments, Inc.) equipped with matched silica cells of 10 mm. light path was employed for estimating griseofulvin in fermentor broth.

The analytical procedure employed in this study was a slight modification of the technique for the estimation of griseofulvin in fermentor broth developed by Holbrook *et al.* (20). The method is based on a process for the isomerization of griseofulvin to isogriseofulvin by acid treatment in methanol, as described by Grove *et al.* (21). Since untreated fermentor broth is unsuitable for spectrophotometric measurement, preliminary extraction of griseofulvin is necessary. Ethyl acetate was selected as the extractant because it does not absorb light between 260 mμ and 280 mμ and griseofulvin is reasonably soluble in it. The applicability of the procedure to a deuterium oxide medium was established by assaying fermentor broth both before and after additions of known quantities of standard griseofulvin.

Deuterium Analysis—At the conclusion of the growth period an aliquot of the culture medium was analyzed spectrophotometrically for D_2O content according to the method of Crespi and Katz (22). Harvested mycelium was analyzed for fixed deuterium which included both exchangeable and non-exchangeable deuterium. Five grams of dried tissue in a combustion boat was placed in a microfurnace and burned in a stream of oxygen at 700°. The water of combustion was collected in a −78° trap and transferred to an ampul which was then analyzed for deuterium content.

RESULTS AND DISCUSSION

Growth Observations—*P. janczewskii* grows well in a shake culture of protio-sugars and water. Growth is observed after 1 or 2 days of incubation. Tan pellicles are formed which reach a maximum diameter of about 70 to 75 mm. after 15 to 20 days. The medium becomes highly pigmented, imparting an amber color to the culture. When the mold is grown in a nutrient consisting of protio-sugars in pure D_2O, a lag period of about 10 days is observed before growth begins. Typically, the maximum pellicle size ranges between 10 and 20 mm. in diameter after 30 to 40 days of incubation (Fig. 1). Pigmentation of the fermentor broth is also delayed until approximately the fifteenth day, at which time the medium becomes tinged with yellow.

The mold also shows excellent growth in surface culture. In the H_2O controls, growth is observed 1 day after inoculation and by the seventh day a floating mycelial mat is formed which covers the entire surface of the culture medium. After about 10 days the mycelial mat begins to change color from white to gray-green. The fermentor broth becomes a deep amber by the eleventh day of incubation. In a culture medium containing 50% deuterium oxide, the appearance of the mycelial mat formed is much like that of the H_2O controls. The growth rate is delayed, but not drastically. A thick mycelial felt covers the entire surface by the fifteenth day of incubation as shown in Fig. 2. Pigmentation imparts a yellow color to the culture liquid early in the fermentation. As the D_2O content of the culture medium is increased to 75%, a further increase in lag period is observed. Little growth is noted before the seventh day of incubation, and by the fifteenth day the mycelial mat does not quite cover the entire surface of the culture medium. The gross morphology of the mycelium was similar to that cultured in 50% D_2O or the water controls. The mycelium differs, however, in that the mat becomes yellow by the fifteenth day. The mold can grow directly in a culture medium containing pure deuterium oxide; subculturing is not required. Only scant growth is observed before the tenth day, and isolated colonies begin to connect, forming a white lattice-type of growth after 15 days of incubation, as shown in Fig. 3. After 35 days, the surface of the culture medium becomes essentially fully covered. At the completion of the fermentation period the mycelium is not as mature as is the H_2O controls (Fig. 4). Figure 5 shows a marked reduction in the mycelial dry weights of the D_2O cultures when compared to the controls. The fermentation period necessary to reach the maximum weight was more than twice that of the water cultures. Dry weights obtained from both the water and deuterium cultures somewhat decrease, after reaching a maximum, because

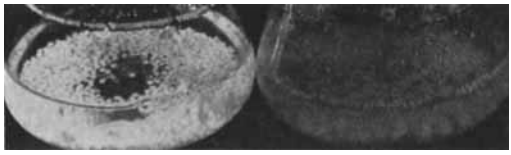

Fig. 1—Shake cultures 30 days after inoculation in 99% D_2O (left) and H_2O (right). Both cultures contain 7% protio-glucose.

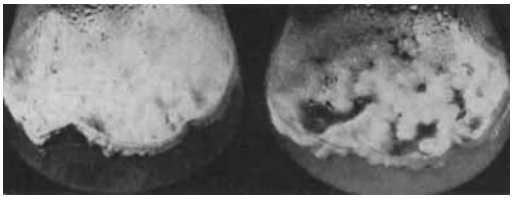

Fig. 2—Surface cultures 15 days after inoculation in 50% D_2O (left) and H_2O (right). Both cultures contain 7% protio-glucose.

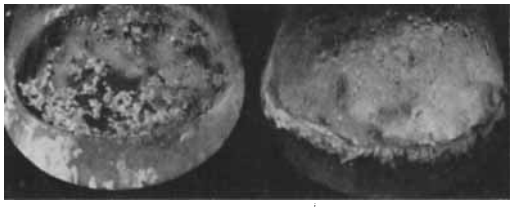

Fig. 3—Surface cultures 15 days after inoculation in 99% D_2O (left) and H_2O (right). The cultures contain 7% deuterio-glucose and 7% protio-glucose, respectively.

Fig. 4—Surface culture after 60 days' growth in medium containing 99% D_2O and 7% deuterio-glucose.

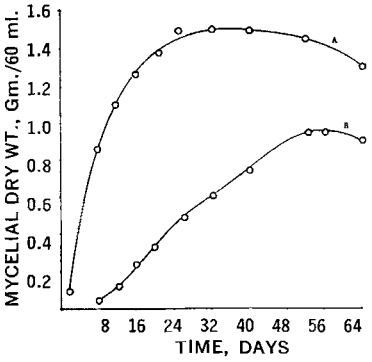

Fig. 5—Comparison of mycelial dry weights of surface cultures grown in (A) water and (B) 99% D_2O. Both cultures contained 7% protio-glucose.

of autolysis. Mature mycelium produced at the 99.6% deuterium level maintains a felt-like appearance. However, the color becomes yellowish-tan and the liquid portion of the medium shows a yellow pigmentation. At the conclusion of each fermentation period, a sample of the broth was analyzed for deuterium content. In no case was the final deuterium oxide concentration found more than 2% below the initial concentration.

Nutritional Factors—An organic substrate is essential to the growth of the mold. Protio-substrates were chosen for study which were also available as deuterio-moieties, and their ability to support growth in pure deuterium oxide was determined. Several concentrations (3, 5, 7, and 9% w/v) of each protio-substrate were prepared with 99.6% D_2O culture media. Growth was evaluated visually by assigning graded responses. The results are recorded in Table III. It is apparent that the mold can efficiently use glucose, mannose, glycerin, and, less successfully, succinic acid. Sodium acetate and dihydroxyacetone were considered as possible substrates since griseofulvin may be considered a condensation of acetic acid units, but the experimental results did not substantiate this hypothesis. Glucose or a deuterio-glucose and deuterio-mannose mixture in a concentration of 7 to 7.5% was employed in all D_2O culture media.

The major difficulty that the mold experiences in growing in a deuteriated environment appears to be in adapting to the solvent D_2O. The incorporation of deuteriated substrates into a culture medium seems to cause less of a problem for the fungus, no matter what the level of solvent deuteriation. Growth response of the organism in a nutrient solution composed of deuterio-sugars (7%) in ordinary water was not unlike that observed in culture media composed of protio-sugars in H_2O. The fixed deuterium of the dried mycelium in this experiment (obtained by combustion analysis) was found to be 18.8%. Growth characteristics observed in a fully deuteriated culture medium composed of deuterio-sugars and D_2O resembled closely those shown in media composed of protio-sugars in D_2O. A greater time period was required before initial growth, but thereafter no significant difference could be detected in the growth pattern. Combustion analysis of the dried mycelium showed the deuterium level to be slightly above 94% in the fully deuteriated mold.

Earlier studies have established that deuteriated fungi often show an increased nutritional fastidiousness. For instance, the yeasts *Torulopsis utilis* and *Saccharomyces cerevisiae* developed additional requirements for vitamins, particularly those of the B-complex group (23). Vitamins as well as algae extracts were necessary for the growth of fully deuteriated *Euglena gracilis* (1). The effect of medium fortification by vitamins was, therefore, studied. The carbohydrate concentration of the culture medium was 7%, and the response to various medium supplements was noted. The vitamin additive appeared to have little effect

on the rate of mold growth. However, the mycelial mat formed was decidedly thicker and obviously superior to the nonvitamin control. Algae extract and bacto-peptone supplements exhibited no marked advantage. Corn steep solids showed a dramatic increase in growth in both water controls and in pure deuterium oxide media. The indefinite composition and the introduction of protio-atoms from such a supplement may interfere with deuteriation of the antibiotic biosynthesized, and was therefore not employed in further studies.

Antibiotic Production—The extent of griseofulvin production in surface cultures is noted in Fig. 6. Each point on the curve represents an average of values obtained from 5 separate batches. Antibiotic production in both surface and shake culture is observed to reach a plateau, which was followed by a gradual reduction in concentration. The effect of D_2O concentrations on peak antibiotic levels and fermentation periods are summarized in Table IV. Shake fermentation methods resulted in lower antibiotic titers than static culture conditions (Fig. 7). Griseofulvin titers in shake cultures of 99% D_2O exhibited a marked depression. Although there was good growth at this D_2O level,

TABLE IV—EFFECT OF D_2O CONCENTRATION ON PEAK GRISEOFULVIN PRODUCTION LEVELS

[a] Vitamin supplementation.

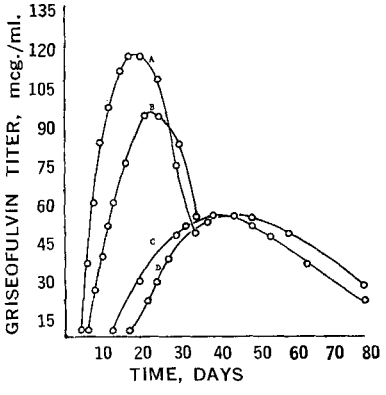

Fig. 6—Effect of D_2O content of the medium on griseofulvin production in surface culture. Key: A, *0% D_2O;* B, *50% D_2O;* C, *75% D_2O;* D, *99% D_2O plus vitamin supplement. All cultures contained 7% protio-glucose.*

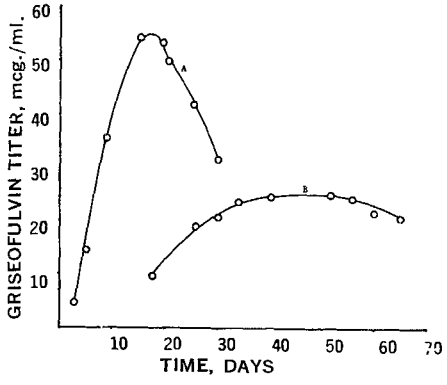

Fig. 7—Production of griseofulvin in shake cultures containing 7% protio-glucose and grown in (A) H_2O *and* (B) *99% D_2O plus vitamin supplement.*

it became apparent during the course of this study that good growth is not synonymous with good griseofulvin production. The fermentation method of choice proved to be surface culture, and was therefore used exclusively throughout the investigation after early fermentation trials.

In surface cultures the culture media, consisting of protio-sugars in 50% D_2O, exhibited about a 20% reduction in griseofulvin titer when compared with H_2O controls. When the concentration of deuterium oxide was increased to 75%, the griseofulvin titer of the fermentor broth was decreased by approximately one-half. At a D_2O concentration of 99.6%, griseofulvin production was severely impaired, and only small amounts of griseofulvin were produced. By supplementing the 99.6% D_2O culture medium with vitamin B-complex, a griseofulvin titer could be attained which approached that observed in the 75% D_2O cultures.

CONCLUSIONS

The deuterium isotope effect on the growth of the mold *P. janczewskii* is clearly a repressive one. Growth, griseofulvin production, and pigmentation of the mold are all inhibited with increasing concentrations of deuterium oxide. Corn steep solids and vitamin B-complex additives have demonstrated an enhancement of both mycelial growth and griseofulvin production in highly deuteriated media. It is tempting to infer from these experimental observations that the isotope effect in the mold is due to an incomplete medium. However, the deuterium effect in biological systems is extremely complex and no doubt many factors are involved. A normally endogenous metabolite may become a required exogenous factor. A maximum enhancement level is reached with such additives; a 5% concentration of vitamin supplement offers no advantage over a 2% concentration. Similar trends were noted with corn steep solids. High deuterium concentrations result in the utilization of available metabolites to maintain the nutrition of the isotopically altered mold. The fungus apparently becomes frugal, meeting only those needs required for survival. Griseofulvin production and elaboration of pigment can be considered to be nonessential for mold survival, and can therefore be depressed without damage to the organism. Deuterium seems to interfere with the basic integrity of the mold enzymes which are necessary to antibiotic and pigment production. The morphological changes in the deuteriated fungi appear to be due to a general disruption of the cell enzyme physiology.

It is the objective of subsequent studies to isolate and characterize the partially and fully deuteriated griseofulvin produced by the organism grown under the conditions described here. Such compounds may prove useful in studying the biogenesis of antibiotics and may contribute to the elucidation of the mechanism by which these compounds function in the body. The effect of deuterium on the antibiotic activity must also be examined. It is expected that since carbon-to-deuterium bonds are more stable than carbon-to-hydrogen bonds, and if detoxification requires the rupture of such bonds, then the deuterio form of the drug should possess a more prolonged antifungal activity. Preliminary results appear to show that this is the case.

Qualitation and Quantitation of Some Terphenylquinones

By M. C. GAYLORD, J. R. DEBOER, and L. R. BRADY

Microchemical and photochemical procedures which would permit rapid, sensitive detection of atromentin, aurantiacin, and thelephoric acid were examined. Photochemically induced fluorescence and chromophore formation with a ceric ammonium sulfate (CAS) reagent were useful for this purpose, especially when the terphenylquinones were adsorbed on polyamide powder. Quantitation of atromentin was possible with a CAS procedure, and all three of the terphenylquinones could be quantitated with pyridine–water (Py–W) and combined Py–W–CAS procedures. The relative sensitivities for the quantitative methods for atromentin were CAS > Py–W–CAS > Py–W. The procedures permitted the determination of atromentin and aurantiacin in concentrations of 2 to 120 mcg./ml. and 4 to 120 mcg./ml., respectively, and of thelephoric acid in concentrations of 2 to 40 mcg./ml. Precise standardization of analytical conditions was critical.

QUINONES comprise a highly reactive, heterogeneous group of compounds which are attracting increasing interest as basic research tools in biochemistry. Quinones and compounds capable of forming quinoid-like structures are strongly conjugated chemical systems which have the capacity for rapid electronic delocalization. This important molecular feature is of potential biochemical significance in energy transfer, long-range transmission of electronic excitation, and resonance stabilization of activated complexes (1). Molecular biology and pharmacology (2, 3), the molecular orbital approach to quantum chemistry (1, 4), photochemistry of organic compounds (5–7), and oxidation-reduction mechanisms in polymers (8) are examples of other areas where study of quinoid systems is useful.

When information about the quinoid compounds is more complete, application of this knowledge will permit elucidation of the mechanisms of action of many drugs and will improve their utilization in therapy. Webb (3) has emphasized the medicinal potential for biologically active quinones by reviewing their use as antitumor or antimitotic agents, as enzyme inhibitors, as possible acceptors in electron transport systems, as uncouplers of oxidative phosphorylation, and as antimicrobial agents. Other interesting functions of quinones in biologic systems include radiosensitizers in tumor therapy (9), antioxidants (10), and storage of solar energy (11).

Terphenylquinones are a group of naturally occurring pigments about which very little is known. The available knowledge of this group of quinones is restricted to elucidation of their chemical structures, distribution of certain of the constituents in a limited sampling of fungi and lichens (12, 13), and gross observations of the antitumor activity of polyporic acid (14, 15) and the anticoagulant action of atromentin (16, 17). There is a paucity of information on many of the chemical properties of these compounds, and information on the biologic involvement of these constituents at the molecular level is totally lacking for both plant and animal systems.

Studies were undertaken to develop sensitive procedures for qualitative and quantitative determination of atromentin, aurantiacin, and thelephoric acid. The availability of such analytical techniques would facilitate investigations on the role of these quinones in biologic systems. A secondary objective of the study was accumulation of data on the chemical properties of the three terphenylquinones.

EXPERIMENTAL

Materials and Reagents—Atromentin, aurantiacin, and thelephoric acid were isolated from suitable fungi using procedures which had been tested in this laboratory (13, 16, 18). Purity of the isolated compounds was verified using melting points, elemental analyses, and absorption spectroscopy (infrared and ultraviolet). Eastman spectrograde methanol and pyridine were used routinely when spectroscopic manipulations were involved. The 1% ceric ammonium sulfate (CAS) reagent in syrupy *o*-phosphoric acid was prepared as described by Farnsworth *et al.* (19) and was stored in a tightly stoppered actinic glass flask. The undiluted CAS reagent was used as a spray for detection of the terphenylquinones on the thin-layer chromatograms, but the reagent was diluted with an equal volume of distilled water immediately prior to its use in quantitative procedures.

General Quantitative Methodology—Preliminary results indicated that daily preparations of standard solutions of the terphenylquinones and storage

3	2.0	640,338

of the solutions in tightly stoppered actinic glass containers were essential for reproducibility. Standard stock solutions were prepared by dissolving 120 mcg./ml. of atromentin or aurantiacin or 40 mcg./ml. of thelephoric acid in pyridine or 10 mcg./ml. of atromentin in an absolute methanol–glacial acetic acid mixture (99:1) using actinic glass volumetric flasks. These concentrations were selected when preliminary evidence indicated that they were near the upper limits which gave reproducible results. Five dilutions were made from each stock solution, and samples of these solutions were utilized in developing the quantitative procedures. The visible spectra of the colored solutions were scanned using a Beckman recording spectrophotometer, model DB, to determine absorption maxima. A corresponding reagent blank was routinely employed in all spectrophotometric examinations. Studies were also conducted to determine the time which was required for maximum color formation and to show the relative stability of the colored complex. After suitable absorption maxima were selected and optimal experimental conditions were determined, standard curves were prepared and molecular extinction coefficients were calculated using average data from triplicate quantitations. The standard curves were plotted on the bases of quinone concentrations in the pyridine or methanol solutions, but allowances were made for the volume of additives in calculating the molecular extinction coefficients of the colored complexes.

Pyridine–Water (Py–W) Colorimetric Procedure—Sawada (20) qualitatively utilized the color change from a grape-red to blue when water was added to a pyridine solution of thelephoric acid. Variations of this approach were found to give quantitative results with atromentin, aurantiacin, and thelephoric acid. The quantity of distilled water which was added to the pyridine solutions of atromentin and aurantiacin had no significant qualitative influence on the color, but the absorption maxima of the colored complex varied when different amounts of water were added to the thelephoric acid solutions (Table I). A standard technique utilizing 3 ml. of a terphenylquinone-containing pyridine solution and 0.75 ml. of water was selected as being feasible. The absorbance of the atromentin solution was measured at 560 mμ 15 to 30 min. after thorough mixing. Absorbance of the thelephoric acid colored complex was measured within 2 to 35 min. at 540 mμ. (Fig. 1.)

Color formation with aurantiacin was very slow to develop at room temperature, and difficulty was noted in obtaining reproducible color intensities. This was presumably caused by the need for hydrolysis of the benzoate esters of aurantiacin to yield atromentin prior to the formation of the colored complex. Satisfactory quantitative results were obtained when the aurantiacin mixture was heated initially. The aqueous pyridine solution was placed in an actinic glass test tube which was covered with a marble to prevent evaporation, the solution was heated in a steam bath for 10 min., and the mixture was cooled rapidly by immersing the tube in water at room temperature. Absorbance was measured at 560 mμ within 30 min. (Fig. 1).

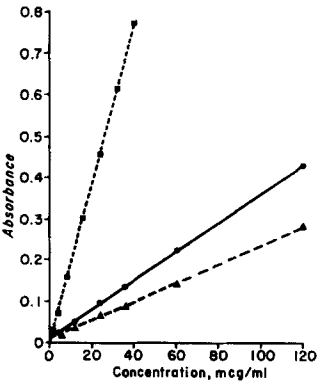

Fig. 1—Quantitation of atromentin, aurantiacin, and thelephoric acid with the Py–W procedure. Key: ●, atromentin, 560 mμ; ▲, aurantiacin, 560 mμ; ■, thelephoric acid, 560 mμ.

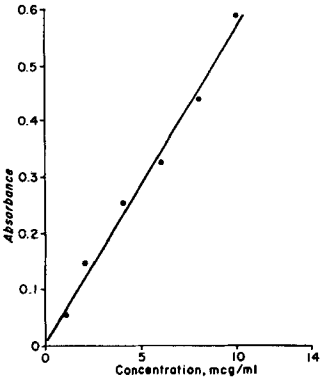

Fig. 2—Quantitation of atromentin at 418 mμ with the CAS procedure.

Reproducibility among the triplicate determinations was excellent, varying no more than ±0.005 absorbance units for any tested concentrations of the terphenylquinones.

CAS Colorimetric Procedure—CAS has been used to measure oxidation-reduction potentials of some quinones (21), and the reagent has been shown to have unusual utility in the chromatographic determination of *Catharanthus* alkaloids (19). These applications suggested the possibility of this reagent for the qualitative or quantitative evaluation of the terphenylquinones. A ceric hydroxide precipitate forms in alkaline solutions, and it was considered desirable to use methanol rather than pyridine to dissolve the pigments. A methanol–glacial acetic acid mixture (99:1) was selected after preliminary results with atromentin revealed that the small quantity of acetic acid did not effect quantitation but did greatly facilitate elution from thin-layer chromatograms. Atromentin could be quantitated by adding 0.04 ml. of the 0.5% CAS reagent to 4 ml. of the methanolic solutions using a 0.1-ml. pipet

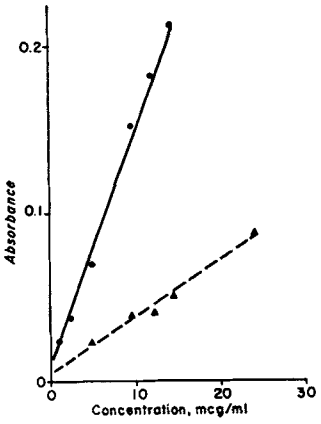

Fig. 3—Quantitation of atromentin and aurantiacin with the Py – W – CAS procedure. Key: ●, atromentin, 525 mμ; ▲, aurantiacin, 500 mμ.

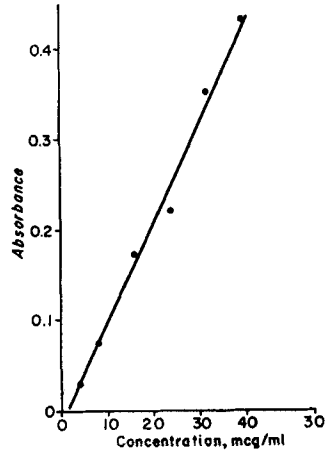

Fig. 4—Quantitation of thelephoric acid at 500 mμ with the Py–W–CAS procedure.

calibrated in 0.002-ml. increments, mixing vigorously several times during a 30-min. reaction period, and measuring the absorbance of the bright yellow color at 418 mμ (Fig. 2). Background absorption with the CAS reagent necessitated particularly careful preparation of the blank.

Reproducibility among the triplicate determinations was approximately ±3%. The procedure had a sensitivity for atromentin that was more than 15 times that of the Py–W procedure. However, the CAS reagent could not be used to quantitate aurantiacin and thelephoric acid. Thelephoric acid is not appreciably soluble in nonbasic organic solvents, and no suitable method was found to hydrolyze aurantiacin without interfering with chromophore formation.

Pyridine–Water–Ceric Ammonium Sulfate (Py–W–CAS) Colorimetric Procedure—The Py–W procedure had the advantage of applicability to all three of the terphenylquinones which were studied, but the advantageous feature of the CAS procedure was increased sensitivity. The possibility of combining these two advantages was explored, and preliminary results revealed that quantitation was possible with dilute solutions of the quinones. Several different combinations of conditions and reagents were observed to give reproducible quantitative results, but the procedure which was selected as being most useful involved the initial measurement of the terphenylquinones using the previously described Py–W procedure. After reading the absorbance of an aqueous pyridine solution, it was transferred quantitatively from the cell to an actinic glass test tube with the aid of 3.75 ml. of methanol, a component which was found to be essential for the subsequent quantitation, and 0.04 ml. of 0.5% CAS reagent was added. The solution was mixed thoroughly, and the color was allowed to develop for 1 hr. Absorbance of the colored complex was measured at 525 mμ for atromentin and at 500 mμ for aurantiacin and thelephoric acid (Figs. 3 and 4).

Reproducibility among the triplicate determinations was equivalent to that obtained with the Py–W procedure. The combined procedure was more sensitive than the Py–W method for atromentin and aurantiacin, but when allowance was made for volume change, the sensitivities of the two procedures were comparable for thelephoric acid. The combined method was approximately half as sensitive as the CAS procedure for atromentin.

Qualitative Determinations—Characteristic absorption maxima (Table II) and other individualistic properties which were observed during development of the quantitative procedures were useful in the qualitative evaluation of the three terphenylquinones. It was also noted that these terphenylquinones were susceptible to oxidative and photochemical changes, properties which are well documented for other quinones. This instability limited the types of manipulations which could be utilized in qualitative verification of small quantities of these pigments, and studies were undertaken to discover additional methods which would contribute to rapid identification. It was considered desirable to include a chromatographic procedure in the qualitative evaluation to permit examination of mixtures and to provide a possible basis for subsequent quantitation of impure materials or components of mixtures.

[a] Methanol–chloroform–water–glacial acetic acid (54:36:6:1) solvent system. [b] Color chip number and trivial name from "Color Harmony Manual." [c] Migration of atromentin was observed to be concentration dependent. Larger quantities of the quinone, up to the point where the system became overloaded, showed greater movement.

Preliminary results revealed that columnar and paper partition chromatographic separations were too slow for any evaluations of these compounds involving ultimate quantitation. Elution of the terphenylquinones following their separation with an established thin-layer chromatographic method (13) was inefficient, and the solvent interfered with quantitative attempts. Thin-layer chromatography with polyamide was found to be useful qualitatively and to offer quantitative possibilities. When the polyamide chromatograms were prepared without a binder, extreme care was necessary to avoid mechanical loss in removing spots of the brittle film from the chromatograms for quantitative purposes. The other extreme was noted with a modified formulation of the adsorbent (22) where adherence to the plates made quantitative applications impractical. The most satisfactory results were obtained with a modification employing one-fourth the rice-starch binder recommended by Nordby *et al.* (22). Rice starch (0.2 Gm.), silica gel without binder (Woelm, 0.1 Gm.), and water (9 ml.) were heated in a covered beaker on a steam bath for 40 min. with frequent stirring. The binder was transferred, with the aid of 3 ml. of water, to a Waring blender containing 5.5 Gm. of Woelm polyamide TLP and 30 ml. of methanol, and the mixture was blended for 5 min. at high speed. The slurry was applied to glass plates with a chromatographic spreader; the plates were allowed to air-dry for 15 min. and were placed in a desiccator over anhydrous $CaCl_2$ for a minimum of 2 hr. before use. Several chromatographic solvent systems effected separation, but some tailing was always noted with atromentin, presumably due to a pronounced tendency for hydrogen bonding. Methanol–chloroform–water–glacial acetic acid (54:36:6:1) was selected as the best solvent for combined qualitative and quantitative objectives; higher proportions of water or acetic acid enhanced the instability of the terphenylquinones. The chromatograms were placed in the dark at room temperature for 15 min. to permit the solvent to evaporate prior to qualitative or quantitative evaluation.

The distinctive colors of the terphenylquinones were recorded by direct comparison with chips from a "Color Harmony Manual" (23, 24), and the chromatograms were subjected to further evaluations. Particularly characteristic results were observed with atromentin when chromatograms were sprayed lightly with 1% CAS reagent. The chromatograms became transparent when sprayed, but the complexes could be visualized by briefly layering the adsorbent with a film of water to make the background opaque. The initial colors were relatively stable with aurantiacin and thelephoric acid, whereas a characteristic color sequence developed with atromentin (Table III).

None of the terphenylquinones fluoresced upon initial examination of the chromatograms under U.V. light, but fluorescence was observed in solutions of the compounds which had undergone photochemical changes while stored in tightly stoppered Pyrex glass containers. Unsprayed chromatograms were exposed to a Hanovia high pressure quartz mercury vapor lamp, model 30600, at approximately 15 cm. for 24 hr.; this radiation produced no detectable changes with thelephoric acid, but a yellow fluorescence was noted with atromentin and aurantiacin.

The qualitative fluorescent properties of the photoproducts of the terphenylquinones were examined further by radiating methanolic solutions of the compounds and determining their excitation and emission peaks with a Baird Atomic Fluorispec, model SF-1. Solutions containing 20 mcg./ml. of atromentin or aurantiacin or 10 mcg./ml. of thelephoric acid were prepared and radiated in Pyrex glass volumetric flasks with the mercury vapor lamp. The fluorescent properties of the photoproducts were determined after radiating atromentin and aurantiacin for 5 days and thelephoric acid for 10 days (Table IV).

Quantitation of Chromatographically Separated Terphenylquinones—Studies with pure terphenylquinones revealed that semiquantitative to quantitative results could be achieved by applying the various colorimetric procedures following thin-layer chromatographic separation. Appropriate zones of the polyamide adsorbent were transferred to actinic glass test tubes as rapidly as possible, and the colorimetric reagents were added to the tubes. The colors were allowed to develop for the

previously indicated periods of time with frequent agitation, the polyamide powder was removed by filtration, and the absorbances were measured spectrophotometrically at the appropriate wavelength.

The Py–W–CAS procedure was found to be the method of choice for atromentin and aurantiacin. In the case of aurantiacin, the aqueous pyridine solution was subjected to the hydrolytic conditions prior to addition of the methanol and CAS reagent. Since the total volume of liquid with this procedure was greater than that required to fill the cell, the sensitivity could be doubled by utilizing only half the specified volume of each component in the reaction mixture. The more complex Py–W–CAS procedure offered no sensitivity advantage over the Py–W method for thelephoric acid, so the latter was utilized. Acceptable quantitation of atromentin was possible upon application of the CAS colorimetric procedure, but the method had little apparent practicality.

Combination of any of the colorimetric procedures with chromatography resulted in the expected losses due to transfer and elution of the adsorbent, but the most critical factor was found to be losses through oxidative and photochemical changes if the manipulations were not handled rapidly. The best results were obtained with the relatively stable thelephoric acid. When chromatograms were exposed to air and light for 2 hr. before evaluation, losses of atromentin were 30% or more. Tailing of atromentin on the chromatograms sometimes further complicated quantitations, and occasionally inexplicable results were obtained following hydrolysis of aurantiacin in the presence of the polyamide powder. However, under optimal conditions the colorimetric results were consistently ±5–10% of the theoretical values.

DISCUSSION

Three rapid and sensitive colorimetric procedures were developed for the quantitation of atromentin, aurantiacin, and thelephoric acid (Figs. 1–4). Reproducibility, both within replicate determinations and with analyses conducted at different times, required strict adherence to precautionary measures to minimize oxidative and photochemical changes. Photochemical changes could be controlled during some of the manipulations by utilizing actinic glassware. However, oxidative interference still necessitated completion of the analyses in the minimum possible time.

Quinones are known to be susceptible to such photochemically induced reactions as fragmentation, polymerization or addition of other available substituents, rearrangement, and reduction (5, 7). The exact nature of the photochemical reaction(s) with the terphenylquinones was not determined due to the difficulty in distinguishing between oxidative and photochemical changes. The shift in fluorescent characteristics when solutions were radiated for varying periods of time suggested the solutions contained mixtures of transformation products. Atromentin was the least stable of the three terphenylquinones, and observations on the changes with this pigment were of the greatest indicative value.

The transformation products were observed to cause two types of problems in the quantitative procedures. These substances did not form the characteristic colored complexes, an observation which was substantiated by adding water to a radiated pyridine solution of atromentin and noting that the absorption maximum at 560 mμ was missing (the absorption peak at 340 mμ remained). The second problem suggested that polymerization was at least one of the photochemical changes. After cells had been used for several analyses, fluorescent interference was noted in the ultraviolet region. It was determined that the interference was caused by the deposition of minute amounts of insoluble photoproducts on the walls of the cells. The problem was noted initially during studies where the absorbance of a solution was read periodically to determine the time interval which gave quantitative results, but subsequent studies showed that the effect was cumulative when a succession of freshly prepared solutions were allowed to remain in the cell for a few minutes each. The deposit could be removed either with alcoholic KOH or dichromate cleaning solution, but it was insoluble in the normal organic solvents. The insolubility of the product suggested it was polymeric, thus making this problem similar to that reported by Pitts *et al.* (25).

Finite characterization of the chromophores in the various colorimetric procedures was not possible with the available data, but observations suggested some of the apparent prerequisite features of the terphenylquinones. The most important molecular feature appeared to be the 3,6-dihydroxy substituents. Aurantiacin was presumably hydrolyzed to atromentin prior to formation of the chromophore in the Py–W quantitation. This presumption was supported by the failure of aurantiacin to form a colored complex immediately and by the observation that the ratio of absorbances of the colored complexes formed with equal quantities of atromentin and aurantiacin was 3:5, a ratio approximately that of their molecular weights. The predicted involvement of the 3,6-dihydroxy groups was consistent with the observed failure of 2,5-diphenyl-1,4-benzoquinone to form a chromophore in the Py–W system. Consideration of the importance of the hydroxyl substituents and the conjugated nature of these terphenylquinones suggested the chromophore in Py–W was probably a resonance hybrid of the parent quinone.

Resonance hybridization also appeared to explain the chromophores which were formed when the terphenylquinones were chromatographed on polyamide powder. The chromophores which were formed on the polyamide chromatograms did not interfere with subsequent chromophore formation in the colorimetric procedures when the quinones were eluted, thus indicating that chemical change was unlikely. The possibility that the nitrogen atoms in the adsorbent stabilize the resonance hybrid, presumably by sharing protons, was further suggested when comparable chromophores were noted upon the addition of the terphenylquinones to solutions of gelatin. It should be noted that the chromophore with thelephoric acid and polyamide or gelatin was greenish turning to pink upon addition of small quantities of acetic acid.

CAS is an oxidizing agent, and chromophores developed with the terphenylquinones and this

reagent appeared to involve irreversible chemical change. Attempts to determine the oxidation-reduction potentials of the terphenylquinones with CAS were unsuccessful, but the availability of this reagent for reaction with the quinones was found to be the limiting factor in the CAS and Py–W–CAS colorimetric procedures. CAS had limited solubility in the solvents which were employed in these methods, and quantitative chromophore formation was limited by this factor. The solubility of CAS in the solvent mixture of the Py–W–CAS procedure was greater than in the methanolic solvent of the CAS method. However, attempts to determine solvent mixtures which permitted higher concentrations of CAS encountered problems with the solubilities of the terphenylquinones or with the fundamental involvement of methanol in the chromophore-yielding reactions. Addition of CAS to an aqueous pyridine solution of atromentin resulted in a loss of the absorption maximum at 560 mμ, but formation of a characteristic new chromophore with peak absorption at 525 mμ was observed only when methanol was in the reaction mixture.

Qualitative data suggested that thelephoric acid did not react with CAS. Addition of methanol and the CAS reagent to an aqueous pyridine solution appeared merely to dilute the colored complex; the color intensity could be predicted by correcting for volume change. Absorption maximum of the thelephoric acid complex with the Py–W–CAS method was 500 mμ, but this shift was attributed to the known qualitative influence of additives on the chromophore of this quinone in pyridine solutions (Table I). The observation that methanol was not an essential component of reaction mixtures containing CAS and thelephoric acid, in contrast to mixtures involving atromentin and aurantiacin, was consistent with the presumed lack of chromophore formation with thelephoric acid, the most stable of the three terphenylquinones.

Preliminary results revealed that the colorimetric methods were suitable for proximate quantitations of pure terphenylquinones following thin-layer chromatography. This suggests the possibility of devising conditions which are suitable for quantitative evaluation of the terphenylquinones in fungi or other biologic systems. Application of some type of rapid analysis appears mandatory to obtain reasonable quantitation of these reactive compounds, but it will be necessary to check each new condition or system to exclude possible interference which may be caused by the new condition or by other components in the biologic system.

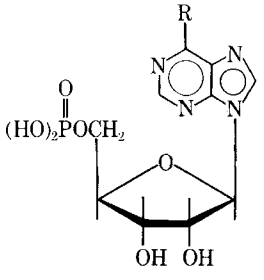
Irreversible Enzyme Inhibitors 98

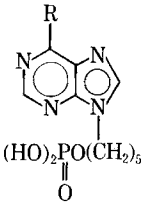
Hydrophobic Interactions with Succinoadenylate Kinosynthetase and 9-Substituted Adenines

By B. R. BAKER and EDWARD H. ERICKSON

Adenines substituted at the 9-position with *n*-butyl or benzyl groups were complexed about tenfold better to succinoadenylate kinosynthetase than 9-methyladenine. The same *n*-butyl or benzyl substituents on 6-mercaptopurine failed to show this hydrophobic interaction even though 5′-adenylate and thioinosinate are complexed equally well to the enzyme. It is proposed that either (*a*) 6-mercaptopurine can complex in only one way to the inosinate binding locus regardless of the 9-substituent, whereas adenine can complex to the inosinate locus as one of two rotomers dependent upon whether the 9-substituent is hydrophilic or hydrophobic, or (*b*) the adenines complex at the inosinate binding locus, but the 6-mercaptopurines complex at the cofactor (guanosine-5′-triphosphate) binding locus.

SUCCINOADENYLATE kinosynthetase is an anabolic enzyme that condenses inosinate (I) with L-aspartate to form succinoadenylate (II) where





I, R = OH
II, R = L-NHCH(COOH)CH_2COOH
III, R = NH_2
IV, R = SH

V, R = NH_2
VI, R = SH

guanosine-5′-triphosphate is used as the cofactor (1–4). The enzyme can be inhibited by 5′-adenylate (III) (3, 4) and by thioinosinate (IV) (4–7). The relative contribution of the functional groups of the ribofuranose moiety of III and IV to binding to the enzyme has been previously reported by Baker and Tanna (4, 8). The phosphate group contributed more than all the other oxygen functions combined; only a thirteenfold loss in binding occurred with the pentanol phosphates V and VI compared to III and IV, while the corresponding nucleosides were less than one-sixtieth as effective as III and IV.

In a further study (4, 9), the conformational aspects of binding of V and VI were considered. It was predicted that the butanol phosphate (VII) should bind better than the pentanol phosphate (V); the staggered ground state conformation of VII should position its phosphate group closer to the binding point for the phosphate of the nucleotide III than does the pentanol phosphate (V). If the dichloroacetamido group was simulating the binding of the phosphate group (10), it was predicted that IX should have a better ground state conformation for optimum binding than VIII (4, 9). The emergence of hydrophobic bonding (11) to such enzymes as adenosine deaminase (12), dihydrofolic reductase (13), thymidine phosphorylase (14), guanine deaminase (15), and others (11) suggested the possibility that V, VI, and VIII might have additional binding to succinoadenylate due to a hydrophobic interaction by part of the pentyl group. Therefore additional studies were performed on the mode of binding of the pentyl group of V, VI, and VIII; the results are reported in this paper, along with inhibition studies on VII and IX.

VIII, $n = 5$
IX, $n = 3$

DISCUSSION

Enzyme Results—In Table I are listed the inhibition results with adenine-9-pentanol phosphate (V) and adenine-9-butanol phosphate (VII); note that the binding of the two compounds is essentially the same. If the phosphate group of V and VII is indeed being complexed to the same locus on the enzyme that complexes the 5′-phosphate of 5′-adenylate (III), then it is apparent that there is no

[a] Succinoadenylate kinosynthetase was isolated from *E. coli* B and assayed with 30.6 μ*M* IMP, 50 μ*M* GTP, and 3.76 μ*M* L-aspartate in pH 7.4 Tris buffer in the presence of 10% *N*,*N*-dimethylformamide as previously described (8). [b] RP = 5-phospho-β,D-ribofuranosyl. [c] Data from *Reference 8*. [d] Prepared in this laboratory by W. F. Wood for another project by the method of Montgomery and Temple (25, 26). [e] Near maximum solubility. [f] Since 25% inhibition is readily detectable, the concentration for 50% inhibition is greater than four times that measured.

difference in the energy required for the butyl and pentyl group to assume the proper conformation; the ground state conformation of the alkylene group of V and VII is not necessarily staggered in aqueous solution as it is in nonaqueous solution (16), but may be slightly coiled due to internal hydrophobic bonding. Since it was found that 9-butyladenine (XI) can bind slightly better than the phosphate (V and VII) by a hydrophobic interaction of the *n*-butyl group with the enzyme, it is possible that V and VII show no phosphate binding of the 9-side chain, but only hydrophobic bonding of the alkyl portion.

The nature of the hydrophobic interaction of the enzyme with adenines bearing a hydrocarbon moiety at the 9-position was then investigated. Note that the 9-butyl group of XI gives an eightfold increment in binding over the 9-methyl group of X. Since the isoamyl (XII), cyclopentyl (XIII), and cyclohexyl (XIV) groups were complexed considerably poorer than *n*-butyl (XI), it appeared that chain branching of these types does not give a good fit to the hydrophobic region of this enzyme; these results are different from those observed with hydrophobic interactions with dihydrofolic reductase (13), where isoamyl is complexed better than *n*-butyl, cyclohexyl is equal to *n*-butyl, and cyclopentyl is poorer than *n*-butyl (17).

Possible hydrophobic interaction with succinoadenylate kinosynthetase by phenylalkyl groups on the 9-position of adenine was then investigated (Table I). The in-plane phenyl group of XV gave no useful amount of hydrophobic bonding. In contrast, the 9-benzyl group of XVI gave the best hydrophobic bonding in Table I, the increment in binding being elevenfold better than the 9-methyl of X. That maximum hydrophobic bonding by an aralkyl group was obtained with the 9-benzyl group of XVI was indicated by the poorer binding of the higher homologs, phenethyl (XVII) and phenylpropyl (XVIII). A further study that might lead to better inhibitors of this enzyme should be performed by substitution on the benzene ring of 9-benzyladenine (24).

Hydrophobic interaction was then investigated with 6-mercaptopurine bearing hydrocarbon groups at the 9-position (Table II). In contrast to the adenine series in Table I, the 9-butyl (XX) and 9-benzyl-6-mercaptopurine (XXIV) did not show detectable hydrophobic interaction. These results are indeed surprising in view of the facts that adenine and 6-mercaptopurine substituted by the 9-ribosyl phosphate moiety (III, IV) bind nearly identically—as do the two purines substituted by the pentanol phosphate moiety (V, VI).

These discrepancies indicated that 9-alkyladenines and 9-alkyl-6-mercaptopurines did not complex to the enzyme in the same way. Three possibilities were considered as follows.

(*a*) Adenines bearing a 9-hydrocarbon group might be complexed to the enzyme locus that normally complexes the cofactor, guanosine-5′-triphosphate, whereas 6-mercaptopurines bearing a 9-hydrocarbon group might bind at the inosinate binding locus.

(*b*) The converse of (*a*) might be possible where the adenines bind at the inosinate locus and the mercaptopurines at the guanosine-5′-triphosphate locus.

(*c*) Both the adenines and the 6-mercaptopurines bind at the inosinate locus, but in different rotomeric configurations depending upon the 9-substituent.

To help differentiate between these explanations, the inhibition by guanines bearing a hydrocarbon group at the 9-position was investigated and the results are shown in Table III. Note that guanine substituted by 9-methyl (XXVI), 9-phenyl (XXIX),

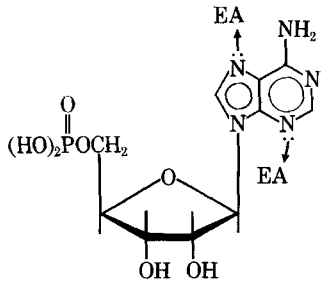
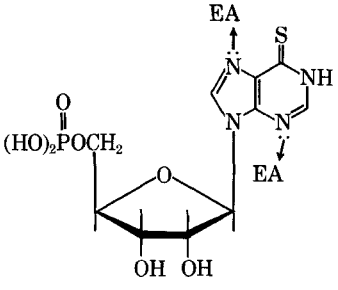
[a] The enzyme from *E. coli* B was prepared and assayed as previously described (8), except that 33 μM GTP and 122 μM IMP were employed. [b] Near maximum solubility. [c] Since 25% inhibition is readily detectable, the concentration for 50% inhibition is at least four times greater than that measured.

and 9-benzyl (XXXIII) have essentially the same binding, thus indicating that there is no hydrophobic bonding by these 9-substituted guanines and that guanines do not bind the same way as the adenines substituted by 9-methyl (X), 9-phenyl (XV), or 9-benzyl (XVI) groups (Table I). Furthermore, a variety of other related compounds such as 8-substituted guanines and 9-substituted 8-azaguanines failed to show hydrophobic bonding. Thus possibility (*a*) is eliminated, but (*b*) and (*c*) remain definite possibilities.

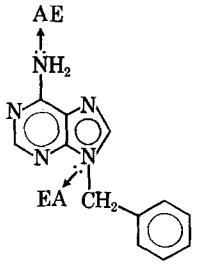
Partial support for possibility (*b*) can be gleaned by noting that 5′-adenylate (III) is a competitive inhibitor of inosinate (I) and a noncompetitive inhibitor of guanosine-5′-triphosphate (3); contrariwise, thioinosinate (IV) is a noncompetitive inhibitor of inosinate (I) but whether it is competitive with guanosine-5′-triphosphate was not determined (37). Although it would not be too difficult to determine whether thioinosinate (IV) is competitive with guanosine-5′-triphosphate, this has not been done, since the interpretation of binding based on competitive or noncompetitive observations is subject to numerous interpretations (38) besides a competitive inhibitor being one that resides on the throne of the active site.



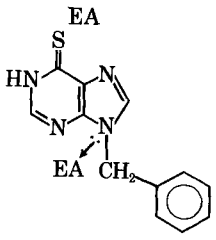
IIIa



IVa



XVIa



XXIVa

Possibility (*c*) merits explanation. Suppose 9-substituted adenines can complex to the inosinate (I) locus in more than one conformation; the particular binding rotomer could be dependent upon whether the 9-substituent is hydrophobic or hydrophilic. Such rotomeric binding conformations have been invoked to account for the binding of unnatural D-isomers to chymotrypsin (18, 19), to dihydrofolic reductase by 5- and 6-hydrophobically substituted pyrimidines (20–22), and for the binding of isoadenosine and isoadenylic acid to certain enzymes (22, 23).

Possibility (*c*) suggests that both the adenines and the 6-mercaptopurines complex with the inosinate (I) locus. If such were the case, then the NHC=S moiety of thioinosinate (IV) and the N=C—NH_2 moiety of 5′-adenylate (III) cannot be binding points to the enzyme, since the latter moiety is an electron donor at the 1-position and the former is an electron acceptor (7, 24); therefore different rotomer configurations for binding adenine would have to consider this difference in binding at the 1- and 6-positions of the purine. For example, suppose the purine ring of 5′-adenylate is complexed as rotomer III*a* where the N-7 and N-3 groups are electron donors to acceptor groups on the enzyme, AE. Thioinosinate could complex similarly through N-7 and N-3 of the purine as rotomer IV*a*. Suppose the hydrophobic bonding region of the enzyme can complex the benzyl group of 9-benzyladenine in conformation XVI*a*; the 6-amino group and 9-nitrogen could now be electron donors to the two acceptor groups on the enzyme in place of N-7 and N-3 of rotomer III*a*. In order for the 9-benzyl group attached to 6-mercaptopurine to bind in this hydrophobic region as depicted in XVI*a*, 9-benzyl-6-mercaptopurine would have to assume the XXIV*a* conformation. But rotomer XXIV*a* will bind poorly since the 6-thione group is a poor electron donor (24); hence, the binding point normally complexing N-3 in configuration III*a* will be lost. Other rotomers to account for the relative binding of 9-benzyladenine (XVI) and 9-benzyl-6-mercaptopurine (XXIV) can probably be visualized, but further experiments would be necessary to differentiate between the possibilities.

Since hydrophobic bonding cannot be detected with 9-benzyl-6-mercaptopurine, possibility (*c*) suggests that all the compounds in Table II complex with the purine as the same rotomer as thioinosinate, such as IV*a*. It follows that VI, VIII, XIX, and XXV should have their extra functional group complexed in the locus for binding the 5-phospho-D-ribosyl moiety of IV*a*. Since the dichloroacetamido group of IX (Table II) binds less effectively than VIII, it also follows that the dichloroacetamido group is not simulating phosphate binding with either possibility (*b*) or (*c*).

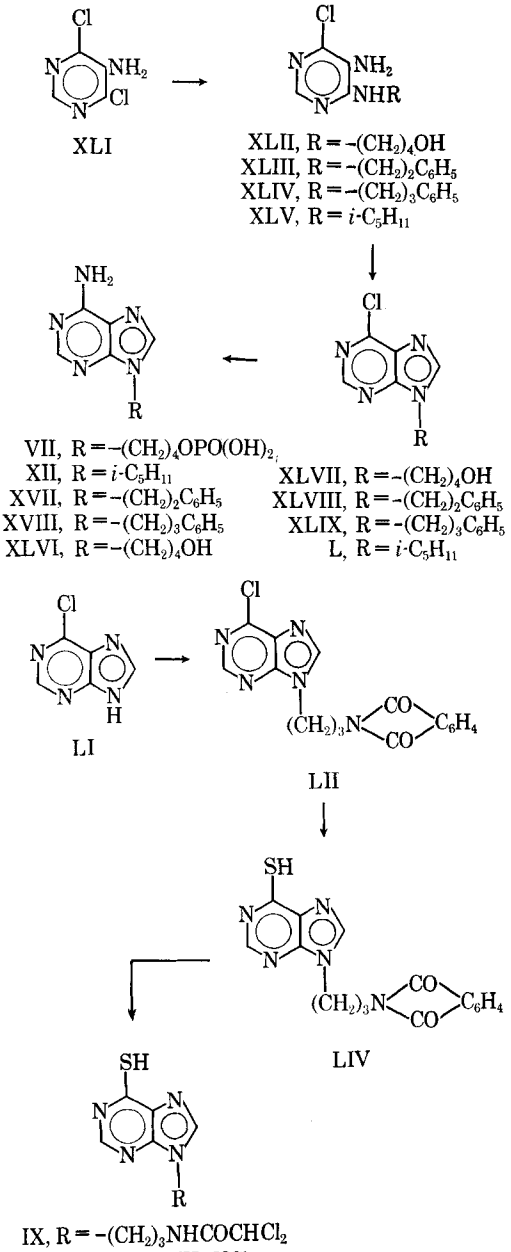
Chemistry[1]—Some of the compounds were available in this laboratory from other enzyme studies, as indicated by the references in the tables. The remainder of the compounds were synthesized as follows (Scheme I).

Reaction of 5-amino-4,6-dichloropyrimidine (XLI) with the appropriate amine in *n*-butanol containing triethylamine afforded the 6-alkylaminopyrimidines (XLII–XLV) by the elegant method of Montgomery and Temple (25, 26). Ring closure of the 6-alkylaminopyrimidines (XLII–XLV) with ethyl orthoformate in the presence of one equivalent of hydrogen chloride (27) afforded the corresponding 6-chloropurines (XLVII–L), which were not purified, but were directly converted to the adenines (XII, XVII, XVIII, XLVI) with ethanolic ammonia at 90° (25). The synthesis of XLVI has been previously described (28), as has the synthesis of XVII (32).

Treatment of 9-(4′-hydroxybutyl)adenine (XLVI) with polyphosphoric acid at 70°, as previously described for the higher homolog (V) (8), gave the butanol phosphate (VII) isolated as its barium salt; the barium salt of VII was converted to the zwitterion of VII with 0.1 *N* aqueous hydrochloric acid.

Alkylation of 6-chloropurine (LI) with *N*-(3-bromopropyl)phthalimide in dimethylsulfoxide in the presence of potassium carbonate (25, 29) afforded a 41% yield of LII; that alkylation had occurred on the 9-position was verified by conversion of LII to the 9-substituted-6-diethylaminopurine with its characteristic U.V. spectra (34–36). Reaction of LII with thiourea (25) smoothly proceeded to the 6-mercaptopurine derivative (LIV). The phthalyl group was cleaved with hydrazine in 2-methoxyethanol (9) and the resultant amine was

[1] The authors thank Drs. J. A. Montgomery, R. K. Robins, H. J. Schaeffer, and H. B. Wood, Jr., CCNSC, for some of the compounds mentioned in the tables.



Scheme I

isolated as its hydrochloride (LIII). Reaction of the free base of LIII with dichloroacetyl chloride in *N,N*-dimethylformamide in the presence of potassium carbonate afforded the desired dichloroacetamide (IX).

EXPERIMENTAL

Melting points were taken in capillary tubes on a Mel-Temp block and those below 230° are corrected. Infrared spectra were determined in KBr pellet with a Perkin-Elmer 137B or 337 spectrophotometer. Ultraviolet spectra were determined in 10% ethanol, unless otherwise indicated, with a Perkin-Elmer 202 spectrophotometer. Thin-layer chromatograms (TLC) were run on Brinkmann Silica Gel GF (unless otherwise indicated), and spots were detected by visual examination under ultraviolet light, except in the case of 6-mercaptopurines where iodine vapor was employed.

9H-Adenine-9-yl-butanol Phosphate (VII)—9-(4′-Hydroxybutyl)adenine (XLVI) (28) was prepared from XLI by the general methods described in the literature (25–27). To a solution of 1.54 Gm. of P_2O_5 in 2.06 Gm. of 85% H_3PO_4 at 66° was added 292 mg. (1.4 mmoles) of XLVI. After being heated in a bath at 66–73° for 18 hr., the solution was diluted with 15 ml. of water and heated on a steam bath for 30 min. The pH was carefully adjusted to pH 6.5 with hot saturated aqueous $Ba(OH)_2$. The barium phosphate was removed by filtration through a pad of diatomaceous earth.[2] The combined filtrate and aqueous washings were spin evaporated *in vacuo;* yield, 91 mg. of crude barium salt that moved as single spot on TLC with Brinkmann MN–polyamide–U.V. 254 in *n*-butanol–water–acetic acid (5:3:2). The barium salt was dissolved in 10 ml. of hot 0.1 *N* aqueous hydrochloric acid; the filtered solution was allowed to stand at 5° for about 18 hr. when crystallization of the zwitterion of VII was complete; yield, 50 mg. (14%) of white crystals that moved as a single spot on polyamide as above. For analysis the zwitterion was recrystallized once more from 0.1 *N* aqueous hydrochloric acid to give white crystals, m.p. 244–245°; $\nu_{max.}$ 3420 (NH); 3200–2600 (NH+); 1700 (C=NH+); 1225, 1050, 940 cm.$^{-1}$ (P—O); $\lambda_{max.}$ (pH 1): 263 mμ; (pH 13); 265 mμ.

Anal.—Calcd. for $C_9H_{14}N_5O_4P$: C, 37.6; H, 4.91; N, 24.4. Found: C, 38.1, 37.4; H, 5.38, 5.05; N, 23.8, 24.0.

9-(i-Amyl)adenine (XII)—A solution of 500 mg. (3.05 mmoles) of XLI, 280 mg. (3.22 mmoles) of isoamylamine, 15 ml. of *n*-butanol, and 1 ml. of triethylamine was refluxed for 17 hr. The solution was spin evaporated *in vacuo.* The residue was extracted with hot ethyl acetate, then the solution filtered to remove the insoluble triethylamine hydrochloride. Spin evaporation of the solution *in vacuo* left crude XLV as a brown oil which was dissolved in 12 ml. of ethyl orthoformate and treated with 0.4 ml. of 12 *N* aqueous HCl. After 18 hr. at ambient temperature, at which time the ultraviolet maximum at 297 mμ had shifted to 263 mμ, the solution was evaporated *in vacuo.* The residual L was dissolved in 15 ml. of ethanol previously saturated with ammonia at 0°, then the solution was heated in a Parr bomb at 90° for 18 hr. The solution was kept at −15° overnight, then the product was collected on a filter; yield, 201 mg. (33%), m.p. 136–141°, that gave one spot on TLC in *n*-butanol–acetic acid–water (10:5:1); additional material could be isolated from the filtrate. Recrystallization from ethanol gave white crystals, m.p. 140–142°; $\lambda_{max.}$ (1 *N* HCl): 252 mμ; (1 *N* NaOH): 264 mμ; $\nu_{max.}$ 3400, 3100 (NH); 1660, 1500 cm.$^{-1}$ (C=C, C=N, NH).

Anal.—Calcd. for $C_{10}H_{15}N_5$: C, 58.5; H, 7.37; N, 34.1. Found: C, 58.4; H, 7.50; N, 34.0.

[2] Marketed as Celite by Johns-Manville Corp., New York, N.Y.

9-(3-Phenylpropyl)adenine (XVIII)—This was prepared in 24% over-all yield from XLI as described for the preparation of XII, white crystals, m.p. 184–186°; $\lambda_{max.}$ (1 *N* HCl): 262 mμ; (1 *N* NaOH): 266 mμ.

Anal.—Calcd. for $C_{14}H_{15}N_5$: C, 66.4; H, 5.97; N, 27.7. Found: C, 66.5; H, 6.01; N, 27.6.

Similarly, 9-(4-phenylbutyl)adenine, m.p. 183–185°, was prepared from XLI in 33% over-all yield.

Anal.—Calcd. for $C_{15}H_{17}N_5$: C, 67.4; H, 6.41; N, 26.2. Found: C, 67.4; H, 6.55; N, 26.2.

9-Phenethyladenine (XVII)—This compound was prepared in 15% over-all yield from XLI; white crystals, m.p. 185–188°. [Lit. (32) m.p. 179–180°.] This compound was also prepared by direct alkylation of the sodium salt of adenine in *N,N*-dimethylformamide (33) to give a 36% yield, m.p. 183–186°; $\lambda_{max.}$ (1 *N* HCl): 262 mμ; (1 *N* NaOH): 266 mμ.

6-Chloro-9-(3′-phthalimidopropyl)purine (LII)—A mixture of 3.30 Gm. (21.3 mmoles) of LI, 130 ml. of dimethylsulfoxide, 2.9 Gm. (21 mmoles) of anhydrous potassium carbonate, and 5.40 Gm. (20.2 mmoles) of *N*-(3-bromopropyl)phthalimide was magnetically stirred at ambient temperature for 17 hr. The mixture was filtered. The filtrate was diluted with water, then the product was collected on a filter; yield, 3.02 Gm. (41%) that moved as a single spot on TLC in chloroform–ethanol (1:1) that was different from each starting material. Recrystallization of a sample from ethanol gave an analytical sample, m.p. 185–188°; $\nu_{max.}$ 1770, 1690 (phthalyl C=O); 1580, 1540 (C=C, C=N); 725, 712 cm.$^{-1}$ (C_6H_4); $\lambda_{max.}$ (EtOH): 267, 299 mμ.

Anal.—Calcd. for $C_{16}H_{12}ClN_5O_2$: C, 56.4; H, 3.72; N, 20.5. Found: C, 56.1; H, 3.52; N, 20.4.

The structure of LII was verified by reaction with diethylamine. A solution of 71 mg. (0.21 mmole) of LII, and 0.21 Gm. (3 mmoles) of diethylamine in 5 ml. of ethanol was refluxed for 90 min.; at this time TLC with petroleum ether–chloroform–ethanol (1:1:1) gave only a single spot which moved differently from starting material. That this was a 9-substituted 6-diethylaminopurine was shown by its $\lambda_{max.}$ (pH 1): 275 mμ; (pH 13): 280 mμ.

6-Mercapto-9-(3′-phthalimidopropyl)purine (LIV)—A mixture of 0.48 Gm. (6.3 mmoles) of thiourea, 1.09 Gm. (3.2 mmoles) of LII, and 50 ml. of ethanol was refluxed with magnetic stirring for 12 hr., during which time the product separated. The cooled mixture was filtered and the product was washed with ethanol; yield, 0.59 Gm. (53%), which was suitable for further transformation. Recrystallization of a sample from 2-methoxyethanol gave nearly white crystals, m.p. 310–315°; $\lambda_{max.}$ (pH 1): 327 mμ; $\nu_{max.}$ 2710 (acidic H); 1760, 1710 (phthalyl C=O); 1540, 1575, 1490 (C=C, C=N); 725, 718 cm.$^{-1}$ (C_6H_4). The compound moved as a single spot on TLC in chloroform–ethanol (1:1).

Anal.—Calcd. for $C_{16}H_{13}N_5O_2S$: C, 56.1; H, 3.41; N, 20.5. Found: C, 56.4; H, 3.62; N, 20.4.
