and of its oxidation products are shown in Fig. 1. The absorption curve of the products is well defined, with absorbance maxima in hexane or ethanol at 278, 258, and 233 mμ and a shoulder at 302 mμ. The reaction products of chlorprothixene extracted from human urine and from the tissues of animals which have received the drug yield almost identical absorption curves to that observed for the reaction products of pure drug (Figs. 2 and 3). Direct analysis of chlorprothixene and its metabolic products from urine and animal tissues does not afford an ultraviolet absorption pattern from which accurate qualitative and quantitative data can be obtained (Fig. 2). The infrared spectrum of the reaction products of pure chlorprothixene is similar to the spectrum obtained from the reaction products of chlorprothixene extracted from human urine. Infrared spectra of chlorprothixene (Fig. 4) and of its reaction products (Fig. 5) show several distinct differences, of which the most significant is the appearance of a band at 1682 cm.$^{-1}$ in the spectrum of the reaction products. This band is thought to be produced by a carbonyl group (4) formed by mild permanganate oxidation of the olefinic carbon-to-carbon bond in the parent compound. Very strong absorption at 1150 and 1305 cm.$^{-1}$ in the spectrum of the chlorprothixene products suggests that a majority of the sulfur is oxidized to a sulfone group. Schrieber (5) examined the spectra of 13 sulfones and found two bands in the sulfones which were absent in the corresponding sulfides. These were at 1120–1160 cm.$^{-1}$ and at 1300–1350 cm.$^{-1}$. It seems likely that some sulfoxide is also present in the reaction products, since a strong band is obtained at 1020–1060 cm.$^{-1}$ (Fig. 5). Most normal sulfoxides will be found to give a strong band in the range 1020–1060 cm.$^{-1}$ in the solid state. The weak absorption

Triprolidine	0.15

[a] The absorbance in each case corresponds to a concentration of 20 mcg. of the compound per ml. of sample. [b] Read at 233 mμ unless otherwise indicated.

by the products in the 2800–3000 cm.$^{-1}$ band area to which carbon-hydrogen stretching vibrations have characteristic assignment (6) implies that the dimethylaminopropylidene group is removed during the oxidation process. Hydrogen, carbon, and nitrogen analysis of two fractions obtained by fractional crystallization of a saturated solution of the products in hexane supports the infrared data. One fraction appears to contain a carbonyl–sulfoxide product, the other a carbonyl–sulfone product.

Many organic bases were investigated for possible interference with quantitative determination of chlorprothixene. Several produced a reaction product(s) which gave considerable absorption at 233 mμ (Table II). However, none showed maximum absorption at 233 mμ, nor did any exhibit the absorption pattern characteristic of the chlorprothixene reaction products (Fig. 1). The reaction products of compounds listed in Table II which absorb maximally at 247 mμ, except that from captodiamine, are all benzophenone, and they can be identified as such by gas chromatography (7). The chlorprothixene reaction products chromatographed under the same conditions exhibit no chromatographic peak (Table III).

TABLE III—RELATIVE RETENTION TIMES OF REACTION PRODUCTS BY GAS CHROMATOGRAPHY[a]

Recoveries of known amounts of chlorprothixene added to whole blood and urine are summarized in Table IV. Standard aqueous solutions of chlorprothixene hydrochloride were added to the biologic material to provide concentrations ranging from 0.50 to 10.0 mg. %. Ten milliliters of blood or 20 ml. of urine with added drug was analyzed. Recoveries of greater than 90% were obtained in each instance. It was observed very early in this work that the pH range 7.0–7.5 used in preliminary recovery studies was inadequate for maximum extraction of chlorprothixene and its metabolites from the urine of individuals who had taken the drug. Table V presents data from a healthy male who had taken a single 50-mg. oral dose, and whose urine was collected during the period 24–48 hr. after the dose. Samples of equivalent amounts were assayed for chlorprothixene, varying the pH for the initial extraction of the drug from 7.0 to greater than 12.5. Optimum recovery was obtained at pH 10.0 or greater.

TABLE IV—RECOVERY OF CHLORPROTHIXENE AFTER *In Vitro* ADDITION TO BLOOD AND URINE

Amt. Added, mcg./ml.	No. of Detn.	Recovery, Mean ± Std. (mcg./ml.) Whole Blood[a]	Urine[b]

TABLE V—EFFECT OF pH ON EFFICIENCY OF EXTRACTION OF CHLORPROTHIXENE FROM HUMAN URINE[a]

pH of Extraction	Concn. Determined, mcg./ml.
7.0	0.29
8.0	0.53
9.0	0.75
10.0	0.92
11.0	0.96
12.0	0.93
12.5–13.0	0.94

[a] Urine obtained during the period 24–48 hr. after an oral dose of 50 mg.

To determine the optimum pH of extraction for biologic specimens other than urine, white albino rats were fed *via* stomach tube 70 mg. of chlorprothixene per kilogram of body weight. They were killed after 3, 4.5, 6, 12, and 24 hr. Tissues were assayed for chlorprothixene in duplicate, using a pH of either 7.0–7.5 or of 11.0–12.0 for the initial extraction (Table VI). In all tissues much more drug was recovered when the specimens were initially extracted at pH 11.0–12.0. Since chlorprothixene itself is efficiently recovered from biologic materials at pH 7.0–7.5 (Table IV) it seems reasonable to assume that certain metabolites in the tissues and urine necessitate the strongly alkaline extraction.

Table VII shows the distribution of the drug among various tissues of the rat 6 to 24 hr. after the animals had received the 70 mg./Kg. of body weight dose. The levels of drug and metabolites in various biologic fluids and organs in decreasing order are urine, liver, brain, fat, skeletal muscle, and blood. With the exception of the data for concentrations of the drug in muscle and fat tissues, the distribution ratios are in good agreement with those previously reported (8).

In three adult human males, each of whom received 50 mg. of chlorprothixene by mouth, the

TABLE VIII—CHLORPROTHIXENE RECOVERED FROM HUMAN URINE[a]

Time, hr.	Adult Male Subject I	II	III
	mcg./ml.		
4	0.14	0.55	3.33
8	1.46	3.76	7.59
12	1.48	4.45	3.99
24	4.19	2.32	2.26
48	2.21	0.88	1.14
72	1.19	0.20	0.35
Total recovered, mg.	3.6	3.4	3.6

[a] Each subject received 50 mg. chlorprothixene by mouth.

concentration of chlorprothixene measured in the urine over a 72-hr. period varied considerably from one subject to another (Table VIII). The total amount excreted in the urine by the three subjects during the 72 hr. was less variable: 3.4 to 3.6 mg.

Although the method for analysis which has been described does not distinguish between chlorprothixene and its sulfoxide metabolite, this lack of specificity is not likely to carry medical or legal importance. Sensitivity of the method is sufficient to permit the analyst to detect the drug and its metabolites in the urine 3 days after an individual has taken a single 50-mg. dose.

SUMMARY

A quantitative ultraviolet spectrophotometric procedure has been developed for the determination of chlorprothixene and its principal sulfoxide metabolite in biologic specimens. In the procedure, the drug is oxidized with buffered permanganate to a carbonyl derivative which has a well-defined ultraviolet absorption spectra. The method is sensitive and the combined ultraviolet spectrum of the oxidation products is sufficiently specific to establish qualitative identification of the drug. Results of a study to establish the excretion pattern of chlorprothixene and its metabolites in man, as well as their distribution in the tissues, and biologic fluids of the rat are presented.

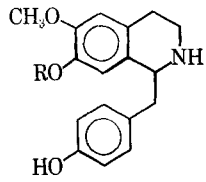
1-Benzyl-1,2,3,4-tetrahydroisoquinolines

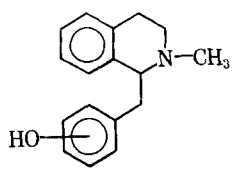
By JOSEPH SAM and A. J. BEJ*

The syntheses of 1-benzyl-1,2,3,4-tetrahydroisoquinolines, particularly phenolic derivatives, are described. Preliminary pharmacological data also are reported.

NUMEROUS CHEMICAL and biological investigations have been conducted with synthetic as well as naturally occurring 1-benzylisoquinolines (1). Limited biological information is available, however, on phenolic 1-benzyl-1,2,3,4-tetrahydroisoquinolines. Kupchan and co-workers (2) noted weak analgesic activity with (−)-*N*-normarmepavine (I*a*). Colacurine (I*b*) was tested for curare-like activity in dogs but manifested no activity (3). Both of these alkaloids are secondary amines. Often the biological activity of secondary amines are lower than the corresponding *N*-methyl or tertiary amines (4). Accordingly, a program was initiated to synthesize and evaluate phenolic 1-benzyl-2-methyl-1,2,3,4-tetrahydroisoquinolines (II) for biological activity.



I*a*, R = CH_3
b, R = H



II

DISCUSSION

The relationship of phenolic 1-benzyl-2-methyl-1,2,3,4-tetrahydroisoquinolines, both structurally (not sterically) and biogenetically (5), to morphine (III) gave additional impetus to the investigation. In this connection, Besendorf and co-workers (6) noted pronounced analgesic activity in 6,7-dimethoxy-1-(4-chlorophenethyl)-2-methyl-1,2,3,4-tetrahydroisoquinoline (IV).

The preparation of 1-(4-hydroxybenzyl)-2-methyl-1,2,3,4-tetrahydroisoquinoline (V) was investigated

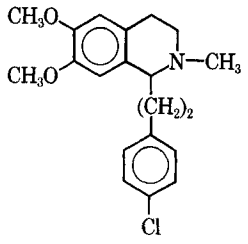
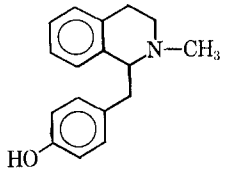
III



IV



V

via (*a*) the Bischler-Napieralski reaction, (*b*) the Grignard reaction, (*c*) the Reissert compound, and (*d*) the reaction of pseudobases with 2- and 4-nitrotoluenes.

Kondo and Ishiwata (7) reported a 51% yield for the cyclization of VI to the corresponding 3,4-dihydroisoquinoline (VII) using phosphorus oxychloride. By using a mixture of phosphorus oxychloride and phosphorus pentoxide, a 70–80% yield of VII was obtained. Polyphosphoric acid on the other hand did not effect cyclization of VI at 190°. (Scheme I.)

The reduction of 1-(4-methoxybenzyl)-3,4-dihydroisoquinoline methiodide (VIII) with sodium borohydride gave the corresponding tetrahydroisoquinoline (IX). Demethylation of IX was effected with either 48% hydrobromic acid or 47% hydroiodic acid to yield V.

The treatment of isoquinoline methiodide (X) with 4-methoxybenzylmagnesium chloride, followed by reduction with sodium borohydride provided an alternate route to IX. The intermediate dihydro derivative (XI) was isolated but not identified. The reaction of 4-methoxybenzylmagnesium chloride with 3,4-dihydroisoquinoline methiodide (XII) also gave the tetrahydroisoquinoline (IX).

The reaction of pseudobases, XIII and XIV (obtained from isoquinoline methiodide and 3,4-dihydroisoquinoline methiodide, respectively), with 2- and 4-nitrotoluenes also was investigated. The condensation of isoquinoline methiodide (X) with 2-nitro-5-benzyloxytoluene (XV) according to the procedure described by Weisbach and co-workers (8) gave XVI. The platinum oxide reduction of XVI yielded XVII. The reaction of 4-nitrotoluene with either X or XIV, however, resulted only in the recovery of 4-nitrotoluene. (Scheme II.)

A final method of preparation of V involved initially the condensation of 1-cyano-2-benzoyl-1,2-dihydroisoquinoline (Reissert compound) (XVIII) with 4-benzyloxybenzyl chloride (XIX) or bromide

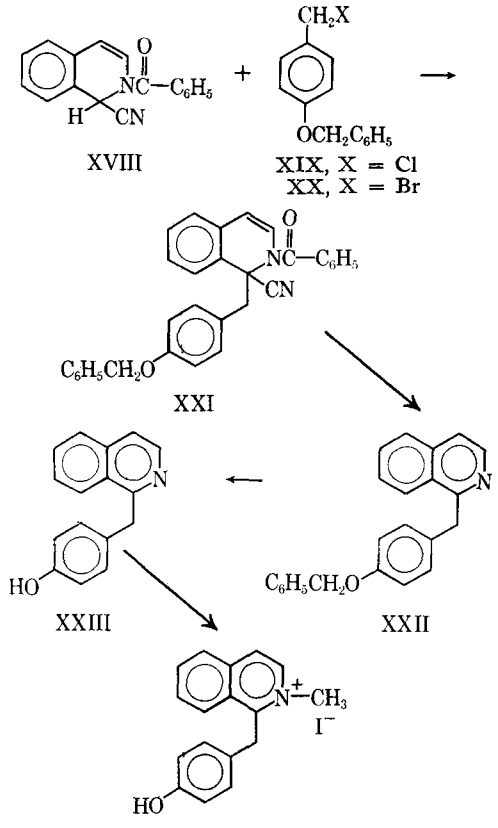
Scheme I

(XX). Alkaline hydrolysis of XXI gave 1-(4-benzyloxybenzyl)isoquinoline (XXII). Heating XXII with 20% hydrochloric acid gave XXIII. The latter was converted to the methiodide (XXIV) and reduced to the desired product (V) with sodium borohydride. (Scheme III.)

Gibson and Popp (9) reported the preparation of XXII and XXIII from XVIII and 4-benzyloxybenzaldehyde. Ikehara (10) reported the synthesis of XXIII by the condensation of 1-chloroisoquinoline with 4-methoxyphenylacetonitrile, followed by demethylation.

Pharmacological Results[1]—Compounds V, XVI, and XVII have been investigated by a gross symptomological procedure in albino mice after intraperitoneal injection. There was little or no significant effect and no lethality with up to 680 mg./Kg. of XVI. However, compound XVII caused early deaths with excitation and clonic convulsions, and had an LD_{50} of 68 mg./Kg. Lower doses showed signs of CNS inhibitory actions; 2.0 and 20 mg./Kg. yielded significant prolongation of hexobarbital sleeping time. In the writhing test for analgesia, an ED_{50} of 11.5 mg./Kg. was noted. In a few albino rats, compound XVII appeared to produce drowsiness and partial analgesia at 10–20 mg/Kg., while at 46 mg./Kg. there was first sedation and later excitation and convulsions. An LD_{50} of 153 mg./Kg. was noted for V. In lethal dosage it produced multiple strong clonic convulsions and terminal tonic convulsion. In lower dosage symptoms of exophthalmos, immobility (catatonia-like), and loss of cutaneous pain reflexes were noted. At 100 mg./Kg., V reduced by 50% the number of writhing responses in the phenylquinone writhing test for analgesic action.



Scheme III

EXPERIMENTAL[2]

N-Phenethyl-4-methoxyphenylacetamide (VI)—The procedure utilized by Decker and Kropp (11) for the preparation of *N*-phenethylphenylacetamide was followed.

A mixture of 16.6 Gm. (1.0 mole) of 4-methoxyphenylacetic acid and 12.1 Gm. (1.0 mole) of β-phenethylamine was fused at 180° and the melt maintained at that temperature for 9 hr. The resulting homogeneous melt was poured into a mortar. The material, which solidified on cooling, was pulverized and recrystallized from ethanol. There was obtained 14.7 Gm. (55%) of a white crystalline solid, m.p. 96–97.5°. [Lit. (7) m.p. 95°.]

1-(4-Methoxybenzyl)-3,4-dihydroisoquinoline Methiodide (VIII)—A mixture of 26 Gm. (0.1 mole) of *N*-phenethyl-4-methoxyphenylacetamide (VI), 25 Gm. (0.22 mole) of phosphorus pentoxide, 23 Gm. (0.15 mole) of phosphorus oxychloride, and 200 ml. of dry toluene was refluxed at 130–135° for 3.5 hr. After 1 hr., 17 Gm. (0.11 mole) of phosphorus oxychloride was added to the reaction mixture. The reaction mixture was cooled to room temperature. The toluene layer was decanted from the brownish semisolid. The latter was treated with crushed ice and then extracted with 10 L. of boiling water. The water extract was divided into five portions; each portion was basified with 20% sodium hydroxide solution, and each portion was extracted with three 300-ml. portions of ether. The combined ether extract was washed with water and dried over anhydrous potassium carbonate. Distillation of the ether under reduced pressure gave 16 Gm. (70%) of the 3,4-dihydro free base. The latter was transferred to a pressure bomb (glass) and treated with 20 ml. of methyl iodide and then heated on an oil bath maintained at 50–55° for 6 hr. The crude solid was recrystallized from ethanol to yield 19 Gm. (50%) of product, m.p. 198–200°. Recrystallization twice from ethanol gave a pale yellow crystalline solid, m.p. 207–209°.

Anal.—Calcd. for $C_{18}H_{20}INO$: C, 54.98; H, 5.12; I, 32.38; N, 3.56. Found: C, 55.04; H, 5.34; I, 32.40; N, 3.34.

1-(4-Methoxybenzyl)-2-methyl-1,2,3,4-tetrahydroisoquinoline (IX)—*Method A*—A stirred solution of 6.25 Gm. (0.017 mole) of 1-(4-methoxybenzyl)-3,4-dihydroisoquinoline methiodide (VIII) in 150 ml. of methanol was treated with 7 Gm. of sodium

[1] The authors are grateful to Dr. Marvin Davis, Department of Pharmacology, School of Pharmacy, University of Mississippi, for the pharmacological data.

[2] Melting points were taken in open glass capillaries using a Thomas-Hoover Uni-Melt apparatus and are uncorrected. Infrared spectra were determined on a Perkin-Elmer model 137 G Infracord spectrophotometer using potassium bromide pellets unless otherwise indicated. The NMR spectrum of V was obtained by means of the Varian A-60A spectrometer using tetramethylsilane (TMS) as the internal standard and deuterochloroform as the solvent. The shifts were measured on the τ-scale relative to the internal standard TMS (τ 10.0). Assignment of protons in a certain area is based on correct integral information from the NMR spectrum.

borohydride in small portions. The resultant mixture was stirred at room temperature for 45 min. and then concentrated under reduced pressure. The residue was treated with 500 ml. of 2% sodium hydroxide and extracted with four 100-ml. portions of ether. The ether extract was washed with 200 ml. of water and dried over anhydrous potassium carbonate. The ether was concentrated under reduced pressure to yield 3.2 Gm. (45%) of pale yellow oil. A picrate was prepared in the usual manner and recrystallized from ethanol, m.p. 159–160.5°.

Anal.—Calcd. for $C_{24}H_{24}N_4O_8$: C, 58.07; H, 4.87; N, 11.30. Found: C, 58.08; H, 4.84; N, 11.32.

Method B—The procedure utilized by Schnider and Grüssner (12) for the preparation of 1-(4-methoxybenzyl)-2-methyl-1,2,5,6,7,8-hexahydroisoquinoline was followed. A stirred ice-cooled suspension of 41 Gm. (0.15 mole) of isoquinoline methiodide (X) in 200 ml. of dry ether was treated dropwise over a 30-min. period with 4-methoxybenzylmagnesium chloride [prepared from 23.4 Gm. (0.15 mole) of 4-methoxybenzyl chloride according to the general method of Van Campen (13) and coworkers]. The resultant mixture was stirred at room temperature for 1 hr. and then poured into 1 Kg. of crushed ice and water containing 30 Gm. of ammonium chloride. The mixture was made alkaline with ammonium hydroxide. The ether layer was separated and the aqueous layer further extracted with ether. The combined ether solution was extracted with seven 100-ml. portions of cold 10% hydrochloric acid. The acid extract was made alkaline with cold ammonium hydroxide and extracted with four 200-ml. portions of ether. The ether extract, after drying over anhydrous sodium sulfate, was concentrated under reduced pressure. Trituration of the residual semisolid with ethanol gave 7 Gm. (17%) of the dihydro compound (XI) as an amorphous solid, m.p. 68–73°. This compound changed to reddish brown when exposed to air, and attempts to purify the substance proved abortive.

A solution of 4 Gm. (0.014 mole) of the above solid in 150 ml. of methanol was treated in portions with 5 Gm. of sodium borohydride and then stirred at room temperature for 2.5 hr. The product was isolated as in method *A* to give 2.3 Gm. (57%) of pale yellow oil. A picrate, m.p. 159–160.5°, showed no depression on admixture with a sample obtained by method *A*. The infrared spectra were identical.

Method C—The procedure employed in method *B* was followed using a mixture of 10 Gm. (0.037 mole) of 3,4-dihydroisoquinoline methiodide (XII) (14), 50 ml. of absolute ether, and 4-methoxybenzoylmagnesium chloride [prepared from 5.8 Gm. (0.037 mole) of 4-methoxybenzyl chloride]. The mixture was treated as in method *B* to yield 1.8 Gm. (17%) of product. The picrate was prepared in the usual manner, m.p. 159–160°. A mixed melting point with the picrate obtained from either method *A* or *B* was undepressed. The infrared spectra were identical.

1-(2-Nitro-5-benzyloxybenzal)-2-methyl-1,2,3,4-tetrahydroisoquinoline (XVI)—The procedure described by Weisbach and co-workers (8) for the preparation of 1-(2-nitrobenzal)-2-methyl-1,2,3,4-tetrahydroisoquinoline was followed. To a warm stirred solution of 1.86 Gm. (0.08 mole) of sodium in 70 ml. of absolute ethanol (commercial ethanol refluxed with calcium oxide and distilled) were added 7.2 Gm. (0.26 mole) of isoquinoline methiodide and 13 Gm. (0.52 mole) of 2-nitro-5-benzyloxytoluene (XV). The resultant solution was kept at room temperature for 24 hr. and then in a refrigerator for 48 hr. The solid that separated was removed by filtration and recrystallized from ethanol to give 8 Gm. (80%) of product, m.p. 102.5–103.5°.

Anal.—Calcd. for $C_{24}H_{22}N_2O_3$: C, 74.59; H, 5.73; N, 7.25. Found: C, 74.63; H, 5.64; N, 7.18.

1-(2-Amino-5-benzyloxybenzyl)-2-methyl-1,2,3,4-tetrahydroisoquinoline Dihydrochloride (XVII)—A modified procedure of Weisbach and co-workers (8) was followed. A mixture of 10.5 Gm. (0.025 mole) of 1-(2-nitro-5-benzyloxybenzal)-2-methyl-1,2,3,4-tetrahydroisoquinoline (XVI), 1 Gm. of platinum oxide, and 250 ml. of absolute ethanol was shaken with hydrogen (initial pressure 40 p.s.i.) in a low pressure Parr hydrogenator for 2 hr. The uptake of hydrogen was essentially complete after the first 15 min. The catalyst was removed by filtration, and the filtrate was concentrated under reduced pressure. Ethanolic hydrogen chloride was added to the residual oil; the resulting solution was kept in a refrigerator for 48 hr. The ethanol was distilled under reduced pressure and the residue treated with 40 ml. of ethanol. The ethanol was again distilled under reduced pressure. The residue was successively treated with three 40-ml. portions of ethyl acetate and finally with 40 ml. of dry benzene; each time the solvent was distilled under reduced pressure. The crude solid was recrystallized from a mixture of methanol and ethyl acetate with the aid of charcoal to give 10.2 Gm. (97%) of product, m.p. 213.5–214.5° dec.

Anal.—Calcd. for $C_{24}H_{28}Cl_2N_2O$: C, 66.80; H, 6.54; Cl, 6.43; N, 6.49. Found: C, 66.79; H, 6.70; Cl, 16.36; N, 6.41.

4-Benzyloxybenzyl Alcohol—To a suspension of 21 Gm. (0.1 mole) of 4-benzyloxybenzaldehyde in 150 ml. of methanol was added dropwise with stirring a solution of 2 Gm. of sodium borohydride in 2 ml. of 2 *N* sodium hydroxide and 18 ml. of water at 18–25°. The reaction mixture was stirred at room temperature for 3 hr. The ethanol was distilled under reduced pressure and the residue diluted with 100 ml. of water and extracted with 600 ml. of ether. The ether solution, after drying over anhydrous magnesium sulfate, was concentrated under reduced pressure. The residue was recrystallized from petroleum ether (30–60°) to give 20 Gm. (95%) of product, m.p. 85–86°. [Lit. (15) m.p. 85–86°.]

1-(4-Benzyloxybenzyl)-2-benzoyl-1,2-dihydroisoquinoaldonitrile (XXI)—*Method A*—The procedure utilized by Kershaw and Uff (16) for the preparation of 1-(4-methoxybenzyl)-2-benzoyl-1,2-dihydroisoquinoaldonitrile was followed. To a cooled (0°) and stirred solution of 2.76 Gm. (0.01 mole) of 1-cyano-2-benzoyl-1,2-dihydroisoquinoline (Reissert compound) (17) and 2.3 Gm. (0.01 mole) of 4-benzyloxybenzyl chloride (XIX) (15) in 50 ml. of *N,N*-dimethylformamide maintained in a nitrogen atmosphere was added 0.24 Gm. (0.01 mole) of a 50% dispersion of sodium hydride in mineral oil. The mixture was stirred at 0° for 1 hr. and at room temperature for 2 hr. The reaction mixture was poured onto 500 Gm. of crushed ice. The product was removed by filtration and recrystallized twice

from absolute ethanol; 3.1 Gm. (70%) of product was obtained, m.p. 144–146°. The infrared spectrum in Nujol possessed a rather weak band for the amide carbonyl group at 6.05 μ, possibly due to an interaction of the oxygen atom of the amide with the carbon atom of the cyano group. This was supported by a very weak absorption at 4.16–4.54 μ, the frequency range in which absorption due to a cyano group is observed.

Anal.—Calcd. for $C_{31}H_{24}N_2O_2$: C, 81.56; H, 5.34; N, 6.14. Found: C, 81.31; H, 5.47; N, 6.21.

Method B—The procedure described in method *A* was followed using 4-benzyloxybenzyl bromide (XX) instead of 4-benzyloxybenzyl chloride (XIX), m.p. 144–146°.

1-(4-Benzyloxybenzyl)isoquinoline (XXII)—The procedure utilized by Boekelheide and Weinstock (18) for the preparation of 1-methylisoquinoline was followed. A solution of 4.5 Gm. (0.01 mole) of 1-(4-benzyloxybenzyl)-2-benzoyl-1,2-dihydroisoquinaldonitrile (XXI) in 70 ml. of methanol was treated with 1.12 Gm. (0.02 mole) of sodium hydroxide in 8 ml. of water and then refluxed for 3.5 hr. The cooled mixture was diluted with 75 ml. of water and extracted with three 200-ml. portions of ether. The ether extract was dried over anhydrous magnesium sulfate. The ether was concentrated under reduced pressure; the residue was recrystallized from ethanol to yield 2.3 Gm. (69%) of product, m.p. 122–123°. [Lit. (9) m.p. 121–122°.]

1-(4-Hydroxybenzyl)isoquinoline (XXIII)—A mixture of 3.25 Gm. (0.01 mole) of 1-(4-benzyloxybenzyl)isoquinoline (XXII) and 100 ml. of 20% hydrochloric acid was heated on a steam bath for 1.5 hr. The reaction mixture was washed with two 30-ml. portions of chloroform and then basified with 28% ammonium hydroxide. The solid was removed by filtration, washed with water, and recrystallized from ethyl acetate to yield 1.5 Gm. (65%) of product, m.p. 180–182°. [Lit. (9) m.p. 177–179°.]

1-(4-Hydroxybenzyl)isoquinoline Methiodide (XXIV)—A solution of 0.9 Gm. (0.004 mole) of 1-(4-hydroxybenzyl)isoquinoline (XXVIII) and 15 ml. of methyl iodide in 10 ml. of methanol was refluxed for 3 hr. and then poured into ether. The solid was removed by filtration and recrystallized from methanol to yield 0.95 Gm. (82%) of product, m.p. 224–227°.

1-(4-Hydroxybenzyl)-2-methyl-1,2,3,4-tetrahydroisoquinoline (V)—*Method A*—The method utilized by Craig and associates (19) for the preparation of 1-alkyl-6,7-dihydroxy-1,2,3,4-tetrahydroisoquinolines was followed. A mixture of 3.5 Gm. (0.013 mole) of 1-(4-methoxybenzyl)-2-methyl-1,2,3,4-tetrahydroisoquinoline (IX) and 40 ml. of 48% hydrobromic acid (redistilled over a trace of 50% hypophosphorous acid and mixed with the latter in the proportion of 1 Gm. of 50% hypophosphorous acid to 100 Gm. of 48% hydrobromic acid) was gently refluxed at 135–140° in a current of nitrogen for 6 hr. The reaction mixture was basified with 28% ammonium hydroxide and extracted with four 100-ml. portions of benzene. The benzene extract was dried over anhydrous sodium sulfate and then distilled under reduced pressure to yield a pale yellow solid, m.p. 72–82°. The crude product was chromatographed on 25 Gm. of neutral Woelm alumina (activity I) prepared in benzene and eluted with 240 ml. of benzene, 210 ml. of acetone, 180 ml. of ethyl acetate, and finally with 180 ml. of methanol. The evaporation of the methanol eluents gave 0.420 Gm. (33%) of product, m.p. 130–132°. Recrystallization from carbon tetrachloride with the aid of charcoal gave product, m.p. 133.5–134.5°.

Anal.—Calcd. for $C_{17}H_{19}NO$: C, 80.6; H, 7.56; N, 5.59. Found: C, 80.8; H, 7.54; N, 5.82.

Method B—The procedure described in method *A* was followed using 47% hydriodic acid instead of 48% hydrobromic acid, m.p. 133.5–134.5°.

Method C—The procedure utilized by Gibson and co-workers (20) for the preparation of 1-(4-hydroxybenzyl)-2-methyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline was followed. A mixture of 0.7 Gm. (0.0019 mole) of 1-(4-hydroxybenzyl)isoquinoline methiodide (XXIV), 2 Gm. of sodium borohydride, 2 ml. of water, and 80 ml. of methanol was refluxed with stirring for 2 hr. Most of the methanol was distilled under reduced pressure, and the residue poured onto ice. The mixture was adjusted to pH 8 and extracted with two 50-ml. portions of ether. The ether extract was dried over anhydrous magnesium sulfate and then concentrated under reduced pressure. The residue was recrystallized from carbon tetrachloride to yield 0.5 Gm. (100%) of product, m.p. 132.5–134°. A mixed melting point with the sample obtained *via* the Bischler-Napieralski reaction was undepressed.

The nuclear magnetic spectrum (NMR) of V in deuterochloroform showed three *N*-methyl protons (singlet τ = 7.49), six ring methylene protons (multiplet centered at τ 7.1), one tertiary proton (triplet τ = 6.1), and eight aromatic protons (τ 2.75–3.5), which is consistent with the structure.

1-(4-Benzoyloxybenzyl)-2-methyl-1,2,3,4-tetrahydroisoquinoline—To a solution of 0.25 Gm. (0.001 mole) of 1-(4-hydroxybenzyl)-2-methyl-1,2,3,4-tetrahydroisoquinoline (V) in 10 ml. of 1 *N* sodium hydroxide was added 0.2 Gm. (0.001 mole) of benzoyl chloride. The mixture was shaken vigorously for 10 min. and then extracted with two 20-ml. portions of chloroform. The chloroform extract was dried over anhydrous sodium sulfate and then concentrated under reduced pressure. The residual oil (0.25 Gm., 70%) was converted to a picrate in the usual manner and recrystallized from methanol, m.p. 201.5–203°.

Anal.—Calcd. for $C_{30}H_{26}N_4O_9$: C, 61.43; H, 4.47; N, 9.55. Found: C, 61.60; H, 4.57; N, 9.62.

Plasticizers in Medical Application I

Analysis and Toxicity Evaluation of Dialkyl Benzenedicarboxylates

By JAY NEMATOLLAHI, WALLACE L. GUESS, and JOHN AUTIAN

A series of dialkyl and dicycloalkyl benzenedicarboxylates (phthalates, isophthalates, terephthalates), of which some have been employed as plasticizers, were synthesized and purified. Thin-layer chromatography and infrared spectrometry were employed as methods of detection and identification of these compounds. Toxicity tests were conducted using mammalian cell cultures and limited mouse studies. The low molecular weight esters and their isomers manifested toxic responses while the esters containing alkyl groups C_6 to C_9 were devoid of toxic effect. The di-*n*-decyl phthalate and terephthalate also elicite toxic actions to cells. Results from this study indicate the need for good quality control procedures to prevent the access of potentially toxic plasticizers in devices for medical and paramedical applications.

A NUMBER of polymeric materials require the presence of one or more plasticizers to impart a degree of softness and flexibility not inherent in the parent polymer. The concentration of the plasticizer may vary from a rather small percentage to as high as 60%, depending upon the desired final properties. Selection of a plasticizer (or plasticizers) for a specific plastic is dependent upon a number of considerations; the initial consideration is that it will impart to the final plastic the optimum properties desired at a minimum cost consistent with quality production. If the plastic material is to be used as a food wrap or a container, the degree of migration of the plasticizer to the food and the toxicity profile of the migrated ingredient must be evaluated under the Food Additive Amendment. Development and use of the plasticized polymeric materials for various medical, pharmaceutical, and dental applications such as tubing, catheters, containers, and protective films raises the question as to the toxic potential of migrated plasticizer which may enter the patient by routes other than oral. In this regard, consideration must also be given to the exact composition of the "migrated ingredient" since it may actually be composed of the intact plasticizer, degraded products of the plasticizer, impurities in the plasticizer, and other additives such as stabilizing agents, antioxidants, degraded products of the additives, and impurities in the additives.

Within the past 5 years, a number of published reports (1–3) have demonstrated that certain types of polyvinyl chloride (PVC) devices could produce toxic effects if one or more ingredients migrated from the device into tissue or into an injectable solution.

Recent investigations (4) on a group of PVC blood bags revealed that certain ingredients were migrating from the plastic into acid citrate dextrose solutions. The combined ingredients were found to be toxic to mammalian cell cultures. Further investigations on the "leached" ingredients showed the presence of several chemicals, presumably plasticizers together with their degradation products. A frequently employed plasticizer in the PVC plastic used for the manufacture of the blood bags was found to be di(2-ethylhexyl)phthalate. Others such as dialkyl sebacates and epoxidized soybean oil were also detected in the PVC.

When a combined chemical and spectrophotometric method was employed for the detection and identification of these additives, it became obvious that a mixture of homologs of a few di-

alkyl phthalates could not be separated easily and under these experimental conditions their infrared spectra were indistinguishable. Likewise, when a commercial medical grade di(2-ethylhexyl) phthalate (DOP) was examined by thin-layer chromatography (TLC), the presence of several spots was observed. Again it was not possible by tedious column chromatography to separate some of the proximately located spots observed on the thin-layer plate, and the I.R. spectra of the fractions did not provide sufficient help for structural elucidation. This, and the fact that the commercial synthesis of plasticizing esters does not rule out the presence of isophthalates and terephthalates in phthalate plasticizers, necessitated the extension of this investigation to the synthesis and analysis of a series of authentic esters of the three isomers of benzenedicarboxylic acids. The detected TLC spots for the medical grade DOP, mentioned above, could be ascribed to the homologs of the phthalic acid esters as well as to its positional isomers (see Table I). One of the industrial methods of preparation of benzenedicarboxylic acids is *via* oxidation of xylenes. Quite often one isomer of xylene contains the other two, whose oxidation would give rise to a mixture of the three corresponding acids.

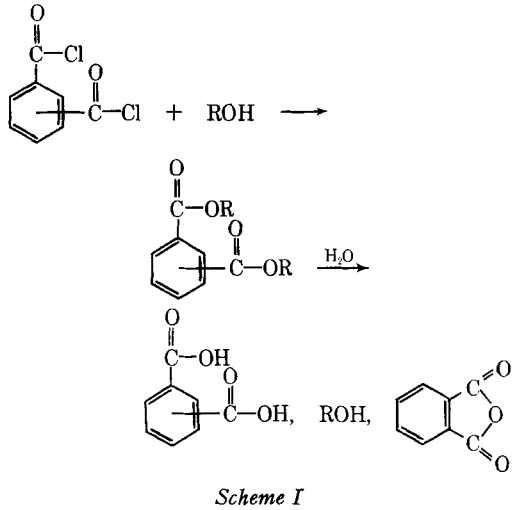
The main objectives of this investigation were: (*a*) to synthesize a homologous series of the authentic dialkyl and dicycloalkyl benzenedicarboxylates in order to acquire information on certain physical properties and spectroscopic data for the series, requisite both for present and further investigations in plastics; (*b*) to search for the existence of a correlation among chemical structures of the esters and their I.R. spectral patterns; (*c*) to correlate the chemical structures of the esters together with their products of hydrolysis to their toxic potential on the mammalian cell cultures and mice; and (*d*) to determine the rate of hydrolysis of the esters and relate this rate to chemical structure and toxic effect. The latter part will be discussed in another paper.

CHEMISTRY

The rapid rate of reaction of phthalyl, isophthalyl, and terephthalyl chloride with alcohol suggested the adoption of this route for the preparation of dialkyl and dicycloalkyl benzenedicarboxylates. The acid chlorides were employed slightly in excess of the stoichiometric quantity of the alcohol in order to facilitate the purification of the final product which consists of the removal of the acid from the ester by ether–dilute aqueous base extraction. In addition to *n*-alkyl and some iso-alkyl esters, four cycloalkyl esters were prepared: cyclopentyl, cyclohexyl, cycloheptyl, and cyclooctyl benzenedicarboxylate. The general method of synthesis and the degradation by hydrolysis of the esters is shown in Scheme I.



Scheme I

Due to cell culture toxicity manifested by some esters and the products of hydrolysis of the esters of benzenedicarboxylic acids, the establishment of a detection method for esters mixed with such products became essential. This purpose was served well by the application of thin-layer chromatography. The esters, acids, and anhydride (the anhydride formed as one of the products of degradation of phthalic acid esters) could be detected visually on the thin-layer plate by the aid of a short wave ultraviolet light. Both the acid and anhydride remained near the origin whereas the esters showed a noticeable R_f value. The position of the alcohol on the TLC plate usually was in between the ester and acid. Since the presence of the alcohol could not be visualized by the aid of a U.V. light, its location was fixed by spraying the plate with a 10% solution of phosphomolybdic acid in 95% ethanol.

The R_f values for the esters are listed in Table I. A possible occurrence of variation in the position of spots, due to change in the atmosphere of the chamber or the proportion of the solvent, was eliminated by spotting DOP as a reference on the plate along with the esters.

TOXICITY EVALUATION

The toxicity of the esters was evaluated by two methods: (*a*) a cell culture method and (*b*) an animal method. The details of the evaluation of a chemical by cell culture methods have been described previously (5).

The results of both animal and cell culture tests are listed in Table II. It is noteworthy that the results from the two tests coincide within the experimental error. A detailed assessment of this is described further under results and discussion.

EXPERIMENTAL

The infrared spectra were determined with a Perkin-Elmer 337 spectrophotometer. The instrument was calibrated with a polystyrene film and the "normal" slit program was employed throughout the experiments. A KBr disk method was used for solid samples and neat (between NaCl windows) for liquid samples. The recorded wave number values are within ±2 cm.$^{-1}$ of the actual values. The plates for thin-layer chromatography (TLC) were prepared using Brinkmann Silica Gel HF 254 + 366 and were activated at 180° for 30 min. A mixture of hexane–ethyl acetate (90:10) was employed at room temperature as a developing solvent. The solvent front height was maintained at 12 cm. ± 1. Spots were located both by visual examination under a short wave ultraviolet light and by the aid of an indicator, 10% alcoholic solution of phosphomolybdic acid. Elemental analyses[1] were conducted by the Microanalytical Laboratory, Department of Chemistry, University of Texas, Austin, Tex.

General Method of Synthesis of Dialkyl and Dicycloalkyl Benzenedicarboxylate—To 0.2 mole of a dry alcohol was added 0.11 mole of benzene dicarboxylic acid chloride. With the provision for exclusion of water, the mixture was heated under reflux for 4–6 hr. The reaction mixture was examined from time to time by the aid of TLC in order to evaluate the progress of the reaction. Upon completion of the reaction, the content of the flask was poured into a separator containing 100 ml. of diethyl ether. The ether solution was extracted with 20-ml. portions of 1 *N* NaOH solution until the aqueous portion became basic to an indicator paper. The ether layer was washed with water to neutrality, and then was placed in a dry flask containing anhydrous sodium sulfate. After 12 to 24 hr. the ether was filtered and evaporated under dry nitrogen. The residue dialkyl or dicycloalkyl benzenedicarboxylate was obtained in 55 to 75% yield. The purity of the product was verified by TLC (Table I). In a few cases, where the presence of the trace quantity of acid or alcohol was observed, the ester was purified by means of a column packed with a mixture of equal quantities of silica gel and diatomaceous earth,[2] and developed with 200 ml. of *n*-hexane, followed by 300–400 ml. of benzene. The collected fractions, 10–15 ml., were examined by TLC for the presence of the pure ester. In general, the benzene fraction contained the pure ester, which was obtained by the evaporation of benzene *in vacuo*. The main peaks of the infrared spectra of the esters are listed in Tables III, IV, and V.

Toxicity Test—*Mammalian Cell Culture Method*—Monolayers of L-cells and chick embryo cells overlaid with agar were used in this evaluation according to a method reported by Guess *et al.* (5). Several modifications, however, were necessary in

[1] Elemental analysis was done only on those dicycloalkyl benzenedicarboxylates whose structures were not well characterized previously. The results were found to coincide with the calculated values. None was reported in this manuscript.

[a] Key: w, weak; d, doublet; b, broad; sh, shoulder; wb, weak broad. Solvent: the spectra of all the esters were determined neat except R = CH_3 and cyclo C_8.

the method to make it suitable for the samples tested in this investigation. If the esters were crystalline, approximately 20 mg. of each was placed directly on the agar overlay. For liquid esters, 35 mg. of each was applied directly to a paper disk, 12.7 mm. diameter, which had previously been placed on the agar overlay. The culture plates were then incubated for a period of 24 hr., at which time the cells adjacent to the test samples were observed for possible toxicity. If the compound affected the cells by creation of zone of dead cells (inhibition zone) it was assumed to be toxic [designated by a positive (+) sign]. If the cells remained intact, the compound was assumed to be nontoxic [negative (−) sign]. In those cases where the results appeared in doubt, pending further tests, the results were identified with a positive–negative sign (±). These results are shown in Table II. Each of the compounds were tested a minimum of 3 times.

Intraperitoneal Mice Method—Each of the compounds was administered i.p. in groups of 3 mice at a concentration level of 5 mmoles/Kg. in either cottonseed oil or in castor oil, depending upon the solubility of the specific compound. The animals were kept under observation for a period of 4 days or until death. In general, the esters exerted a depressant effect in mice and induced observable ptosis. Gross toxicity results based upon death are included in

Table II. A negative sign (−) indicates no deaths, a positive sign (+) 2 or 3 deaths, and a positive-negative sign (±) only one death.

DISCUSSION

Infrared—The major peaks of the I.R. spectra of dialkyl and dicycloalkyl benzenedicarboxylates, together with the spectra of phthalic acid, phthalic anhydride, and isophthalic and terephthalic acid, are listed in Tables III–VI. The peaks for stretching frequencies of C=O and of C—H for acids and their appropriate esters occur in different regions of the infrared spectrum. The presence of phthalic acid, a hydrolysis product of a dialkyl phthalate, can be verified by the presence of C=O band at 1700 cm.$^{-1}$ next to a conjugated ester C=O band at 1740 cm.$^{-1}$. This distinction, however, cannot be made if the quantity of acid to ester is less than 5%—only the peak for ester C=O will be observed. The presence of phthalic anhydride can be identified in a like manner by the presence of C=O bands at 1760 and 1855 cm.$^{-1}$. The bands in the fingerprint region, which are characteristic of a given compound, are further means of identifying an unknown molecule, providing the spectrum of the authentic sample is available. The latter statement, however, is not quite applicable in those cases where the compound ought to be differentiated from its closely related homologs.

The esters of the three isomeric benzenedicarboxylic acids can be differentiated (*a*) on the basis of peak positions for carbonyl frequency, 1710–1745 cm.$^{-1}$; (*b*) aromatic ring skeletal vibration, 1500–1605 cm.$^{-1}$; (*c*) in-plane C—H bending, 1350–1490 cm.$^{-1}$; (*d*) C_6H_5—$\overset{\overset{O}{\|}}{C}$—OR stretching vibration, 1230–1290 cm.$^{-1}$; and (*e*) out-of-plane aromatic C—H bending vibration, 720–840 cm.$^{-1}$. In general, the stretching frequency for C=O of

[a] Key: same as in Table III.

phthalates are slightly higher than isophthalates and terephthalates. The field effect of the proximately located C=O group may be a reason for observing a higher C=O stretching frequency for phthalates.

The doublet for aromatic ring skeletal vibration at 1580–1600 cm.$^{-1}$ observed in the spectra of a phthalate is absent in the spectra of iso- and terephthalates. Instead there is a single band at 1605 cm.$^{-1}$ for iso- and two bands at 1570 (weak) and 1500 cm.$^{-1}$ for terephthalates.

The bands due to the in-plane bending vibration, 1350–1490 cm.$^{-1}$, quite often vary somewhat among the esters of the three benzenedicarboxylic acids. The variation in this region, however, is not sufficient to lead one to an unequivocal identification of an unknown ester; a reference to the spectrum of an authentic sample is necessary.

Out-of-plane bending bands, 700–900 cm.$^{-1}$, are characteristic of the esters of each of the three isomeric acids. Positional isomers of disubstituted benzene usually contain I.R. bands which are at 690–840 cm.$^{-1}$.

$$C_6H_5—\overset{\overset{O}{\|}}{C}—OR$$

The stretching band for C_6H_5—COR for phthalates is quite close to terephthalates at 1275–1280 cm.$^{-1}$. This band for isophthalate comes at 1235–1240 cm.$^{-1}$ and can serve for identification purposes.

Finally, the position of the unassigned peaks in the tables could function as fingerprints for detection and differentiation of the esters of the three isomeric acids. Various esters of a given acid, such as phthalic acid, can also be discerned if the molecular weight of the homologs are not too close.

Thin-Layer Chromatography—TLC proved to be an excellent and rapid method for the detection of the product of hydrolysis of an ester or the presence of other esters and the parent acid and alcohol mixed with a given ester. The R_f values for the esters of the three isomeric benzenedicarboxylic acids are listed in Table I. In general, the R_f value in this series increases from *ortho* to *meta* to *para* isomer. Apparently, the R_f value in the hexane–ethyl acetate developer for a given molecular weight of these esters is inversely proportional to their dipole moment value. Cyclic compounds show lower R_f values as compared to their straight chain counterpart which, in a sense, indicates the influence of polarity of a compound on its R_f value. Since only a fraction of a mg. is necessary to identify a compound by TLC, this technique in conjunction with I.R. manifests a great potential in the detection and identification of plasticizers leached out of a plastic. Such identification, however, may become laborious if some esters unrelated to benzenedicarboxylate are in the mixture.

Toxicity—As is depicted in Table II, toxicity results obtained by the cell culture method quite frequently coincide with the toxicity evaluation conducted on mice.

In general, low molecular weight dialkyl benzenedicarboxylates (alkyl group C1 to C5) manifest toxic effect. This toxic effect could be ascribed to the higher degree of solubility of the low molecular weight esters, as compared with their higher homologs. However, since both di-*n*-decyl phthalate and di-*n*-decyl terephthalate show toxicity to cell cultures, the conclusion based merely on relating the toxicity of a compound in the series to its solubility or molecular weight becomes subject to some doubts. It is noteworthy that, unlike a freshly synthesized pure di-*n*-decyl phthalate, the commercial sample of this compound was found to be extremely toxic to mice. Although determining the toxicity of a commercial plasticizer is beyond the scope of this investigation, the importance of purity and stability of a compound should not be ignored. Apparently identical plasticizers obtained from various sources or subjected to various conditions during the process of incorporation into a polymer may manifest quite different toxic effects.

The question of whether toxicity effects of the esters are due only to their degradation products rather than to the intact ester molecule has been examined in the past with citrate plasticizers (6), where toxicity proved to be due to the ester, despite the fact that citric acid *per se* was also toxic. In the dialkyl benzenedicarboxylates, although their products of hydrolysis were found to be toxic, evaluation of toxicity data suggested that these esters, as citrates, exert their toxic effects as the intact ester molecule. The molecules, di-*n*-propyl, di-iso-propyl, di-*n*-butyl, di-iso-butyl, di-*n*-pentyl, and di-iso-pentyl, all show similar ratings in the toxicity evaluation, whereas the rate of hydrolysis of the iso derivatives would be expected to be lower than the *n* derivatives. Likewise, no great difference, if any, would be expected in the rate of hydrolysis of di-*n*-pentyl and its homolog di-*n*-hexyl phthalates, but biologically these two behave differently. As indicated above, phthalates with alkyl groups C_6 to C_9 do not show a toxic effect on the cell.

The reason for the toxic manifestation of di-*n*-decyl phthalate and terephthalate is not yet clear. Such behavior, however, could be postulated to be due to the inhibition of the function of certain enzyme systems, whose metabolites possess a structure analogous to that of the ester.

The mice tests were included only as another screening method to observe if the results noted in the cell tests could be manifested in animals. Keeping in mind the limitation in the mouse test, it is still interesting to note that a good correlation exists between the results shown for the mammalian cell method and for the i.p. mouse test. Further animal studies would, of course, be needed to establish true toxicity patterns based upon definite dose levels of the compounds. It is, however, important to state that the close correlation between the animal test and cell test result renders the latter an appealing method due to its inherent convenience, rapidity, and economy.

In conclusion, perhaps the important point to be gained from this study is that greater attention should be paid to the actual composition of the plasticizer which is to be used for a medical application. A pure plasticizer may have no demonstrable toxic response, but the presence of related homologs and isomers could add a toxic potential to the plasticizer. To this possibility one must also include the potential toxic effects from degradation products present or forming in the plasticizer during manufacture of a plastic device, or occurring after the device is stored under various conditions for undetermined periods of time. Good quality control procedures in the manufacture of a medical device should prevent the entrance of potentially toxic

plasticizers to the medical and para-medical professions.

Synthesis of Tropine-Labeled Atropine II

Prototype Synthesis for the Preparation of Tropine-^{14}C and Atropine-^{14}C from Arabinose-^{14}C

By GILBERT C. SCHMIDT*, THOMAS E. ELING, JOHN M. McOWEN, and JOHN C. DRACH†

Prototype methods for the synthesis of tropines-^{14}C and tropine-labeled atropines are described. These compounds and the requisite labeled intermediates may be synthesized from arabinose-5-^{14}C or arabinose-UL-^{14}C. Yields for each step in the conversion of arabinose to succindialdehyde *via* 2,5-diethoxytetrahydrofuran have been determined. Predicted yields of 27 per cent atropine, based on starting pentose, were confirmed by synthesis of the alkaloid from 2 mmole quantities of arabinose. This procedure is the first published method for labeling atropine in the carbon skeleton of the tropine moiety.

FEW METHODS for selectively labeling atropine have been published. Labeled tropic acid has been synthesized by adaptations of Blicke's procedure (1), then converted to correspondingly labeled atropine by modifications of the Wolffenstein esterification (2). Using these methods, atropine has been labled with ^{14}C in the carboxyl position (3) and in the α-position (4) of the tropic acid moiety. Subsequent studies with the labeled alkaloids (5–9) have contributed much to an understanding of atropine metabolism, but the metabolic fate of the tropine moiety is not known.

The virtual absence of studies concerned with the metabolic fate of tropine indicates that suitably labeled compounds are not readily available for study. Randomly ^{14}C-labeled atropine has been biosynthesized (10) and atropine has been randomly labeled with tritium (11), but these compounds lack the desired specificity of labeling. Selective tritiation of tropine has been accomplished recently (12), but the heterocycle was converted to deptropine rather than atropine (13). *Datura metel* is known to incorporate 80–85% of the radioactivity from acetate-2-^{14}C into positions 2,3,4 of tropine (14, 15), but the exact position or positions of labeling are unknown. When *D. metel* is grown on acetate-1-^{14}C (14, 15) or *Datura stramonium* is grown on ornithine-2-^{14}C (16, 17), radioactivity is incorporated with stereochemical specificity into position 1 or position 5 of the tropine moiety. These biosynthetic compounds have not been available for metabolic studies and problems inherent in biosynthetic methods limit feasibility of this approach to tropine labeling. Standard synthetic methods for labeling the tropine moiety of atropine are needed, but few have been reported. Werner *et al.* (3), Fodor *et al.* (18), and Eling *et al.* (19) have used classical organic syntheses to obtain *N*-methyl-^{14}C-tropine and *N*-methyl-^{14}C-atropine, but these compounds are of limited value because the methyl carbon attached to the endo nitrogen bridge, rather than the carbon skeleton of tropine, is labeled. The need of practical methods for labeling the carbon skeleton of tropine is acute and the problem remains unsolved.

Three fundamental problems are encountered in the synthesis of tropine-labeled atropine: reproducibility of the esterification, feasibility of the Robinson condensation, and availability of labeled intermediates suitable for synthesis of succindialdehyde and acetone dicarboxylic acid, the

key compounds in the Robinson condensation. The problems of condensation and esterification have been studied recently (20) and reproducible microsynthetic methods now are available. The present needs are for suitably labeled intermediates and microsynthetic methods for converting them to labeled succindialdehyde or labeled acetone dicarboxylic acid.

This communication presents, in detail, a prototype method for the synthesis of tropine-labeled atropine from arabinose.[1] The starting material is available in labeled forms suitable for the synthesis of tropine-1,5,6,7-^{14}C or tropine-1-^{14}C (or tropine-5-^{14}C), from which the correspondingly labeled atropines can be synthesized. Except for biosynthetic procedures, it is the first microsynthesis suitable for selectively labeling the carbon skeleton of tropine.

EXPERIMENTAL

Synthesis of Furaldehyde from Arabinose—Furaldehyde was synthesized from arabinose by a modification of Pervier and Gortner's method (22). In a 500-ml. round-bottom flask fitted for steam distillation, 300 ml. of 12% HCl was heated to 100° and 300 mg. arabinose[2] dissolved in the hot solution.[3] While heating with a heating mantle at a rate to maintain the vapor phase at 103.5–105.5°, steam was passed into the distilling flask and distillation continued until 1000 ml. of distillate had been collected.[4] At this point, single drops of distillate were tested with 2,4-dinitrophenylhydrazine solution[5] until the red precipitate characteristic of furaldehyde no longer appeared.[6] The entire solution was used, without concentration, for conversion of furaldehyde to furoic acid.

Conversion of Furaldehyde to Furoic Acid—Furoic acid was prepared from furaldehyde by a modification of Wagner and Simons' procedure (25). Furaldehyde from the previous step,[7] contained in a 2-L. beaker, was adjusted to pH 12 with saturated NaOH, cooled to 10°, and continuously stirred with a mechanical stirrer during the gradual addition of 0.3 Gm. $KMnO_4$ dissolved in 25 ml. water. The reaction mixture was boiled gently for 15 min.,[8] filtered, and the filtrate acidified with HCl. The acidified filtrate was concentrated *in vacuo* at 70° to a volume of 30 ml., then five times extracted with 50-ml. portions of diethyl ether. The ether solution of furoic acid was transferred to

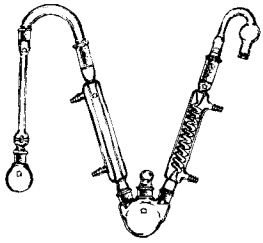

Fig. 1—Simplified decarboxylation apparatus.

a sublimation flask,[9] the solvent removed *in vacuo*, and the sublimation flask, containing the light tan product, dried for 2 hr. in a vacuum desiccator. After drying the flask was fitted with a cold finger containing dry ice–acetone and the furoic acid sublimed onto the cold finger by heating the flask for 30 min. at 15 mm. and 100°. The sublimates[10] were removed from the cold fingers with a small amount of absolute ether, the solvent was evaporated, and a residue of pure, white furoic acid obtained.[11]

Synthesis of Furan from Furoic Acid—Furoic acid was decarboxylated to furan by adapting for microsynthesis the method of Wagner and Simons (25). A simplified decarboxylation apparatus,[12] shown in Fig. 1 and constructed entirely of standard-taper microglassware,[13] was used. A 50-ml. three-neck flask was used as a receiving vessel. One opening of the receiver was fitted with a spiral water-cooled condenser, protected by a soda and lime tube. The second opening was fitted with a water-cooled straight condenser. The middle opening was fitted with a glass plug to permit access to contents of the receiver. The reaction vessel, a 5-ml. round-bottom flask, was fitted to the delivery end of an air-cooled condenser. Receiver and reaction assemblies were connected by a modified U-tube constructed of two adapters bent to the proper angles.

The receiver, containing a mixture of 5 ml. absolute ethanol and 20 ml. absolute diethyl ether,[14] was cooled to −40° and the temperature maintained at this level throughout subsequent steps. Furoic acid from the previous step,[15] 8.5 mg. cupric oxide, and 0.5 ml. water-free quinolin[16] were introduced into the reaction vessel and all joints sealed. The reaction vessel was heated on an oil bath until gas evolution became vigorous (about 200°) and the temperature gradually raised to 275°, at which point it was maintained for 15 min.[17] The resulting furan,

[1] A preliminary report was presented to the American Association for the Advancement of Science (21).

[2] Matheson, Coleman and Bell, Cincinnati, Ohio, m.p. 157–160°, used without further purification.

[3] In preliminary experiments to determine yields, 100–500 mg. arabinose was used. For conversion to tropanone, a minimum of 300 mg. arabinose is recommended.

[4] Complete distillation usually required 6–8 hr. and produced 1000–1250 ml. distillate. It is essential that the stated distillation range be maintained. At lower temperatures furaldehyde does not distil properly, and at higher temperatures decomposition of the product decreases yields.

[5] A standard solution of 2,4-dinitrophenylhydrazine, as described by Shriner *et al.* (23), was used in qualitative and quantitative precipitations.

[6] In quantitative studies to determine the yield for this step, the dinitrophenylhydrazone was isolated and weighed, m.p. 230°, after recrystallization from ethanol (24).

[7] In experiments to determine yields for this step, 0.2 ml. freshly distilled furaldehyde was dissolved in 1000 ml. water and treated as described.

[8] To insure complete precipitation of MnO_2.

[9] Of the design described by Werner (3), having a capacity of 250 ml.

[10] To obtain the last traces of furoic acid after the first sublimation, the flask was washed with ether to dissolve selectively any residual furoic acid. The solution was decanted into another sublimation flask, the solvent evaporated, and the residue sublimed as described previously.

[11] Melting point 130–132° without recrystallization.

[12] In the original apparatus there was a soda and lime trap between the two condensers, to remove CO_2 and water. In microsyntheses, the small quantities of furan produced were adsorbed on the soda and lime. The trap was, therefore, omitted from the reaction train.

[13] Microware, Kontes Glass Co., Vineland, N. J.

[14] Anhydrous conditions must be maintained.

[15] In experiments to determine yields for the conversion of furoic acid to furan, 190 mg. furoic acid was used routinely with the stated quantities of reagents. In other experiments, 5-Gm. quantities of furoic acid were used with corresponding increases in reagents.

[16] Quinolin must be water free and was redistilled immediately before use.

[17] At the stated temperature, quinolin refluxes about halfway up the air condenser. While heating from 200°–275°, furan began to distil into the receiving vessel. When larger quantities of furoic acid were used (5 Gm.), the resulting furan was purified by fractionally distilling at 31–32° and atmospheric pressure.

representing an 88% yield from furoic acid and a 70% yield from arabinose, was immediately converted to tetrahydrofuran, as described below.[18] The bromine number of furan was calculated from the difference in amounts of thiosulfate required to titrate blank and standard solutions.[19] Replicate determinations with known furan solutions gave bromine values of 460–470 mg. bromine per 100 mg. furan. To determine the furan yield in a particular synthesis, an aliquot of the diluted, glacial acetic acid solution of the product was assayed as just described. Furan production was then calculated on the basis of the previously determined bromine number for furan.[20]

Synthesis of 2,5-Diethoxytetrahydrofuran—Furan was converted to diethoxydihydrofuran and diethoxytetrahydrofuran by a micro modification of Fakstorp's (27) procedure. The solution of furan in ethanol and ether,[21] from the preceding step, was introduced into the reaction vessel,[22] cooled to −40° in a dry ice–acetone bath, and a solution of 0.08 ml. bromine in absolute ethanol[23] added, while stirring continually, at a rate to prevent a rise in temperature. Stirring was continued for 15 min. after adding all the bromine, the dropping funnel was replaced with an inlet tube and, while stirring, dry ammonia was bubbled into the reaction mixture until pH 6 was attained.[24] Stirring was continued until the color had disappeared, ammonia was again bubbled in to obtain a pH of 8, precipitated ammonium bromide removed by centrifugation, and the solution of 2,5-diethoxydihydrofuran concentrated to 10 ml.[25] The pale yellow solution of diethoxytetrahydrofuran was transferred to a micro hydrogenation apparatus,[26] using small volumes of absolute ethanol to transfer the last traces, and the volume finally adjusted to 50 ml. with absolute ethanol. With the magnetic stirrer in motion, three "micro spatelafuls" of freshly prepared Raney nickel[27] were added and a very slow[28] stream of hydrogen passed through the reaction mixture until reduction was complete.[29] Hydrogenation usually was complete in about 2 hr., at which time the catalyst was removed by centrifugation, leaving a colorless solution of diethoxytetrahydrofuran in ethanol.[30] The catalyst was washed with several 1-ml. portions of absolute ethanol and the washings combined with the previously obtained alcoholic solution of product.

Synthesis of Tropanone—Tropanone was prepared by the "standard" micro Robinson condensation previously described (20). Succindialdehyde was obtained *in situ* by removal of the solvent,[31] and was then condensed *in situ* with equimolar quantities of methylamine HCl and freshly prepared acetone dicarboxylic acid. The product was purified by micro sublimation and dried in a desiccator[32] before reduction to tropine.

Reduction to Tropine and Esterification with Tropic Acid—Tropanone was reduced to tropine,[33] converted to the hydrochloride and esterified with tropic acid,[34] as described previously (20).[35]

RESULTS AND DISCUSSION

The development of micro methods for the synthesis of tropine and for esterification of this heterocycle with tropic acid has made feasible the synthesis of tropine-labeled atropine. Atropine has been labeled in the bridge position of the tropine moiety by use of methylamine-^{14}C in the micro Robinson condensation, but methods for labeling the carbon skeleton of the tropine moiety have not been published. The feasibility of such labeling depends on on the availability of labeled Robinson intermediates

[18] The apparatus was allowed to cool to room temperature, then the last traces of product were washed from the condenser into the receiver. Receiver and contents were maintained at −40° until used in subsequent steps. In experiments to determine the yield of furan from furoic acid, 25 ml. of glacial acetic acid replaced the ether–alcohol mixture in the receiving vessel. After washing the condenser with a little glacial acetic acid, the solidified solution of furan in glacial acetic acid was allowed to liquefy and was then assayed as described.

[19] The bromine number of furan, defined as mg. bromine reacting with 100 mg. furan, was calculated as follows:

$$\frac{(\text{blank} - \text{sample})(N\ Na_2S_2O_3)(\text{mol. wt. } Br_2)(100)}{(\text{mg. furan in the known aliquot assayed})} =$$

bromine No. of furan = 460

[20] Using the previously determined bromine value of 460 mg. bromine/100 mg. furan, the furan contents of unknown samples were calculated as follows:

$$\frac{(\text{blank} - \text{unknown})(N\ Na_2S_2O_3) \times (\text{mol. wt. } Br_2)(100)\ (\text{dilution factor})}{460} = \text{mg. furan in total distillate}$$

[21] To determine yields of diethoxydihydrofuran and diethoxytetrahydrofuran from furan, 100 mg. pure furan was dissolved in a mixture of 20 ml. absolute diethyl ether and 5 ml. absolute ethanol.

[22] The reaction vessel was a 50-ml. three-neck flask that had been fitted with a thermometer, dropping funnel, and mechanical stirrer. Prior to use, the apparatus was dried by warming with a flame from a Bunsen burner.

[23] Bromine was dissolved in commercial, absolute ethanol, and a 1–2-ml. aliquot containing the stated amount of bromine was used. The alcoholic solution of bromine was cooled to −40° before addition to the cold furan solution.

[24] On bubbling in ammonia, ammonium bromide separated immediately. At pH 6 (Hydrion paper), the temperature had risen to −5° and was not permitted to rise above this level.

[25] To determine the yield of diethoxydihydrofuran from furan, the product from 500 mg. 5-Gm. furan was purified by fractional distillation at 69–72° and 5 mm. Fakstorp (27) reported b.p. 50–53° at 1 mm. Yield was determined by weighing the purified product.

[26] Available from Microware, Inc., Vineland, N. J. The apparatus was immersed in ice water and ice water was used to cool the "cold finger," to prevent evaporation of both product and reactant. Unless extreme care is exercised, losses occur by volatilization on passage of hydrogen.

[27] Raney nickel was prepared as described previously (20).

[28] It is essential that the flow of hydrogen be very slow to prevent losses of reactant and product by volatilization. It is probable that hydrogenation in a closed system, used in syntheses to be reported subsequently, would be equally effective and more convenient. This method was not, however, used in syntheses from arabinose.

[29] To test for completeness of reduction, a 1-ml. aliquot was removed and treated with 2,4-dinitrophenylhydrazine solution. A yellow precipitate of the succindialdehyde derivative indicated complete reduction, while an orange-red precipitate of the malaldehyde derivative indicated incomplete reduction.

[30] In experiments to determine the yield of 2,4-diethoxytetrahydrofuran, the product was acid-hydrolyzed to succindialdehyde, from which the bis-dinitrophenylhydrazone was prepared. The melting point (28) in semimicro and macro experiments was 260° without recrystallization and 272° on recrystallization from ethanol. In micro syntheses m.p. 272° was obtained without recrystallization.

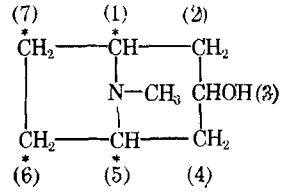
[31] Solvent was removed on the flash evaporator; succindialdehyde distilling at 78–80° and 20 mm. In experiments to determine succindialdehyde yields from diethoxytetrahydrofuran, the furan derivative was purchased from Beacon Chemicals, Cambridge, Mass., and was used without purification. In experiments to determine the dialdehyde yields from succinaldoxime, the oxime was prepared as described by Keagle and Hartung (28) and was recrystallized from water before use in the condensation.

[32] Tropanone yields were determined as the free base, after purification by micro sublimation, and as the picrate, m.p. tropanone 41–43°, m.p. tropanone picrate 220°.

[33] Because Raney nickel is extremely susceptible to poisoning, it was necessary to use highly purified hydrogen available in small cylinders, or to purify by washing the hydrogen obtained commercially in large cylinders.

[34] Nutritional Biochemicals, Cleveland, Ohio, m.p. 157–160°, used without further purification.

[35] Atropine determined gravimetrically and an aliquot converted to the picrate, m.p. free base 114–116°, m.p. picrate 174–175°. All melting points reported in this communication were determined with a Fisher-Johns melting point apparatus.

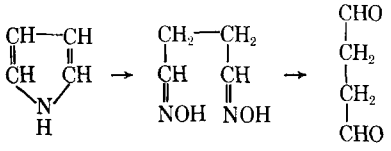


Tropine

other than methylamine. Starting with succindialdehyde, any or all of the indicated positions of tropine could be labeled, depending upon the labeling in succindialdehyde.

Succindialdehyde, the key intermediate for labeling positions 1,5,6,7 of tropine, has been prepared in a number of ways, many of which are not suitable for ^{14}C-labeling because of experimental conditions or because suitable starting materials are are not available. Among the potentially applicable procedures are preparation by ozonolysis of cyclooctadiene (29), oxidation and subsequent reduction of furan (30), preparation from pyrrole (28, 31), and synthesis by hydrolysis of 2,5-diethoxytetrahydrofuran (20, 32).

The authors initially prepared succinaldoxime from pyrrole, and the dialdehyde from this intermediate, as described by Keagle and Hartung (28).



Pyrrole Succinaldoxime Succindialdehyde

Using micro quantities of pyrrole, the expected 45% conversion to the intermediary dioxime was obtained. The purified dioxime was then converted to succindialdehyde, which was determined as the bis-dinitrophenylhydrazone. That the dioxime undergoes 90% conversion to the dialdehyde, as reported by Keagle and Hartung, was confirmed. When used in the Robinson condensation, the dioxime did not react to the same extent, as is shown in Table I. This difference in reactivity appears to account for the different yields reported by Keagle and Hartung (28) and by Werner *et al.* (3).

Because they obtained 90% conversion of succinaldoxime to the bis-dinitrophenylhydrazone of succindialdehyde, Keagle and Hartung assumed the same conversion to dialdehyde in the Robinson condensation.

Based on the calculated amount of aldehyde, 60% of theoretical tropanone yields were reported. Using the same method of calculation, the authors repeatedly confirmed the reported yields. In contrast, Werner *et al.* used a relatively large excess of dioxime and calculated tropanone yields on the basis of methylamine. Using the method of Werner and co-workers, the authors also obtained 70–75% tropanone yields from methylamine. Using 2,5-diethoxytetrahydrofuran as a source of succindialdehyde, and no excess of either reactant, 75% of theoretical tropanone yields were obtained. From these observations, it was concluded that an unpredictable excess of succinaldoxime is required in the Robinson condensation. Determination of the succindialdehyde as the bis-dinitrophenylhydrazone is not a reliable measure of the extent to which the oxime will react in the condensation.

TABLE I—COMPARISON OF TROPANONE AND SUCCINDIALDEHYDE YIELDS FROM PURIFIED SUCCINALDOXIME AND 2,5-DIETHOXYTETRAHYDROFURAN

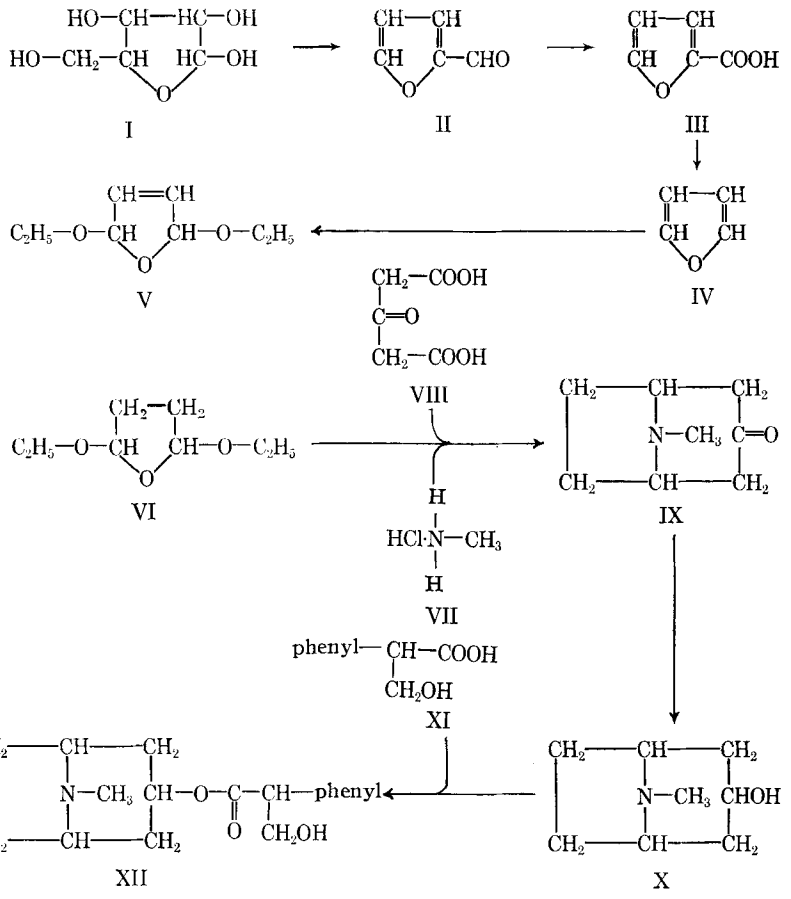
Source of Succindialdehyde	mmoles of Source Employed	Succindialdehyde[a] Yield, %	Tropanone[b] Yield, %
Succinaldoxime[c]	1.12	90 (89–91)	60 (58–62)
Succinaldoxime[d]	1.50	90 (89–92)	72 (70–75)
2,5-Diethoxytetrahydrofuran[e]	1.00	99.5 (99–100)	73 (70–75)
2,5-Diethoxytetrahydrofuran[e]	1.50	99.5 (99–100)	71 (68–74)
2,5-Diethoxytetrahydrofuran[e]	2.00	99.5 (99–100)	75 (74–77)

[a] Succindialdehyde was isolated and determined as the bis-dinitrophenylhydrazone, m.p. 278–279°. [b] Yields are tropanone, purified by microsublimation and melting at 41–43°; yields as the picrate, m.p. 220°, were 1–2% higher. [c] Tropanone yields based on calculated aldehyde production, as described by Keagle and Hartung (19); no excess of succinaldoxime. [d] Tropanone yields based on methylamine, using an excess of succinaldoxime, as described by Werner *et al.* (3). [e] Yields based on methylamine; equimolar quantities of methylamine, acetone dicarboxylic acid, and diethoxytetrahydrofuran were used in the Robinson condensation.

When the *N*-methyl carbon is to be labeled, poor conversion of pyrrole to the dioxime, the need to recrystallize this intermediate, and the requirement for an unpredictable excess of the purified oxime are disadvantages of little consequence. Circumstances are quite different if the resulting succindialdehyde is to be utilized as the instrument for ring labeling. The stated disadvantages then become a major concern and practically exclude pyrrole as a labeled precursor to radioactive succindialdehyde. As a result, 2,5-diethoxytetrahydrofuran was considered for use in the synthesis of labeled succindialdehyde.

Compared to pyrrole, the furan derivative proved to be a far superior source of succindialdehyde. Its use for this purpose has been reported in both chemical and patent literature, but it has not been used previously in the Robinson condensation, nor has the aldehyde been produced so simply as described in this communication. Most authors have hydrolyzed diethoxytetrahydrofuran with acid, in an atmosphere of nitrogen, and have removed the acid as the barium salt. Neither of these steps was necessary for use of this compound in the Robinson condensation. Direct conversion of the intermediate to succindialdehyde was effected by a very simple, rapid, *in situ* acid hydrolysis at room temperature. Derivatives of the resulting dialdehyde melted sharply and correctly without recrystallization. When used in the Robinson condensation, *in situ* hydrolysis obviated the need for isolation of an intermediate. No excess of diethoxytetrahydrofuran was required, the condensation proceeded smoothly, and reproducible 70–75% tropanone yields were obtained with 1 mmole or less of the aldehyde source.

The superiority of 2,5-diethoxytetrahydrofuran as a source of succindialdehyde led to development of the reaction sequence shown in Scheme I for its synthesis from commercially available labeled compounds.



Scheme I

For the proposed sequence, the steps from diethoxytetrahydrofuran (VI) to atropine (X) have been established by microsynthetic studies of the individual reactions (20). Diethoxytetrahydrofuran (VI) yields tropanone (IX) in 75% of theoretical quantities, conversion of tropanone to tropine (X) is essentially quantitative, and esterification of tropine with tropic acid (XI) produces atropine (XII) in 70–75% of theoretical yield. The predicted 49–53% yield of atropine from diethoxytetrahydrofuran has been confirmed repeatedly by microsynthesis of the alkaloid. Usefulness of the proposed method for labeling atropine therefore depends on the efficient conversion of arabinose to 2,5-diethoxytetrahydrofuran.

That arabinose (I) can be converted quantitatively to furaldehyde (II) was shown by Pervier and Gortner (22) during the development of a titrimetric assay for pentosans. Large volumes of distillate were required, but furaldehyde yields from either arabinose or xylose were quantitative. Bonner and Roth (33) prepared furaldehyde from xylose by essentially the same procedure, but did not isolate the intermediate furaldehyde. Direct oxidation with silver oxide gave 30% furoic acid (III), based on starting pentose. In contrast, Wagner and Simons (25) obtained "over 80%" furoic acid by permanganate oxidation of furaldehyde. Using the micro adaptations described under *Experimental*, the authors obtained 98% furaldehyde from arabinose and 83% furoic acid from furaldehyde. Observed and previously reported data are compared in Table II. These findings were confirmed by the direct conversion of micro quantities of arabinose to furoic acid. As shown in Table III, experimental yields were slightly below levels predicted from the individual steps. Based on these observations, the microsynthesis of furaldehyde (II) and furoic acid (III) from arabinose (I) was assumed to be practical. The efficiency of subsequent steps in the proposed sequence therefore became the key to tropine labeling.

For the conversion of furoic acid (III) to furan (IV), the catalytic decarboxylation of Wagner and Simons (25) was modified as described under *Experimental*. To determine efficiency of the conversion, micro quantities of furoic acid were decarboxylated, the product was trapped in glacial acetic acid, and the resulting solution assayed by a modification of Angelli's method (26). In parallel experiments, the acetic acid solution of furan was prepared directly from arabinose, then assayed. The data, shown in Tables II and III, confirm the findings of Wagner and Simons and establish the practicality of converting arabinose (I) to furan (IV).

The subsequent conversion of furan (IV) to the intermediate diethoxydihydrofuran (V) and to diethoxytetrahydrofuran (VI) was equally feasible.

TABLE II—COMPARISON OF OBSERVED AND REPORTED YIELDS FOR INDIVIDUAL STEPS IN THE CONVERSION OF ARABINOSE TO SUCCINDIALDEHYDE

Reaction	Ref.	Wt. of Starting Material	Yield for the Step Shown, %
Arabinose	[a]	500 mg.	98

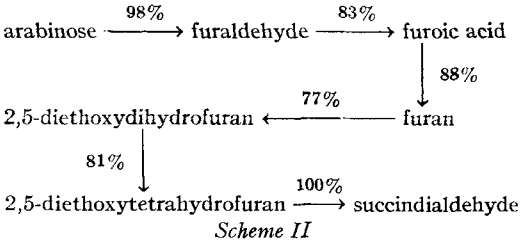
Tropanone	75	34	38
Tropine	98	33	34
Atropine	71–75	22–25	24

Yields for the individual steps were first determined with 5-Gm. quantities of furan and diethoxydihydrofuran. On isolation and purification of the dihydro compound, 77% of theoretical yields were obtained from furan. Conversion of the dihydro compound to the tetrahydro compound which was assayed by hydrolysis to succindialdehyde and isolation of the bis-dinitrophenylhydrazone, gave 81% of theoretical yields. In confirmatory, micro experiments furan was converted to diethoxytetrahydrofuran, without isolation of the intermediate. Yields for the direct conversion (70%) were higher than predicted from the individual steps (63%), a discrepancy that probably arose from losses during isolation and purification of the intermediate. Data for the conversion are in agreement with the findings of Fakstorp (27) and were confirmed by synthesis of 2,5-diethoxytetrahydrofuran from micro quantities of arabinose. The data, shown in Tables II and III, establish feasibility of these conversions and of the entire sequence from arabinose (I) to succindialdehyde. Establishment of this sequence simultaneously establishes the feasiblity of using labeled arabinose as an instrument for labeling tropine and the tropine moiety of atropine.

SUMMARY AND CONCLUSIONS

Previous work (20) has shown that the micro Robinson condensation is practical, that the reduction of tropanone to tropine is essentially quantitative, and that esterification of tropine with tropic acid gives 70–75% of theoretical atropine yields. In the present report, it has been shown that 2,5-diethoxytetrahydrofuran yields 75% tropanone when hydrolyzed *in situ*, employing a very simple procedure. Predicted yields of 49–53% atropine from 2,5-diethoxytetrahydrofuran have been confirmed by microsynthesis.

A reaction sequence for the production of diethoxytetrahydrofuran from arabinose has been proposed. Quantitative studies of each step in the sequence have yields for the individual steps shown in Scheme II.



Scheme II

Cumulative yields at each point in the sequence have confirmed yields for the individual steps. Validity of the sequence was finally established by the synthesis of 50% succindialdehyde and 37% tropine from arabinose. Additional verification was obtained by the synthesis of 26% atropine sulfate from 300-mg. quantities of arabinose.

Since arabinose-5-^{14}C and arabinose-UL-^{14}C are available commercially, the proposed sequence is a practical approach to the synthesis of tropine-1-^{14}C, tropine-1,5,6,7-^{14}C, and of atropines correspondingly labeled in the tropine moiety. Based on ^{14}C, 37% tropine and 26% atropine yields may be expected from arabinose-5-^{14}C, 29.6% labeled tropine and 20.8% labeled atropine from the uniformly labeled pentose. Expected yields of labeled furaldehydes, furoic acids, furans, and diethoxytetrahydrofurans can be calculated from the data presented and will vary, depending on which of the available pentoses is used and on whether one carbon of the uniformly labeled compound is lost during synthesis of the desired product.

Results of this investigation make available, for

the first time, a synthetic method for labeling the carbon skeleton of tropine, for synthesizing tropine-labeled atropine, and for synthesizing labeled intermediates between arabinose and tropine. Further studies will be published in the third paper of this series.

Model Catalysts Which Simulate Penicillinase II

Mechanism of Hydrolysis of Penicillins Catalyzed by Catechol

By MICHAEL A. SCHWARTZ and GERALD R. PFLUG

Studies have been made of the rates of loss of benzylpenicillin and methicillin from solutions containing catechol. The dependence upon pH of the specific rate constants for these hydrolyses catalyzed by monocatecholate ion is nonlinear, demonstrating the presence of metastable intermediates in the reaction pathway. The rates of penicillin loss at the higher pH's studied are faster than the rates of acid formation in the same systems indicating the presence of a covalent intermediate, probably catechol monopenicilloate. Analogy of this mechanism to that of hydrolyses of penicillins catalyzed by 3,6-bis(dimethylaminomethyl)catechol and by penicillinase is discussed.

IT WAS PREVIOUSLY reported that the compound 3,6-bis(dimethylaminomethyl)catechol (CDM) rapidly catalyzed the hydrolysis of penicillin to penicilloic acid (1). Pyrocatechol itself, as the monoanion, was also shown to be catalytic but at a much lower rate than CDM. Studies of the relationship between structure of the catalyst and its reactivity revealed that the catalytic efficiency of CDM was at least partly due to an ionic interaction between catalyst and substrate, similar to the type of interaction which might be expected in formation of an enzyme–substrate complex. It was speculated at that time that this reaction proceeded by covalent catalysis (2) to form a penicilloate ester of the catecholamine which would then be rapidly hydrolyzed to product, releasing free catalyst.

$$\text{penicillin} + \text{CDM} \rightarrow \text{ester} \rightarrow \text{penicilloic acid} + \text{CDM}$$

The above-mentioned studies were conducted by measuring the rate of acid production by means of a pH-stat. The presence of an ester intermediate might be demonstrated, however, by also following loss of penicillin. If the latter were more rapid than acid formation there would be no doubt as to the presence of an intermediate in the reaction pathway. The present report concerns the results of such studies in which pyrocatechol was utilized as the catalyst rather than CDM because it was felt that ester hydrolysis would be slower with pyrocatechol than with

CDM where the amino groups might accelerate the reaction by intramolecular general acid catalysis. As will be seen, the data provide evidence not only for an ester intermediate but also for metastable intermediates in the reaction pathway prior to ester formation

EXPERIMENTAL

Materials and Apparatus—Potassium benzylpenicillin and sodium methicillin were supplied by Bristol Laboratories. Pyrocatechol, mercuric chloride, and buffer ingredients were all reagent grade. pH measurements were made with the Radiometer TTT-1 meter in a glass cell thermostated at the temperature of the kinetic studies. The meter was standardized with both pH 6.83 and 9.18 buffers. The Hitachi Perkin-Elmer model 139 spectrophotometer was used in the penicillin assays and the Radiometer TTT-1 pH-stat with SBR-2C recorder used for measurement of acid formation rates.

Kinetic Studies—All the rate measurements were carried out at 31.5° at ionic strength 0.2 maintained by addition of sufficient potassium chloride to the reaction mixture. All solutions were prepared with water which had been freshly boiled and cooled under nitrogen and a nitrogen atmosphere was maintained throughout the rate measurements to minimize oxidation of catechol.

Rates of acid formation from penicillin in the presence of catechol were measured on the pH-stat as previously described (1).

Rates of penicillin loss were measured as follows. Catechol solution containing sufficient potassium chloride was placed in the reaction cell of the Radiometer pH-stat and allowed to come to bath temperature. The pH was adjusted to the desired value by addition of NaOH solution and the reaction was initiated by addition of a solution of the penicillin which had been kept at bath temperature. Samples were removed at appropriate intervals and transferred to a 0.2 *M* pH 2.7 glycine buffer containing 0.01 *M* mercuric chloride. After standing a specified time (80 min. for benzylpenicillin, 130 min. for methicillin), the absorbance was read at 322 mμ for benzylpenicillin or 328 mμ for methicillin. This assay for residual penicillin in solution has been described previously (3).

The rates of alkaline hydrolysis of the penicillins in absence of catechol were determined by following acid production rates on the pH-stat.

RESULTS

Figure 1 shows the typical first-order dependence of rate of penicillin loss upon concentration of benzylpenicillin at constant pH. Similar linear plots were obtained for methicillin. The rate constants ($k_{obs.}$) obtained from the slopes of these plots were corrected for alkaline hydrolysis of the penicillin and converted to specific rate constants for monocatecholate ion (k_c) by Eq. 1:

$$k_c = \frac{k_{obs.} - k_{OH}[OH^-]}{\frac{K_a[C]_t}{K_a + [H^+]}} \qquad \text{(Eq. 1)}$$

where $[C]_t$ is the total of all catechol species in the system and K_a is the dissociation constant of catechol. The data are tabulated in Table I. The pKa of catechol under the conditions of these experiments was 9.40. The alkaline hydrolysis rate constants (k_{OH}) were: benzylpenicillin 12.5 and methicillin 6.0 L. mole^{-1} min.$^{-1}$.

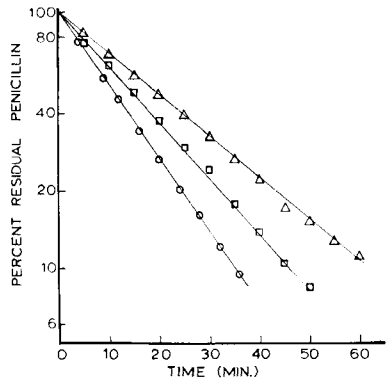

Fig. 1—First-order rate of loss of benzylpenicillin at various pH's. Catechol concentrations: O, *0.0435* M, *pH 9.15;* □, *0.0174* M, *pH 9.50;* △, *0.0087* M, *pH 10.0.*

At a single pH the observed first-order rate constants were found to be directly proportional to catechol concentration as shown in Fig. 2.

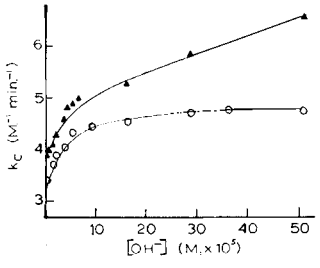

Fig. 3—Dependence of k_C *upon hydroxyl-ion concentration. Curves were fitted to Eqs. 2 and 3 for benzylpenicillin and methicillin, respectively. The points are the values determined experimentally. Key: ▲, benzylpenicillin; ○, methicillin.*

It was found that the values of k_c determined from rate of penicillin loss were not constant over the pH range studied, but varied as shown in Fig. 3.

In the case of benzylpenicillin the data were fitted to a curve of the form of Eq. 2:

$$k_c = \frac{a + b\,[OH^-] + c\,[OH^-]^2}{d + [OH^-]} \qquad \text{(Eq. 2)}$$

where a, b, c, and d are constants. For methicillin the data were fitted to Eq. 3:

$$k_c = \frac{a + b(OH^-)}{d + (OH^-)} \qquad \text{(Eq. 3)}$$

The curves in Fig. 3 were constructed from the values of the constants given in Table II, while the points are the actual values obtained experimentally. In both cases when (OH^-) is zero, $k_c = a/d$, whereas at high (OH^-):

benzylpenicillin: $k_c = b + c(OH^-)$
methicillin: $k_c = b$

The rates of acid formation were apparently first order and rate constants $k_{obs.}$ were determined from Guggenheim plots of the data. These values are given in Table III.

DISCUSSION

The specific rate constants (k_c) for loss of benzylpenicillin from solution, catalyzed by monocatecholate ion, are not independent of hydroxyl-ion concentration. This variation from a high degree of dependence at pH below 9.5 to only slight dependence at higher alkalinity is indicative of a change in mechanism of the reaction with increasing pH.

When (OH^-) = 0 the rate expression is:

$$\text{rate} = \frac{a\,(P)(C^-)}{d} \qquad \text{(Eq. 4)}$$

which is the typical expression for nucleophilic catalysis by (C^-).

At high [OH^-] the rate expression becomes:

$$\text{rate} = b\,[P][C^-] + c\,[P][C^-][OH^-] \qquad \text{(Eq. 5)}$$

Equation 5 contains terms showing both nucleophilic catalysis by monocatecholate ion and by dicatecholate ion. The second term could alternatively be attributed to specific base-catalyzed

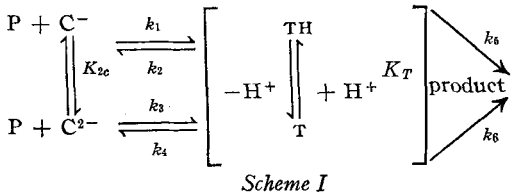
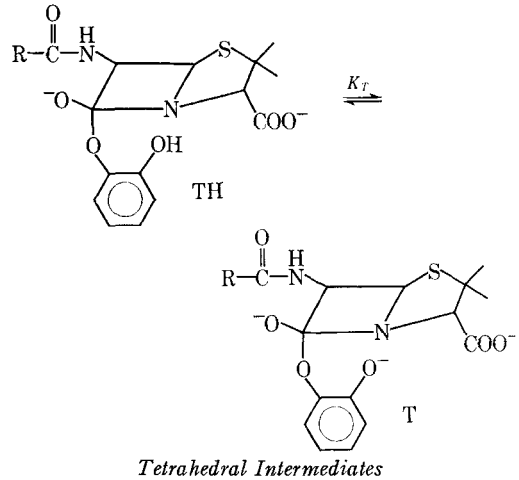
[a] Initial penicillin concentration was 0.02 M.

nucleophilic attack by monocatecholate ion, which is kinetically equivalent. At intermediate hydroxyl-ion concentrations a complex expression holds. This situation can only occur with the involvement of intermediates which are in acid-base equilibrium (4).

Such a mechanism is shown in Scheme I. C^{2-} represents dicatecholate ion, K_{2c} the second dissociation constant of catechol, and TH and T represent tetrahedral addition intermediates formed by nucleophilic attack of the catecholate ions on the penicillin.[1] These intermediates are depicted in Scheme II. The dissociation constant for TH is represented by K_T.



Scheme I



Tetrahedral Intermediates
Scheme II

Taking a steady state in both TH and T, since these would be metastable intermediates, gives the following expression for k_c:[2]

$$\frac{\text{rate}}{[P][C^-]} = k_c = \frac{\frac{k_1k_5K_w}{(k_4 + k_6)K_T} + \frac{k_1k_6K_T + k_3k_5K_{2c}}{(k_4 + k_6)K_T}[OH^-] + \frac{k_3k_6K_{2c}}{(k_4 + k_6)K_w}[OH^-]^2}{\frac{(k_2 + k_5)K_w}{(k_4 + k_6)K_T} + [OH^-]} \quad \text{(Eq. 6)}$$

This equation is the same form as Eq. 2 showing that this mechanism fits the experimental data.

In the case of methicillin there is a plateau reached above pH 9.5 where k_c becomes independent of hydroxyl-ion concentration. This would occur if the pathway through dicatecholate ion were not contributing significantly to the over-all reaction. If k_3 and k_4 are both set equal to zero, Eq. 6 becomes:

$$k_c = \frac{\frac{k_1k_5K_w}{k_6K_T} + k_1[OH^-]}{\frac{(k_2 + k_5)K_w}{k_6K_T} + [OH^-]} \quad \text{(Eq. 7)}$$

which is of the form of Eq. 3 to which the data for methicillin were fitted. From Eq. 7 it can be seen that when $[OH^-] = 0$:

$$k_c = \frac{k_1k_5}{k_2 + k_5}$$

and when $[OH^-]$ is high:

$$k_c = k_1$$

For methicillin k_1 equals 4.9 L. mole^{-1} min.$^{-1}$ and therefore:

$$\frac{k_5}{k_2 + k_5} = 0.7 \text{ or } k_5 = 2.3\ k_2$$

It is difficult at this time to explain the differences in reactivity toward dicatecholate ion shown by benzylpenicillin and methicillin. The latter, judging from its lower rate of reaction with hydroxyl ion in the absence of catechol, is generally less susceptible to nucleophilic attack and this difference may be sufficient to obscure any contribution made by dicatecholate ion in the pH range studied.

For both penicillins the apparent first-order rate constants for acid formation at the higher pH values are lower than those for penicillin loss at the same catechol concentration. This is a clear indication of a buildup of a covalent intermediate in the reaction pathway.

This intermediate is apparently the monopenicilloate ester of catechol. Thus, the over-all reaction scheme at one pH may be depicted as:

$$P + C^- \xrightarrow{k_1'} \text{ester} \xrightarrow{k_2'} \text{product} + C^-$$

It is quite difficult to determine the values of k_2' from the present data because the concentration of intermediate ester must be determined by difference. Thus, small errors in the amount of acid formed and residual penicillin could lead to large errors in ester concentration. Approximate values of k_2' were determined nevertheless, from the maxima in plots of ester concentration *versus* time. At the time when the concentration of intermediate ester is maximal:

$$k_1'[P] = k_2'[E]$$

The values of k_2' thus calculated were found to be fairly constant for both penicillins in the pH range 9.5–10.5. For methicillin the values were about 0.2 min.$^{-1}$ and for benzylpenicillin about 0.4 min.$^{-1}$.

It has been shown that the rates of hydrolysis of catechol monobenzoate (5) and catechol monoacetate (6) depend on the concentration of anion, and the rapid rates of these hydrolyses are attributable to intramolecular general base catalysis by the *ortho*-hydroxyl ion.

In the two reactions cited the rates were almost constant at pH values where all of the *ortho*-hydroxyl group was ionized. The pKa of the acetate and

[1] Attempts were made to find other mechanisms which would fit the experimental data, but none could be found.
[2] See *Appendix* for derivation of Eq. 6.

benzoate esters were 8.56 and 8.70, respectively, and the pKa of the penicilloate ester is therefore probably in the range 8.5–9.0. Thus, it would be expected that its rate of hydrolysis above pH 9.5 would become almost independent of pH as has been observed experimentally.

The ratio of k_2' for benzylpenicillin to that for methicillin is about 2 which is the same as the ratio of the k_{OH} values. The difference probably reflects the effect of the side chain on the susceptibility to nucleophilic attack of the β-lactam carbonyl. A similar mechanism has been proposed for the catechol-catalyzed hydrolysis of phenyl chloroacetate (7). Here it was shown that catechol monochloroacetate hydrolyzed much faster than phenyl chloroacetate, implicating the catechol monoester as a reaction intermediate.

In the catalysis of hydrolysis of benzylpenicillin by CDM it was shown (1) that one of the charged amino groups was responsible for binding the penicillin through ionic interaction with the carboxylate ion on the latter. The role of the other amino group, which apparently participated in the reaction, was not as clear. If the mechanism of hydrolysis catalyzed by catechol may be extrapolated to the situation with CDM, then there are revealed several possible functions for this second amino group. It may act to polarize the carbonyl group of the β-lactam increasing the susceptibility of the latter to nucleophilic attack by the adjacent hydroxyl ion. The amino function may also interact with the negatively charged oxygen of the tetrahedral intermediate thus stabilizing the latter relative to the reactants. Each of these actions would increase the rate of formation of ester relative to that observed with catechol. The amino group in all probability would also enhance the rate of hydrolysis of the ester by intramolecular hydrogen bonding to the ester carbonyl as has been shown in the hydrolysis of tertiary aminoalkyl acetates (8).

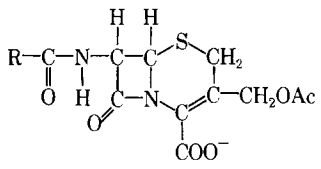
ANALOGY TO PENICILLINASE

The mechanism of action of the enzyme penicillinase and the nature of the functional groups involved in its active site are not known (9). Some speculation on these problems may, however, be based on consideration of the mechanism of hydrolysis of penicillins catalyzed by catechol and the aminocatechol derivatives previously reported (1).

While it would not be expected that catecholamines or even catechol groups will be found in the active site of the enzyme it would seem likely that a combination of nucleophilic and electrophilic (general acid) functions, located so as to act in concerted fashion could be responsible for its catalytic action. The binding of substrate to the enzyme is probably partly due to an ionic interaction between the carboxylate ion of the penicillin and a positively charged group in the active site of the enzyme. It has been shown that conversion of the carboxyl group to carboxamide decreases its susceptibility to enzymic hydrolysis (10, 11). Also, evidence for the presence of a positively charged group on the enzyme active site has been presented (12).

It has been shown that some penicillins resistant to the enzyme (such as methicillin) are competitive inhibitors of benzylpenicillin (13, 14) and activity is recovered only very slowly. In the light of the mechanism of catalysis of benzylpenicillin by catechol it may be that the competitive inhibition is due to a covalent compound formed by acylation of the enzyme by methicillin, analogous to the catechol ester. If the rate of hydrolysis of the "methicilloyl-enzyme" were slow, then the slow recovery of enzymic activity would be explained. In the catechol ester the adjacent groups which assist hydrolysis are fixed in position. In the penicilloyl-enzyme this need not be so and the side chain may cause conformational changes as a result of which the groups catalyzing deacylation may be shifted to a position in which they can no longer influence hydrolysis rate.

One further point meriting attention is the difference in enzymic activity toward penicillins and cephalosporins (15). The cephalosporins are generally resistant to hydrolysis by penicillinase and are also relatively resistant to hydrolysis catalyzed by CDM as shown by preliminary studies in this laboratory. It can be readily seen with molecular models that in the cephalosporins the steric relationship between the carboxylate ion and the β-lactam carbonyl is quite different from that of the pencillins. Thus, even though CDM may associate with the cephalosporins by ionic interaction, the nucleophilic hydroxyl ion would not be in an optimum position to exert its catalytic action. This argument may account for the simultaneous lack of catalytic activity on cephalosporins by penicillinase and the observed competitive inhibition of the enzyme by these compounds (15).



Cephalosporins

Derivation of Eq. 6

$$\text{rate} = \frac{d\,(\text{product})}{dt} = k_5\,[\text{TH}] + k_6[\text{T}]$$

$$\text{TH} = \frac{[\text{H}^+]}{K_T + [\text{H}^+]}\,[\text{T}]_T;\quad \text{T} = \frac{K_T}{K_T + [\text{H}^+]}\,[\text{T}]_T$$

where $[\text{T}]_T$ represents [TH] + [T]

$$\text{rate} = \frac{k_5\,[\text{H}^+] + k_6K_T}{K_T + [\text{H}^+]}\,[\text{T}]_T$$

$$\frac{d\,[\text{T}]_T}{d_t} = k_1\,[\text{P}][\text{C}^-] + k_3\,[\text{P}][\text{C}^{2-}] -$$

$$[k_2 + k_5]\,[\text{TH}] - [k_4 + k_6][\text{T}] = 0 =$$

$$k_1\,[\text{P}][\text{C}^-] + \frac{k_3K_{2C}\,[\text{P}][\text{C}^-]}{\text{H}^+} -$$

$$\frac{(k_2 + k_5)\,[\text{H}^+] - [k_4 + k_6]\,K_T}{K_T + [\text{H}^+]}\,[\text{T}]_T$$

$$\text{T}_T = \frac{\left[k_1 + \frac{k_3K_{2C}}{[\text{H}^+]}\right][K_T + \text{H}^+]\,[\text{P}][\text{C}^-]}{(k_2 + k_5)\,[\text{H}^+] + (k_4 + k_6)\,K_T}$$

$$\text{rate} = \left\{\frac{k_1k_5\,[\text{H}^+] + k_1k_6K_T + k_3k_5K_{2c} + \frac{k_3k_6K_TK_{2c}}{[\text{H}^+]}}{(k_2 + k_5)\,[\text{H}^+] + (k_4 + k_6)\,K_T}\right\} \times [\text{P}][\text{C}^-]$$

Substituting $K_w/[OH^-]$ for $[H^+]$ and dividing numerator and denominator by $(k_4 + k_6)K_T$:

$$\frac{\text{rate}}{[P][C^-]} = \frac{\frac{k_1k_5K_w}{(k_4 + k_6)K_T} + \frac{k_1k_6K_T + k_3k_5K_{2c}}{(k_4 + k_6)K_T}[OH^-] + \frac{k_3k_6K_{2c}}{(k_4 + k_6)K_w}[OH^-]^2}{\frac{(k_2 + k_5)K_w}{(k_4 + k_6)K_T} + [OH^-]}$$

Bactericidal Properties of Straight-Chained Alkyltrimethylammonium Bromides in a Simple Emulsion System

By THOMAS L. WELSH, GEORGE C. HOSS, BLAZE T. PALERMO, and ALLEN I. DINES*

The individual constituents of the potent bactericidal agent cetrimide B.P. are among those alkyltrimethylammonium bromides (C_8 through C_{18}). which have been synthesized by classical methods. Each of these quaternary compounds was then emulsified with six (C_8 through C_{18}) fatty alcohols. The bactericidal properties of these emulsions are compared by the critical killing dilution method. When emulsified, only the C_{12} and C_{14} quaternary compounds exhibited any appreciable bactericidal action. All of the quaternary compounds in the series are inactivated when emulsified with myristyl alcohol.

THE OFFICIAL COMPOSITION of the quaternary ammonium bactericidal agent cetrimide B.P. has gradually changed over the last decade (1–3). Other investigators (4, 5) have recorded significant effects on their studies brought about by these changes.

Similar effects were noted in this laboratory during *in vitro* bactericidal testing of an experimental product. This product, a medicated cream, was an oil-in-water emulsion which utilized cetrimide B.P. as its bactericidal agent. The disperse phase was comprised mainly of stearyl alcohol.

The erratic bactericidal results were discovered to have been caused by a shift in the predominant constituent in the cetrimide utilized. Cetrimide conforming to the 1963 B.P. monograph, *i.e.*, "comprised mainly of tetradecyltrimethylammonium bromide . . ." afforded excellent bactericidal activity. Cetrimide which conformed to the 1953 B.P. monograph, *i.e.*, "comprised mainly of hexadecyltrimethylammonium bromide . . ." was completely inactive in the product. Some anomalous bactericidal results were also obtained when alcohols other than stearyl were introduced into the formula.

The present study was initiated to determine: (*a*) the bactericidal properties of the component compounds which comprise cetrimide when they are incorporated into a simple emulsion system, and (*b*) if a pattern of relationship can be deter-

mined among these constituents when fatty alcohols of varying chain lengths are used as the oil phase in the emulsion.

EXPERIMENTAL

Preparation of the Alkyltrimethylammonium Bromides—Straight-chained alkyltrimethylammonium bromides from C_8 to C_{18} were synthesized by classical methods (6). High purity synthetic fatty alcohols were used as starting materials.[1] The preparation of *n*-dodecyltrimethylammonium bromide is cited below for illustrative purposes.

In a 1-L. three-neck flask containing 102.3 Gm. (0.55 mole) of *n*-dodecyl alcohol, 62 Gm. (34 ml.) of concentrated sulfuric acid was slowly added along with 240 Gm. (1.4 moles) of 48% hydrobromic acid. This mixture was refluxed 7 hr. and allowed to cool to room temperature overnight. The mixture was diluted with 400 ml. water, then filtered through a sintered-glass funnel. The organic layer was separated mechanically and then was successively washed with 75-ml. portions of concentrated sulfuric acid, water, and 10% sodium carbonate solution. It was then dried over calcium chloride. The yield was 81 Gm.

The *n*-dodecylbromide, 81 Gm. (0.32 mole), was dissolved in 150 ml. dry acetone and 100 ml. of a 20% w/w solution of trimethylamine (0.33 mole) in dry acetone was added. After about 20 min. the crystalline *n*-dodecyltrimethylammonium bromide began to form. The crystals were collected after 5 hr., washed with dry acetone, dried, and weighed. The yield was 60 Gm. (60% of theory).

Recrystallization of the quaternary compounds with acetone A.R. resulted in products of excellent purity. The physical constants of these compounds are listed in Table I.

Establishment of the Critical Killing Dilution of the Quaternary Compounds in Solution—The complete technique for establishment of the critical killing dilution is outlined in the Association of Official Agricultural Chemists, Official Methods of Analysis (7). An excellent review of the method is offered by Reddish (8).

[1] These ethylene condensation compounds were generously supplied by the Continental Oil Co., Petroleum Chemicals Department, Ponca City, Okla., as Alfols 8 through 18.

Preparation of the 15% o/w Emulsion System Containing 0.5% Quaternary Compound—Each of the six quaternary compounds (C_8 through C_{18}) was emulsified with each of the six corresponding fatty alcohols (C_8 through C_{18}) in the following manner. The alkyltrimethylammonium bromide (0.5 Gm.) was dissolved in water (84.5 ml.) and heated on a water bath to 65°. The fatty alcohol (15.0 Gm.) was heated in a 250-ml. conical flask to 65°. The aqueous solution was then added to the alcohol and the flask was agitated for 5 min. on a wrist shaker. The emulsion was allowed to return to room temperature (about 1 hr.) and its physical appearance noted. These emulsions were left at ambient laboratory conditions and were examined after 24 hr. and again after 30 days for physical appearance.

Establishment of the Critical Killing Dilution for the Emulsions—To test the emulsions, the following modifications from the AOAC method (as cited above) are introduced. A 3.33% dilution of the emulsion is made in a glass-stoppered cylinder. Care is taken to insure that there is adequate uniform dispersion of the emulsion droplets throughout this system. Further dilutions are made from this stock solution. Five milliliters of the desired dilution is inoculated with the test organism. At time intervals of 5, 10, 15, and 20 min. a loopful of the seeded emulsion solution is withdrawn and subcultured in a nutrient broth. The subcultures are incubated at 37° for 48 hr. and examined macroscopically for growth. A standardized 5% phenol solution is used as a control to validate the results.

RESULTS AND DISCUSSION

The bactericidal properties, in solution, of the alkyltrimethylammonium bromides which were prepared from synthetic alcohols as well as those made from naturally occurring alcohols (9, 10) are summarized in Table I. In general, it can be seen that the same over-all pattern of CKD's has been manifested. Because strains of bacteria exhibit varying resistance in tests such as these, it is not possible to say if there has been a significant improvement in bactericidal action due to the purity of the starting materials. The values obtained, particularly those for the C_{18} homolog, are somewhat higher than the literature values against the Gram-negative *S. typhosa*.

References to the behavior of cetrimide or its con-

stituent compounds in emulsion systems are somewhat limited. Christenson and Shelton (11) reported inactivation of cetyltrimethylammonium bromide (CTAB) by various grades of lanolin in some pectin lotions. They also reported that any additions to the oil phase, such as glyceryl monostearate, glyceryl monooleate, or vegetable oils, increased the killing time of the lotion. Prusak and Mattocks (12) reported inactivation of CTAB by hydrophilic ointment U.S.P. and hydrophilic petrolatum U.S.P. Of the 6 ointment bases which they studied, only a Carbowax ointment and pectin paste N.F. appeared suitable to obtain bactericidal action with CTAB. Davies (13) noted that a fatty glycol ethylene oxide condensate neutralized the bacteriostatic effect of CTAB. Frank and Stark (14) found cetrimide to be completely inactivated in hydrous emulsifying ointment B.P.

Thirty-six 15% o/w emulsions with the quaternary compound present at 0.5% were prepared and were tested for bactericidal action by a modification of the AOAC phenol coefficient test. This test establishes the critical killing dilution (CKD) (that is, the maximum dilution which will kill a specified organism in 10 min. but not in 5). Any emulsion which achieved complete kill against *S. aureus* at a dilution of 1 to 30 or greater was then tested against the Gram-negative *Ps. aeruginosa*. Emulsions which failed to kill *S. aureus* at 1 to 30 were assessed as having no appreciable bactericidal activity. The critical killing dilutions for this series of emulsions are shown in Table II. Also shown in this table are the pharmaceutical properties of these emulsions based on their physical appearance.

None of the emulsions made with the C_8 and C_{10} quaternary compounds met the 1 to 30 criterion for bactericidal activity. This is not surprising in view of their relatively weak bactericidal action in aqueous solution. Because of poor physical stability, none of these emulsions were acceptable from a pharmaceutical standpoint. However, all of the emulsions made with the C_{12} and C_{14} quaternary compounds had CKD's of at least 1 to 30 with the exception of those made with myristyl alcohol. The C_{12} emulsions exhibited surprising strength against the very resistant Gram-negative *Ps. aeruginosa*.

The inactivation of these compounds by myristyl alcohol is, as yet, unexplained. Emulsions have been made with three other commercial sources of this alcohol, all of which inactivate these quaternary compounds.

Table II also shows that cetyltrimethylammonium bromide, by far the most active of the series in aqueous solution, was completely inactivated in this system; except when combined with the C_8 alcohol. This activity is attributed to the fact that more of the quaternary compound is in the aqueous phase be-

cause of the relatively poor emulsion. The C_{18} analog parallels the C_{16} closely. Emulsions in these series have superior pharmaceutical properties and yet are inactive from a bactericidal standpoint.

Because emulsions made wih the C_8 alcohol did exhibit satisfactory bactericidal activity, although they were not pharmaceutically stable, a series of emulsions was made utilizing 7.5% of the C_8 alcohol and 7.5% of the C_{16} alcohol. It was postulated that they could have an acceptable bactericidal level as well as pharmaceutical stability. The CKD's for this series of emulsions are shown in Table III. Bactericidal activity is again found to be restricted to the C_{12} and C_{14} quaternary compounds. The C_{12} compound again shows its effectiveness against *Pseudomonas*. The C_{16} and C_{18} compounds again are inactivated in this system.

SUMMARY

Six straight-chained (C_8 to C_{18}) alkyltrimethylammonium bromides have been synthesized by classical methods, utilizing high purity synthetic alcohols as starting materials. Among these compounds are the individual constituents which comprise the bactericidal agent cetrimide B.P. The critical killing dilutions of these compounds, in solution, are comparable to those obtained from compounds prepared from naturally occurring alcohols. These quaternary compounds were then used as the emulsifying agent in a model oil-in-water system. Thirty-six emulsions were prepared and evaluated for bactericidal properties by the critical killing dilution method against *S. aureus* and *Ps. aeruginosa*. The results indicate that in addition to their poor bactericidal activity, the C_8 and C_{10} quaternary compounds lack the power to emulsify any of the alcohols in the selected system. The C_{12} and C_{14} quaternary compounds exhibit the greatest bactericidal activity. The C_{16} and C_{18} quaternary compounds are virtually inactivated by incorporation into this system. Emulsification with myristyl alcohol inactivates all of the quaternary compounds in this series.

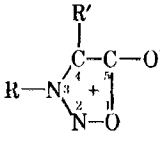
Solvolysis of 3,4-Dialkyl Sydnones

By EDWARD R. GARRETT and PARIMAL J. MEHTA

The kinetics of solvolysis of various dialkyl sydnones: 3-*tert*-butyl-4-methyl, 3-*n*-propyl-4-ethyl, 3-ethyl-4-methyl, 3-isopropyl-4-ethyl, 3-*n*-propyl-4-methyl, and 3-*n*-propyl-4-*n*-butyl sydnone, have been studied spectrophotometrically as a function of HCl and NaOH concentrations, pH, and temperature. The reactivity on acid-catalyzed solvolysis decreased in the order cited with only the first compound exhibiting pH-independent solvolysis and high reactivity, about 600 times that of the others. The reactivities of the remainder were only over a threefold range. The order of reactivity tended to reverse on alkaline solvolysis within a similar range, where 3-ethyl-4-methylsydnone was 1.7 times more reactive than the equally reactive 3-*n*-propyl-4-ethyl, 3-*n*-propyl-4-methyl, and 3-isopropyl-4-ethyl sydnones. The 3-*n*-propyl-4-*n*-butylsydnone was half as reactive as this group, whereas the 3-*tert*-butyl-4-methylsydnone was one quarter as reactive. The presence of α-hydrogens on the alkyl substituted sydnones tends to stabilize such structures against hydrogen ion and water attack. This can be explained by postulating extended equilibria among tautomeric structures which decrease the effective concentration of the reactive intermediate. The 3-benzylsydnone demonstrates a reactivity to hydroxyl ion attack equivalent to the more reactive furfuryl sydnone where the electron-attracting powers of the rings are not completely inhibited by the intervening methylene groups. The acid-catalyzed solvolysis of 3-benzylsydnone is of the order of magnitude of other 3-alkyl sydnones with α-hydrogens. The observed second-order dependency of reactivity on hydrogen ion concentration may be assigned to the delocalization of the charge of the singly protonated species, due to the probability of many mesomeric forms with the benzyl substituent.

THE MESOIONIC SYDNONES are of interest because of their unique structure and properties (1–3). In common with other mesoionic systems they may be potential medicinal agents (2–7). Some sydnones possess fungicidal (4) and ascaricidal (5) properties. Others have effects on the central nervous system (6) and show antitumor activity (7–9).

The sydnones have a small, planar, heterocyclic ring system and an aromatic character. They are highly polarized with relatively high dipole moments. Yet they are electrically neutral and have no apparent potentiometric or spectrophotometric pKa values (1–3). The sydnones cannot be represented by a single covalent structure. Suitable symbolism is as a hybrid of a large number of mesomeric structures such as I (1).



I

They also possess a relatively high lipid solubility for such polar molecules (3). The sydnones are thus interesting model compounds to gain insight into the solvolytic mechanisms of mesoionic compounds or the transport of dipolar molecules across biological membranes.

The sydnones are prepared by cyclodehydration of a properly substituted *N*-nitrosoglycine (1–3, 10, 11). Alkaline hydrolysis results in formation of the starting *N*-nitrosoglycine. Acid hydrolysis gives a substituted hydrazine, a carboxylic acid, and carbon dioxide (1–3, 10, 11). The solvolytic stability of the sydnone ring has been shown to depend significantly on the nature of the substituents in the 3-position in the ring (12) in contrast to previous statements (11). Electron donating 4-substituents are said to cause an instability in the sydnone ring, but the need for further work has been stated (2).

The present work was undertaken to obtain further evidence to improve understanding of the solvolytic processes in the sydnone series. In particular, the effects of alkyl 4-substituents which should have greater electron-donating properties than hydrogen are investigated to compare the results with those obtained for relevant 3-alkyl sydnones. The hydrolysis of 3-benzylsydnone was also studied to gain insight as to the possible reasons for the anomalous solvolytic behavior of 3-furfurylsydnone (12) which is similar in structure.

EXPERIMENTAL

Materials and Apparatus—The synthesis and characterization of the sydnones studied here have been reported previously by Kier and Dhawan (13), who also prepared the 3-benzylsydnone by methods in the literature (14). The compounds were stored

Received May 25, 1967, from the College of Pharmacy, University of Florida, Gainesville, FL 32601

Accepted for publication August 2, 1967.

Presented in part to the Basic Pharmaceutics Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

This investigation was supported by grant GM-09864-03,04,05 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

The authors thank Drs. L. B. Kier and D. Dhawan for the supplies of sydnones studied.

in a vacuum desiccator in a refrigerator. All other chemicals used were of analytical reagent grade. Nitrogen-purged, glass-distilled water was used to make up all solutions. Spectrophotometric readings were taken on the Beckman model DU spectrophotometer. Spectra were recorded on the Cary model 15 recording spectrophotometer. Matched quartz cells (1.00 cm.) were used for all measurements and a slit width of 0.10 mm. employed. Acid and alkali solutions were standardized using the Sargent recording titrator model D. The pH values at the temperatures of study were calculated from activity coefficient data available in the literature (15) or extrapolated from those values. Ionic strengths of all other buffer solutions were adjusted to 0.10. The pH of these buffers was measured at the temperature of study by a Beckman model G pH meter. Constant-temperature baths were maintained to within ± 0.1° of the temperature of study. The sydnones studied and the absorptivities at the wavelengths of their maximum spectrophotometric absorbances are listed in Table I.

Kinetic Procedures—The general procedure was to dissolve a sydnone, 2.0×10^{-4} moles, in a few drops of ethanol and to make up the volume to 200 ml. with distilled water. This 10^{-3} *M* master solution was used for kinetic runs in acidic and alkaline media. In a typical case, 10 ml. of the master solution was pipeted into a 100-ml. volumetric flask containing 80 ml. of 1.0 *M* hydrochloric acid solution maintained at 80°. The volume was brought to mark with distilled water maintained at the same temperature to give a 10^{-4} *M* sydnone in 0.80 *M* hydrochloric acid at 80°.

In the acetate and phosphate buffers, a weighed amount of sydnone to obtain a 10^{-4} *M* solution was dissolved with the aid of a few drops of ethanol and the volume brought to 100 ml. with the appropriate buffer solution maintained at the temperature of study.

The wavelengths of maximum absorbance of these sydnones in aqueous solution were between 284 and 292 mμ (ε 6,000 to 8,000) in acidic, neutral, and alkaline solutions (Table I). The wavelengths of maximum absorbance and the magnitude of absorbance did not show any significant change with pH.

The absorbance at the wavelength of maximum absorbance decreased with time in each case. The decrease was followed by withdrawal of samples at intervals of time, cooling rapidly to room temperature, and reading against an appropriate blank until the residual absorbance, A_∞, remained constant or asymptotically approached zero.

In all cases, except with the 3-*tert*-butyl-4-methylsydnone, a spectrophotometric absorbance assignable to the corresponding *N*-nitrosoglycine was found to increase concomitantly at a shorter wavelength (about 240 mμ) and strongly indicated a 1:1 transformation.

No such band assignable to an alkyl substituted *N*-nitrosoglycine appeared during the hydrolysis of 3-*tert*-butyl-4-methylsydnone in sodium hydroxide, or for all the sydnones in hydrochloric acid, acetate, and phosphate buffers. Typical spectral curves are given in Fig. 1 for the alkali-catalyzed hydrolysis of 3-benzylsydnone.

Thin-Layer Chromatography—The degradation in 0.8 *M* HCl of 10^{-2} *M* solutions of 3-benzylsydnone at 80° was followed by thin-layer chromatography. A small volume of reaction mixture was brought to pH 6–7 and 20 mm.[3] of the neutralized solution was applied on a thin-layer chromatography (TLC) plate. The TLC plates were prepared to obtain 0.4-mm. thick layers of Silica Gel GF_{254} containing phosphor indicator (catalog No. 7730, Brinkmann Institute, Westbury, N. Y.). The chromatograms were developed in *n*-butanol–acetic acid–water (4:1:5) system until the solvent front reached a height of 10 cm. They were then dried and the resulting separation observed under a short wavelength ultraviolet lamp. The relative positions of the spots were noted. For control purposes, 10^{-2} *M* solutions of the benzylsydnone and benzyl hydrazine (Aldrich Chemical Co., Milwaukee, Wis.) were also spotted on the TLC plate.

TABLE I—3R, 4R′ DIALKYLSYDNONES USED IN THE PRESENT INVESTIGATION

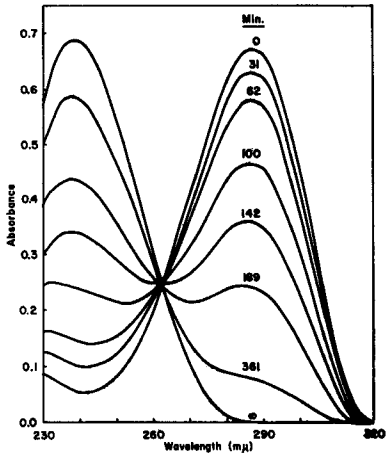

Fig. 1—Spectrophotometric absorbance curves for the solvolysis in 0.25 N *NaOH of 3-benzylsydnone* (10^{-4} M) *at 70.0°.*

RESULTS

Rate Constants—The apparent first-order rate constants, *k*, were calculated from the slopes of the plots of the logarithm of the difference in the absorbance *A* at time *t* and the final absorbance A_∞ against time according to:

$$\log (A - A_\infty) = \log A_0 - kt/2.303 \quad \text{(Eq. 1)}$$

where A_0 is the absorbance at zero time. Typical first-order fits obtained are shown for the acid-catalyzed hydrolysis of 3-*n*-propyl-4-methylsydnone in Fig. 2.

The conditions and rate constants for the apparent

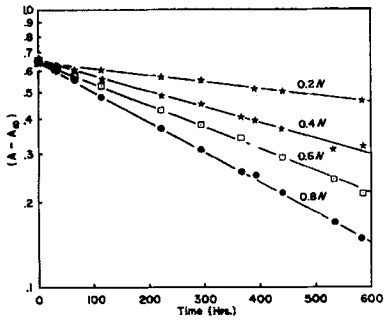

Fig. 2—Typical first-order plots at several [HCl] for the loss of the 284 mμ absorbance (A) *by acid-catalyzed solvolysis of 3-n-propyl-4-methylsydnone at 80.0°. The A_∞ value is the residual absorbance at infinite time.*

first-order acid- and alkali-catalyzed degradations of the sydnones studied are given in Tables II and III. The only compound showing pH-independent hydrolysis was 3-*tert*-butyl-4-methylsydnone (75°; pH 4.53, acetate buffer, $k_0 = 2.03 \times 10^{-5}$ sec.$^{-1}$; pH 5.83, phosphate buffer, $k_0 = 2.10 \times 10^{-5}$ sec.$^{-1}$; pH 7.82, phosphate buffer, $k_0 = 2.12 \times 10^{-5}$ sec.$^{-1}$). Catalysis by the buffer species was found to be absent (75°; pH 6.75, phosphate buffer in buffer strength 25% to 100% with a maintained ionic strength of 0.1, $k_0 = 1.95$ to 2.02×10^{-5} sec.$^{-1}$).

Dependence of Rate on the Catalytic Species—The dependence of the apparent first-order rate constants on the catalytic species is defined for specific alkali catalysis by:

$$k = k_{NaOH}[NaOH] + k_0 \qquad \text{(Eq. 2)}$$

where k is the apparent first-order rate constant, and k_0 is the apparent first-order rate constant for pH-independent hydrolysis. Plots of k against [NaOH] should give straight lines with slopes k_{NaOH}, the bimolecular rate constant for the NaOH-catalyzed hydrolysis where the k_0 values are the intercepts of such plots. The k_{NaOH} and k_0 values are given in Table IV.

The dependence of k on hydrochloric acid is defined by:

$$k = k_{HCl}[HCl] + k_0 \qquad \text{(Eq. 3)}$$

where k_{HCl}, the bimolecular rate constant for the HCl catalyzed hydrolysis is obtained from the slopes of the plots of k against [HCl] and k_0, the pH-independent apparent first-order rate constant, is obtained from the intercepts. The k_{HCl} and k_0 values are given in Table V. Examples of these plots are given in Figs. 3 and 4 where nonzero intercepts of Fig. 3 demonstrate the presence of pH-independent hydrolysis in 3-*tert*-butyl-4-methylsydnone.

The log k-pH profiles for the hydrolysis of the 3-*tert*-butyl-4-methylsydnone at several temperatures exhibit a pH-independent hydrolysis (Fig. 5). The slopes of the log k-pH graphs related to acid- and alkali-catalyzed hydrolysis for all sydnones that do not exhibit pH-independent hydrolysis are −1 and +1, respectively, and are characteristic of specific hydrogen and specific hydroxyl ion-catalyzed hydrolysis.

In the case of the 3-benzylsydnone, good first-order plots were obtained for the degradation in the

acid medium. Plots of the apparent first-order rate constants, k against [HCl], however, did not yield the expected straight lines but showed an apparent exponential increase in such constants with [HCl]. This was most readily observed at the higher temperatures. The plots were reasonably linear when k was plotted against [HCl] . In solutions of the

TABLE VII—APPARENT THERMODYNAMIC QUANTITIES[a] FOR THE SOLVOLYSIS OF SYDNONES

Sydnone	HCl ΔH_a Kcal./mole	HCl log P	NaOH ΔH_a Kcal./mole	NaOH log P
3-*tert*-Butyl-4-methyl	32.8	16.9	33.1	17.0
3-*n*-Propyl-4-methyl	23.6	8.5	23.1	10.8
3-*n*-Propyl-4-ethyl	23.6	8.6	19.2	9.3
3-*n*-Propyl-4-*n*-butyl	30.0	12.2	24.2	10.2
3-Ethyl-4-methyl	31.8	13.2	20.0	9.0
3-Isopropyl-4-ethyl	24.1	8.9	23.6	8.3
3-Benzyl	27.5[b] 3.20[c]	10.8[b] 14.1[c]	18.6	8.1

[a] These quantities are obtained from the logarithmic form of the Arrhenius equation: $\log k = \log P - \Delta H_a/2.303RT$, where k is in sec.$^{-1}$ for the hydrolysis in 1.0 *M* HCl and 1.0 *M* NaOH, the ΔH_a is the experimental activation energy in Kcal./mole, R is the gas constant in cal. deg.$^{-1}$ mole^{-1}, T is the absolute temperature, and log P is a constant associated with the entropy of activation. [b] Determined from intercepts, k_1, of the plot of k/[HCl] against [HCl] according to the expression $k/[HCl] = k_1 + k_2$ [HCl]. [c] Determined from the slope, k_2, of such plots.

same hydrochloric acid concentration but differing ionic strengths, the apparent k increased as would be expected for a reaction between two like-charged species (16), according to the following equation:

$$\log k = \log k' + z_A z_B \sqrt{\mu} \qquad \text{(Eq. 4)}$$

where z_A and z_B are the respective signed charges on the reacting species.

The hydrolysis of 3-isopropylsydnone was also studied under similar conditions as a model compound for the other 3-alkyl sydnones. A smaller salt effect was observed in this case. The apparent first-order rate constants for these two sydnones as a function of the ionic strength are given in Table VI.

Plot of log k against pH for the acid-catalyzed hydrolysis of the 3-benzylsydnone gave slopes ranging from −1.4 at 60° to −1.8 at 80°, rather than the normally expected slopes of −1 for the single proton catalyzed hydrolysis.

Dependence of Rate on Temperature—The Arrhenius expression $k = Pe^{-\Delta H_a/RT}$ can be written in the logarithmic form:

$$\log k = \log P - \frac{\Delta H_a}{2.303\,RT} \qquad \text{(Eq. 5)}$$

Plots of the logarithms of the various catalytic rate constants against the reciprocal of the absolute temperature permit calculation of the ΔH_a and log P values of Eq. 5. These values are listed in Table VII.

Thin-Layer Chromatography—The acid hydrolysis of 3-benzylsydnone was monitored by thin-layer chromatography (*n*-butanol–acetic acid–water, 4:1:5) and observed under ultraviolet light. The spot, $R_f = 0.65$, due to the benzylsydnone became smaller and fainter with time and finally disappeared completely. The only other spot was due to appearance of benzyl hydrazine, $R_f = 0.48$, which increased in size and intensity with time. This showed that benzyl hydrazine was the major product of acid hydrolysis.

DISCUSSION

Comparative Reactivities of Sydnones—The reactivities of the 3,4-dialkyl sydnones can be readily compared with respect to their solvolytic rate constants (Tables II–V) when one substituent is kept constant and the other is varied. This is shown in Table VIII for alkali- and acid-catalyzed hydrolysis at 75°. The comparison for 4-H sydnones was based on data given previously (12).

The sequences (Table VIII) when the 4-substituent is methyl and the 3-substituent is varied, and when the 3-substituent is *n*-propyl and the 4-substituent is varied in the acid-catalyzed region, are in accordance with the expected induction effects of the alkyl groups. It is expected that the greater the electron-releasing capacity of a substituent, the less positive the sydnone ring, the less the reactivity to hydroxyl ion attack, and the greater the reactivity to hydrogen ion attack. However, the sequence is not rigorous in those cases (Table VIII) when the 4-substituent is ethyl, the 3-substituent is *n*-propyl, and the other substituent is varied. In fact, substitution of an ethyl or a methyl for a hydrogen in the 4-position does not significantly change the reactivity of 3-*n*-propyl sydnones to alkaline solvolysis. It does have an effect on acid solvolysis, however.

Kier and Roche (3) have cited unpublished data to support their contention that the 2-nitrogen is predicted to be energetically the least likely point of attack of hydroxide ion as based on molecular orbital calculations of anion localization energies. They preferred hydroxyl ion attack on the 5-carbon in I, the atom adjacent to the oxygen assigned a high formal and localized negative charge (3). Since the presence of a formal charge in all known molecules inhibits the attack of a like charged species (16), it is difficult to expect that a highly polar anion such as hydroxyl would attack an atom

TABLE VIII—RELATIVE REACTIVITIES OF THE 3R, 4R′-DIALKYL SYDNONES AS COMPARED AT 75°

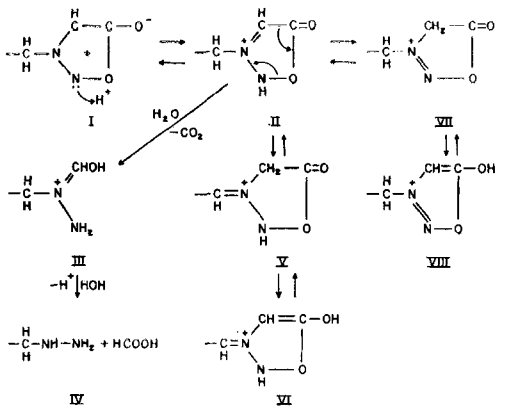
adjacent to one with a highly localized negative charge. It was predicted (12) that if this were so, 3,4-dialkylated sydnones should demonstrate significantly less susceptibility to hydroxyl ion attack than solely 3-alkylated sydnones. It is apparent (Table VIII) that the more electron-donating methyl and ethyl substitution for hydrogen in the 4-position, which is adjacent to the postulated attack on the 5-carbon site, had no effect on diminishing reactivity to hydroxyl ion attack. Substitution of a methyl for a hydrogen in the 4-position did decrease the rate of hydroxyl ion attack on the 3-*n*-propyl and 3 *tert*-butylsydnones by 40–60%, but substitution of an ethyl had no significant effect on 3-*n*-propylsydnone reactivity and actually increased the reactivity of 3-*i*-propylsydnone to hydroxyl ion attack by 40%.

It is just as probable that hydroxyl ion attack occurs elsewhere in the sydnone ring than on the 5-position adjacent to the strong anionic charge. Electronic redistributions can be readily induced on the approach of the hydroxyl ion through the bonded *p*-orbital of the atoms of the aromatic sydnone ring, and this sensitizes other sites for reaction. Orbital calculations are based on approximations for the ground state of a molecule, and the results reflect these approximations and exclude the perturbations induced by attacking species. A definitive experiment is needed to resolve the question of site and mechanism of hydroxyl ion attack on sydnones in aqueous solutions.

Still unresolved are the reasons for the enhancement of comparative acid-catalyzed solvolytic rates when the 3-substituent in 3-alkyl sydnones is highly branched, tertiary, and possesses no α-hydrogens, *e.g.*, 1,1,3,3-tetramethylbutyl, 3-*tert*-butyl (12), and 3-*tert*-butyl-4-methyl sydnones (Table V). In addition, these are the only alkyl sydnones that show significant water attack.

We may accept as likely the mechanism of acid hydrolysis based on that of Baker and Ollis (3, 17), *i.e.*, the sequence I–IV to the hydrazine in Scheme I. The net mechanism is similar whether we add water to II and then form III (12) or have the decomposition products of II react with the components of water (3). It is possible that the availability of hydrogens on the α-carbon of the 3-alkyl substituent permits the equilibria to V and VI *via* acid-catalyzed enolization-like mechanisms. This distribution among other species diminishes the concentration of a reactive intermediate, such as II, necessary for the production of the hydrazine product in acid solution. The conjugations of VI and VIII should be stabilizing influences. When no α-hydrogens on a 3-alkyl are available, such as in the *tert*-alkyl sydnone cases cited, the equilibria with VI and VII are not possible. Thus, the increased concentration of the reactive intermediate (II) could lead to a higher over-all rate of acid catalyzed solvolysis.



Scheme I

There is a great enhancement of hydrogen ion-catalyzed solvolysis when a methyl is substituted for a hydrogen in the 4-position in the case of *tert*-butylsydnone. The second-order rate constant for the acid catalyzed solvolysis of 3-*tert*-butyl-4-methylsydnone at 75° (Table V) is 16 times greater than that of 3-*tert*-butylsydnone (12). Admittedly, it could be argued that the electron-releasing properties of the 4-methyl substituent promoted the hydrogen ion attack on a more negative site in the sydnone ring. Its magnitude is difficult to accept on this premise, however, since the introduction of a 4-alkyl for the hydrogen has only minor enhancing effects on acid-catalyzed solvolysis of 3-alkyl sydnones with α-hydrogens. (Compare Table V and the data in *Reference 12.*) A possible explanation may be based on consideration of the equilibria in Scheme I of II ↔ VII ↔ VIII remaining available to *tert*-butylsydnone. Substitution of a methyl for a hydrogen in the 4-position should lower the electron density on the 4-carbon and not favor the net transfer of hydrogen from the 2-nitrogen in this equilibria. This could lead to a net increase in the concentration of the reactive species II.

The fact that of all the 3-alkyl sydnones only these tertiary alkyl sydnones demonstrate pH-independent solvolysis is significant. This pH-independent solvolysis implicates water attack since it drastically decreases in alcohol–water mixtures of lessened water content (12). An activated state similar to one or several of the postulated hybrids of the numerous dipolar and tetrapolar forms (3, 17) may undergo attack by water in a mechanism similar to that of Scheme I with an activated state similar to II (12). It can be argued that the concentration of this reactive intermediate is reduced by the formation of equilibrating structures similar to V and VI when α-hydrogens on the 3-alkyl are present. Only in the cases of 3-*tert*-alkyl sydnones may there be a sufficient concentration of the reactive intermediate for a pH-independent water attack to be observed. An argument similar to that made previously for increased concentration of the reactive species may be made for the enhancement of water attack on 3-*tert*-butyl-4-methylsydnone over 3-*tert*-butylsydnone, about 10 times more reactive at 75°. (Compare Table V and the data in *Reference 12.*)

Reactivity of 3-Benzylsydnone—The results obtained for the alkali-catalyzed hydrolysis of 3-benzylsydnone agree with expectations for an apparent first-order dependence on hydroxide ion concentration (Table III). However, the apparent first-order rate constant, k, is not strictly linear with the HCl concentration (Table II). It is a function of some power of the HCl concentration and this dependence is more pronounced at higher

temperatures. The log k-pH plots in their acid branch vary from -1.4 at 60° to -1.8 at 80°. The ionic strength effect is of the type expected for a reaction between two like-charged species (Table VI), and the main product of the acid hydrolysis is benzyl hydrazine. These results suggest that acid-catalyzed hydrolysis of 3-benzylsydnone contains a contribution proportional to $[HCl]^2$. At constant acid concentrations the rate dependence of benzylsydnone solvolysis can be formulated (18) as:

$$-d[\text{benzylsydnone}]/dt = k_1[HCl][\text{benzylsydnone}] + k_2[HCl]^2[\text{benzylsydnone}] \quad \text{(Eq. 6)}$$

where the apparent first-order rate constant is:

$$k = k_1[HCl] + k_2[HCl]^2 \quad \text{(Eq. 7)}$$

and

$$k/[HCl] = k_1 + k_2[HCl] \quad \text{(Eq. 8)}$$

A plot of $k/[HCl]$ against [HCl] should give a straight line with a slope k_2, the apparent termolecular rate constant, where the intercept, k_1, should estimate the bimolecular rate constant for the HCl-catalyzed hydrolysis. The values of k_1 and k_2 obtained from such a plot (Fig. 6) show that, for 1.0 M HCl, the relative contribution of k_2 to the over-all rate constant, k, with respect to k_1, *i.e.*, the ratio k_2/k_1, increases from 60° to 80° (Table V). Plots of log k_1 and log k_2 against $1/T$ give activation energies of 27.5 and 32.0 Kcal./mole, respectively, and show that k_2 is favored over k_1 at the higher temperatures. Similar plots of the data in Table II for other dialkyl sydnones also show that there may be present, although to a much lesser extent, a concurrent first and second-order dependence on hydrogen ion of the type expressed by Eq. 8. The $k/[HCl]$ values showed a tendency to increase with [HCl], but the slopes of such plots were small and the major contribution to solvolysis was the first power of the HCl concentration. The compound other than benzylsydnone that showed the greatest such dependency on the $[HCl]^2$ was 3-ethyl-4-methylsydnone. However, Eq. 3 was reasonably adequate for quantitative characterization since the k_2 value was relatively small.

These kinetic observations can be interpreted in terms of two concurrent pathways, one discussed previously in Scheme I and the other involving a second protonation.

Second protonation is likely in cases similar to 3-benzylsydnones because of the possibility of mesomeric structures and delocalization of the positive charge through the many possible mesomeric structures mediated by the benzyl substituent and its labile α-hydrogens. A few typical examples are given in Scheme II before and after single protonation, *i.e.*, structures like IX, X, and XI can be represented where one positive charge can be delocalized.

It can be argued that the labile hydrogens of the benzylsydnone permit contributions of structures which may be similar to the V, VI, VII, and VIII of Scheme I. These may dilute out the effective concentration of an activated state as represented by II. Thus, an effective concentration of single protonated hybrids such as XI may occur which react further to products after a second protonation.

Confirmation of the existence of these additional

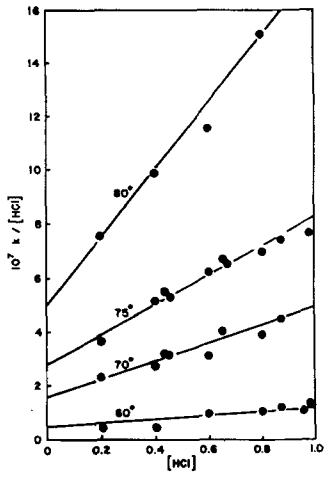


Fig. 6—Dependence of k/[*HCl*] *on* [*HCl*] *at different temperatures, according to* $k/[HCl] = k_1 + k_2[HCl]$, *for the apparent first-order rate constant values,* k, *of benzylsydnone.*

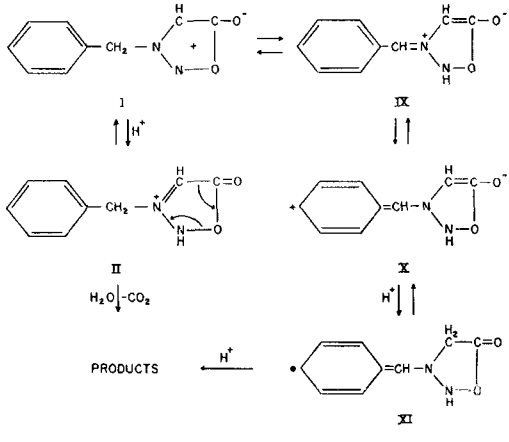
mesomeric structures with 3-benzylsydnone is obtained from its ultraviolet spectrum (Fig. 1). The 3-benzylsydnone, with one methylene group intervening between the benzene and sydnone rings, shows a single absorbance maximum at 292 mμ (ε = 7,000). However, 3-phenylethylsydnone, with two intervening methylene groups between the rings, exhibits two distinct absorbance maxima at 254 and 286 mμ (ϵ_{286} = 3,000) (12). This indicates that the benzene ring and the sydnone ring maintain their separate chromophores in 3-phenethylsydnone and that there is little or no conjugation between the π-electron systems of these rings. In the case of the 3-benzylsydnone, however, the solitary methylene group does not appear to prevent such conjugation. The ultraviolet absorption spectrum indicates that conjugation of the π-electron systems of the two rings exists, together with a bathochromic shift in the wavelength of maximum absorbance, as has been predicted for such cases (19). The partial positive charge, instead of remaining on the sydnone



Scheme II

ring only, may now be smeared over two rings. This results in the sydnone ring in 3-benzylsydnone having less partial positive charge than in the case of the other 3-alkyl sydnones. The results obtained in the study of the ionic strength effects (Table VI) also support this explanation of a smaller positive charge on the neutral sydnone ring in the 3-benzylsydnone, since the greater positive ionic strength effect on acid-catalyzed solvolysis implies a greater significant hydrogen ion attack on a positively charged species.

On the basis of energetic factors, hydrogen ion attack on the nonprotonated sydnones is the favored pathway at lower temperatures because of the smaller activation energy (Table VII). At higher temperatures, however, hydrogen ion attack on the protonated sydnone will be the major route (Scheme II).

It was previously anticipated (12) that the benzyl radical would behave similarly to the furfuryl radical, in that the intervening single methylene group does not insulate the rings and both these radicals may act as electron sinks with greater electron attracting properties on hydroxyl ion attack. In the general sense this anticipation was confirmed and the rates of alkaline solvolysis were equivalent. The hydroxyl-ion-catalyzed solvolyses of benzyl (Table III) and furfuryl sydnones (12) are more than twice the rates of other 3-alkyl sydnones at comparable temperatures (12).

However, the acid-catalyzed solvolysis of 3-benzylsydnone (Table II) is similar in magnitude to those values for the simpler 3-alkyl sydnones, whereas the 3-furfurylsydnone acid- and water-catalyzed solvolyses are anomalously high (12). Thus, the previously given prediction (12) that benzylsydnone would not be as readily solvolyzed in acid and neutral solutions as furfurylsydnone appears valid. This prediction was based on the feasible stabilization of the activated complex of furfurylsydnone by the oxygen of the furfuryl ring which is sterically positioned adjacent to the 2-nitrogen.

Extrathermodynamic Free Energy Relationships—Simple linear free energy relationships can also usually provide information as to whether any substituent effects are present. The best known of these is the Hammett $\sigma\rho$ equation. Use of the σ values obtained from the literature (20) did not provide any meaningful correlation in the Hammett plot (20). Since the sydnones were considered to be of an aromatic nature, these substituent values for phenyl systems were preferred over the Taft parameters.

It is interesting to note that when, according to Leffler and Grunwald (21), the derived ΔH^* values for the sydnones were plotted against the derived ΔS^* values (22) a reasonably linear relationship was obtained with a slope of 380°. This should represent the isokinetic temperature when all reactions of this series of compounds have the same free energy of activation. At this temperature, effects due to alkyl substituent should completely disappear (21). However, in our case the criticism of Petersen (23, 24) of this approach is valid since plots of log k/T *versus* $1/T$ had no common point of intersection, and the observation of an apparent isokinetic temperature was an artifact of the data in the Leffler and Grunwald method (21) of determining extrathermodynamic parameters.

Subcutaneous Absorption Kinetics of Benzyl Alcohol

By BERTON E. BALLARD and EFRAIM MENCZEL*

Benzyl alcohol (BA) was used as a model compound to study subcutaneous (s.c.) drug absorption kinetics in the rat. It has been used extensively as an adjuvant in pharmaceuticals intended for parenteral administration. Benzyl alcohol has a high lipid–water partition coefficient, and is a neutral, relatively nontoxic local anesthetic. The area of s.c. tissue exposed to the BA solution was controlled by a glass absorption cell affixed to the s.c. tissue by a silicone adhesive. The about 1 percent (w/v) BA in normal saline solution was stirred in the cell at an equilibrium temperature. Multiple doses of the drug were used to monitor any volume changes in the cell. Benzyl alcohol was extracted from the fluids at the site into *n*-hexane and assayed spectrophotometrically at 208 mμ. The BA mean absorption half-life in the s.c. cell was 1.6 hr.

THE PURPOSE of this study was to develop general experimental methods for studying the kinetics of drug absorption from the subcutaneous (s.c.) site following the administration of multiple doses of a drug. Schou (1) pointed out that the experimental method of choice where feasible for studying the rate of drug absorption from s.c. tissue is to record the clearance of injected drug from the local area. To date no investigators have used a direct method of studying drug absorption rate per unit area (p.u.a.) of s.c. tissue, very likely because of the difficulty of controlling the spreading of drug solution at the site.

In this work, benzyl alcohol (BA) was selected as a model drug for studying the kinetics of s.c. drug absorption because (*a*) it is a valuable pharmaceutical adjuvant in parenteral products intended for s.c. or intramuscular (i.m.) administration due to its local anesthetic and bacteriostatic properties; (*b*) it is relatively nontoxic (2–4) compared to other local anesthetics; (*c*) it is a lipid-soluble, neutral molecule not subject to the usual pH-partition effects expected of organic anionic and cationic drugs; and (*d*) it is quantitatively assayable in the biological fluids found at the s.c. region.

THEORETICAL

If one can assume the BA molecules penetrate the s.c. tissue by passive diffusion, then the penetration rate of the drug from the site of administration can be described by Fick's law in one direction:

$$dN/dt = \bar{D}\,A\,(dC/dx) \qquad \text{(Eq. 1)}$$

where dN/dt is the penetration rate, and N is the amount of drug penetrating the membrane. In a well-stirred system the rate is proportional to the mean diffusion coefficient (5) of drug in the membrane, $\bar{D}$, the area, A, of the solution exposed to the absorbing membrane, and the concentration gradient (dC/dx) of drug across the membrane. Under conditions of this experiment where the penetration rate is fairly rapid, Eq. 1 can be approximated (6) by:

$$dN/dt = \frac{\bar{D}AK}{\delta}(C_c - C_b) \qquad \text{(Eq. 2)}$$

where the dx term of Eq. 1 has been replaced by δ, the thickness of the thin s.c. membrane which is assumed to be constant for each animal, and the dC term of Eq. 1 has been replaced by the terms K and $(C_c - C_b)$. The term K is the equilibrium distribution ratio or partition coefficient of the drug between the membrane lipids and the aqueous phases of the absorption cell or body fluids. The term $(C_c - C_b)$ is the difference between the drug concentration in the absorption cell, C_c, and the drug concentration C_b, in the fluids, *e.g.*, blood and lymph, flowing past the absorption site at any time.

The term C_b can be ignored in these experiments, since it can be reasonably assumed that the drug's concentration in the fluids of distribution is negligible compared to its concentration at the absorption site at any time. Thus Eq. 2 can be written as:

$$dN/dt = \frac{\bar{D}AK}{\delta}(C_c) \qquad \text{(Eq. 3)}$$

When the mean volume of the drug solution at the absorption site, $\bar{V}_c$, remains nearly constant throughout the experiment, the rate of penetration will be equal to:

$$dN/dt = \left(\frac{\bar{D}AK}{\delta \bar{V}_c}\right)Ac \qquad \text{(Eq. 4)}$$

where Ac is the amount of drug in the cell at any time. The penetration rate per unit area (p.u.a.) equals:

$$\frac{dN/dt}{A} = \bar{P}\,\frac{Ac}{A} \qquad \text{(Eq. 5)}$$

where $\bar{P}$ is the mean penetration coefficient which includes the terms $\bar{D}$, A, K, δ, and $\bar{V}_c$, and has the

Accepted for publication August 9, 1967.

Presented to the Basic Pharmaceutics Section, A.PH.A. Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

This study was supported in part by research funds of the University of California, a general research support grant FR 05453 from the Division of Research Facilities and Resources, National Institutes of Health, U. S. Public Health Service, Bethesda, Md., and additional research funds allocated by the Eastern Mediterranean Office of WHO, and approved by the Washington WHO Regional Office (January 13, 1966).

The authors are indebted to Mr. Silas Braley, Dow Corning Center for Aid to Medical Research, Midland, Mich., for supplying samples of the silicone medical adhesive used in this study, Dr. Louis A. Strait and Mr. Michael K. Hrenoff for their assistance in developing some of the spectrographic assay procedures used, and to Mr. Russell Vossbrink and Mr. John R. Cafiso for technical assistance.

units of time^{-1}. The mean penetration coefficient or absorption rate constant has the same magnitude as the clearance constant, but the opposite sign. Equation 5 may therefore be simplified to:

$$dB/dt = \bar{P}Bc \qquad \text{(Eq. 6)}$$

where dB/dt is the penetration rate p.u.a., and Bc is the amount of drug in the cell p.u.a. at any time. The term Bc equals the initial amount of drug p.u.a., Bi, less the amount of drug p.u.a., B, that has penetrated the membrane to any time, thus:

$$Bc = Bi - B \qquad \text{(Eq. 7)}$$

Substitution of Eq. 7 into Eq. 6 and integrating between the limits of zero and infinite time yields:

$$Bc = Bie^{-\bar{P}t} \qquad \text{(Eq. 8)}$$

When the same amount of BA p.u.a., B', is administered repeatedly at the times of zero, τ, 2τ, $3\tau \ldots$, the amount of drug in the cell p.u.a. after n doses will be:

$$Bc = B' + B'e^{-\bar{P}\tau} + B'e^{-\bar{P}2\tau} + B'e^{-\bar{P}3\tau} + \ldots + B'e^{-\bar{P}(n-1)\tau} \qquad \text{(Eq. 9)}$$

where the time τ is the dosing interval and is a constant. The amount of drug in the cell p.u.a. just after the administration of the nth dose p.u.a. can be calculated from:

$$B_c = \frac{B'(1 - e^{-\bar{P}n\tau})}{(1 - e^{-\bar{P}\tau})} \qquad \text{(Eq. 10)}$$

Equation 10 applies when Bi and the mean maintenance dose(s) p.u.a., $\overline{Bm}$, are both equal to B' in magnitude. When the initial and mean maintenance dose(s) p.u.a. are not equal in magnitude, then the term Bc at any time can be computed from Eq. 11:

$$Bc = Bie^{-\bar{P}t} + \left\{\overline{Bm}\left[\frac{1 - e^{-\bar{P}(n-1)\tau}}{1 - e^{-\bar{P}\tau}}\right]\right\}e^{-\bar{P}T} \qquad \text{(Eq. 11)}$$

where n, in this case, is an integer number of initial and maintenance doses p.u.a. administered, and T is another clock time starting at zero immediately after the administration of the last maintenance dose p.u.a.

When the number of doses p.u.a. approaches infinity (and the contribution of $Bie^{-\bar{P}t}$ becomes nil), the value of Bc as defined by Eq. 11 approaches a maximum limiting value, $Bc_{max.}$, just after the administration of the last mean maintenance dose p.u.a.:

$$Bc_{max.} = \overline{Bm}\left(\frac{1}{1 - e^{-\bar{P}\tau}}\right) \qquad \text{(Eq. 12)}$$

and a minimum limiting value, $Bc_{min.}$, just before the administration of the next mean maintenance dose p.u.a.:

$$Bc_{min.} = \overline{Bm}\left(\frac{e^{-\bar{P}\tau}}{1 - e^{-\bar{P}\tau}}\right) \qquad \text{(Eq. 13)}$$

Most of the equations described above have been discussed in connection with blood or serum drug concentration changes following intravenous, i.m., and oral drug administration (7–10), but have not been discussed in connection with changes in drug concentration at the s.c. absorption site as a function of time.

An equation for calculating the limiting value for $\overline{Bc}$, the asymptotic mean amount of drug in the cell p.u.a., can be derived using the values of $Bc_{max.}$ and $Bc_{min.}$ (11). The area under the curve from $Bc_{max.}$ to $Bc_{min.}$ over the time interval of one τ can be calculated from:

$$\text{area} = \frac{(Bc_{max.} - Bc_{min.})\tau}{\ln (Bc_{max.}/Bc_{min.})} \qquad \text{(Eq. 14)}$$

Substitution of Eqs. 12 and 13 into Eq. 14, and subsequent division by the dosing time interval, τ, yields:

$$\overline{Bc} = \frac{\overline{Bm}}{\bar{P}\tau} \qquad \text{(Eq. 15)}$$

Since $\bar{P}$ equals $(\ln 2/\overline{t_{0.5}})$, where $\overline{t_{0.5}}$ is the drug's mean absorption half-life in the cell, Eq. 15 can be written:

$$\overline{Bc} = \frac{\overline{Bm}}{(\tau/\overline{t_{0.5}})\ln 2} \qquad \text{(Eq. 16)}$$

A more general expression than Eq. 16 was derived by Wagner and co-workers (12) for drug blood levels at the equilibrium state after multiple dosing.[1] The term, $\overline{Bc}$, can also be calculated from:

$$\overline{Bc} = Bc_{max.}e^{-\bar{P}Z\tau} \qquad \text{(Eq. 17)}$$

where Z is the fractional part of τ at which time $\overline{Bc}$ is reached following the last maintenance dose p.u.a. given at a time infinite in terms of the experiment. Substitution of Eq. 12 into Eq. 17 yields:

$$\overline{Bc} = \overline{Bm}\left(\frac{1}{1 - e^{-\bar{P}\tau}}\right)e^{-\bar{P}Z\tau} \qquad \text{(Eq. 18)}$$

Substitution of Eq. 15 into Eq. 18, and solving for the term Z yields:

$$Z = \frac{1}{\bar{P}\tau}\ln\left(\frac{\bar{P}\tau}{1 - e^{-\bar{P}\tau}}\right) \qquad \text{(Eq. 19)}$$

Equation 19 can also be written in terms of the drug's absorption half-life:

$$Z = \frac{1}{(\tau/\overline{t_{0.5}})\ln 2}\ln\left[\frac{(\tau/\overline{t_{0.5}})\ln 2}{1 - e^{-(\tau/\overline{t_{0.5}})\ln 2}}\right] \qquad \text{(Eq. 20)}$$

The magnitude of the unitless Z term is a complex function of the ratio $\tau/\overline{t_{0.5}}$ and is dose independent. The significance of the term Z will be indicated under *Results and Discussion*.

[1] Equation 16 of this paper and Eq. 6 found in Wagner and co-workers' report (12) are mathematically similar, but are different in some important respects. Their Eq. 6 is $V\bar{C} = 1.44\,F\,D\,t_{1/2}/\tau$, where V is the apparent volume of distribution of the drug, $\bar{C}$ is the average asymptotic blood concentration, F is the fraction of each dose which is absorbed, $t_{1/2}$ is the biological half-life of the drug in a particular animal or individual, and τ is the length of the dosing interval (12). The two equations differ in terms of their definitions of half-life. In Eq. 16 the half-life is for absorption, while in Eq. 6 above it is the biological half-life. In Eq. 16 the term $\overline{Bm}$ equals the magnitude of the product of the terms F and D found in Eq. 6 above only when the fraction of each dose absorbed is equal to one. The term (VC) is the average amount of the drug in the "body" during a dosage interval at the steady state, whereas $\overline{Bc}$ is the asymptotic mean amount of drug in the s.c. cell p.u.a. during a dosing interval.

MATERIALS AND METHODS

Animals—Large Sprague-Dawley female rats weighing between 400 and 500 Gm. were deliberately chosen for this study because the drug's distribution volume in them would be large. After the animals were anesthetized with ethyl ether, a circular portion of the ventral skin approximately 3 cm. in diameter was carefully excised, exposing the s.c. connective tissue. The exposed region was anatomically at about the same location as that described in previous work with s.c. implants (13). As the experiment progressed, the amount of anesthetic had to be decreased to prevent death.

Reagents—The BA used was reagent grade (Merck) with a boiling point of 205°/752 mm. which agrees closely with that reported in the literature (14, 15). The complete solution of BA in 0.9% (w/v) aqueous sodium chloride or normal saline solution (NS) was effected by warming and stirring the mixture on a steam bath for about 1 hr. and then allowing it to cool to room temperature. The *n*-hexane used as the extraction solvent in the assay was of spectrographic grade[2] with an ultraviolet cut-off of 199 mμ or less.

Subcutaneous Absorption Cell—A cylindrical glass absorption cell was constructed to hold the drug solutions in contact with the s.c. tissue. It was about 21 mm. high and had an inside diameter of 17.2 mm. At one end of this cell was a rim having an outside diameter of about 26 mm. The part of the rim adjacent to the s.c. tissue was ground flat. The inner cross-sectional area of the cell was 2.322 cm.^{2}.

Adhesive—The rim of the absorption cell was attached to the moist s.c. tissue by a medical silicone adhesive[3] commercially available as a developmental aerosol formulation in a pressurized container. The use of silicones in biological research has been recently reviewed (16). According to the manufacturer, this adhesive appears to be completely inert to living tissue and will not cause irritation or sensitization. The adhesive qualities are retained in the presence of moisture. The only solvent present is a volatile fluorocarbon propellent,[4] which evaporates after a few minutes. The adhesive could not be sprayed accurately onto the cell's narrow glass rim. A special nozzle supplied by the company was inserted into the spray orifice. The nozzle was directed into an inverted 9.52 mm. diameter ophthalmic ointment tube with cap in place. The tube was nearly filled with the adhesive, allowed to stand for about 5 min., and placed in a dry oven at 104° until it reached a suitable semisolid consistency which usually took about 15 min. The ointment tube was cooled to room temperature and crimped in the usual manner. The adhesive could now be applied directly to the rim from the small orifice at the tube tip. Under experimental conditions this adhesive made the glass rim adhere to the moist tissue and formed a water-tight seal which prevented the solution from spreading onto the surrounding regions.

Assay—A method for determining the amount of BA in NS has been reported previously (15). However, the procedure is too tedious to perform routinely and not sufficiently sensitive for the present purposes. Instead, an assay procedure was developed which involved the extraction of BA from a small sample of the fluids present in the absorption cell into a suitable solvent and analyzing the resulting mixture by ultraviolet spectrophotometry. The extraction step was required because proteins qualitatively similar to those which could be present in the absorption cell shortly after the experiment had begun have chromophores that absorb in the same 205–210 mμ region of the U.V. as does BA in aqueous solution (17). According to the literature BA has a $\lambda_{max.}$ of 210 mμ (log ϵ = 3.88) in methanol (18) and 208 mμ (log ϵ = 3.83) in ethanol (19). Preliminary determinations using a Cary spectrophotometer, model 11, having a continuous recording attachment showed that BA dissolved in distilled water and spectrographic grade *n*-hexane had a $\lambda_{max.}$ of 208 mμ in both solvents. The values for log ϵ in water and *n*-hexane, respectively, were 3.82 and 3.88. Stock solutions were prepared containing 1 to 4% (w/v) BA dissolved in NS. Standard curves for the absorbance of BA extracted into *n*-hexane *versus* the BA concentration in NS were made by the method of least squares. The two instruments used were the Cary spectrophotometer, model 11, and the Beckman spectrophotometer, model DU, with a hydrogen lamp accessory. A 20-μl. sample of a saline blank and each stock solution was added to 50-ml. glass-stoppered volumetric flasks using a 25-μl. Hamilton syringe.[5] Three milliliters of NS was then added in order to rinse the drug sample down from the sides of the flask. Duplicate samples were run in each case. About 25 ml. of spectrographic grade *n*-hexane was added to each flask. It was stoppered and shaken for 0.5 hr. on a mechanical shaker. Afterward, sufficient *n*-hexane was added to bring the total volume up to the 50-ml. mark, and the shaking was repeated for another 0.5 hr. Samples of the *n*-

TABLE I—ULTRAVIOLET ABSORBANCE OF BENZYL ALCOHOL

Concn. of BA in NS, mg./ml.	Amt. of BA in Flask, μm.[a]	Absorbance in Hexane Extract at 208 mμ Cary Model 11[b]	Absorbance in Hexane Extract at 208 mμ Beckman Model DU[b]	Calcd. Concn. of BA in NS, mg./ml.[c]

30.0	5.55	0.655	...	30.1
35.0	6.47	...	0.778	34.9
40.0	7.40	0.875	...	40.0

[a] The amount of BA contained in 20 μl. of the solution listed in column 1 partitioned between 3 ml. of NS and sufficient *n*-hexane to make 50 ml. of total solution. [b] The equation for the standard curve by the least squares method in the Cary instrument is: concn. (mg./ml.) BA = (absorbance + 0.020)/0.0224 and that in the Beckman instrument is: concn. (mg./ml.) BA = (absorbance − 0.011)/0.0220. [c] The concentrations were computed using the appropriate standard curve equations for the respective instruments.

hexane layer were removed from each flask and were read in the respective instruments at 208 mμ against the *n*-hexane blank similarly treated with NS solution. The absorbances in *n*-hexane were proportional to BA concentration in NS from 9.9 to 40 mg./ml. (See Table I.) Potential problems of stray radiation at this wavelength were investigated (20). Using the method described by Ofler (21), calculations were made with the intent to improve the linearity of the absorbance *versus* concentration standard curves mentioned above. No improvement in linearity could be achieved. Column 5 of Table I shows with both spectrophotometers that the calculated values of drug concentration using the respective standard curves agreed closely with the actual concentrations listed in column 1 of Table I.

The question of whether the silicone adhesive might interfere with the BA assay was investigated. The insides of two 1.9 cm. diameter test tubes were sprayed with a thin film of the silicone adhesive and allowed to stand until the volatile solvent had evaporated. Two milliliters of a 2.04% (w/v) BA stock solution in NS was added to each tube. One tube was shaken by hand intermittently for 4 hr. and the other for 24 hr. Then 20-μl. samples of these solutions, the original stock solution, and the NS blank solution were transferred to 50-ml. volumetric flasks and assayed according to the procedures described above. All determinations were made in triplicate. There was no significant difference between the absorbance values for the BA stock solutions exposed to the silicone adhesive and the BA stock solution not so exposed. It was concluded that the adhesive did not interfere with the assay at the BA concentration used.

Penetration Coefficient Determinations—Shortly after the absorption cell was securely affixed to the s.c. tissue, 0.5 ml. of NS preheated to 28° was introduced into the cell to ensure that the exposed tissue would remain moist before the introduction of the BA solution. A hollow glass rod 5.1 mm. in diameter and 34 cm. long was fastened by a rubber band to the metal spatula of a vibrating stirrer.[6] To avoid splashing of the test solution and injury to the s.c. tissue, one end of a piece of glass wool was twisted to a fine tip and the other end was attached to the glass rod by another rubber band. The strand of vibrating glass wool was introduced into the test solution. After about 10 min., 1.0 ml. of 2.04% (w/v) BA dissolved in NS also preheated to 28° was pipeted into the absorption cell. This was zero time in terms of this experiment. Four to five 20-μl. samples of solution were withdrawn each 0.5 hr. indicated in Table II. Each 20-μl. sample was transferred to a 50-ml. glass-stoppered volumetric flask and assayed for BA content according to the method described previously. At the end of each 0.5-hr. period, 0.1 ml. of 3.42% (w/v) BA in NS solution was added to the cell. From time to time the accuracy of the sampling technique with the Hamilton syringe was checked. The syringe containing the aliquot was weighed on a Sartorius analytical balance, and reweighed after the sample was transferred for the U.V. assay. In all cases the difference between the two weights corresponding to the volume of sample delivered (1 μl. = 1 mg.) agreed with that estimated from the syringe barrel markings within ±1%.

The magnitude of both the mean diffusion and partition coefficients and the resulting penetration coefficient as defined by Eq. 5 may be temperature dependent. It was therefore necessary to determine what the mean solution temperature was in the cell and the magnitude of possible fluctuations during the experiment. The temperature of the BA solution in one anesthetized animal was continuously recorded,[7] using a small thermocouple probe introduced into the cell. The thermocouple and accompanying equipment was specially designed[8] for routine pyrogen testing of parenteral solutions. After about 15 min., thermal equilibrium between the animal, the absorption cell contents, and the room environment was established. The temperature of the solution oscillated about a mean value of 28.3 ± 0.2°. In a parallel *in vitro* experiment the same absorption cell was affixed to a metal block heated to constant temperature, and no measurable amount of evaporation from the stirred solution used above was found when maintained at 28° for 3 hr. For each 0.5-hr. period, an estimate of the penetration coefficient, P, was made by plotting the logarithm of the amount of BA p.u.a. in the cell at any time, against the sampling times shown in Table II and by multiplying by −2.303 the resultant slope obtained by the least squares method. In this study all computations were programmed for the Wyle calculator.[9] In some cases in Tables II through IV extra digits obtained by computational means and indicated by subscripts, are listed to minimize rounding off errors in subsequent calculations, and do not imply that four significant figure experimental accuracy was achieved.

In a few cases each reading for the amount of BA p.u.a. was determined according to the weighting method described by Paradine and Rivett (22) to determine the value for P again. This latter method was discontinued, since the values for P calculated by this method seldom differed from the previous one by more than one digit in the third decimal place. The half-life values reported in Table III were calculated from the relationship: $t_{0.5} = \ln 2/P$.

Volume Determinations—The calculated intercepts of drug concentration in the cell at the beginning and end of each 0.5-hr. period were used to estimate any possible volume changes in the cell as a function of time. The values in Table II are expressed in terms of amount of BA p.u.a. and are reconvertible to units of concentration (mg./ml.) by the equation:

$$\text{concn. BA (mg./ml.)} = Bc\ (\text{mg./cm.}^2) \times \frac{A\ (\text{cm.}^2)}{\bar{V}_c\ (\text{ml.})} \quad \text{(Eq. 21)}$$

where A is the tissue area of 2.322 cm.^{2} exposed to the drug solution, and $\bar{V}_c$ is the mean volume of solution tabulated in column 9 of Table III for the respective animals. One could calculate the final concentration, C_f, of BA at the *end* of a given 0.5-hr. time from the 0.5-hr. intercepts of the regression line computed from the logarithm of BA concentra-

tions *versus* sampling times. This equals

$$C_f = B_f/V_f \qquad \text{(Eq. 22)}$$

where B_f is the final amount of BA dissolved in the final volume, V_f, at that time. The initial concentration, C_i, of drug at the *beginning* of the next 0.5-hr. period following the addition of more BA in the amount ΔB dissolved in a NS solution with a volume, ΔV, may be calculated from the zero intercept of the regression line for the next 0.5-hr. period. This equals:

$$C_i = (B_f + \Delta B)/(V_f + \Delta V) = B_i/V_i \qquad \text{(Eq. 23)}$$

where B_i is the initial amount of BA dissolved in the initial volume, V_i, at the initial time for the next 0.5-hr. period. If the values for ΔB and ΔV are

[a] The experimental points for the first and last 0.5-hr. periods are not included in this table. Consult text for discussion. [b] This value may be converted back to the original concentration of drug in the cell by Eq. 21. [c] The first number within the parentheses is the value for the amount of BA per cm.^{2} of absorption site as calculated from the equation for the regression line derived from the experimental values. The second number is the value for the lower limit of the 95% confidence limit. The upper and lower 95% confidence limits are equidistant from the first number in the parenthesis on a logarithmic scale (23).

known in Eq. 23, one can calculate the values for V_f and B_f from:

$$V_f = \left[\frac{\Delta B - (\Delta V)(C_i)}{C_i - C_f}\right] \quad \text{(Eq. 24)}$$

and

$$B_f = C_f\left[\frac{\Delta B - (\Delta V)(C_i)}{C_i - C_f}\right] \quad \text{(Eq. 25)}$$

The amounts of ΔB and ΔV added to the cell were kept constant and were 3.42 mg. and 0.10 ml., respectively. The mean volume, $\bar{V}'$, during any 0.5-hr. interval is:

$$\bar{V}' = (V_i' + V_f')/2 \quad \text{(Eq. 26)}$$

where the primes over each quantity indicate that

[a] Absorption half-life (hr.) of drug in the cell. [b] The half-lives for the first and last 0.5-hr. runs appear in parentheses and were calculated on the assumption that the mean volume in the cell at these time periods was identical to the mean volume listed in column 9 for the 2nd through 5th half-hour intervals. [c] Mean half-life, $\overline{t_{0.5}}$, of intervals two through five. The mean penetration coefficient, $\bar{P}$, for animal D, for example, equals $\ln 2/1.33$ hr. or 0.52 hr.$^{-1}$. [d] Mean volume (ml.), $\overline{V}'$, calculated according to Eq. 26 for each 0.5-hr. interval. [e] Mean volume, $\overline{Vc}$, for intervals two through five followed by the plus and minus values for the 95% confidence limits about the mean in parentheses. [f] The values of $B_{max.}$ (mg./cm.²) are the calculated intercepts of the equation for the regression line and are identical to values shown in Table II at the beginning of the respective 0.5-hr. intervals. [g] Mean of the three values of $B_{max.}$. The value in parentheses is not included in this mean, but was used to calculate $B_{min.}$ at the end of the second interval. [h] The values of $B_{min.}$ (mg./cm.²) were calculated from Eq. 27. [i] The value of $\overline{Bm}$ was calculated by subtracting the mean of $B_{min.}$ from the mean of $B_{max.}$ shown in column 9.

[a] The value of τ is the experimental one of 0.5 hr. as shown in Table II, and the value of $\overline{t_{0.5}}$ is the mean value found in column 9 of Table III. [b] The initial amount of drug/cm.² at the absorption site as calculated from the regression line equation. This is the first number within the parentheses at 0.5 hr. in column 2 of Table II. [c] See column 10 of Table III. [d] The experimental value of the ratio calculated from items 2 and 3 of this column. [e] The calculated value of the ratio at infinite time from Eq. 31 using the ratio of $\tau/\overline{t_{0.5}}$ tabulated as item 1 in this column. [f] The calculated maximum value at infinite time from Eq. 12. [g] The calculated value for the asymptotic mean value at infinite time from Eq. 16, using the ratio of $\tau/\overline{t_{0.5}}$ found as item 1 of this column. [h] Calculated from Eq. 20. [i] Calculated minimum value using Eq. 11 up to four τ. [j] Calculated according to Eq. 13. [k] Calculated from the appropriate form of Eq. 11.

the initial and final calculated volumes are from the same 0.5-hr. time interval.

RESULTS AND DISCUSSION

The results of the *in vivo* absorption experiments are presented in Tables II through IV and Fig. 1. The experiment for each animal lasted 3 hr. Table II shows the experimental values for the amount of BA in the absorption cell p.u.a. of s.c. tissue exposed to the drug solution as a function of time. It also lists the calculated values of the amount of BA p.u.a. from the regression line for each 0.5 hr., and the lower value for the 95% confidence limit (23) for each calculated point all at the same sampling times. In Table II no data points are presented for the zero to 0.5 and the 2.5 to 3-hr. time intervals, although four to five samples were withdrawn from the absorption cell and analyzed for BA content in the same manner as samples taken during the intervening 0.5-hr. intervals. The main reason for excluding details of the data for the first and sixth 0.5-hr. intervals is that mean volume calculations for these two runs could not be made according to Eq. 26, because values for V_i and V_f were not determined. At zero time no estimate of V_i could be made according to the experi-

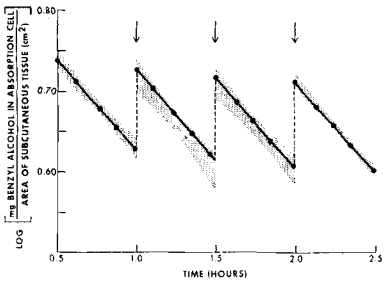

Fig. 1—The calculated logarithmic amount of BA present at the subcutaneous site per unit area as a function of dosing regimen and time for animal D. The solid lines were calculated using Eq. 11 where the value for $\bar{P}$ *is 0.52 hr.*$^{-1}$, B_i *is 5.47 mg./cm.*^{2}, $\bar{B}_m$ *is 1.11 mg./cm.*^{2}, τ *is 0.5 hr., and* n *is four. The arrows indicate the times of administration of maintenance doses. The upper and lower boundaries of the shaded areas are the logarithmic values for the 95% confidence limits* vs. *time about the regression line for the experimental points for each 0.5 hr.* (*See Table II.*)

mental procedures used, and at the end of 3 hr. no estimate of V_f could be made according to Eq. 24, since another maintenance dose was not given at that time.

In Table III the half-life of BA for each animal was calculated during each 0.5-hr. period from 0.5 to 2.5 hr. and is shown in columns 4 through 7. For each animal, the mean half-life, $\overline{t_{0.5}}$, shown in column 9 was calculated using *all* data points for the intervals from 0.5 to 2.5 hr. To do this, the data given in Table II were transposed in the following manner. The ordinate values at 0.5, 1.0, 1.5, and 2.0 hr. as obtained from the least square fit of the points for the 0.5-hr. intervals were divided into all the experimental points for that 0.5 hr. Thus, there was a common reference point for each of the four runs. Then, for purposes of calculation, the times of 0.5, 1.0, 1.5, and 2.0 hr. were all made equal to a zero clock time. For each animal $\overline{t_{0.5}}$ was computed by the least squares method from the slope of the plot of the logarithm of *Bc versus* time using all transposed experimental points listed in Table II. This mean half-life differed only slightly from the arithmetic mean half-life of the four runs because of weighting effects (22) and possible errors due to numerical rounding off. The half-lives for the first and last 0.5-hr. time periods are also included in Table II in parentheses. They were calculated on the assumption that the mean volume in the cell during these periods was identical to the mean volume shown in column 9 for the 0.5 to 2.5-hr. periods. The values of $\overline{t_{0.5}}$ for BA at the s.c. absorption site for all animals range from 0.96 to 2.58 with an average of about 1.6 hr. This mean is little affected even when one includes the values in parentheses.

In general, the variations in half-lives for the four runs in any one animal are less than those found among all animals. Probably the larger inter-animal variations in $\overline{t_{0.5}}$ are due to differences in membrane thickness. With the surgical procedures used in this study there was no way to ensure that all animals had the same membrane thickness at the absorption site. In Eq. 4, the penetration coefficient is inversely proportional to the membrane thickness, and therefore the half-life is directly proportional to membrane thickness. There is no easy way to explain the variations in half-lives with successive doses in any one animal, since membrane thickness in each case would be constant. Apart from analytical errors, the one possible reason for the half-life differences in successive 30-min. periods might be traceable to flow rate changes in the microcirculation supplying the s.c. site (24). It is not known at present how and to what extent the regional blood and lymph flows near the absorption site are affected at various times by changes in blood concentrations of ethyl ether and BA in the animal.

Table III shows the mean volume, $\bar{V}'$, of the solution in the cell during each 0.5-hr. period from 0.5 to 2.5 hr. in columns 4 through 7 as calculated from Eq. 26. The arithmetic mean values, $\bar{V}_c$, of these volumes for each animal are given in column 9 along with the plus and minus 95% confidence limits about the mean. The range of the 95% confidence limits for these volumes for the four animals is 0.07 to 0.18 ml. These small variations indicate that the volume of the BA solution in the cell remains essentially constant throughout the experiment. Equation 4 is therefore valid in so far as constancy of volume is concerned.

Table III also shows the calculated values of $B_{max.}$ and $B_{min.}$ The terms $B_{max.}$ are the initial intercepts of the equation for the regression line calculated from the logarithm of the BA amounts p.u.a. *versus* time at the beginnings of the third through fifth time intervals (see Table II). The terms $B_{min.}$ are the final intercepts during the second through fourth 0.5-hr. periods using the mean penetration coefficient, $\bar{P}$, in the equation:

$$B_{min.} = B_{max.}e^{-\bar{P}\tau} \qquad \text{(Eq. 27)}$$

where τ is equal to 0.5 hr. The mean value of the maintenance dose p.u.a., $\overline{Bm}$, was calculated by subtracting the mean values of $B_{min.}$ and $B_{max.}$ shown in column 9 of Table III. These values for $\overline{Bm}$ for each animal were used in Table IV to calculate the asymptotic values for $Bc_{max.}$ and $Bc_{min.}$ at times infinite in terms of these experiments.[10]

Multiple Dosing—Multiple dosing of the drug was used in this study for the following reasons: (*a*) the concentration of BA in the absorption cell could be maintained at a level much higher than that found at all times in the animal's fluids of distribution so that the assumption made in connection with Eq. 3 would be valid; (*b*) the volume of drug solution in the cell could be maintained nearly constant by replacing solution lost through the frequent sampling; (*c*) the drug could be used as its own "marker" for detecting possible volume changes in the cell as a function of time, and (*d*) several independent determinations of absorption half-life of BA in the cell could be made in the same animal under comparable experimental conditions.

There may be instances under multiple dosing

[10] Note that $Bc_{max.}$ and $Bc_{min.}$ are constant and can be calculated from Eqs. 12 and 13, respectively, whereas both $B_{max.}$ and $B_{min.}$ are not constant except at infinite time when $B_{max.} = Bc_{max.}$ and $B_{min.} = Bc_{min.}$ provided that the original maintenance dosing regimen is continued.

conditions where it is desirable to establish constant values for the maximum and minimum amounts of drug p.u.a. at the s.c. site at all times starting with the initial dose. At the beginning of the experiment, let:

$$Bc_{max.} = Bi \qquad \text{(Eq. 28)}$$

and at the end of the initial dosing interval of one τ, let:

$$Bc_{min.} = Bie^{-\bar{P}\tau} \qquad \text{(Eq. 29)}$$

Immediately after an infinite number of mean maintenance doses p.u.a. have been administered, the value for $Bc_{max.}$ can be calculated using Eq. 12. Substitution of Eq. 28 into Eq. 12 yields:

$$Bi = \overline{Bm}\left(\frac{1}{1 - e^{-\bar{P}\tau}}\right) \qquad \text{(Eq. 30)}$$

The same equation results when Eq. 29 is substituted into Eq. 13. The ratio of the respective doses p.u.a. is:

$$R = \frac{Bi}{\overline{Bm}} = \left(\frac{1}{1 - e^{-\bar{P}\tau}}\right) = \left[\frac{1}{1 - e^{-(\tau/\overline{t_{0.5}})\ln 2}}\right] \qquad \text{(Eq. 31)}$$

and is constant as long as the terms $\bar{P}$ and τ are constant.

Constant values for the maximum and minimum amounts of drug p.u.a. of tissue at the s.c. site can be maintained at all times by adjusting the ratio $Bi/\overline{Bm}$ in accordance to any fixed value of the ratio $\tau/\overline{t_{0.5}}$. For example, if the ratio $\tau/\overline{t_{0.5}}$ is fixed at unity, the ratio $Bi/\overline{Bm}$ must equal the value of two. In this case if the ratio $Bi/\overline{Bm}$ is greater than two, the amount of drug p.u.a. in the cell will decrease with time until the appropriate asymptotic values for $Bc_{max.}$ or $Bc_{min.}$ are reached. On the other hand, if the $Bi/\overline{Bm}$ ratio is less than two, the amount of drug p.u.a. in the cell will increase with time until the appropriate asymptotic values for $Bc_{max.}$ or $Bc_{min.}$ are reached.

One can see examples of this type of descending or ascending behavior in the data compiled for Table IV. With animal A the $\tau/\overline{t_{0.5}}$ ratio was 0.193 and the experimental $Bi/\overline{Bm}$ ratio was 7.35. This ratio was not large enough to maintain constant values for $B_{min.}$ (and $B_{max.}$) from the first dose on. Values for $B_{min.}$ increase gradually from a value of 6.46 at the end of the first dosing interval to the asymptotic value of 7.00 at the end of an infinite number of dosing intervals. If the $Bi/\overline{Bm}$ ratio of 7.97 calculated according to Eq. 31 had been used, then values for $Bc_{max.}$ and $Bc_{min.}$ would have remained at constant levels throughout the experiment on to an infinite number of doses. With animal D, the $\tau/\overline{t_{0.5}}$ ratio was 0.375 and the experimental $Bi/\overline{Bm}$ ratio was 4.92. This ratio was too large to maintain constant values for $B_{min.}$ (and $B_{max.}$) from the first dose on. Values for $B_{min.}$ decrease from a value of 4.22 at the end of the first dosing interval to the asymptotic value of 3.75 at the end of an infinite number of dosing intervals. According to calculations that can be made from Eq. 31, the correct $Bi/\overline{Bm}$ ratio should have been 4.37 instead of 4.92 to effect constant values for $Bc_{max.}$ or $Bc_{min.}$ from the first dose on. Results for animals B and C are similar in this regard to those for animal D.

The asymptotic mean amount of drug p.u.a., $\overline{Bc}$, can be calculated according to Eq. 15 when the number of doses p.u.a. approaches infinity. For animal A this value is 7.49. The value of $\overline{Bc}$ can be closely approximated by Eq. 32 only when the $\tau/t_{0.5}$ ratio is small:

$$\overline{Bc} \simeq \frac{Bc_{max.} + Bc_{min.}}{2} \qquad \text{(Eq. 32)}$$

From Eq. 17 one should be able to determine when the value of $\overline{Bc}$ is reached after the administration of the last mean maintenance dose p.u.a. at a time infinite in terms of the experiment. The value of $\overline{Bc}$ should be reached at some time, $Z\tau$, after $Bc_{max.}$ is reached. Solution of Eqs. 17 and 18 for Z yielded Eqs. 19 and 20. It should be evident from Eq. 20 that when the ratio $\tau/\overline{t_{0.5}}$ tends toward zero, or the drug is being administered by continuous infusion at a constant rate, the term Z tends toward a value of 0.5. On the other hand, when the ratio $\tau/\overline{t_{0.5}}$ tends toward infinity, or the drug is administered only once, the term Z tends toward zero. In Table IV the calculated values of Z for all animals is nearly equal to 0.5, since the $\tau/\overline{t_{0.5}}$ ratios are all small. Table IV also shows the total number of doses p.u.a. needed to approach within 1% of the values of $Bc_{min.}$ after the administration of an infinite number of doses p.u.a. By the use of Eq. 11, one can see that the value approaching 1% of $Bc_{min.}$ is reached with animals A through D in the range of more than 10 to 18 total doses.

Figure 1 represents some of the data given in Table II for animal D. The boundaries of the shaded regions represent plots of the logarithms of the calculated upper and lower 95% confidence limits of *Bc versus* time. The actual experimental points and the regression lines calculated from these points for each 0.5 hr. are omitted from this figure. The solid dots represent times at which samples were withdrawn from the absorption cell for analysis. The solid lines are plots of the logarithm of *Bc versus* time and were calculated from Eq. 11, where the initial dose p.u.a., Bi, is 5.47 mg./cm.^{2}, the mean value for the penetration coefficient, $\bar{P}$, is 0.52 hr.$^{-1}$, t is clock time from 0.5 to 2.5 hr., the mean value for the maintenance doses p.u.a., $\overline{Bm}$, is 1.11 mg./cm.^{2}, n is the total number of doses and ranges in whole numbers from one to four, τ is the dosing time interval of 0.5 hr., and the time, T, ranges from zero to 0.5 hr. after the last maintenance dose p.u.a. The arrows represent times at which the three mean maintenance doses p.u.a. were administered. The vertical dashed lines in Fig. 1 represent the magnitude of logarithm of $\overline{Bm}$. Figure 1 shows with animal D, when values for $\overline{Bm}$ and $\bar{P}$ are substituted into Eq. 11, that the straight lines generated by plotting the logarithm of *Bc versus t* all fall within the shaded areas. Qualitatively similar results are obtained with data treated in the same manner for animals A through C.

In conclusion, the procedures outlined in this report illustrate some quantitative methods of studying drug absorption from the s.c. site. Although BA in NS was used as a model drug system

for this work, one can reasonably expect that other drugs in the same or different vehicles could be similarly studied in various animal species in order to discover fundamental factors affecting drug absorption rate from the s.c. site.

Automatic Determination of Ethinyl Estradiol in Pharmaceutical Preparations

By A. J. KHOURY* and L. J. CALI†

An automated method for determining ethinyl estradiol or ethinyl estradiol methyl ether is described. The method is based on the fluorescence exhibited by ethinyl estradiol when it is treated with 90 per cent sulfuric acid. The nonvarying time, temperature, and volume characteristics of an automatic analyzer (AutoAnalyzer) system have been used to study a number of variables which might affect the data. Specificity of the fluorescence method with respect to degradation products, interference from other estrogens and progestational agents, as well as repeatability and sensitivity of the method are discussed. Also presented are data on trade packages of a number of antifertility formulations. Samples can be analyzed using the automated method at a rate of 20 samples per hour as opposed to one or two samples per hour by manual techniques.

SINCE THE USE of progesterone and ethisterone (17α-ethinyltestosterone), was first described by Inhoffen and Hohlweg (1) a number of antifertility products have become available. All of these products contain ethinyl estradiol (EE) or its methyl ether (EEME) in combination with a progestational steroid hormone. EE is usually formulated into tablets at concentrations as low as 0.05% of the total tablet weight along with another steroid whose concentration is 50 to 500 times greater than that of EE. The analysis of EE in this environment has presented a difficult analytical problem. The U.S.P. method of analysis (2) is very time consuming, while the colorimetric method described by Urbanyi and Rehm (3) does not distinguish between EE and other estrogens, and also is not applicable to the methyl ether of EE. methods (4) have been applied with some success but are limited due to the lack of accuracy and precision generally afforded by such procedures. Spectrofluorometric methods (5) while generally yielding specific data at low levels of concentration, can yield inaccurate data due to fluorescence quenching. Methods based on the Kober reaction (6) are inapplicable unless a separation technique is first applied. Talmage (7) described a gas chromatographic method for EE, but this procedure does not lend itself to analysis of large numbers of samples. A method which has not been reported previously but which is applicable to the analysis of EE in tablets of low dosage has been developed. The method is based on the chemically induced fluorescence which is manifested by EE in 90% H_2SO_4. The specificity afforded by this reaction makes it possible to directly apply this method to the analysis of EE in oral contraceptive preparations or in preparations containing similar estrogenic substances. Although the procedure may be carried out by conventional techniques, application of the method to the automatic analyzer[1] provides a method of analysis which can be used to obtain unit-to-unit variation of formulations containing as little as 5 mcg. of EE.

EXPERIMENTAL

Materials—Automatic analyzer equipment was used for the study. (*a*) Solid-prep sampler; volume set at 75 ml. and programmed at 20 samples per hour. (*b*) Proportioning pump. (*c*) Continuous filter; speed 3. (*d*) Fluorometer; primary filter (513 mμ) is a combination of Corning No. 1–60 (nearest lamp) and Wratten No. 58. Secondary filter (545 mμ) is a Wratten No. 23A. Sensitivity settings; activation source 30X; slit-3. (*e*) Linear recorder. (*f*) Acid flex tubing; conditioned by allowing the system to flush for 1 hr. Assemble the apparatus as shown in the flow diagram of Fig. 1.

Reagents and Solutions—Ninety per cent sulfuric acid in water (v/v); denatured alcohol (ethyl–methyl, 10:1) with water 40%.

Standard Ethinyl Estradiol Solutions—Prepare solutions of ethinyl estradiol in the denatured alcohol to contain 35, 40, 45, 50, and 55 mcg. of EE per ml. Place 1 ml. of the standards in the cups of the Solid-prep unit and obtain a standard curve.

Preparation of Samples—Place a weighed, finely powdered sample containing the equivalent of about 50 mcg. of EE in each sample cup. Obtain the reading from the recorder and calculate the number of micrograms of EE per weight of sample. For study of unit-to-unit variation, place 1 tablet in each of the sample cups.

RESULTS AND DISCUSSION

Linearity—An actual working curve which was obtained by analyzing standards of known concentration may be found in Fig. 2. A linear relationship exists for fluorescence and EE concentration in the range which was studied.

10,	101.0	*20*,	100.0

[a] 1.0 mcg./ml., 95% alcohol.

Sensitivity—The automated method which has been developed was done so with the application of the method to individual EE dose variation in mind. The flow diagram of Fig. 1 is therefore applicable

to the analysis of samples which contain 25–100 mcg. of EE. The final concentration of the EE in the flow diagram indicated is about 0.06 mcg./ml. However, the practical limit of detectability has been shown to be 0.004 mcg./ml. of EE.[2]

Specificity—It has been known for some time that phenolsteroids (estrogens) when treated with sulfuric acid give rise to derivatives having a characteristic fluorescence. This effect was first observed in 1929 by Weiland, Straub, and Dorfmuller (8). The absorption and/or excitation spectra of these estrogen–H_2SO_4 chromogens exhibit maxima with broad peaks ranging from 410–450 mμ. The fluorescence characteristics of the EE–H_2SO_4 chromogen are vastly different from those of the other estrogens. EE has its activation maximum displaced at least 60 mμ toward the long wave region of the spectrum (λ_A = 513 mμ), and its fluorescence maximum at 545 mμ is displaced about 45 mμ. Figure 3 indicates the difference between

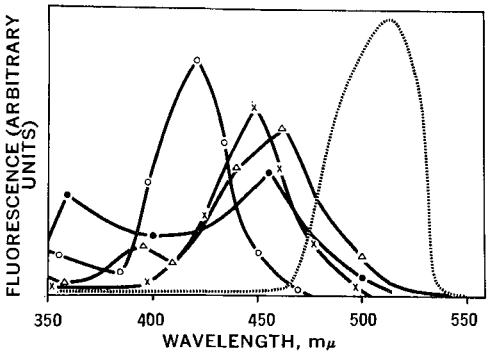

Fig. 3—Activation spectra of estrogen-sulfuric acid chromogens. Key: O, β-estradiol; ●, equilin; △ equilenin; X, estrone; ...., ethinyl estradiol.

the activation spectrum of the EE–H_2SO_4 chromogen and the activation spectra of other typical estrogen–H_2SO_4 chromogens.[3] This is quite significant if one considers that the only structural difference between EE and a typical estrogen, *e.g.*, β-estradiol, is the ethinyl moiety in position 17. When synthetic samples of EE plus a tenfold excess of equilin, equilenin, estrone, and β-estradiol were analyzed, less than 3% interference was contributed by these estrogenic substances.

The specificity of the reaction with respect to ethinyl estradiol degradation products was demonstrated by thin-layer chromatography.

Thin-layer plates were prepared from Silica Gel G HR after Stahl. The solvent system consisted of 1:1 hexane–ethylacetate. Two spray reagents, phosphomolybdic acid (9) and 90% sulfuric acid, were used.

Samples of thermally and photochemically degraded raw material exhibit a number of spots when phosphomolybdic acid detection is employed. This is illustrated in the chromatoplate on the left side of Fig. 4. Phosphomolybdic acid is a nonspecific reagent and is used only to indicate the absence or presence of components other than intact EE. When 90% H_2SO_4 was used for visualization of the same degraded raw material, one fluorescent component which corresponds in R_f to pure EE was detected. This is illustrated in the chromatoplate on the right side of Fig. 4. This indicates that the

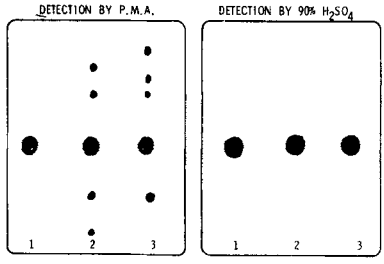

Fig. 4—Thin-layer chromatoplates of EE raw material. Key: 1, 20 mcg. of EE raw material; 2, 20 mcg. of the same raw material after exposure to direct U.V. light for 1 month; 3, 20 mcg. of the same raw material after storage at 100° for 1 month.

specificity of the sulfuric acid reagent eliminates the need for lengthy separation techniques. Further proof of H_2SO_4 specificity with respect to raw material EE decomposition products was obtained by quantitatively evaluating the degraded raw material by the automatic analyzer method and also by native fluorescence and the U.S.P. colorimetric methods. The data which are contained in Table II indicate that comparable results are obtained by all three assay procedures.

TABLE II—QUANTITATIVE ANALYSIS OF ETHINYL ESTRADIOL RAW MATERIAL BY THREE ASSAY PROCEDURES

Sample No.	Storage Condition	Native Fluorescence, % of Theory	Modified Kober, % of Theory	Automatic Analyzer, % of Theory
1	1 mo. 75° C.	67.6	69.0	69.8

3	1 mo. direct U.V. light exposure	88.8	89.1	88.9

Compressed tablets containing only EE (50 mcg./tablet) were subjected to accelerated conditions of heat and light. When these tablets were evaluated by the automated procedure and by the same two referee methods which were used previously, the results in Table III were obtained. These data indicate that the automatic analyzer method gives results which agree with native fluorescence and the colorimetric procedure.

The progestational type steroid hormone which is commonly found in oral contraceptive products

6	12 mo., R.T.	93.1	97.2	97.0

along with EE is generally of the Δ^4-3-keto structural variety. The concentration of this steroid is such that it may usually be determined by direct ultraviolet spectrophotometric methods, with no interference from EE. Usually the Δ^4-3-ketosteroid will be 50–500 times more concentrated than EE in an individual dosage unit. In spite of this large difference in concentration, significant interference was not encountered when a number of antifertility products were examined by the automated procedure. Table IV indicates a tabulation of data which were obtained when a number of commercial products were assayed by the automated procedure. These four products contained 3 different progestational steroids ranging in concentration from 2 to 10 mg. per tablet.

TABLE VI—COMPARISON OF RESULTS BY COLORIMETRIC, NATIVE FLUORESCENCE, AND SULFURIC ACID FLUORESCENCE OF EE-Δ^4-3-KETOSTEROID FORMULATION

Aged Sample No.	Ethinyl Estradiol, mcg.: Natural Fluorescence Before Extn.	Natural Fluorescence After Extn.	Colorimetric	Sulfuric Acid Fluorescence
1	36.2	46.7	46.8	47.2
2	33.0	44.8	45.0	44.7

In order to study Δ^4-3-ketosteroid interference with the method, EE was separated from the progestational steroid by solvent extraction, and then assayed by the automated method. The data in Table V show that results with and without extraction are equivalent, indicating little or no interference from the progestational steroid.

Two trade materials were not amenable to the automated sulfuric acid fluorescence assay. One contains a Δ^5-3-ketosteroid which interferes with the sulfuric acid fluorescence causing high results. Another product contains a material in the formulation which quenches the fluorescence and causes low results. In the latter case, a chloroform extraction removed the active ingredients away from the interfering substances. The chloroform was removed by evaporation and the residue was analyzed by the method described earlier. This separation technique was not successful for the Δ^5-3-ketosteroid containing products.

This sulfuric acid fluorescence method was used successfully in controlling developmental samples of a new Wyeth (10) antifertility product. This product contains 0.5 mg. of a new progestational steroid,[4] in combination with 50 mcg. of ethinyl estradiol. Since this quantity of progestational steroid is much lower than that found in other commercial products (2–25 mg.), attempts were made to analyze these products for EE by the native fluorescence method mentioned earlier. This provided a striking example of the problems that can occur when assaying by the native fluorescence procedure.

[4] WY-3707, 13-β-ethyl-17α-ethinyl-17-hydroxygon-4en-3-one.

Two aged samples of the combination tablets were assayed by the native fluorescence method, the colorimetric method, and the sulfuric acid fluorescence method. The data in Table VI show that the results by the native fluorescence method are much lower indicating that there may be a quenching effect operative. When the ethinyl estradiol was extracted from these sample mixtures and then assayed by the native fluorescence method, the results agreed with those obtained by the other two methods. This quenching effect was not noted with tablets containing only ethinyl estradiol.

SUMMARY

Application of the automatic analyzer to the analysis of ethinyl estradiol has been accomplished. The nonvarying volume, time, and temperature characteristics of this system have enabled the development of a repeatable assay procedure even for very low concentrations of EE. The procedure has been shown to be specific for intact EE in the presence of thermal and photochemical decomposition products. The procedure was also demonstrated to be specific for EE in combination with large amounts of the usual progestational steroid hormones and in the presence of large amounts of other similar estrogenic substances. A number of trade packages of antifertility products were successfully analyzed by the automated method. Twenty samples per hour can be handled easily as opposed to one to two samples per hour by conventional methods. This laboratory has found the automated method very convenient for determining unit-to-unit variation in formulations.

New System of Disk Electrophoresis Using Large Acrylamide Gels

By ROBERT C. PETERSON

The disk electrophoretic method has been modified to use gels of 22-mm. diameter. A gel tube base was designed to produce a gel with a convex base, and a special buffer cell was provided. With the future goal of preparative electrophoresis, a quenched fluorescence technique was developed which locates the major protein zones without dyeing. A transverse destainer was designed for rapid removal of unbound dye from stained protein patterns.

THE THEORY, methods, and applications of gel electrophoresis have been well reviewed (1, 2). It has been our purpose to develop a simple, convenient method of columnar electrophoresis which could be adapted to preparative electrophoresis. Preliminary work has indicated that this approach is very promising.

The method of Ornstein (3) and Davis (4) has been modified to give gels 22 mm. in diameter by about 11.4 cm. in length.

METHODS AND MATERIALS

The pilot compound for this work was N.F. trypsin crystallized reference standard, lot 6040, 3226 N.F. units/mg. (5). The pH 5 buffer, pH 4.3 gel, and solutions for a gel concentration of 15% have been described.[1] Acrylamide, *N,N'*-methylenebisacrylamide, and β-alanine were of good purity.[2] *N,N,N',N'*-Tetramethylethylenediamine was practical grade, redistilled.[3] The ammonium persulfate and riboflavin were reagent grade.[3] The acetic acid was reagent grade.[4]

The gel tube was placed in the new base (see Fig. 1), and 40 ml. of lower gel ingredients[1] were introduced with the usual water layering. Teflon was selected for the base material in order to give less wear and a minimum of contamination. The 12.7-cm. long glass tube fits snugly within the O-ring and on the shelf in plug C.

When plug C is threaded into block B, the concavity in plug C forms the gel base for glass tube A. This rounded gel base (convex on the gel) is neces-

New System of Disk Electrophoresis Using Large Acrylamide Gels

By ROBERT C. PETERSON

The disk electrophoretic method has been modified to use gels of 22-mm. diameter. A gel tube base was designed to produce a gel with a convex base, and a special buffer cell was provided. With the future goal of preparative electrophoresis, a quenched fluorescence technique was developed which locates the major protein zones without dyeing. A transverse destainer was designed for rapid removal of unbound dye from stained protein patterns.

THE THEORY, methods, and applications of gel electrophoresis have been well reviewed (1, 2). It has been our purpose to develop a simple, convenient method of columnar electrophoresis which could be adapted to preparative electrophoresis. Preliminary work has indicated that this approach is very promising.

The method of Ornstein (3) and Davis (4) has been modified to give gels 22 mm. in diameter by about 11.4 cm. in length.

METHODS AND MATERIALS

The pilot compound for this work was N.F. trypsin crystallized reference standard, lot 6040, 3226 N.F. units/mg. (5). The pH 5 buffer, pH 4.3 gel, and solutions for a gel concentration of 15% have been described.[1] Acrylamide, *N,N'*-methylenebisacrylamide, and β-alanine were of good purity.[2] *N,N,N',N'*-Tetramethylethylenediamine was practical grade, redistilled.[3] The ammonium persulfate and riboflavin were reagent grade.[3] The acetic acid was reagent grade.[4]

The gel tube was placed in the new base (see Fig. 1), and 40 ml. of lower gel ingredients[1] were introduced with the usual water layering. Teflon was selected for the base material in order to give less wear and a minimum of contamination. The 12.7-cm. long glass tube fits snugly within the O-ring and on the shelf in plug C.

When plug C is threaded into block B, the concavity in plug C forms the gel base for glass tube A. This rounded gel base (convex on the gel) is neces-

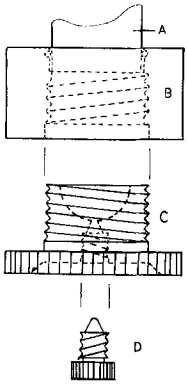

Fig. 1—Gel tube base. Key: A, glass gelation tube; B, Teflon block fitted with O-ring to hold glass tube and threaded to take plug C; C, Teflon plug milled to form base for gelation tube, threaded to fit block B and also to admit air plug D; D, plug to admit air.

sary. During polymerization, larger gels such as this tend to contract at the bottom and become concave. This cavity will collect gases during electrophoresis which stop the flow of current. A convex gel bottom as we have prepared will not hold these gases.

Plug C is made removable from block B in order to leave a minimum of surface holding the gel tube; this reduces the chances of detaching the gel from the tube when the tube is removed. Plug D is necessary to provide access of air to plug C before it is removed; otherwise, suction is created when plug C is removed which detaches the gel. This base has worked very satisfactorily.

The critical dimensions of this gel tube base assembly can be furnished by the author upon request.

The polymerization of these larger gels produces considerable heat; this heat can form cavities in the gel from dissolved gases which separate the gel from the tube. However, if polymerization is carried out in a refrigerator (about 6°), it is successful very nearly 100% of the time. Gelation is accomplished in about 1 hr.; this can be detected by the disappearance of heat from the gel tube.

For use with trypsin, the gels were pre-run overnight without spacer gel to remove possible interfering contaminants. Fresh buffer was used for the actual run. It was found empirically that this treatment improved resolution and definition. The electrophoresis assembly is illustrated in Fig. 2. The vertical glass tube buffer compartment is 40 mm. in diameter (o.d.) by 153 mm. The lower rectangular buffer compartment is made from 1/4-in. Lucite and measures 152 mm. long, 114 mm.

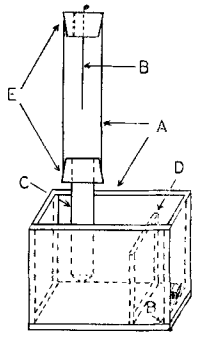

Fig. 2—Electrophoresis assembly. Key: A, buffer compartments; B, platinum electrodes; C, glass gel tube; D, baffle plate; E, rubber stoppers.

wide, and 108 mm. deep. The baffle in this compartment is just covered when the volume is 1100 ml. This baffle aids in keeping electrophoresis gases away from the gel.

Before the actual run, 8 ml. of spacer gel solution was added in the usual manner[1] above the small pore gel and photopolymerized for about 20 min. Trypsin, 5 mg., was added in 0.5 ml. of pH 5 buffer[1] containing 30% sucrose w/v.

Movement of trypsin components is downward when the upper electrode is made the anode. The d.c. power source was variable voltage regulated.[5] The fractionation was carried out for 9 hr. at 200 v. and about 24 ma. Both the pre-run and fractionation were done in the refrigerator (about 6°). Removal of the gel was accomplished by rimming with a 22-gauge hypodermic needle through which distilled water was continually forced from a syringe. Immediately upon removal, the gel was placed on a fluorescent plate (see Fig. 3) under a low wavelength (253.7 mμ) mercury lamp.[6] The gel must be lying over the slot with its long axis horizontal to the slot. Zones of highly concentrated protein appear as medium to dark blue zones where the fluorescence of the green fluorophor[7] is quenched. Figure 4 shows a sketch of the quenched pattern above the stained pattern of the same gel. The dye solution is 1% naphthol blue black[8] w/v in methanol–acetic

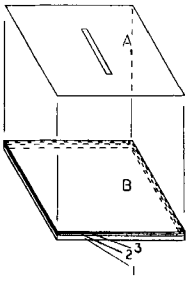

Fig. 3—Fluorescent plate. Key: A, black paper mask with slot (4 1/4 in. × 3/16 in.); B, glass plate with indicated layers (1, 6-in. square glass; 2, sprayed coating of fluorophor; 3, dipped coating of paraffin).

acid–water (5:1:5 by vol.). The gel is kept in the dye solution for 48 hr. before destaining. The authors have found that an aqueous acetic acid solution of the dye is insufficient in its complexing of the protein to prevent zone removal during destaining. Also in this figure is shown a sketch of the pattern of proteolysis of gelatin[9] as given by a gel column run in identical fashion. The gel was not stained, and transverse sections about 0.25 in.

thick were incubated on the plate of gelatin at room temperature for 25 hr. The gelatin, approximately 15% w/v, had been dissolved with heat in pH 7.6, 0.067 *M* phosphate buffer and hardened in a refrigerator before use. Correlation of most zones is seen with the dyed pattern and the quenched fluorescence and proteolytic pattern. These will be discussed later.

When using the transverse destainer, it was noticed that after most of the blue dye was removed some red dye remained. Multiplicity of the dye was suspected. Paper chromatography did indeed show 2 distinct zones, blue and red. Further investigation by cellulose acetate[10] electrophoresis showed 4 zones. The buffer was formic acid (90%)–pyridine–water (15:2.5:982.5 by vol.), pH 2.65. The main blue pigment stayed at the origin; at its tip was a small spot of brown pigment. Both of these pigments were preceded by 2 red pigments. Obviously this dye consists of at least 4 pigments. It appears that, in particular, those investigators who are quantitating proteins with this dye for clinical study should consider the possible variability in dye absorption by various proteins and the variability in wavelength of absorption among these pigments.

A transverse destainer has been designed and used in these laboratories for nearly 2 years. It is shown in Fig. 5. Other destainers using the same principle have been made (6–10), but to the author's knowledge these have been for 5–6-mm. gels or slabs. Although not shown in the figure, the 2 strips on either side of the gel compartment are each drilled through with about 100 holes, $^1/_{32}$ in. in diameter. The holes are staggered to give uniform current transfer. Destaining of the gel can be accomplished within 4 to 8 hr., or if more convenient, overnight at 50 to 100 v. (50 to 100 ma.). Four per cent acetic acid was the electrolyte.

RESULTS AND DISCUSSION

This system gives 6 to 7 zones in the dyed pattern of trypsin N.F. The electrophoretic pattern can be duplicated. This resolution can be compared with 2 zones by paper electrophoresis (11) and 4 zones by cellulose acetate electrophoresis (12). The variation in number of zones occurs with the light, lead zones in the region of zone 6. They vary from 1 to 2. These, to the best of the author's knowledge, have not been noted before. No attempt was made to identify these proteins, but from electrophoresis on cellulose acetate, followed by reaction with specific substrate (12), one would predict that the dark and largest zone would contain the tryptic activity.

Acrylamide gel electrophoresis of this same trypsin in the commonly used 5-mm. gels and with the same electrolyte system has shown only 4 or 5 zones. It seems that the larger gel gives much greater resolution partly due, no doubt, to the larger amount of material (5–15 mg.) which can be run and which results in being able to see what are probably mcg. quantities in a separated zone. It is felt that this approach is ideal for preparative electrophoresis. Since, in most cases, the desired compound already will be 80–90% pure, the major zone can be located by quenched fluorescence and sectioned out, and the purified compound can be removed by various means from the gel for further purification, if needed. Also, it is felt that this method will give better separation of zones both mechanically and electrically than the familiar continuous electrophoresis methods.

From Fig. 4, good correlation is seen for the major zone in quenching of fluorescence, staining, and proteolytic activity. A small amount of proteolytic activity is found in other areas of the gel. This indicates the probable presence of other proteolytic enzymes, such as chymotrypsin. The considerable quenching of fluorescence which is seen in the region of zone 6 routinely is found in the electrophoresis of trypsin. Its cause is not understood.

The broad, quenched area in the region of dyed zones 1 and 2 is considered to be the effect of scattered light from these zones.

Any possibility of the zones, other than the main one, being artifacts seems very unlikely. The pattern can be duplicated. In addition, the proteolytic pattern indicates the difference in activities shown by the various zones. Possibly more conclusive is an experiment in which the major zone (zone 5) was cut out using the fluorescent plate (a butter and cheese cutter is excellent) and placed on top of a new gel column. Conditions were the same except that the run time was slightly longer. The stained pattern had 2 zones, the major one and a very light following zone which probably was a portion of zone 4 that was cut out with it. The gel section which had been placed on top also was dyed and destained. It showed no protein zones.

It has not been a purpose here to quantitate by densitometry or other means the stained protein zones of these larger gels. The aim is to use large gels for preparative electrophoresis of practical amounts of various compounds of high purity, and the work noted in this paper is considered to be a step in this direction. With the fluorescent plate method of locating the major zone, the greatest hurdle has been eliminated. It should be mentioned that gels 2 in. in diameter have been used with good results.

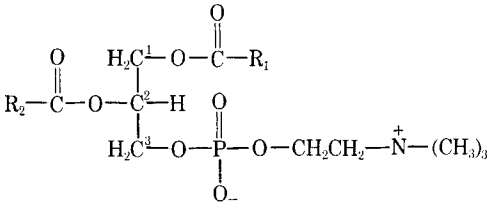
Solubilization and Rate of Dissolution of Drugs in the Presence of Physiologic Concentrations of Lysolecithin

By THEODORE R. BATES*, SONG-LING LIN, and MILO GIBALDI†

The micellar solubilizing properties of physiologic concentrations of lysolecithin for hexestrol, dienestrol, and griseofulvin are demonstrated. The extent of solubilization was found to decrease in the following order: hexestrol > dienestrol ≫ griseofulvin. Dissolution rate studies showed that lysolecithin significantly enhances the rate of solution of hexestrol, dienestrol, and griseofulvin. A role for this physiologic surfactant in the absorption process of hydrophobic drug molecules is explored.

HUMAN BILE is chiefly composed of cholesterol, calcium, bile salts, and phospholipids. Lecithin is the major phospholipid component of bile. It belongs to the class of compounds referred to as phosphatidylcholines (I).



R_1, R_2 = alkyl chains of fatty acids

I

The enzyme, phospholipase A, is capable of removing only one of the fatty acids from the lecithin molecule to form either 1- or 2-acyl lysolecithins. Phospholipase A is found in abundance in snake venom (*Crotalus adamanteus*) and also occurs in humans and animals. Its presence has been established in the mucous membrane of the small intestine (1), in duodenal fluid (2, 3), in the pancreas (4–6), and in blood serum (7). Commercially available lysolecithin is usually prepared by the enzymatic action of snake venom on purified egg lecithin. This material has palmitic or stearic acid in the 1-position of the glycerol moiety, since snake venom phospholipase A specifically catalyzes the hydrolysis of the fatty acid linkage at the 2-position (8–11).

Aqueous solutions of lysolecithin exhibit a more or less abrupt change in their physical properties over a narrow concentration range suggesting the formation of aggregates or micelles. The marked surface activity of this compound as well as other physical properties of its solutions have been reported by a number of investigators (9, 11–18). Surface tension *versus* concentration curves indicate that the critical micelle concentration (CMC) for this compound is in the concentration range of 1–2 $\times 10^{-3}$% (11, 14).

One of the most interesting properties of surface-active agents is their ability to bring into aqueous solution, at concentrations above the CMC, otherwise water-insoluble compounds. This phenomenon is known as micellar solubilization (19). There have been only a limited number of reports demonstrating the solubilizing ability of lysolecithin. Robinson and Saunders (20) found that aqueous solutions of lysolecithin possess a marked solubilizing power for cholesterol, triolein, and monostearin.

Lysolecithin appears to occur in small concentrations in human bile (21) and in high concentrations in the contents of the duodenal region of the small intestinal lumen (2). On examination of human small intestinal contents, following a test meal free of phospholipids, Borgström found that most of the phospholipids contained therein were in the form of monopalmitoyl-lysolecithin. This material was identical to that prepared by the action of snake venom on purified egg lecithin. The presence of phos-

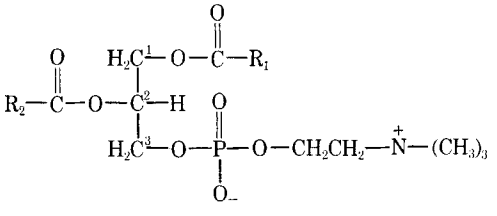
Solubilization and Rate of Dissolution of Drugs in the Presence of Physiologic Concentrations of Lysolecithin

By THEODORE R. BATES*, SONG-LING LIN, and MILO GIBALDI†

The micellar solubilizing properties of physiologic concentrations of lysolecithin for hexestrol, dienestrol, and griseofulvin are demonstrated. The extent of solubilization was found to decrease in the following order: hexestrol > dienestrol ≫ griseofulvin. Dissolution rate studies showed that lysolecithin significantly enhances the rate of solution of hexestrol, dienestrol, and griseofulvin. A role for this physiologic surfactant in the absorption process of hydrophobic drug molecules is explored.

HUMAN BILE is chiefly composed of cholesterol, calcium, bile salts, and phospholipids. Lecithin is the major phospholipid component of bile. It belongs to the class of compounds referred to as phosphatidylcholines (I).



R_1, R_2 = alkyl chains of fatty acids

I

The enzyme, phospholipase A, is capable of removing only one of the fatty acids from the lecithin molecule to form either 1- or 2-acyl lysolecithins. Phospholipase A is found in abundance in snake venom (*Crotalus adamanteus*) and also occurs in humans and animals. Its presence has been established in the mucous membrane of the small intestine (1), in duodenal fluid (2, 3), in the pancreas (4–6), and in blood serum (7). Commercially available lysolecithin is usually prepared by the enzymatic action of snake venom on purified egg lecithin. This material has palmitic or stearic acid in the 1-position of the glycerol moiety, since snake venom phospholipase A specifically catalyzes the hydrolysis of the fatty acid linkage at the 2-position (8–11).

Aqueous solutions of lysolecithin exhibit a more or less abrupt change in their physical properties over a narrow concentration range suggesting the formation of aggregates or micelles. The marked surface activity of this compound as well as other physical properties of its solutions have been reported by a number of investigators (9, 11–18). Surface tension *versus* concentration curves indicate that the critical micelle concentration (CMC) for this compound is in the concentration range of 1–2 $\times 10^{-3}$% (11, 14).

One of the most interesting properties of surface-active agents is their ability to bring into aqueous solution, at concentrations above the CMC, otherwise water-insoluble compounds. This phenomenon is known as micellar solubilization (19). There have been only a limited number of reports demonstrating the solubilizing ability of lysolecithin. Robinson and Saunders (20) found that aqueous solutions of lysolecithin possess a marked solubilizing power for cholesterol, triolein, and monostearin.

Lysolecithin appears to occur in small concentrations in human bile (21) and in high concentrations in the contents of the duodenal region of the small intestinal lumen (2). On examination of human small intestinal contents, following a test meal free of phospholipids, Borgström found that most of the phospholipids contained therein were in the form of monopalmitoyl-lysolecithin. This material was identical to that prepared by the action of snake venom on purified egg lecithin. The presence of phos-

pholipase A (3) and lysolecithin (2) in duodenal fluids suggests that lysolecithin in the lumen results from the action of phospholipase on bile lecithin.

Borgström *et al.* (22) have reported that the human gall bladder is emptied during the first 30 min. after a balanced test meal, giving rise to high concentrations of bile salts and phospholipid in the content of the duodenum and proximal jejunum. The main part of the test meal is mixed with liver bile and digested and absorbed from a mixture with concentrations of bile acid of about 1 to 3 mg./ml. and of phospholipids of about 0.5 to 1 mg./ml. chiefly as lysolecithin.

The role of physiologic surface-active agents in the absorption mechanism of water-insoluble drug molecules has received scant attention. Recent reports have demonstrated the effect of physiologic bile salt solutions on the solubilization (23, 24) and dissolution rate (25) of water-insoluble drugs. On the basis of these *in vitro* findings, it was proposed that bile salts play a role in the dissolution step of the absorption process from the small intestine.

The present communication is concerned with the interaction between relatively water-insoluble drug molecules and lysolecithin, another component of the intestinal fluids, and the effect of lysolecithin on the rate of solution of these compounds.

EXPERIMENTAL

Materials—Dienestrol,[1] hexestrol,[1] and griseofulvin[2] were used as received. Chromatographically pure lysolecithin[3] was dried *in vacuo* for 24 hr. prior to use.

Equilibration—An excess quantity of drug was added to ampuls containing varying concentrations of lysolecithin solutions. The ampuls were sealed and rotated in a constant-temperature water bath at 37° until equilibrium was established. Equilibrium was determined by repetitive sampling. The solutions were then rapidly filtered through a Millipore filter assembly (0.45 μ pore size) to remove undissolved drug, and the filtrate was appropriately diluted with anhydrous reagent methanol and assayed spectrophotometrically. (See under *Assay Procedure.*)

Dissolution Rate Determination—The method employed was essentially that of Higuchi and Shefter (26). One hundred milligrams of drug in excess of its predetermined solubility in 0.05% lysolecithin solution was added to exactly 100 ml. of dissolution medium maintained at 37 ± 1° in a water-jacketed vessel. Water or a 0.05% lysolecithin solution was used as the dissolution medium.

The solution was agitated by means of an overhead stirrer (2.5-cm. blade). The agitation intensity[4] was high (800 r.p.m.) to insure complete wetting of the hydrophobic drug when water served as the dissolution medium. At appropriate time intervals a 5-ml. sample was withdrawn from the vessel and replaced by the same volume of dissolution medium. The sample was treated as outlined under *Equilibration.* A cumulative correction was made to account for the previously removed samples.

Assay Procedure—Beer's law curves were constructed for hexestrol (278 mμ), dienestrol (228 mμ), and griseofulvin (292 mμ). A methanol–water (4:1) solvent system was employed for each drug. A Beckman DB recording spectrophotometer was used to obtain absorbance readings. Lysolecithin was found not to interfere with the spectrophotometric analysis in the concentrations present in the diluted samples.

RESULTS AND DISCUSSION

The Influence of Lysolecithin Concentration on Solubilization—The solubilization curves for hexestrol and dienestrol in varying concentrations of lysolecithin at 37° are depicted in Fig. 1. It can be seen from these curves that the solubility of both drugs increases, in a linear fashion, after a certain minimum concentration (about 2.5 × 10^{-3}%) of lysolecithin has been exceeded (*i.e.*, the CMC).

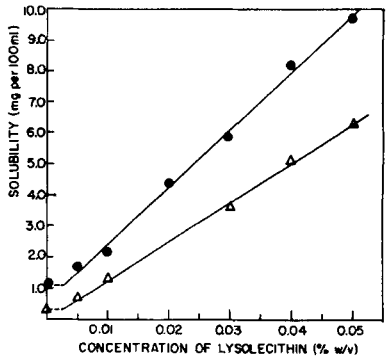

Fig. 1—Solubilization of hexestrol and dienestrol in dilute solutions of lysolecithin at 37°. Key: ○, hexestrol; △, dienestrol.

The apparent saturation capacities or ratios of the lysolecithin micelles for the drug-solubilizate molecules were obtained from the least squares slopes of the linear portion of the solubilization curves. These values, expressed as moles of micellar solubilized drug per mole of lysolecithin,[5] were found to be 0.34 and 0.23 for hexestrol and dienestrol, respectively.

Figure 2 shows the solubility of griseofulvin in solutions of lysolecithin at 37°. The saturation capacity determined for this solubilizate was 0.042.

Based on the saturation ratios found for the three solubilizates under investigation it can be seen that the lysolecithin micelle displays a somewhat similar affinity for hexestrol and dienestrol and a significantly lower affinity for griseofulvin. These differences are examples of the well established fact that the extent of micellar solubilization, in any surfactant solution, is influenced by the nature of the solubilizate molecule (19).

Lysolecithin forms essentially spherical micelles in solution, with its polar group oriented away from the

[4] Constant agitation intensity was achieved by utilizing a Servodyne constant torque system.

[5] Based on a theoretical molecular weight of 495.6 for monopalmitoyl-lysolecithin.

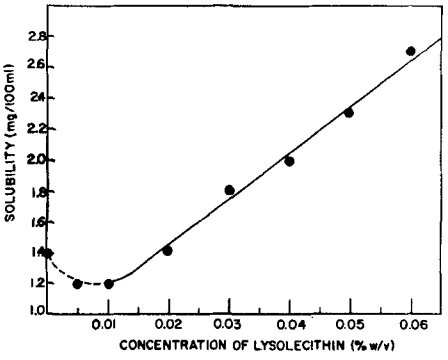

Fig. 2—Solubilization of griseofulvin in dilute solutions of lysolecithin at 37°.

"hydrocarbon" center of the micelle (14, 17, 27). Its isoelectric point is about 6.7 and in aqueous solutions it functions primarily like a nonionic surfactant (11). The lower degree of interaction of griseofulvin with the lysolecithin micelle can probably be attributed to steric effects. The volume available within the micelle for the solubilizate molecule is limited. As a result, griseofulvin being the largest of the three solubilizate molecules would encounter the greatest difficulty in packing within this restricted space.

The presence of free hydroxyl groups in the hexestrol and dienestrol molecules permits strong dipole interactions with the polar head group of the lysolecithin molecules in the micelle. This interaction may act as a driving force for the solubilization process.

Dienestrol and hexestrol are quite similar in chemical structure. The sole difference between the two molecules is the presence of double bonds in the 2 and 4 position of dienestrol, whereas the alkyl chain of hexestrol is saturated. The reduced affinity of lysolecithin for dienestrol relative to the affinity for hexestrol may be related to the fact that dienestrol is a more rigid molecule (because of conjugation) and may be restricted in its ability to pack within the micelle.

It is also of interest to compare the inverse saturation ratios (*i.e.*, moles of solubilizer/mole of drug) found with lysolecithin in the present study and with various bile salts in previous studies (23). Approximately 3 moles and 24 moles of lysolecithin were required to solubilize 1 mole of hexestrol and 1 mole of griseofulvin, respectively. The affinity of the various bile salts for hexestrol was similar to the affinity of lysolecithin for the drug. A range of about 4–6 moles of bile salt was needed to solubilize 1 mole of hexestrol. A marked difference exists, however, in the relative affinity for griseofulvin. The bile salts were much less effective solubilizers; a range of about 160–200 moles of bile salt was needed to solubilize 1 mole of griseofulvin. Nevertheless, it is apparent that both surface-active components of intestinal fluid have marked detergent properties.

The Influence of Lysolecithin on Dissolution Rate—For a drug to be absorbed across the gastrointestinal mucosa it must be in solution. In many instances the rate-limiting step in the absorption process of drugs administered in a solid form is the rate of dissolution in the gastrointestinal fluids.

Only one report has appeared in the literature concerning the influence of bile components on the dissolution rate of water-insoluble drugs (25). These investigators demonstrated that bile salts markedly enhance the dissolution characteristics of the drugs investigated.

Figures 3–5 show the dissolution behavior, in water and 0.05% lysolecithin solution, of hexestrol, dienestrol, and griseofulvin, respectively. Each curve is drawn through points which represent an average of two dissolution runs. It can be seen from these curves that the presence of lysolecithin in the dissolution medium significantly enhances the rate of dissolution of these drugs compared to the rate found in water. Inspection of these curves shows that after 2 min. the ratios of the amount of drug dissolved in the 0.05% lysolecithin solution

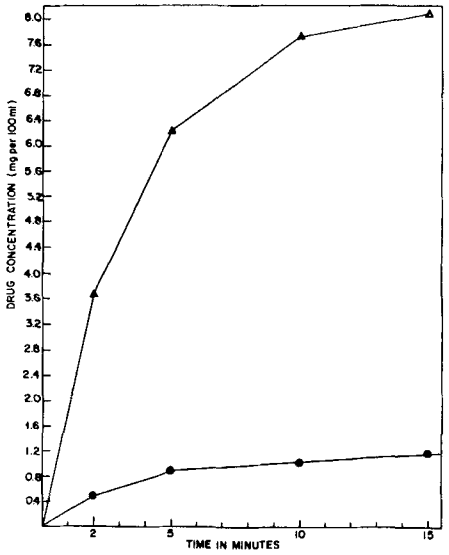

Fig. 3—Dissolution rates of hexestrol in water (●) and 0.05% lysolecithin (△) at 37°.

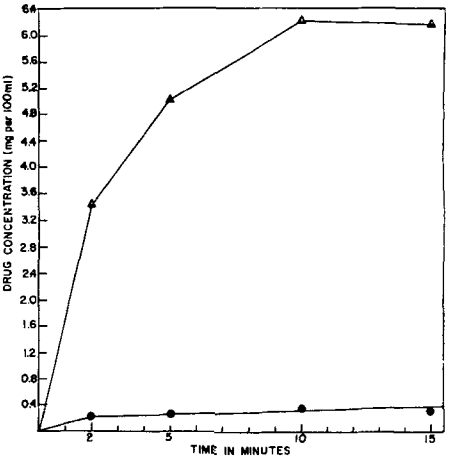

Fig. 4—Dissolution rates of dienestrol in water (●) and 0.05% lysolecithin (△) at 37°.

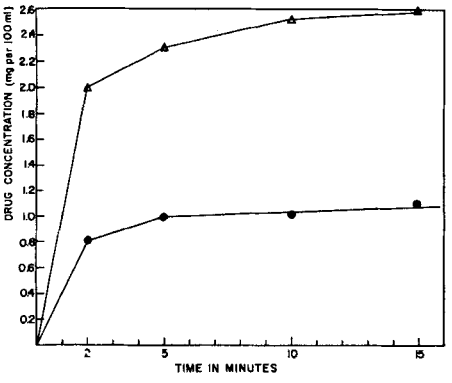

Fig. 5—Dissolution rates of griseofulvin in water (●) and 0.05% lysolecithin (△) at 37°.

to that amount dissolved in water are, 7.0, 15.6, and 2.4 for hexestrol, dienestrol, and griseofulvin, respectively. Preliminary studies indicate a threefold increase in the amount of reserpine dissolved in 0.05% lysolecithin solution at the 2-min. interval as compared to that present *at equilibrium* in water. The increased dissolution rate of these water-insoluble drugs in the presence of lysolecithin can be attributed essentially to micellar solubilization.

The presence of physiologic surfactants (*i.e.*, conjugated bile salts and lysolecithin) in the fluids of the upper region of the small intestine coupled with the strong interactions observed between these surfactants and certain poorly soluble drugs suggests that these surfactants play a role in the dissolution step of the absorption process of these pharmaceuticals.

It is anticipated that such physicochemical studies of the nature of the interactions of drugs with normal constituents of the gastrointestinal tract will significantly contribute to a greater understanding of the complex process of drug absorption.

Ultraviolet and Attenuated Total Reflectance Infrared Spectra of Chlorpromazine Metabolites

By R. J. WARREN, W. E. THOMPSON, J. E. ZAREMBO, and I. B. EISDORFER

Ultraviolet absorption and attenuated total reflectance infrared spectra of chlorpromazine and 14 possible metabolites have been recorded and analyzed. Structural correlations of the absorption bands are presented and discussed. This collection provides a positive means of identifying chlorpromazine metabolites extracted from body fluids and tissues and separated by chromatographic techniques. Spectral identification can be made on microgram samples.

IDENTIFICATION of the metabolites of chlorpromazine has been the subject of considerable research effort over the past decade. As a result of this research, many, if not most, of its important metabolites have been identified. The usual procedure for identifying chlorpromazine metabolites has been comparison of either paper or thin-layer chromatograms of the metabolites, and of standards run at the same time. Very few investigators have used infrared spectroscopy for metabolite identification, principally no doubt because of the small amounts of metabolites available. With the advent of attenuated total reflectance spectroscopy (ATR), this obstacle has been effectively removed. The technique of ATR was developed by Fahrenfort (1) and has been described in detail by him and by Harrick (2). Its application to the identification of metabolites has been reported by several investigators. The ATR method provides infrared spectra from samples of the order of 10 mcg. In most cases, the unchanged sample can be recovered easily for further study. The combination of ATR and ultraviolet absorption spectroscopy provides an effective and positive means of identifying chlorpromazine metabolites and other materials from biological systems.

The purpose of this paper is to report the results of a spectral study of 14 possible metabolites of chlorpromazine. The ATR and ultraviolet spectral data presented here make possible a positive identification of these compounds.

EXPERIMENTAL

The infrared spectra were recorded on a Perkin-Elmer model 521 spectrometer equipped with a Wilks Scientific model 12 attenuated total reflectance attachment. The samples were prepared and run as natural films dispersed over KRS-5 plates by evaporation from chloroform solution. The average sample size was of the order of 75 to 100 mcg.

The ultraviolet spectra were recorded between 200 and 400 mμ with a Cary model 14 spectrophotometer using matched fused silica cells with a 1 cm. path length.

All spectral data were obtained from the same samples of analytical standards of a purity of 98% or greater.

RESULTS AND DISCUSSION

Infrared Spectra (ATR)—Although it is possible that transmission spectra and ATR spectra of the same materials may show slight differences (*e.g.*, band shape, relative intensities), no significant differences between transmission and ATR spectra have been found in this study. Figure 1 shows a comparison of the I.R. transmission spectrum of chlorpromazine (top) and the ATR spectrum of the same material (bottom). It is readily apparent that, for all practical purposes, the two spectra are identical. The remaining spectra of the reference materials are ATR spectra rather than transmission spectra because it is believed that, in most cases of metabolite study, the use of ATR rather than transmission spectra will be dictated by the size of the sample.

For infrared study the compounds can be separated into six groups: four groups are distinguished by the type of side chain on the nitrogen atom; the fifth group is made up of hydroxylated derivatives; and the sixth of *N*-oxides.

Figure 2 shows the spectrum of 2-chlorophenothiazine-5-oxide. This is the only member of the series without a side chain. The spectrum is typical of a 2-substituted phenothiazine (3). The strong S=O absorption band in the vicinity of 1000 cm.$^{-1}$ identifies the material as a sulfoxide.

Figure 3 shows the spectra of chlorpromazine derivatives with a primary amine side chain on the nitrogen atom. The side chain is the same in each case but the compounds shown from top to bottom are the sulfide, sulfoxide, and sulfone analogs. The spectra agree with the expected pattern of a 2,10-disubstituted phenothiazine (3); and a strong S=O absorption band at 1000 cm.$^{-1}$ ($\pm$20) and SO_2 bands at 1250–1300 cm.$^{-1}$ and 1140–1160 cm.$^{-1}$ identify the sulfoxide and sulfone derivatives.

Figure 4 shows the spectra of chlorpromazine analogs with a secondary amine side chain. Again, the order of spectra from top to bottom is sulfide, sulfoxide, sulfone.

Figure 5 shows chlorpromazine sulfoxide, chlorpromazine sulfone, and promazine. Chlorpromazine itself is shown in Fig. 1. The comments regarding 2,10-disubstituted phenothiazines in Figs. 3 and 4 apply to the sulfoxide and sulfone. Promazine gives the expected pattern of a 10-substituted phenothiazine, *i.e.*, the strong absorption band in the 720–770 cm.$^{-1}$ region of the 4 adjacent ring hydrogens (4).

Figure 6 shows the spectra of the 7- and 8-hydroxy derivatives of chlorpromazine, which differ in several respects from those of other metabolites. Since these two materials have ring substituents in addition to the 2-position, the aromatic substitution pattern would be expected to be different, and in fact it is. The peak in the 770–735 cm.$^{-1}$ region which is

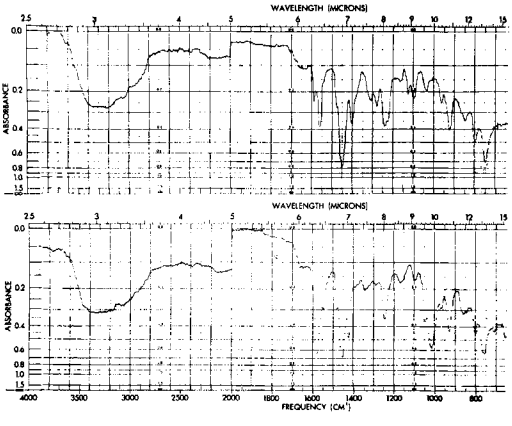

Fig. 7—ATR spectra of 2-chloro-10-(3′-dimethylaminopropyl)phenothiazine-N-oxide (top) and 2-chloro-10-(3′-dimethylaminopropyl)phenothiazine-N-oxide-5-oxide (bottom).

characteristic enough to allow differentiation from each other as well as from the other metabolites.

Figure 7 shows the ATR spectra of *N*-oxide derivatives of chlorpromazine. The *N*-oxide absorption band is located at 1200–1250 cm.$^{-1}$ and, in the case of the *N*-oxide-sulfoxide derivative, this absorption band and the strong band in the 1000 cm.$^{-1}$ region confirm the structure.

Ultraviolet Spectra—The ultraviolet spectra of chlorpromazine, chlorpromazine sulfoxide, and sulfone have been previously reported (3) by these laboratories. In addition to the ultraviolet data on these compounds, Table I gives data on the primary and secondary amine side chain analogs of these materials as well as data on hydroxy and *N*-oxide derivatives. As expected, the derivatives within a single group have the same over-all ultraviolet spectrum; thus, with the exception of hydroxy derivatives, identification of a specific sulfide, sulfoxide, or sulfone could not be made on the basis of the ultraviolet spectrum alone. Nevertheless, the ultraviolet spectra of these analogs assume greater importance when coupled with the ATR spectra, which provide positive identification of the material in question. Once identity has been established, the ultraviolet spectra provide quantitative data on the amount of material present.

The over-all differences between sulfide, sulfoxide, and sulfone are well known, as has been mentioned above. Not yet reported are the ultraviolet spectra and their differentiation of the 7- and 8-hydroxy and of the *N*-oxide derivatives. The ultraviolet data for the hydroxy compounds in acidic and basic media are given in Table I, which shows that the spectrum of either of these materials can be easily distinguished from the other metabolites listed. The shift in peak locations on change in pH is a ready identification, even in mixtures of two or more of the metabolites.

The ultraviolet spectra of the *N*-oxide derivatives are not much different from those of chlorpromazine and the sulfoxide. With the exception of a slight shift of the long wavelength peak, the spectrum of the *N*-oxide is very similar to that of chlorpromazine itself. A similar relationship is found also between the spectra of the *N*-oxide sulfoxide and chlorpromazine sulfoxide (see Table I).

The value of these ultraviolet data is increased immeasurably after identity has been confirmed by ATR spectra, and relative amounts of the various metabolites can be calculated from standard reference data.

SUMMARY

Attenuated total reflectance infrared spectra and ultraviolet absorption spectra of chlorpromazine and 14 metabolites have been presented. On the basis of these data, it is possible to make an identification of any of the materials listed.

Uropepsin Excretion and the Effect of Antacid Materials

By D. D. ABBOTT, J. W. E. HARRISSON, and R. C. BROGLE*

The effect of a series of antacid materials upon uropepsin output was evaluated in a group of 15 normal adults. The antacids, namely, sodium bicarbonate, calcium carbonate, magnesium hydroxide, hydrated magnesium aluminate-sulfate activated (HMAS), and bismuth subsalicylate, were administered on the comparable basis of acid consuming power (ACP). Urine specimens, both control and test, were evaluated for total proteolytic activity. Statistical analysis of the results showed all test materials, except calcium carbonate, to have elicited significant decreases ($P < 0.05$) in uropepsin excretion.

THE THERAPEUTIC usefulness of gastric antacids in the treatment of gastritis and peptic ulcer is a result of their capacity to both reduce the acidity and inactivate pepsin of gastric secretions (1). This latter action has been mainly attributed to a denaturation of pepsin at pH values of 4 or higher. This has been demonstrated for aluminum hydroxide, in animals, by Komarov and Komarov (2), Komarov and Kruegar (3), and Schiffrin and Komarov (4).

A previous investigation (5), in these laboratories, studied dihydroxyaluminum sodium carbonate (DASC), aluminum hydroxide, calcium carbonate, and sodium bicarbonate for antisecretory and antipeptic activity in histamine stimulated rabbits. Therein the aluminum containing antacids elicited greater antisecretory effects than did calcium carbonate and sodium bicarbonate. *In vivo* decreases in proteolytic activity for the various antacids were in relation to the degree of pH elevation. However, under *in vitro* conditions DASC was observed to decrease proteolytic activity to a greater degree than could be anticipated from pH changes alone.

The present study in humans was conducted in an effort to study further the antisecretory effect of antacids using uropepsin excretion as an indirect means of determination. Janowitz and Hollander (6) have estimated that the proteolytic activity of urine, attributed to uropepsin, approximates 1% of gastric peptic output. This relationship is dependent upon many variables but mainly the rate at which pepsinogen enters the general circulation from the chief cells of the gastric mucosa and its subsequent excretion, into the urine, through the glomerular apparatus. Although uropepsin as an index of gastric pepsin secretion is subject to many inconsistencies, the authors have attempted to employ this parameter in the evaluation of a series of antacid materials.

EXPERIMENTAL

Materials—Sodium bicarbonate; calcium carbonate; magnesium hydroxide (as milk of magnesia); hydrated magnesium aluminate-sulfate activated (HMAS); HMAS, 4.22% and bismuth subsalicylate 4.54% (liquid); bismuth subsalicylate.

Dosages—The dosages of the antacid test materials, given t.i.d., after meals, were based upon the acid consuming power (ACP) of the individual items. The ACP values and the individual doses for each of the antacid materials appear in Table I.

Procedure—A total of 15 subjects (13 males and 2 females) ranging in age from 20 to 55 years were utilized. None of the subjects claimed any past history of gastroenterological condition that would preclude their participation.

During the course of study a total of six 24-hr. control urine specimens were obtained from each subject at weekly intervals. Comparable urine specimens were obtained on the day following the collection of the control specimens, during which each subject took the assigned test material, three times a day after each meal. The subjects were assigned to each of the individual test materials in a random fashion.

TABLE I—ACP AND DOSAGE (t.i.d.) OF ANTACID MATERIALS

Material	ACP[a]	Dose[b]
Sodium bicarbonate	124/Gm.	1.303 Gm.
Calcium carbonate	222/Gm.	0.728 Gm.
Magnesium hydroxide (milk of magnesia)	26.6/ml.	6.08 ml.
Hydrated magnesium aluminate-sulfate activated (HMAS)	248.6/Gm.	0.65 Gm.
HMAS and bismuth subsalicylate, 2.3% (liquid)	17.6/ml.	9.2 ml.
Bismuth subsalicylate	0	0.210 Gm.[c]

[a] Milliters 0.1 *N* HCl neutralized. [b] Amount required to neutralize 161.6 ml. 0.1 *N* HCl. [c] Amount contained in HMAS–bismuth subsalicylate combination.

The total volume of each 24-hr. urine specimen was measured prior to the determination of uropepsin activity in accordance with the method of Grey *et al.* (7) as described by Green and Power (8). A unit of uropepsin activity is defined as that amount which during 30 min. of incubation at 37°, under the conditions of assay, releases 0.04 mg. of tyrosine-like substances from a hemoglobin substrate.

RESULTS

The total 24-hr. uropepsin excretion levels during drug administration and during the paired control periods are presented in Table II. Both the mean values and the ranges are given. The results for the individual subjects with each of the test materials are presented in Fig. 1.

The significance of the observed differences in uropepsin excretion between the individual pairs of control and test specimens for each subject on each test material was assessed using a one-sided *t* test.

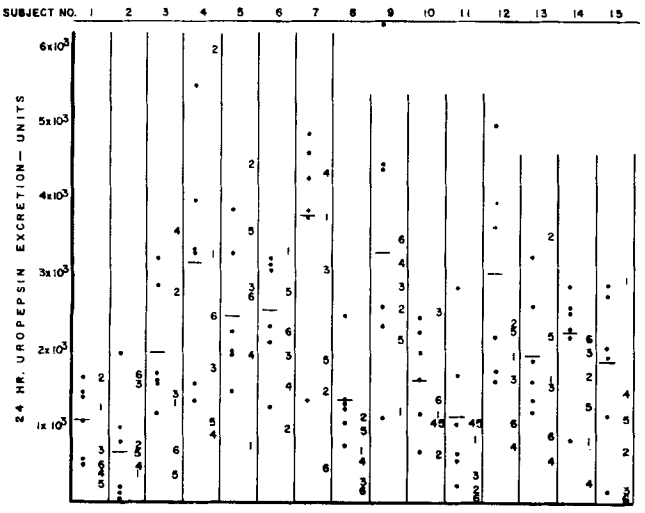

Fig. 1—Uropepsin excretion (units/24 hr.) test and control data. Key: 1, sodium bicarbonate; 2, calcium carbonate; 3, magnesium hydroxide; 4, HMAS; 5, HMAS and bismuth subsalicylate; 6, bismuth subsalicylate; ●, individual control values; —, mean values.

When the results were so evaluated, all test materials, except calcium carbonate, elicited significant decreases ($P < 0.05$) in uropepsin excretion.

An evaluation of the data showed a significant correlation ($P < 0.001$) within treatment groups between the magnitude of the control uropepsin level and the decrease in level upon treatment with the test materials. Higher control levels tended to be associated with greater decreases. Therefore, using an analysis of covariance, the decreases were adjusted for the differences in control levels. Based on Duncan's new multiple range test and owing to the large residual variances, none of the differences among the adjusted mean decreases for the various test treatments are statistically significant.

DISCUSSION

Of major consequence to the over-all evaluation of the uropepsin results obtained in this study is the extremely large variation in the 24-hr. excretion values by the individual subjects under the control conditions. The majority of subjects showed a variation in control uropepsin values of approximately two to fivefold. The over-all range of the control uropepsin values was 0–6265. These findings are in keeping with normal range by Corazzo and Myerson (9).

Notwithstanding the wide variations observed in the normal control values, both within and among the test subjects, there were statistically significant decreases in uropepsin excretion associated with the administration of all the test materials, except calcium carbonate. The basic reason for this occurrence remains to be elucidated. The decrease could result from inhibition of over-all gastric secretion, selective inhibition of pepsinogen formation, change in the partition of pepsinogen between gastric secretion and plasma, or a decrease in the excretion of pepsinogen by the glomerular apparatus. The results of earlier studies in animals (5) tend to support the initial possibility.

It is apparent from these findings that the usefulness of uropepsin excretion as a parameter in the evaluation of antacids is limited. This limitation is accentuated by the large variations noted in uropepsin excretion both within and among the test subjects.

SUMMARY

The effect of six antacid materials upon uropepsin excretion was evaluated in 15 test subjects. The effect was assessed by comparing total uropepsin excretion during a 24-hr. control period with that excreted in the next 24-hr. period during which a test material was taken three times a day after meals. The doses of the antacid were comparable, based upon their acid consuming power. All test materials evaluated, except calcium carbonate, resulted in decreases in uropepsin excretion that were significant at $P < 0.05$. The rationale of this effect upon uropepsin excretion requires further study of the many factors influencing uropepsin excretion.

Demonstation of Enhanced Lethality of Drugs in Hypoexcretory Animals

By JAMES E. GIBSON and BERNARD A. BECKER

Hypoexcretory states were produced in mice: anuria by penile ligation, extrahepatic cholestasis by bile duct ligation, intrahepatic cholestasis by phenylisothiocyanate treatment, and reduced bile flow by α-naphthylisothiocyanate treatment. Intraperitoneal administration of ouabain to mice with no or diminished bile flow resulted in enhanced mortality rates. Digoxin and digitoxin effected enhanced lethality in anuric mice. Lanatoside-C was not more toxic to hypoexcretory mice. The use of hypoexcretory mice in toxicologic evaluations of pharmacologic agents is suggested.

THE PURPOSE of this paper is to compare the acute lethalities of certain drugs in hypoexcretory animals with acute lethalities obtained in normal animals. While drugs may be excreted by several routes, the major routes of excretion are the urinary and biliary routes. Urinary excretion can be prevented in male mice by the production of anuria (1). Biliary excretion may be totally blocked by ligation of the common bile duct which produces extrahepatic cholestasis. A condition resembling intrahepatic cholestasis can be induced by treatment with aryl isothiocyanates in mice (2) or rats (3). Only two aryl isothiocyanates, phenylisothiocyanate (PIT) and α-naphthylisothiocyanate (ANIT), possess cholestatic activity (4); both ANIT and PIT have been used in these investigations. The drugs selected as test agents in these studies are four cardiac glycosides: ouabain, lanatoside-C, digoxin, and digitoxin. The excretion of these agents has been studied by Cox and Wright (5), who show that ouabain is excreted primarily *via* bile, lanatoside-C mainly *via* bile with a small degree of urinary excretion, digoxin excreted approximately equally in the bile and urine, and digitoxin excreted primarily in the urine.

METHODS

Adult, male, Swiss-Webster-type mice weighing 25–40 Gm., were housed in groups of 10 in stainless steel "shoebox" cages and allowed food and water *ad libitum* before and after treatment. Groups of 20 mice were anesthetized with ether and rendered anuric by the penile ligation (PL) method of Becker and Gibson (1). Other groups of 20 mice, anesthetized and sham-ligated (PL-sham), served as controls. Other mice were anesthetized with ether and the common bile duct isolated. The common bile duct was ligated near its junction with the duodenum and the incision closed with wound clips. Cholestasis or reduced bile flow was also induced by treating groups of 20 mice with 85 mg./Kg. of PIT[1] or ANIT.[1]

Total cholestasis was demonstrated 24 hr. after treatment by the method of Plaa and Becker (6) in which treated mice are injected intravenously with a saturated solution of fluorescein in isotonic sodium bicarbonate. Fifteen minutes after fluorescein was injected, the bile ducts were exposed and examined under ultraviolet light. A cholestatic animal showed no fluorescence in the bile duct. Actual flow of bile in ANIT treated mice was determined by cannulation of the common bile duct according to the method of Plaa and Becker (6) 24 hr. after oral administration of ANIT.

Groups of PL, PL-sham, and normal animals were injected intraperitoneally 2 hr. after operation with varying concentrations of the selected glycoside. Twelve hours after glycoside treatment, the number dead in each group was counted. Ouabain was dissolved in water, the other glycosides were dissolved in ethanol, and the concentration adjusted so that the desired drug dosage was administered intraperitoneally in 0.1 ml. of 47.5% ethanol and the final average dosage (mg./Kg.) was calculated from the average body weight per group. Preliminary tests showed that 0.1 ml. of 47.5% ethanol was not lethal to mice. In other experiments, groups of 20 BDL and 20 BDL-sham mice were treated 24 hr. after surgery, along with groups of 20 PIT, ANIT, corn oil vehicle treated, and normal mice, by intraperitoneal injection of varying dosages of the selected glycosides. The number dead in each group 24 hr. after glycoside treatment was recorded.

For both the anuria and cholestasis studies, the number dead in each group was expressed as percentage of the number treated and the standard error calculated by the binomial expansion method. Statistical significance ($P < 0.05$) between test groups and sham-operated and normal groups was also found by the binomial expansion method (7). Statistical analysis of bile flow data was made by Student's t test with the level of significance chosen as $P < 0.05$.

RESULTS

Cholestasis and Impaired Bile Flow—Twenty four hours after PIT, 85 mg./Kg., ten treated mice were tested for bile flow by the fluorescein method; nine (90%) showed no fluorescein, indicating total cholestasis. On the other hand, ANIT, 85 mg./Kg., effected total cholestasis in only 12 of 33 animals (35%). However, actual bile flow as measured in 4 mice 24 hr. after ANIT treatment was found to be definitely reduced in all but one animal (Table I). The percentage of animals shown in Table I which produced no bile agrees well with the 35% value obtained by the indirect (fluorescein) method.

Lethality in Anuric Mice—Digitoxin in three dosages, 2.5, 3.5, and 6.0 mg./Kg., effected significantly higher mortality rates in anuric mice than in sham-operated or normal mice. Similarly, digoxin in two dosages, 5.0 and 9.2 mg./Kg., also

ouabain or lanatoside-C (Table II). Lethality in sham-operated animals did not differ significantly from that in normal mice.

Lethality in Cholestatic or Impaired Bile Flow Mice—Ouabain was the only cardiac glycoside tested which effected increased mortality in mice with experimentally induced extrahepatic (BDL), intrahepatic cholestasis (PIT), or reduced bile flow (ANIT). Results are given in Table III.

DISCUSSION

The enhanced lethality of ouabain in animals with poor or no bile flow is a reasonable result as ouabain is believed to be excreted only in the bile. Similarly, the enhanced lethality of digitoxin in anuric animals is reasonable since digitoxin is excreted primarily *via* the urinary route. The increase in mortality rates seen in anuric animals treated with digoxin suggests that the urinary route of excretion is more important in mice than the biliary route, although the drug is believed to be excreted by both routes in the normal animal. Lanatoside-C, which according to Cox and Wright (5) is about 70% excreted in the bile and to a small degree in the urine, failed to effect enhanced lethality in either biliary or urinary hypoexcretory mice. This unexpected and challenging finding indicates that lanatoside-C can be eliminated, apparently, by either route of excretion with equal facility. The mechanism of the change in excretory routes remains to be investigated. The polarity of lanatoside-C is approximately that of ouabain as both compounds have five free hydroxyl groups. Another question which arises, then, is why the biliary hypoexcretory mouse cannot shift the elimination of ouabain to the urinary route.

Enhancement of toxicity of drugs in hypoexcretory animals other than the mouse has also been demonstrated. Enhanced lethality of ouabain in bile duct ligated cats has been reported by Kusakari and Uchida (8). Marcus *et al.* (9) studied the distribution of digitoxin in anuric dogs and humans in

[a] Intraperitoneal administration. Minimum group size: 20 mice. [b] Per cent dead ± standard error. [c] Eighty-five mg./Kg. in corn oil by mouth, 24 hr. before test drug administration. [d] Twenty-four hours before test drug administration. [e] Sham-treated animals of the various cholestatic groups were not significantly different from normals. [f] Probability of no difference between the smallest lethality in any cholestatic group and the normal group. [g] N.S., no significant differences between the various groups ($P > 0.05$).

effected enhanced lethality in anuric mice. The lowest digoxin dosage, 4.0 mg./Kg., effected higher but nonsignificant increases in lethality. No significant changes in mortality rates were effected by renal failure and found increased storage of digitoxin in these species when urinary flow was diminished.

The possibility of enhanced lethality of therapeutic agents in hypoexcretory humans, therefore,

exists. Physicians have intuitively recognized the need to reduce dosages of some agents, notably certain antibiotics, in patients with renal insufficiency. Toxicologists might properly concern themselves with the need to evaluate the toxicity of new pharmacologic agents in hypoexcretory animals as the mouse preparations described here. Such evaluation might be made as a part of drug safety evaluation during the preclinical testing period.

Determination of Benzoyl Peroxide Stability in Pharmaceuticals

By MURRAY P. GRUBER and ROBERT W. KLEIN

Spectrophotometric, titrimetric, and polarographic techniques were compared for stability testing of commercially available benzoyl peroxide pharmaceuticals. Initial testing revealed comparable results but significant discrepancies were observed on prolonged testing. The titrimetric procedure employed showed little degradation of the benzoyl peroxide at elevated temperatures, while both the spectrophotometric and polarographic methods demonstrated radical potency losses under the conditions of testing. Agreement was excellent between the polarographic and spectrophotometric procedures above 70 per cent of the original assay with a significant divergence being noted only below this level. A rapid, reproducible procedure of sufficient accuracy for pharmaceutical product stability and control purposes is presented.

WITH THE INTRODUCTION of benzoyl peroxide as a topical medicinal, this laboratory began an investigation into the published methods of analysis with a view to pharmaceutical stability evaluation. Previous methods have been employed to establish the absence of residual peroxides and associated by-products in the manufacture of plastics, polymers, fats, oils, breads, and flours. Since the primary purpose of any pharmaceutical test is specificity, it was believed that a more intensive investigation of the available methods was necessary prior to the adoption of any particular technique.

Titrimetric, spectrophotometric, and polarographic methods were compared for the determination of benzoyl peroxide stability in the dry form and in commercially available pharmaceutical preparations. The titrimetric method employed in this comparison was a modification of Wheeler's (1) procedure, a variation of the technique originally proposed by Lea (2).

Many spectrophotometric procedures have been described for the determination of organic peroxides, and the relative merits and disadvantages of these techniques have been thoroughly evaluated by Kolthoff and Medalia (3) and others (4, 5). The spectrophotometric procedure employed in this comparison was a modified form of the method of Banerjee and Budke (6). They adapted the iodimetric procedure of Heaton and Uri (7), using a 2 to 1 mixture of acetic acid and chloroform, instead of the proportions suggested by Lea (2). This technique proved to be the most promising due to the reduction of any tendency toward continued autooxidation, catalyzed oxidation, and/or induced oxidation. These properties were associated with the higher polarity of the solvent system. This procedure was designed for trace quantities of peroxide, but it was found applicable, by judicious choice of sample size and dilutions, to pharmaceutical preparations containing up to 10% benzoyl peroxide, with excellent accuracy and reproducibility.

A polarographic method was utilized for comparison as a result of the work of Ricciuti, Coleman, and Willets (8), who performed a statistical evaluation of a modified Wheeler procedure compared to a polarographic method for the analysis of tetralin hydro-peroxide and found the polarographic technique to be more reliable where impure products were encountered, due to its greater specificity. The various methods for polarographic measurement of organic peroxides are closely related in procedure and similar in results; therefore, a modification of the procedure of Bezuglyi and Dmitrieva (9) was employed.

Many pharmaceutical laboratories do not have polarographic instrumentation available because of the limited applications of polarography in this field. For this reason, a rapid, accurate, and reproducible spectrophotometric method is proposed for laboratory control and stability testing of benzoyl peroxide in pharmaceutical preparations.

EXPERIMENTAL

Spectrophotometric Assay

Determination of Benzoyl Peroxide Stability in Pharmaceuticals

By MURRAY P. GRUBER and ROBERT W. KLEIN

Spectrophotometric, titrimetric, and polarographic techniques were compared for stability testing of commercially available benzoyl peroxide pharmaceuticals. Initial testing revealed comparable results but significant discrepancies were observed on prolonged testing. The titrimetric procedure employed showed little degradation of the benzoyl peroxide at elevated temperatures, while both the spectrophotometric and polarographic methods demonstrated radical potency losses under the conditions of testing. Agreement was excellent between the polarographic and spectrophotometric procedures above 70 per cent of the original assay with a significant divergence being noted only below this level. A rapid, reproducible procedure of sufficient accuracy for pharmaceutical product stability and control purposes is presented.

WITH THE INTRODUCTION of benzoyl peroxide as a topical medicinal, this laboratory began an investigation into the published methods of analysis with a view to pharmaceutical stability evaluation. Previous methods have been employed to establish the absence of residual peroxides and associated by-products in the manufacture of plastics, polymers, fats, oils, breads, and flours. Since the primary purpose of any pharmaceutical test is specificity, it was believed that a more intensive investigation of the available methods was necessary prior to the adoption of any particular technique.

Titrimetric, spectrophotometric, and polarographic methods were compared for the determination of benzoyl peroxide stability in the dry form and in commercially available pharmaceutical preparations. The titrimetric method employed in this comparison was a modification of Wheeler's (1) procedure, a variation of the technique originally proposed by Lea (2).

Many spectrophotometric procedures have been described for the determination of organic peroxides, and the relative merits and disadvantages of these techniques have been thoroughly evaluated by Kolthoff and Medalia (3) and others (4, 5). The spectrophotometric procedure employed in this comparison was a modified form of the method of Banerjee and Budke (6). They adapted the iodimetric procedure of Heaton and Uri (7), using a 2 to 1 mixture of acetic acid and chloroform, instead of the proportions suggested by Lea (2). This technique proved to be the most promising due to the reduction of any tendency toward continued autooxidation, catalyzed oxidation, and/or induced oxidation. These properties were associated with the higher polarity of the solvent system. This procedure was designed for trace quantities of peroxide, but it was found applicable, by judicious choice of sample size and dilutions, to pharmaceutical preparations containing up to 10% benzoyl peroxide, with excellent accuracy and reproducibility.

A polarographic method was utilized for comparison as a result of the work of Ricciuti, Coleman, and Willets (8), who performed a statistical evaluation of a modified Wheeler procedure compared to a polarographic method for the analysis of tetralin hydro-peroxide and found the polarographic technique to be more reliable where impure products were encountered, due to its greater specificity. The various methods for polarographic measurement of organic peroxides are closely related in procedure and similar in results; therefore, a modification of the procedure of Bezuglyi and Dmitrieva (9) was employed.

Many pharmaceutical laboratories do not have polarographic instrumentation available because of the limited applications of polarography in this field. For this reason, a rapid, accurate, and reproducible spectrophotometric method is proposed for laboratory control and stability testing of benzoyl peroxide in pharmaceutical preparations.

EXPERIMENTAL

Spectrophotometric Assay

Apparatus—Beckman model DU spectrophotometer: 1-cm. matched cells were used.

Reagents—Nitrogen, research grade; iodine, A.R.; glacial acetic acid, A.R.; chloroform, A.R.;

Received March 15, 1967, from the Analytical Research Department, Dermik Laboratories, Inc., Syosset, NY 11791
Accepted for publication July 17, 1967.
The authors are indebted to Professor Mary J. Kingkade, Department of Chemistry, Hunter College, City University of New York, for suggestions and a review of this manuscript.

potassium iodide solution: dissolve 50.0 Gm. of potassium iodide, A.R., in 50 ml. of freshly deionized water in a 100-ml. graduated cylinder. Dilute to 100 ml. with freshly deionized water. This solution must be made up fresh, and should be colorless.

Procedure—*Standard Curve Preparation*—Weigh accurately about 635 mg. of iodine and dissolve in approximately 300 ml. of 2:1 glacial acetic acid–chloroform. Care should be taken to assure complete solution of the iodine. This is best accomplished by warming the iodine in the solvent on a water bath with frequent stirring. Keep the solution covered to avoid any loss of iodine. Dilute the solution to 500.0 ml. with the solvent mixture. Pipet 0, 1-, 2-, 3-, 4-, and 5-ml. aliquots into glass-stoppered test tubes; dilute to 25.0 ml. with the 2:1 acetic acid–chloroform solution. Insert a glass capillary tube into the bottom of the test tube and purge solution for 1.5 min. with nitrogen. Add 1 ml. of the potassium iodide solution, purge for 1 min. with nitrogen, stopper, and mix. Measure the absorbance of the solution immediately at 470 mμ in a 1-cm. covered cell *versus* a 2:1 acetic acid–chloroform blank. Plot the mg. of benzoyl peroxide (121.1/126.9 × mg. iodine) *versus* the absorbance at 470 mμ.

Sampling Procedure for Stability Assays—This section would ordinarily not be included. However, it is the authors' opinion that other investigators may lose valuable time in setting up stability tests, only to find that the samples under consideration had irreversibly separated during storage at elevated temperatures, thereby invalidating any further exploration.

Accurately weigh a sample equivalent to approximately 50 mg. of benzoyl peroxide into a screw-top glass vial. Record the exact weight and place an identifying mark on the vial. Repeat this procedure for as many analyses as required for the entire study. Place the vials in a controlled temperature oven at the desired test temperature. Two vials should be removed from the oven at predetermined intervals for (duplicate) stability assays.

For initial assays, weigh the sample into a tared 150-ml. beaker and proceed as directed under *Sample Preparation and Analysis*, beginning with "Bring the volume of liquid . . . ."

Sample Preparation and Analysis—To the sample vial, add 2:1 glacial acetic acid–chloroform and carefully wash entire contents into a 150-ml. beaker. Repeat four additional times, taking care that no residue remains in vial. Bring the volume of liquid in beaker to approximately 50 ml. with the 2:1 acetic acid–chloroform. Stir for 5 min. Quantitatively transfer the solution to a 100-ml. volumetric flask, filtering through a Whatman No. 4 filter paper (previously washed with the 2:1 acetic acid–chloroform). Wash the beaker with two additional portions of the 2:1 acetic acid–chloroform, filtering these into the volumetric flask; bring to volume with same. Mix well. Pipet a 5-ml. aliquot of the above into a 50-ml. glass-stoppered test tube. Pipet in 20.0 ml. of the 2:1 acetic acid–chloroform, mix, and purge the solution with nitrogen for 1.5 min. Immediately add 1.0 ml. of the 50% w/v KI solution and purge with nitrogen for 1 min. Stopper immediately. Place in the dark for exactly 1 hr. Then rapidly read the absorbance at 470 mμ in a covered 1-cm. cell *versus* a 2:1 acetic acid–chloroform blank. Determine the weight of benzoyl peroxide from the standard curve.

$$\text{benzoyl peroxide } \%(\text{w/w}) = \frac{\text{mg. benzoyl peroxide (from curve)} \times 2}{\text{sample wt. (Gm.)}}$$

Titration Assay

Reagents—Sodium iodide solution: dissolve a sufficient quantity of sodium iodide, A.R., in 20 ml. of freshly deionized water to make a saturated solution. This solution must be made up fresh and should be colorless. Glacial acetic acid, A.R.; methylene chloride, A.R.; carbon dioxide, research grade; and standardized sodium thiosulfate solution, 0.1 *N*.

Procedure—*Sampling Procedure for Stability Assays*—Accurately weigh a sample equivalent to 250–275 mg. of benzoyl peroxide into a screw-top glass vial. Record the exact weight and place an identifying mark on the vial. Repeat this procedure for as many analyses as required for the entire study. Place the vials in a controlled temperature oven at the desired test temperature. Two vials should be removed from the oven at predetermined intervals for (duplicate) stability assays.

For initial assays, weigh the sample into a tared 500-ml. iodine flask. Pipet in 20.0 ml. of glacial acetic acid and proceed as directed under *Sample Preparation and Analysis*, beginning with "Add 10 ml. of methylene chloride . . . ."

Sample Preparation and Analysis—To the sample vial, add 5.0 ml. (pipeted) glacial acetic acid and carefully wash the entire contents into a 500-ml. iodine flask. Repeat three additional times (total, 20.0 ml. acetic acid), taking care that no residue remains in vial. Using a graduated cylinder, add 10 ml. methylene chloride and swirl to dissolve sample (lotions and creams may leave a turbid solution). Purge the solution for exactly 2 min. with carbon dioxide. Immediately pipet in 5.0 ml. of saturated sodium iodide solution and stopper. Swirl and stand solution in the dark for 30 min. After 28 min. have elapsed, purge 200 ml. of deionized water for 2 min. with carbon dioxide. Add 50 ml. of this deaerated water to the solution. Swirl and titrate to a colorless end point with 0.1 *N* sodium thiosulfate solution. Near the end point, deaerated starch T.S. may be used as an indicator.

$$\text{benzoyl peroxide } \%(\text{w/w}) = \frac{(\text{ml. thiosulfate}) \times (N \text{ thiosulfate}) \times 0.1211 \times 100}{\text{Gm. of sample}}$$

where 0.1211 = meq. wt.

Polarographic Assay

Apparatus—Polarograph (recording polarograph preferred) equipped with an H cell, using a dropping mercury electrode (2–7 sec. drop time) as recording electrode and a saturated calomel electrode as reference electrode.

Reagents—Benzene, A.R.; methanol, A.R.; ammonia, A.R. concentrated; methyl red, 0.2% w/v in methanol.

Procedure—Accurately weigh a sample equivalent to 10 mg. of benzoyl peroxide into a 250-ml. volumetric flask. Add 50 ml. of benzene, shake for 15 min. on a shaker, add 100 ml. of methanol, and swirl. Add, in order, 5 ml. of ammonia and 2.5 ml.

of 0.2% methyl red solution. Swirl, dilute to volume with methanol, and mix thoroughly. Transfer a portion to the sample side of the H cell. Bubble nitrogen or hydrogen through the solution for 10 min. Polarograph the solution from +0.45 v. to −0.2 v. . . $E_{1/2}$ = +0.27 v. *versus* S.C.E.

Calculate the diffusion current i_d in the conventional manner [limiting current (i_l) − residual current (i_r)].

Prepare a standard by dissolving an accurately weighed sample of approximately 100 mg. of benzoyl peroxide in benzene and diluting to 100 ml. Transfer a 10-ml. aliquot to a 250-ml. volumetric flask, add 40 ml. of benzene, and continue as directed above, beginning with "Add 100 ml. of methanol. . ."

$$\text{benzoyl peroxide } \%(w/w) = \frac{\frac{i_d \text{ sample}}{i_d \text{ std.}} \times \text{concn. BP std. (mg./ml.)} \times 25}{\text{Gm. of sample}}$$

where BP = benzoyl peroxide.

RESULTS AND DISCUSSION

A comparison of the titrimetric and spectrophotometric methods was performed to determine the accuracy and precision of the two procedures. Analyses were performed on a reagent grade benzoyl peroxide and a nonflammable pharmaceutical grade (35% active). Known concentrations were incorporated in an oil-in-water lotion and analyses repeated. Table I indicates the results of duplicate assays and demonstrates that all three methods are interchangeable for pure or freshly compounded mixtures. The polarographic procedure was eliminated as an analysis of reagent grade benzoyl peroxide. The diffusion current constant obtained, however, was used for the calculation of peroxide content of the other preparations.

TABLE I—COMPARISON OF RESULTS BY TITRIMETRIC, SPECTROPHOTOMETRIC, AND POLAROGRAPHIC METHODS ON PURE BENZOYL PEROXIDE POWDER AND FRESHLY PREPARED MIXTURES

	Method		
	Titrimetric, %	Spectrophotometric, %	Polarographic, %
Benzoyl peroxide, 99%	98.91	98.94	. . .
Benzoyl peroxide, 35%	35.00	35.01	35.00
Oil-in-water lotion (= 5.29% benzoyl peroxide)	5.25	5.33	5.28

Based on these findings, stability studies involving the three methods were instituted on commercial preparations containing 5 and 10% benzoyl peroxide. Two of these are lotions manufactured in the United States; the third is a cream produced in Canada.

One of these commercial formulations differs from the others in two respects. First, the benzoyl peroxide is packaged separately as a nonflammable powder containing 35% peroxide which is added by the pharmacist at the time the prescription is dispensed. Second, the pharmacist is directed to place an expiration date on the product at the time of compounding. The other formulations bear no expiration date, implying indefinite stability.

Additional tests were performed on the separately packaged powder to determine the stability of the peroxide in the mixture. The powder was tested at 49° C. and 60° C., while the finished formulations were tested at 46° C. The temperature of 46° C. (115° F.) was chosen since it is not uncommon for this temperature to be encountered in transit and in storage areas during the summer months, and in warmer climates for even longer periods. The powder was tested at higher temperatures because of the increased stability of benzoyl peroxide in the dry form. The results for the dry material, as determined by spectrophotometric analysis and polarographic assay, are indicated in Table II.

TABLE II—STABILITY ANALYSIS OF BENZOYL PEROXIDE POWDER

Temp.	Benzoyl Peroxide Content— Initial, %	8 Wk., %	27 Wk., %
49°C. (120° F.)	34.2	. . .	33.6
60°C. (140° F.)	34.4	33.1	. . .

This benzoyl peroxide appears to be quite stable at 60° C. after 8 weeks and at 49° C. even after 27 weeks The stability may be attributable to the filler employed (dicalcium phosphate), but no attempt has been made to ascertain the reasons for this since they are outside the scope of this study.

In order to test all three medications under the same condition, the 35% benzoyl peroxide mixture was added to its lotion base (lotion 1) as directed. Figures 1–3 summarize the results of 6.5 weeks of accelerated testing at 46 °C.

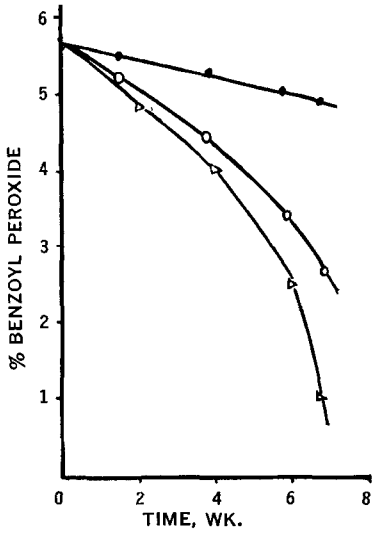

Fig. 1—Lotion 1. Key: ●, titrimetric; ○, spectrophotometric; △, polarographic.

The results of the three methods indicate some rather interesting discrepancies. According to the titrimetric procedure, both lotion formulations contained more than 90% of their original peroxide concentrations at the end of the 6.5-week testing period.

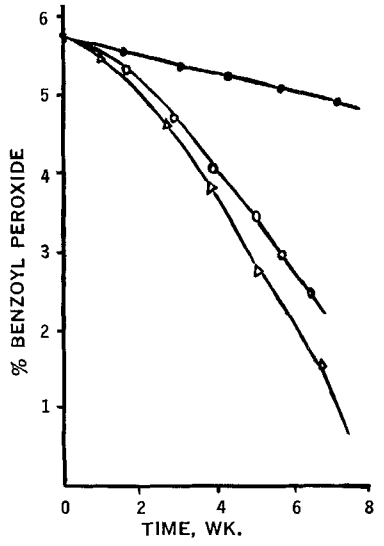

Fig. 2—Lotion 2. Key: ●, titrimetric; O, spectrophotometric; △, polarographic.

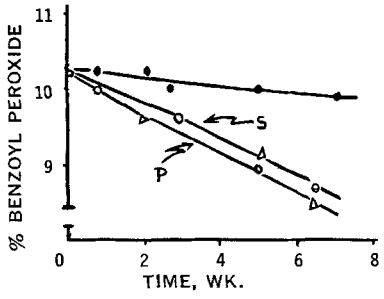

Fig. 3—Cream. Key: ●, titrimetric; O, spectrophotometric (S); △, *polarographic* (P).

Similarly, the cream formulation yielded nearly 97% of the benzoyl peroxide initially found. The spectrophotometric method, however, indicates a loss of more than 50% potency for both lotions, while the cream showed a loss of 17%. The polarographic method indicated losses, similar to those found spectrophotometrically, to approximately 70% of original potency. Below this point the divergence becomes significant and increases to yield a nearly 70% loss in one lotion and 78% in the other after 6.5 weeks' storage at 46°C. It is also noteworthy that a secondary wave appeared with $E_{1/2}$ values in the region of 0 v. *versus* S.C.E. after an apparent peroxide loss of 30%. This wave(s) exhibited sharp fluctuations in recorded microamperages. The intensity of the fluctuations and size of this wave increased with longer storage and decreasing benzoyl peroxide concentration. Continued investigation into the nature of the waves(s) and isolation of the component(s) causing this phenomenon is under way at the time of this writing.

From the available data, it seems that the titration procedure apparently does not differentiate some of the degradation products associated with benzoyl peroxide from the parent compound. The polarographic procedure appears to be the most accurate due to its specificity, particularly where significant breakdown has occurred. These results are in line with the finding of Ricciuti *et al.* (8) as previously noted. The spectrophotometric procedure indicates a significant amount of decomposition under prolonged storage conditions, but does not exhibit the full extent of this deterioration as exposed by the polarographic technique, the disparity becoming significant only below the 70% potency level. Values below this level are of little significance for pharmaceutical purposes since the usually accepted minimum limit of potency is 90% of the specified concentration. The method is simple, straightforward, and of sufficient accuracy above 70% potency to be extremely useful for pharmaceutical control and stability testing.

SUMMARY

Several commercially available benzoyl peroxide pharmaceuticals were subjected to quantitative analysis by a conventional titration method, a spectrophotometric procedure, and a polarographic assay. Although the titration and spectrophotometric methods compared favorably with each other for analysis of the pure benzoyl peroxide substance, the titration procedure proved inadequate for accurately determining the stability of benzoyl peroxide formulations, as confirmed by polarographic investigation. It is ascertained that a dry combination of benzoyl peroxide (35%) and dicalcium phosphate (65%) forms a stable mixture with long storage life. Both the polarographic and spectrophotometric procedures indicate that benzoyl peroxide dispersed in a lotion or cream vehicle has a limited shelf-life and should bear an expiration date. Because of its failure to discriminate between benzoyl peroxide and some of its associated decomposition products, the titrimetric technique cannot be applied with reliability to stability studies of these products.

The preferred method of analysis for adequate control and stability evaluation of pharmaceutical lotions and creams containing benzoyl peroxide (simulating elevated temperature conditions as commonly encountered in pharmaceutical transit and storage), where potency levels must be maintained at 90% or more of the label claim, is a simple spectrophotometric procedure. This method has been demonstrated to be accurate at levels of 70% or more of the original concentration.

Separation of Some Estrogen Sulfates from Their Oxidation Products

By A. R. HURWITZ, H. J. BURKE, and R. A. MARRA

Quantitative separations of sodium equilin sulfate from sodium equilenin sulfate and sodium 17β-dihydroequilin sulfate from sodium 17β-dihydroequilenin sulfate were obtained on dextran gel columns. It appears that these separations were the result of differences in adsorption character.

ALTHOUGH many quantitative methods are available for the determination of estrogens, it is generally necessary that the free form, the phenolic species, be used. Thus, naturally occurring sulfate or glucuronide esters have been submitted to hydrolysis of one form or another prior to analysis. In many instances direct separation of the conjugates would be preferred.

Steroid conjugates have been isolated from biological fluids by extraction with organic solvents (1), extraction as pyridinium salts into chloroform (3), gel filtration (4–7), and adsorption on charcoal or alumina–diatomaceous earth[1] (2, 8). Group separations of steroid sulfates and glucuronides have been accomplished by adsorption chromatography on alumina (9, 10) or diatomaceous earth (11), paper chromatography (12), thin-layer chromatography (13), and ion exchange (14). Steroid sulfates have been separated by partition chromatography on diatomaceous earth (15) or on methylated dextran gel (16), by ion exchange (14), and steroid glucuronides have been partially separated by gel filtration on dextran gel (7).

Procedures for the separation of estrogen conjugates have been generally concerned with estrone, estradiol, and estriol. Where other estrogens such as equilin, dihydroequilin, equilenin, and dihydroequilenin are also of interest, hydrolytic procedures have been employed prior to analysis.

The objective of this study was the separation of sodium equilin sulfate from sodium equilenin sulfate and sodium 17β-dihydroequilin sulfate from sodium 17β-dihydroequilenin sulfate. These separations were achieved on dextran gel[2] and were found to be quantitative and readily adaptable to ultraviolet determination. It was also possible to separate colored oxidation products of equilenin by this method. Observations made previously and independently elsewhere (17) have shown dextran gels to be useful in the qualitative separation of complex mixtures of estrogen conjugates. Observations on individual estrogens appear to indicate that quantitative separations of complex mixtures may now be possible. Apparently the separations are the result of differences in adsorption on the gel.

EXPERIMENTAL

Reagents—The sodium sulfate derivatives of the various estrogens used were prepared by D. Irvine, Ayerst Laboratories, Division of Ayerst, McKenna and Harrison Limited, Montreal, Canada. Dextran gel filtration media of various degrees of cross linking, G10, G15, and G25, were obtained from Pharmacia Fine Chemicals. Retention of sodium equilin sulfate on G10 and G15 was about the same and greater than that on G25. After these initial trials, G15 was used exclusively. The water used throughout the study was finally distilled from acid permanganate. All other reagents used were of analytical reagent grade and were used without further purification.

Preparation and Operation of Columns—The dextran gel was soaked in an excess of water for at least 4 hr. to allow for complete swelling. The slurried material was added to a 50-ml. buret, 70 cm. × 1.1 cm. i.d., containing a pledget of glass wool. While the water was allowed to drain out and as settling progressed, more slurry was added. Where salt or buffer solutions were used in elution, the column was prepared using these solutions. The columns were left to stand for several hours for completion of gel settling. The excess eluant above the gel surface was removed and the sample solution was carefully pipetted on to the top of the bed. After the sample had passed into the column bed, the eluant was added and maintained at an approximately steady level using a reservoir to decrease the chances of a change in flow rate, about 18 ml. per hour, during the course of the separation.

Eluate fractions of about 2 ml. were collected using an automatic siphon fraction collector[3] or a Volumeter collector.[4] For initial trials an ultraviolet absorbance spectrum, as shown in Fig. 1, was obtained for each fraction using a Cary 14 recording spectrophotometer, whereby the identity and concentration of the eluted materials could be determined. Chromatograms were obtained by plotting observed absorbance, corrected for dilution, against volume eluted.

Preparation of Samples—Fresh solutions of the sodium estrogen sulfate salts were prepared in a minimum amount of water prior to addition to the column. Samples of sodium equilin sulfate in phosphate buffer solution prepared for oxidation studies were applied to the column directly. Partially hydrolyzed samples were extracted with chloroform to remove free estrogens and the aqueous layer containing the conjugates was applied to the column.

RESULTS AND DISCUSSION

The column chromatographic procedure described permits the separation, isolation, and direct quantitative determination of two estrogen conjugates and their oxidation products. Initially, on

5, 17β-Dihydroequilin	17.3	17.1	98.9
6, Equilin	940	873	92.9
Equilenin (trace impurity)		11.9	1.3
7, Equilin	235	219	93.2
Equilenin (trace impurity)		3.0	1.3

a 7-Gm. column with water as the eluant, after the elution of the traces of inorganic salts present in the samples, sodium equilin sulfate and sodium equilenin sulfate were eluted with only partial separation. By increasing the column length with twice the amount of dextran gel, these two compounds were separated, as shown in Fig. 2. Samples subjected to accelerated oxidation gave elution patterns in which the appearance of equilin and equilenin was preceded by the elution of colored oxidation products of equilenin. Similar chromatograms were obtained for sodium 17β-dihydroequilin sulfate and sodium 17β-dihydroequilenin sulfate, as shown in Fig. 3.

A compilation of some theoretical and recovered weight data for various trials is given in Tables I and II. From the data presented in Tables I and II it can be seen that the procedure should also offer a means of purifying large amounts of individual estrogen conjugates. Purification methods would necessitate modification of column dimensions, bed volume, and eluent composition in order to improve capacity. Data of this type will be reported at a later date.

TABLE II—PER CENT RECOVERED FOR STANDARD SODIUM ESTROGEN SULFATE SAMPLES (ELUANT: SALT OR BUFFER SOLUTION)

Estrogen Moiety	Eluant	Added, mg.	Found, mg.	Recovery, %

[a] Elution incomplete after 150 ml. of eluate collected.

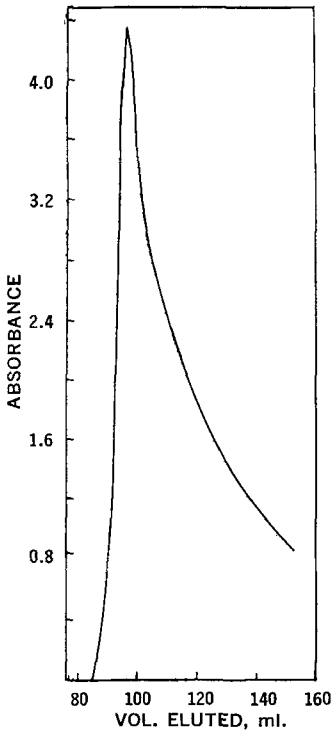

Fig. 4—Elution of sodium equilin sulfate from dextran gel (14 Gm.) with 0.01 M *sodium chloride as eluant. Recovery data shown in Table II,* 4.

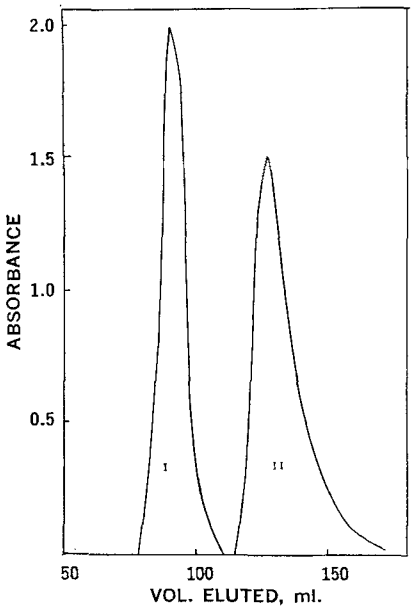

Fig. 5—Separation of sodium equilin sulfate from sodium equilenin sulfate on dextran gel (14 Gm.) with 5×10^{-4} M *sodium chloride as the eluant. Key:* I, *sodium equilin sulfate, absorbance 275 mμ;* II, *sodium equilenin sulfate, absorbance 280 mμ. Recovery data shown in Table II,* 1.

There are three possible factors to be considered when interpreting elution patterns on dextran gels: gel filtration, adsorption, and ion exchange. Simple gel filtration depends on the molecular size with the larger molecules being eluted first. Aromatic, heterocyclic, or basic compounds have been observed to adsorb reversibly with the degree of adsorption increasing with the amount of cross linking in the gel. Dextran gels also exhibit a weak ion-exchange property where the active functional groups are available carboxylic acid groups.

In separations that were performed with small amounts of sodium chloride or buffer present using water as the eluant, the electrolyte was eluted prior to the elution of the estrogen conjugate. Varying the pH (4.3 and 10.0, 0.001 *M* phosphate) of the eluant had little or no effect on the elution pattern. When 0.01 *M* sodium chloride was used as the eluant, the retention of sodium equilin sulfate on the gel was increased, as shown in Fig. 4, while higher salt concentrations resulted in nearly complete retention. From these observations, it would appear that the major factor operative in the observed separations was adsorption.

Proper selection of eluant electrolyte concentration slightly improves the separation of sodium equilin sulfate from sodium equilenin sulfate, as shown in Fig. 5. A sample of sodium equilin sulfate was prepared and subjected to accelerated oxidation conditions until only sodium equilenin sulfate and further oxidation products remained as determined by equilin and equilenin color tests. To this sample, 33.8 mg. of sodium equilin sulfate was added and the mixture placed on a dextran gel column for separation using 5×10^{-4} *M* sodium chloride as the eluant. Colored oxidation products were either irreversibly adsorbed on the gel or were eluted initially. Sodium equilin sulfate was recovered at 33.5 mg. or 99%.

The difference in the adsorption and elution be-

TABLE III—APPROXIMATE ELUATE VOLUME AT PEAK APPEARANCE IN THE CHROMATOGRAMS OF SEVERAL SODIUM ESTROGEN 3-SULFATE SALTS (14-GM. COLUMN, BED VOLUME, 45. ML.)

Estrogen	Vol. at Peak (ml.) Eluant: H_2O	Eluant: 5×10^{-4} M NaCl
 Estrone	70	73
 Equilin	75	90
 17β-Dihydroequilin	90	100
 Equilenin	95	125
 17β-Dihydroequilenin	110	160

havior of the individual estrogen salts and the effect of dilute aqueous sodium chloride eluant can be seen from the comparison of eluate volumes at peak appearance, as shown in Table III.

With due consideration of experimental conditions, it should be possible to modify this chromatographic procedure for the quantitative separation of complex mixtures of sodium estrogen sulfate salts. Preliminary work toward this end is already under way (17).

Nigerian Plants III. Phytochemical Screening for Alkaloids, Saponins, and Tannins

By GEORGIA J. PERSINOS* and MAYNARD W. QUIMBY

Fifty species of Nigerian plants were evaluated for the presence of alkaloids, saponins, and tannins. Of these, 24 contained alkaloids, 43 contained tannins, and 16 contained saponins.

THIS WORK is a continuation of the investigation carried out on plants used as medicinals by a pagan tribe, the Anagutas, living on the Jos Plateau in northern Nigeria, and the Hausas, living throughout northern Nigeria. Since plants occupy an important and sometimes central role in the religious beliefs and social practices of these peoples, an investigation of certain of these plants[1] has been undertaken

Received March 29, 1967, from the Department of Biological Sciences, Massachusetts College of Pharmacy, Boston, MA 02115
Accepted for publication July 27, 1967.
Abstracted in part from a thesis submitted by Georgia J. Persinos to the Massachusetts College of Pharmacy, in partial fulfillment of Doctor of Philosophy degree requirements.
This investigation was supported by research grant GM-08798 from the National Institutes of Health, Bethesda, Md.
* Present address: Research Pathology Associates, Division of Phytochemistry, Rockville, MD 20851
[1] The plant specimens were authenticated by Dr. Quimby and were made a part of the botanical collections of the Massachusetts College of Pharmacy.

EXPERIMENTAL

Preparation of Extracts—The screening procedures for alkaloids, saponins, and tannins were adapted from those described by Wall *et al.*(1, 2). An extract of each plant was prepared by refluxing 10 Gm. of the air-dried milled plant sample with 100 ml. of 80% ethanol for 1 hr. Each extract was then cooled to room temperature, suction-filtered, and washed with sufficient 80% ethanol to bring the volume of filtrate to 100 ml.

Alkaloids—Twenty milliliters of each extract, equivalent to 2 Gm. of dried plant material, was evaporated to dryness using a steam bath and the residue was stirred with 5 ml. of 1% aqueous hydrochloric acid. One milliliter of the filtrate was treated with a few drops of Mayer's reagent and a separate 1-ml. portion was treated similarly with silicotungstic acid reagent (12% aqueous). Precipitation or turbidity with either of these reagents was taken as preliminary evidence for the presence of alkaloids in the extract being evaluated. A confirmatory test designed to remove nonalkaloidal compounds capable of eliciting "false-positive" reactions with either of these reagents was conducted

[a] sb, stem bark; s, stem; r, root; rb, root bark; rz, rhizome; l, leaves; wp, whole plant. [b] Wall *et al.* procedure (1), based on confirmatory test. [c] Mayer's reagent. [d] Silicotungstic acid. [e] Farnsworth and Euler procedure (3). [f] bk/g, back-green; g, green; b/b, blue-black; br, brown; dg, dark green; bk, black; bl/g, blue-green. [g] Positive with 60 μl. [h] Positive with 70 μl.

in the following manner with all extracts giving a preliminary positive test for alkaloids.

Two milliliters of the acidic aqueous extract, prepared as described above, was treated with 28% ammonium hydroxide solution until the solution was distinctly alkaline to litmus paper, and then extracted several times with chloroform. The chloroform extracts were combined and concentrated *in vacuo* to about 2 ml., and then extracted with an equal volume of 1% aqueous hydrochloric acid.

One milliliter of the separated acid extract was treated with a few drops of Mayer's reagent, and a second 1-ml. portion was treated with silicotungstic acid reagent as previously described. Turbidity or precipitation after the addition of either of these reagents was taken as a confirmed positive test for the presence of alkaloids in the extract. The results of these tests are presented in Table I.

Each plant sample was also screened for alkaloids using thin-layer chromatography according to the method of Farnsworth and Euler (3). This procedure was modified only in that the final volume of fraction I (chloroform extract) applied to each thin-layer plate was 30 μl. The results from this test are also presented in Table I.

Saponins—Since all saponins, whether steroidal or triterpenoid, will hemolyze red blood cells, utilization of this property is advantageous for detecting this class of compounds in plant material. A red blood cell suspension was prepared and standardized against digitonin according to the protocol of Wall *et al.* (2). One milliliter of each plant extract was mixed with 10 ml. of the red blood suspension and the mixtures were allowed to stand for 1 hr. before observing the results. Complete hemolysis of the red blood cells in any instance was taken as evidence for a positive test, the results of which are presented in Table I.

Tannins—Twenty milliliters of the original 80% ethanol extract from each plant sample was evaporated to dryness on a steam bath and the residue was stirred with 5 ml. of distilled water and filtered. Two milliliters of the filtrate was treated with a few drops of gelatin–salt reagent (1), and precipitation was taken as evidence for the presence of tannins. The addition of ferric chloride reagent to extracts of plants giving positive gelatin–salt tests served to further categorize the tannin present as to hydrolyzable (blue, blue-black), or condensed types (green, blue-green). These results are presented in Table I.

SUMMARY

Of the 50 species screened for alkaloids, 24 showed the presence of tertiary alkaloids, representing 14 families of plants. Only two species exhibited the presence of quaternary alkaloids, one in the *Annonaceae*, and the other in the *Pedaliaceae*. Sixteen species, distributed in 13 families, contained saponins. The 43 species giving positive tests for tannins were in 29 different families.

Isolation and Characterization of Alkaloids from *Caulophyllum thalictroides*

By MICHAEL S. FLOM, RAYMOND W. DOSKOTCH, and JACK L. BEAL

The lupin alkaloids, methylcytisine, baptifoline, and anagyrine, and the aporphine alkaloid, magnoflorine, were isolated from the roots and rhizomes of *Caulophyllum thalictroides*. Separation of the tertiary lupin alkaloids was by partition column chromatography while magnoflorine was obtained after chromatography on alumina.

THE PRESENCE of methylcytisine (I) in the roots and rhizomes of *Caulophyllum thalictroides* (L.) Michx., (family, *Berberidaceae*), commonly called blue cohosh, has been known for many years (1). On re-examination of this source for alkaloids, a thin-layer chromatographic analysis of the tertiary alkaloid fraction revealed at least six spots reacting with Dragendorff's spray reagent. The quaternary alkaloid fraction indicated only one spot when tested by the same spray reagent.

Partition column chromatography on diatomaceous earth with Skellysolve B–ethylene dichloride–methanol–water (10:6:2.5:0.5) as solvent system separated the tertiary alkaloids. The three major alkaloids from this fraction were obtained crystalline or as crystalline salts and were identified as methylcytisine (I), baptifoline (II), and anagyrine (III).

Received April 14, 1967, from the College of Pharmacy, Ohio State University, Columbus, OH 43210

Accepted for publication July 24, 1967.

Presented to the Pharmacognosy and Natural Products Section, A.PH.A. Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

This work was supported by research grant GM-05640 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

The quaternary alkaloid fraction was obtained *via* the reineckate salt which when converted to the chloride salt and chromatographed on alumina yielded crystalline magnoflorine chloride (IV).

One milliliter of the separated acid extract was treated with a few drops of Mayer's reagent, and a second 1-ml. portion was treated with silicotungstic acid reagent as previously described. Turbidity or precipitation after the addition of either of these reagents was taken as a confirmed positive test for the presence of alkaloids in the extract. The results of these tests are presented in Table I.

Each plant sample was also screened for alkaloids using thin-layer chromatography according to the method of Farnsworth and Euler (3). This procedure was modified only in that the final volume of fraction I (chloroform extract) applied to each thin-layer plate was 30 μl. The results from this test are also presented in Table I.

Saponins—Since all saponins, whether steroidal or triterpenoid, will hemolyze red blood cells, utilization of this property is advantageous for detecting this class of compounds in plant material. A red blood cell suspension was prepared and standardized against digitonin according to the protocol of Wall *et al.* (2). One milliliter of each plant extract was mixed with 10 ml. of the red blood suspension and the mixtures were allowed to stand for 1 hr. before observing the results. Complete hemolysis of the red blood cells in any instance was taken as evidence for a positive test, the results of which are presented in Table I.

Tannins—Twenty milliliters of the original 80% ethanol extract from each plant sample was evaporated to dryness on a steam bath and the residue was stirred with 5 ml. of distilled water and filtered. Two milliliters of the filtrate was treated with a few drops of gelatin–salt reagent (1), and precipitation was taken as evidence for the presence of tannins. The addition of ferric chloride reagent to extracts of plants giving positive gelatin–salt tests served to further categorize the tannin present as to hydrolyzable (blue, blue-black), or condensed types (green, blue-green). These results are presented in Table I.

EXPERIMENTAL[1]

Plant Material—The roots and rhizomes of *Caulophyllum thalictroides* (L.) Michx. used in this investigation were obtained from S. B. Penick and Co. (lot No. 668 BA W-80576).

Extraction and Initial Separation—The plant material (13.7 Kg.) was extracted by percolation at room temperature with ethanol U.S.P. requiring about 74 L. of solvent to completely exhaust the material of alkaloids as evidenced by a negative Valser's test. Evaporation of the solvent at reduced pressure at 40° left 2.24 Kg. of residue. This was partitioned between chloroform and 2% aqueous citric acid in 100-Gm. quantities requiring 300 ml. of each phase. The citric acid phase was extracted three times with equal volumes of chloroform and then brought to pH 9 with concentrated ammonium hydroxide and then extracted with chloroform. This extract was dried over anhydrous sodium sulfate and on evaporation of the solvent left 30.6 Gm. of crude tertiary alkaloids.

Thin-layer chromatography of the tertiary alkaloids on Silica Gel G[2] with chloroform–methanol–ammonium hydroxide (200:20:1) indicated the presence of six tertiary alkaloids when detected with Dragendorff's reagent (2).

The ammonium hydroxide solution after removal of the tertiary alkaloids was acidified with 10% hydrochloric acid producing a gelatinous precipitate which was collected by filtration. From this precipitate it was possible to isolate caulosaponin, m.p. 257–259° [lit. values m.p. 250–255° (1), 254–255° (3)] by the procedure of Power and Salway (1). Hydrolysis of caulosaponin with aqueous alcoholic hydrochloric acid yielded hederagenin, m.p. 333–335°, $[\alpha]_D^{29}$ + 80° (c, 0.10% in ethanol), ultraviolet end absorption, λ = 210 mμ (ϵ = 4380); the literature values (3) are m.p. 332–333°, $[\alpha]_D^{20}$ + 78° (c, 0.10% in ethanol), ultraviolet absorption $\lambda_{max.}$ = 210 mμ (ϵ = 2860). Refluxing hederagenin in acetic anhydride for 1.5 hr. gave the acetate, m.p. 172–174° [lit. value (3) m.p. 173–174°]. The acidic filtrate was treated with a saturated aqueous solution of ammonium reineckate (2 Gm. reagent/100 ml. solution) while stirring. The precipitate of alkaloid reineckate was collected by suction filtration, sucked dry, and then washed with ether giving a yield of 285 Gm. TLC examination of the crude quaternary chloride (see below) on Silica Gel G with *n*-propanol–ammonium hydroxide–water (4:1:1) as solvent system showed one spot (R_f 0.55) when sprayed with Dragendorff's reagent.

Isolation of Magnoflorine Chloride—The alkaloid reineckate (190 Gm.) was dissolved in 3 L. of acetone–water (1:1) and the solution passed through a column containing 1700 ml. of Amberlite IRA-410 (Cl) resin. The crude quaternary alkaloid chloride (81 Gm.) from the effluent was chromatographed on Woelm neutral alumina,[3] activity V. The mixture was placed on the column as a methanol solution and eluted with methanol. The effluent was examined by TLC and the alkaloid fraction collected. Crystallization of the alkaloid fraction (72 Gm.) from ethanol gave magnoflorine chloride, m.p. 240–241° dec., $[\alpha]_D^{27}$ + 208° (c, 0.144% in methanol). The reported values (4) are m.p. 242–243° dec. and $[\alpha]_D^{31}$ + 213°. The infrared spectrum of the isolated substance and that of an authentic sample of magnoflorine chloride were superimposable. Mobility of the two samples was the same on TLC plates.

Separation of the Tertiary Alkaloids—The mixture of tertiary alkaloids, which on TLC indicated six components, was separated on a partition chromatographic column according to the procedure of Brown and Kupchan (5). The solvent system was Skellysolve B–ethylene dichloride–methanol–water (10:6:2.5:0.5). A column, 3.7 cm. (i.d.) × 47 cm., was prepared by mixing 182 ml. of the stationary phase (upper phase) with 300 Gm. of diatomaceous earth[4] and packing the material in 1-cm. segments with the aid of a ramrod. The mobile phase was passed through the packed column till all of the air had been removed (about 2 days). The holdup volume of the column was 395 ml.

The tertiary alkaloid mixture of 1.32 Gm. in 20 ml. of the mobile phase was passed into the column. The flow rate was 30 ml./hr. Fractions of effluent (20 ml.) after passage of the holdup volume were collected and analyzed by TLC. A summary of the separation obtained is given in Table I along with the tubes pooled according to the materials present.

Of the fractions examined only fractions 2, 3, and 8 yielded crystalline product or a crystalline salt. All the other fractions remained as heavy oils. These latter fractions account for only about 9% of the crude tertiary alkaloids. (Table I.)

Methylcytisine (I)—From pooled fraction No. 3, the 343 mg. of crude material yielded 194 mg. of crystalline product from benzene–Skellysolve B, m.p. 137° [lit. value (1) m.p. 137°]. The perchlorate salt was prepared by the usual procedure, m.p. 280–281° [lit. value (6) m.p. 282°] as well as the crystalline picrate, m.p. 221–222° [lit. value (1) m.p. 228°]. The specific rotation was $[\alpha]_D^{30}$ − 224° (c, 1.05% in water) [lit. value (1) $[\alpha]_D$ − 221.6°]. The ultraviolet absorption spectrum showed $\lambda_{max.}$ = 309 mμ (ϵ = 7,560); 234(6,860). In addition, a known sample of cytisine was methylated by the Eschweiler-Clarke procedure of the Leuckart reaction (7) to give a product identical with the isolated material (I.R., U.V., and mixed melting point determination).

Baptifoline (II)—The pooled column fraction No. 8 (241 mg.) was crystallized from benzene to yield 118 mg. of product, m.p. 210°. [Baptifoline lit. value (8) m.p. 210°.] The crystalline perchlorate salt, m.p. 286–287°, and the picrate which sinters at 145° then melts at 252° were prepared by the usual methods. The values in the literature are m.p. 286–287° (8) and m.p. 145° (sinters), then 256° (6). The optical rotation was $[\alpha]_D^{27}$ − 133° (c,

[1] Melting points were determined with a Thomas-Hoover Uni-Melt capillary melting point apparatus in sealed evacuated capillaries and were corrected. The infrared spectra were taken in chloroform and as KBr pellets on a Perkin-Elmer model 237 infrared spectrophotometer. The ultraviolet spectra were determined on a Cary model 15 recording spectrophotometer, in ethanol.

[2] Made by E. Merck (Darmstadt, West Germany), obtained from Brinkmann Instruments, Inc., Westbury, N. Y.

[3] Obtained from Alupharm Chemicals, New Orleans, La.

[4] Celite 545, a product of Johns-Manville Corp., New York, N. Y., which was purified by dispersing in 6 *N* HCl, three times, then filtering by suction and washing successively with distilled water, methanol, benzene, Skellysolve B, and methanol. Skellysolve B is a petroleum ether fraction, b.p. 60–80°. Ethylene dichloride, C.P., was from Union Carbide Co., and methanol A.R. was from Mallinckrodt Chemicals.

TABLE I—SEPARATION OF TERTIARY ALKALOID MIXTURE

Fraction No.	Tube No., 20 ml.	TLC R_f	Pooled Wt., mg.	Crystalline Product, mg.	% Yield[a]	Compd.
1	12–14	0.74	35	...	...	...
2	16–19	0.67	144	109[b]	0.012	Anagyrine
3	21–28	0.60	343	194	0.033	Methylcytisine
4	43–50	0.38	25	...	...	...
5	54–58	0.28	14	...	...	...
6	71–85	0.27	22	...	...	...

8	105–165	0.28	241	118	0.020	Baptifoline

[a] Based on dry plant material. [b] As perchlorate salt.

0.325% in ethanol). [Lit. value $[\alpha]_D^{18}$ − 147.7° (6).] The ultraviolet absorption spectrum showed $\lambda_{max.}$ = 309 mμ (ε = 7,540); 234(7,150). The infrared spectrum of authentic baptifoline[5] taken in a Nujol mull was identical to that of our compound determined in the same way.

Anagyrine (III)—The oil (144 mg.) in the pooled fraction No. 2 provided a crystalline perchlorate from methanol, m.p. 315°, and a picrate from methanol, m.p. 247–249°. Anagyrine perchlorate melts at 315° (8) and the picrate at 249–251° (6). The ultraviolet absorption spectrum of the perchlorate salt showed $\lambda_{max.}$ = 308 mμ (ε = 7,460); 234(6,900) and an infrared absorption spectrum with peaks at $\nu_{max.}$ 1650, 1570, and 1560 cm.$^{-1}$ when taken in a Nujol mull, and are consistent with the reported values for anagyrine (9).

DISCUSSION

C. thalictroides has been known for over 50 years to contain methylcytisine. With the application of modern isolation and analytical methods this source has been found to contain many more alkaloids of which three not previously recognized have been isolated in pure form and identified.

The three lupin tertiary alkaloids, methylcytisine, baptifoline, and anagyrine, were readily separated by partition column chromatography and are the first example of the isolation of the latter two alkaloids from the family *Berberidaceae*. The other alkaloids (at least three) in this fraction were present in very small amounts, remained as oils, and could not be induced to crystallize or to form crystalline salts, although separated by the column method so as to show only one spot reacting with Dragendorff's reagent. Further identification of the minor tertiary alkaloids must await the processing of large amounts of plant material. Undoubtedly they will also be of the lupin type.

The presence of magnoflorine in *Caulophyllum robustum* Maxim., has been reported by Tomita and Takahashi (10). The presence of this ubiquitous alkaloid has now been confirmed in *C. thalictroides*.

Grayanotoxin I. Occurrence in Additional *Ericaceae* Species

By G. H. CONSTANTINE, JR., KIRTI SHETH*, and PHILIP CATALFOMO

The title compound was identified in five of seven ericaceous species not previously investigated but listed as being poisonous. Thin-layer chromatography and spectral analyses established the presence of grayanotoxin (acetylandromedol) in *Rhododendron macrophyllum*. Comparative chromatography and U.V. spectral analysis indicated that the compound was present in four additional species.

THE GRAYANOTOXINS (I) are known to occur only in the family *Ericaceae* (1). Several members of this family, which occur in the Pacific Northwest and are reported to be poisonous (2–4), have never been investigated for the presence of these compounds. This study was undertaken to determine if the grayanotoxins could be identified in certain native species thereby verifying, at least in part, the agent responsible for the reported toxicity.

	R	R′
Grayanotoxin I	CH_3, OH	OAc
Grayanotoxin II	CH_2	H, OH
Grayanotoxin III	CH_3, OH	H, OH

EXPERIMENTAL

Chromatographic Screening—The plants were collected in Oregon during the summer of 1966.[1] The leaves were dried in a forced-air dryer, ground to a coarse powder, and stored in plastic bags until time for extraction.

One hundred-gram samples of each plant were defatted with petroleum ether in a Soxhlet apparatus and then exhaustively extracted with ethanol U.S.P. The ethanol extracts were concentrated *in vacuo* to a lesser volume (about 50 ml.) and diluted with an equal volume of distilled water. These mixtures were subjected to liquid–liquid extraction with chloroform U.S.P. The chloroform extracts were concentrated to dryness *in vacuo*, redissolved in a minimum amount of chloroform, and examined chromatographically.

Thin-layer chromatography on Silica Gel G plates, prepared according to Stahl, was employed as the preliminary screening procedure. Three solvent systems were found to separate authentic samples of the grayanotoxins.[2] The results of the co-spotting experiments are recorded in Table I. Grayanotoxin I (G-I) was verified as being present in the following: *Rhododendron albiflorum* Hook, *R. macrophyllum* D. Don., *R. occidentale* (T. and G.) Gray, *Kalmia polifolia* Wang. var. *microphylla* Hook, and *K. polifolia* Wang. var. *polifolia*. The toxic principle could not be detected in either *Ledum glandulosum* Nutt or *Menziesea ferruginea* Smith.

A vacuum-zone extractor was used to remove samples from unsprayed chromatoplates for U.V. analyses. Areas corresponding in R_f to G-I for each of the five plants, as well as G-I, were then removed from the extractor with boiling methanol (spectral grade). Aliquots were scanned in a Beckman DB recording spectrophotometer and all gave a characteristic maximum at 255 mμ.

TABLE II—COLUMN CHROMATOGRAPHY OF *Rhododendron* EXTRACT

Solvent	Fractions	Vol., ml.	R_f Value[a]
1, EtOAc	4	250	...
2, *n*-Propanol (10%) in EtOAc	4	250	0.33[b]
3, *n*-Propanol (50%) in EtOAc	4	250	0.33
4, *n*-Propanol	4	250	...
Grayanotoxin I	...	...	0.33

[a] Solvent system: TEFF, toluene–ethyl formate–formic acid (5:4:1). [b] Detection: see Table I.

TABLE III—COLUMN CHROMATOGRAPHY OF *Rhododendron* FRACTION

Solvent	Fractions	Vol., ml.	R_f Value[a]
1, Benzene	1	500	...
2, EtOAc	6	250	0.34[b]
3, *n*-Propanol (5%) in EtOAc	4	250	0.34
4, *n*-Propanol (10%) in EtOAc	4	250	...
Grayanotoxin I	...	...	0.34

[a] Solvent system: TEFF, toluene–ethyl formate–formic acid (5:4:1). [b] Detection: see Table I.

purified on three identical 450-Gm. alumina columns (5 × 50 cm.).[3] The column was eluted first with twelve 250-ml. fractions of ethyl acetate followed by six 250-ml. fractions of 10% methanol in ethyl acetate.

The progress of the column was monitored by using the solvent system TEF (see Table I). The third and fourth fractions of the second solvent clearly demonstrated the presence of G-I. The combined fractions yielded 4.5 Gm. of greenish residue which was placed upon another 450-Gm. alumina column and eluted as shown in Table II.

The G-I containing fractions thus collected were combined, concentrated to dryness, washed with boiling *n*-hexane, and dissolved in ethyl acetate–*n*-hexane (1:1) in an attempt to precipitate the compound. This procedure yielded a dark green oil which was placed upon a 100-Gm. alumina column (2.5 × 25 cm.) and eluted as shown in Table III.

The positive fractions were combined, dried, and crystallized from *n*-hexane–acetone to yield a green-white precipitate. Two recrystallizations from *n*-hexane–ethyl acetate yielded 5 mg. of pure white needles, m.p. 256–258°.[4] [Reported m.p. 240–243° (5), 259–260° (6), and 264–266° (7).]

Co-chromatography using known G-I and the isolated compound was employed as an additional verification procedure. The co-spot did not separate in the same three solvent systems as in Table I and had an R_f value equivalent to both controls.

The I.R. (KBr pellet) and U.V. spectra (spectral grade methanol) of the isolated as well as the reference G-I were identical.

SUMMARY

Seven species of reportedly poisonous ericaceous plants were screened by thin-layer chromatography in order to detect the presence of the grayanotoxins. Grayanotoxin I was isolated and identified from one of the species. Five of the plants screened were found to contain grayanotoxin I whereas grayanotoxins II and III were not detected. Poisoning reportedly caused by *Ledum glandulosum* and *Menziesea ferruginea* cannot be attributed to the grayanotoxins because of their apparent absence in these species.

3-Aminopiperidones IV. 2-(*N*,*N*-Diethylamino)-2-*p*-chlorophenylglutarimide and 2-(*N*,*N*-Diethylamino)-2-*p*-tolylglutarimide

By S. K. ARYA, K'UN CHANG, and C. F. MARTIN

The syntheses of two new modifications of the model compound, 2-(*N*,*N*-diethylamino)-2-phenylglutarimide (V) bearing chloro- and methyl-substituents on the *para* position of the phenyl group are described. The preparations of these compounds are extensions of work designed to provide a basis for studies of structure *versus* antiepileptic activity relationships among 3-aminopiperidones.

PREVIOUS WORK, which led to the synthesis and pharmacological screening of the model compound, 2-(*N*, *N*-diethylamino)-2-phenylglutarimide (V) (1, 2), suggested that of several possibilities, *p*-hydroxylation of the phenyl group, with subsequent glucuronide conjugation of the molecule in the biological system, could account in part for its short duration of action. The present communication deals, therefore, with routes to the synthesis of modifications V*a* and V*b* of the model compound (V) designed not only to block this position from metabolic attack, but also to provide a basis for studies of the effect on activity of substituents that would reasonably be expected to have opposite electronic influences on the phenyl ring and, in turn, on the molecular stability, drug–receptor interactions, and biotransportation of the compounds.

DISCUSSION

The syntheses of 2-(*N*, *N*-diethylamino)-2-*p*-chlorophenylglutarimide (V*a*) and of 2-(*N*, *N*-diethylamino)-2-*p*-tolylglutarimide (V*b*) were accomplished by following the reaction sequence shown in Scheme I. In both instances, ethyl α-bromo-*p*-chlorophenylacetate (I*a*) and ethyl α-bromo-*p*-tolylacetate (I*b*) were prepared by modifications of the procedure of Anschütz (3). In the subsequent displacement reaction (I→II) using diethylamine as the nucleophile, aminolysis of the ester was avoided by using a short-term, high-temperature procedure as reported in earlier work (1, 4).

Based upon experience in this laboratory with the unsubstituted phenyl compound of this series (1), the next step in the reaction sequence, that of adding the 3-carbon chain to the appropriate amino ester, was accomplished by employing the general procedure developed by Zaugg *et al.* (5) using β-bromopropionitrile. Treatment of III*a* and III*b* with a 1:1 mixture of concentrated sulfuric and glacial acetic acids at steam-bath temperature for 30 min. afforded a fair yield of the amido ester (IV*a* and IV*b*).

The cyclizations of IV*a* and IV*b* were accomplished by adaptations of the procedure used in the alkylation step (II→III). It was observed in both instances that upon heating IV*a* and IV*b* in the sodium hydride–dimethylformamide system, hydrogen abstraction (as evidenced by cessation of gas evolution) was essentially complete after 2.5 hr. of heating at 55°. However, if the reaction was stopped at this point, the starting material was recovered. Continued heating of the reaction mixture beyond this point at a higher bath temperature (100–105°) did effect the desired cyclizations to V*a* and V*b*.

As is the case with the unsubstituted phenyl derivative, it is expected that the imide portions of both V*a* and V*b* are relatively flat (6), and as both the substituted phenyl and diethylamino groups are large, they will tend to assume quasi-equatorial and quasi-axial positions with respect to the adjacent carbonyl (7).

EXPERIMENTAL

Melting points were determined on a Fisher-Johns melting point block and are uncorrected. Infrared spectra were obtained with a Beckman IR-5 spectrophotometer; all were run on 10% solutions in a cell with a 0.1-mm. path length unless otherwise stated. Nuclear magnetic resonance spectra were determined on the 60 Mc. NMR manufactured by Varian Associates. The Beckman DB spectrophotometer was used for the ultraviolet absorption spectra reported. Microanalyses were performed by the Weiler and Strauss Microanalytical Laboratory, Oxford, England, or by the Galbraith Laboratories, Inc., Knoxville, Tenn.

Ethyl α-Bromo-p-chlorophenylacetate (Ia)—A modification of the procedure described by Anschütz (3) was used. To a stirred mixture of 34.1 Gm. (0.2 mole) of *p*-chlorophenylacetic acid and 1.2 Gm. of red phosphorus, 64.0 Gm. (0.4 mole) of bromine was added at 75–85° over a period of 5 hr. The mixture was stirred for an additional 5 hr. at 80°. After cooling, 12.5 Gm. (0.25 mole) of absolute ethanol was added slowly with stirring and the reaction mixture was heated at 75–80° for 10 hr. At the end of the period, the mixture was poured into ice water, the ester layer separated with ether, washed successively with 10% sodium bisulfite solution and water, and dried (Na_2SO_4). After filtering and flash evaporating the ether, the oil was distilled to yield 44.5 Gm. (80.5%) of liquid, b. p. 96° (0.06 mm.). Redistillation gave a center cut of product I*a*, b. p. 94–95° (0.06 mm.); infrared ($CHCl_3$): 1732 (C=O ester); NMR (CCl_4): triplet 1.25 p.p.m. (methyl protons of ester ethyl); quartet 4.20 p.p.m.

Received April 14, 1967, from the College of Pharmacy, Washington State University, Pullman, WA 99163
Accepted for publication August 1, 1967.
Presented to the Medicinal Chemistry Section, A.PH.A. Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.
This investigation was supported in part by funds provided for medical and biological research by the State of Washington Initiative Measure No. 171, and by research grant NB 05032-01 and -02, National Institutes of Health, U. S. Public Health Service, Bethesda, Md.
Abstracted from portions of theses submitted by S. K. Arya (1964) and K'un Chang (1966) to the Graduate School, Washington State University, in partial fulfillment of Master of Science degree requirements.

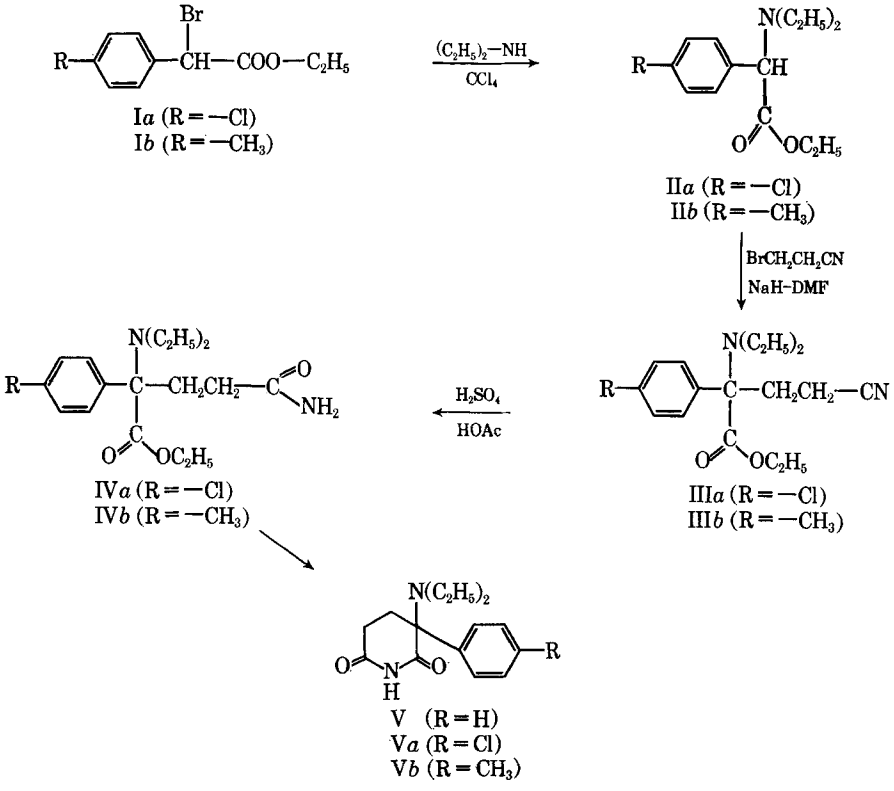

Scheme I

(methylene protons of ester ethyl); singlet 5.15 p.p.m. (proton on α-carbon) with phenyl protons centered at 7.45 p.p.m.

Anal.—Calcd. for $C_{10}H_{10}BrClO_2$: C, 43.28; H, 3.63; Br, 28.54; Cl, 12.77. Found: C, 43.50; H, 3.82; Br, 28.54; Cl, 12.59.

Ethyl α-Bromo-p-tolylacetate (Ib)—To a stirred mixture of 150.2 Gm. (1.0 mole) of *p*-tolylacetic acid and 6.0 Gm. of red phosphorus, 320.0 Gm. (2.0 moles) of bromine was added at 60–70° over a period of 12 hr. The mixture was stirred for an additional 5 hr. at 70°. After cooling, 62.5 Gm. (1.25 moles) of absolute ethanol was added slowly with stirring and the reaction mixture was heated at 75–80° for 10 hr. At the end of the period, the mixture was poured into ice water, the ester layer separated with ether, washed successively with 10% sodium bicarbonate solution, water, 10% sodium bisulfite solution and water, and dried (Na_2SO_4). After filtering and flash evaporating the ether, the oil was distilled to yield 194.0 Gm. (75.4%) of liquid, b. p. 125–129° (2.1 mm.). Redistillation twice yielded product *Ib*, b.p. 124.5° (2.1 mm.); infrared ($CHCl_3$): 1745 (C=O ester).

Anal.—Calcd. for $C_{11}H_{13}BrO_2$: C, 51.38; H, 5.09; Br, 31.08. Found: C, 51.59; H, 5.13; Br, 31.20.

Ethyl α-(N,N-Diethylamino)-p-chlorophenylacetate (IIa)—A well-stirred solution of 55.5 Gm. (0.2 mole) of freshly distilled *Ia* and 58.5 Gm. (0.8 mole) of diethylamine in 50 ml. of dry CCl_4 was heated gently under reflux for 10 hr. The mixture of precipitated hydrobromides was filtered, washed with CCl_4, dissolved in water, the solution adjusted to pH 9.5 (cooling), and extracted with ether. The CCl_4 solution was extracted with 5% HCl, and after adjustment of the pH of the acidic extract to 9.5 (cooling), it was also extracted with ether. The ethereal extracts were combined and dried (Na_2SO_4). The solvent was flash evaporated and the product distilled to yield 48.5 Gm. (95%) of pale yellow mobile liquid, b. p. 102–105° (0.1 mm.). Redistillation twice yielded product *IIa*, b. p. 102° (0.1 mm.); infrared ($CHCl_3$): 2975 (—CH arom.); 2800–2950 (—CH aliph.); 1725 $cm.^{-1}$ (C=O ester).

Anal.—Calcd. for $C_{14}H_{20}ClNO_2$: C, 62.34; H, 7.41; Cl, 13.14; N, 5.19. Found: C, 62.48; H, 7.39; Cl, 13.16; N, 5.18.

Ethyl α-(N,N-Diethylamino)-p-tolylacetate (IIb)—A well-stirred solution of 124.7 Gm. (0.5 mole) of freshly distilled *Ib* and 146.0 Gm. (2.0 moles) of diethylamine in 130 ml. of dry CCl_4 was heated gently under reflux for 10 hr. The mixture of precipitated hydrobromides was filtered, washed with CCl_4, dissolved in water, the solution adjusted to pH 9.5 (cooling), and extracted with ether. The CCl_4 solution was extracted with 10% HCl, and after adjustment of the pH of the acidic extract to 9.5 (cooling), it was also extracted with ether. The ethereal extracts were combined and dried (Na_2SO_4). The solvent was flash evaporated and the product distilled to yield 80.9 Gm. (64.8%) of pale yellow mobile liquid, b. p. 104–107° (0.4 mm.). Redistillation twice yielded product *IIb*, b. p. 102° (0.35 mm.); infrared ($CHCl_3$): 2850–2970 (—CH aliph.); 1730 (C=O ester).

Anal.—Calcd. for $C_{15}H_{23}NO_2$: C, 72.25; H, 9.29;

N, 5.62. Found: C, 72.36; H, 9.40; N, 5.71.

4 - Carbethoxy - 4 - (N,N - diethylamino) - 4 - p-chlorophenylbutyronitrile (IIIa)—All of the glassware used in this reaction was flame-dried. Spectroquality dimethylformamide (DMF) was used, and the entire reaction was run under a blanket of dry nitrogen.

To a well-stirred suspension of 2.5 Gm. (0.11 mole) of sodium hydride in 50 ml. of dry DMF, 27.7 Gm. (0.1 mole) of freshly distilled II*a* was added at such a rate as to maintain an internal temperature of 45–50° (addition time, 3 hr.). The resulting thick red liquid was cooled in ice (0–5°) and 15.5 Gm. (0.11 mole) of freshly distilled β-bromopropionitrile was added dropwise, with continuous stirring, over a period of 4 hr. The temperature was not allowed to exceed 5° during the addition. The mixture, containing the precipitated NaBr, was stirred overnight at room temperature under dry N_2. The residue left after removal of the solvent was taken up in 100 ml. of ice water and extracted with ether. The ether extract was washed with water and dried ($MgSO_4$). After removal of the ether, the residual product was fractionally distilled to yield 19.7 Gm. (60%) of III*a* as a pale yellow viscous liquid, b. p. 162° (0.01 mm.). An analytical sample was obtained by an additional distillation, b. p. 159–160° (0.01 mm.); infrared ($CHCl_3$): 2975 (—CH arom.); 2800–2950 (—CH aliph.); 2250 (—CN); 1720 $cm.^{-1}$ (C=O ester).

Anal.—Calcd. for $C_{17}H_{23}ClN_2O_2$: C, 63.25; H, 7.20; Cl, 10.99; N, 8.64. Found: C, 63.37; H, 7.25; Cl, 11.31; N, 8.43.

4 - Carbethoxy - 4 - (N,N - diethylamino) - 4 - p-tolylbutyronitrile (IIIb)—The use of flame-dried glassware, the maintenance of a dry, inert atmosphere, and the use of spectroquality dimethylformamide (DMF) were criteria for success in this reaction as they were for the synthesis of III*a*.

To a well-stirred suspension of 5.5 Gm. (0.23 mole) of sodium hydride in 100 ml. of dry DMF, 49.8 Gm. (0.20 mole) of freshly distilled II*b* was added at such a rate as to maintain an internal temperature of 40–45° (addition time, 3 hr.). The resulting thick red liquid was cooled in ice (0–5°) and 29.5 Gm. (0.22 mole) of freshly distilled β-bromopropionitrile was added dropwise, with continuous stirring, over a period of 3 hr. The temperature was not allowed to exceed 5° during the addition. The mixture, containing the precipitated NaBr, was stirred overnight at room temperature under dry N_2. The mixture, in this case, instead of first being stripped of solvent was poured into 150 ml. of ice water and extracted with ether. The ether extract was washed with water and dried ($MgSO_4$). After removal of the ether, the residue was fractionally distilled to yield 20.8 Gm. (34.4%) of III*b* as a pale yellow viscous liquid, b. p. 136–139° (0.06 mm.). An analytical sample was obtained by an additional distillation, b.p. 135° (0.06 mm.); infrared (neat film): 2975 (—CH arom.); 2850–2950 (—CH aliph.); 2250 (—CN); 1720 $cm.^{-1}$ (C=O ester).

Anal.—Calcd. for $C_{18}H_{26}N_2O_2$: C, 71.49; H, 8.67; N, 9.27. Found: C, 71.44; H, 8.63; N, 9.44.

4 - Carbethoxy - 4 - (N,N - diethylamino) - 4 - p-chlorophenylbutyramide (IVa)—A mixture of 32.3 Gm. (0.1 mole) of III*a* and 30 ml. of glacial acetic acid was stirred at room temperature for 20 min. Concentrated H_2SO_4 (30 ml.) was added slowly and the mixture heated on a steam bath with stirring for 30 min. The brownish-red liquid obtained was poured into stirred ice water, and 30% aqueous NaOH was added until the mixture was alkaline (pH 8.5). The product was extracted with chloroform, washed with water, dried (Na_2SO_4), and concentrated. Because attempts to solidify the resulting thick oil by rubbing with *n*-hexane and with ligroin were unsuccessful, the product was distilled to yield 23.8 Gm. (70.5%) of light yellow viscous liquid, b. p. 190° (0.05 mm.); infrared ($CHCl_3$): 3490, 3390, 3150 (NH amide, 2 free, 1 bonded); 1720 (C=O ester); 1680 (amide I); 1595 (amide II); no nitrile band at 2250 $cm.^{-1}$.

Anal.—Calcd. for $C_{17}H_{25}ClN_2O_3$: C, 59.94; H, 7.34; Cl, 10.42; N, 8.22. Found: C, 59.83; H, 7.19; Cl, 10.15; N, 8.41.

4 - Carbethoxy - 4 - (N,N - diethylamino) - 4 - p-tolylbutyramide (IVb)—A mixture of 30.2 Gm. (0.1 mole) of III*b* and 30 ml. of glacial acetic acid was stirred at room temperature for 20 min. Concentrated H_2SO_4 (30 ml.) was added slowly and the mixture heated on a steam bath for 30 min. The brownish-red liquid obtained was poured into stirred ice water, and 30% NaOH was added until the mixture was alkaline (pH 8.5). The product was extracted with chloroform, washed with water, dried (Na_2SO_4), and concentrated. The thick oil which could not be crystallized or distilled without decomposition, was obtained as a crude product in a yield of 31.8 Gm. (99.1%); infrared ($CHCl_3$): 3500, 3400, 3160 (NH amide, 2 free, 1 bonded); 1720 (C=O ester); 1680 (amide I); 1595 (amide II); no nitrile band at 2250 $cm.^{-1}$. It was used in the final step without further purification.

2 - (N,N - Diethylamino) - 2 - p - chlorophenylglutarimide (Va)—Spectroquality DMF was used. All glassware was flame-dried. The reaction was carried out under an atmosphere of dry nitrogen.

A solution of 10.0 Gm. (0.028 mole) of freshly distilled 4 - carbethoxy - 4 - (*N, N* - diethylamino) - 4 - *p* - chlorophenylbutyramide (IV*a*) in 25 ml. of dry DMF (warming aids the dissolution process) was added dropwise to a stirred suspension of 0.8 Gm. (0.03 mole) of NaH in 50 ml. of dry DMF. The mixture was stirred at 55° for 2.5 hr., by which time the formation of anion was complete as evidenced by the cessation of H_2 evolution. The bath temperature was raised to 105° and maintained at this point for 15 hr. The residue, left after distilling off the solvent under reduced pressure, was well stirred with ice water, the solution adjusted to pH 8.5 (cooling), and the product extracted with chloroform, washed with water, and dried (Na_2SO_4). Filtration and removal of the chloroform left a thick oil which was washed with *n*-hexane and ligroin. The partially purified product was redissolved in chloroform, extracted with 10% HCl, and the acid extract, upon evaporation on a steam bath, yielded a residue which, after rubbing with a chloroform–ether mixture, gave 4.2 Gm. (46.0%) of V*a* as the solid hydrochloride. Recrystallization of the product from hot chloroform yielded a white powder, m.p. 132–135°; infrared (Nujol): 3150, 3050 (NH); 1710 with shoulder at 1730 (C=O); 2535, 2450 $cm.^{-1}$ (amine salt); ultraviolet (95% ethanol): 220 mμ (flat shoulder) and evidence of peak below 200 mμ out of

range of instrument; ($10^{-2}M$ ethanolic KOH): bathochromic shift to 225 mμ (flat shoulder) and 215 mμ (peak).

Anal.—Calcd. for $C_{15}H_{20}Cl_2N_2O_2$: C, 53.39; H, 6.08; Cl, 21.20; N, 8.45. Found: C, 53.03; H, 5.96; Cl, 20.21; N, 8.81.

2-(N,N-Diethylamino)-2-p-tolylglutarimide (Vb)—Spectroquality DMF was used. All glassware was flame-dried, and the reaction was carried out under an atmosphere of dry nitrogen.

A solution of 16.0 Gm. (0.05 mole) of crude, but dried, 4 - carbethoxy - 4 - (*N, N* - diethylamino) - 4 - *p* - tolylbutyramide (IV*b*) in 50 ml. of dry DMF was added dropwise to a stirred suspension of 1.4 Gm. (0.057 mole) of NaH in 100 ml. of dry DMF. The mixture was stirred at 55° for 2.5 hr., by which time the formation of anion was complete as evidenced by the cessation of H_2 evolution. The bath temperature was raised to 105° and maintained at this point for 15 hr. The residue, left after distilling off the solvent under reduced pressure, was well stirred with ice water, the solution adjusted to pH 8.5 (cooling), and the product extracted with chloroform, washed with water, and dried (Na_2SO_4). Filtration and removal of the chloroform left a thick oil which solidified on rubbing with dry *n*-hexane. Recrystallizations from dry chloroform–hexane[1] yielded 1.62 Gm. (11.8%) of V*b* as white crystals, m. p. 112°; infrared ($CHCl_3$): 3375, 3200 (NH); 1720 $cm.^{-1}$ (C=O).

Anal.—Calcd. for $C_{16}H_{22}N_2O_2$: C, 70.04; H, 8.08; N, 10.21. Found: C 69.95; H, 8.04; N, 10.21.

Segregation Kinetics of Particulate Solids Systems IV. Effect of Particle Shape on Energy Requirements

By E. G. RIPPIE, M. D. FAIMAN*, and M. K. PRAMODA

The relative energy requirements of the processes of segregation and mixing, which occur in systems of particulate solids, are shown to be a function of the shape and size of the particles. These energy requirements, as reflected by agitation coefficients, have been determined for several idealized systems. Granular solids, as represented by crushed quartz and pyrite, were found to behave in conformity with predictions based on the idealized systems.

PARTICLE SHAPE is known to exert a marked influence on the behavior of particulate solids. This is true, moreover, when powdered or granular material is either in a dynamic state of flow or is at rest. Little is presently known regarding the specific cause and effect relationships between bulk behavior and particle shape, a situation which arises because of difficulties in expressing the latter as a single scalar quantity.

The problem is frequently approached by the use of shape factors as a quantitative expression of the average shape of particles in a system. The function of shape factors, however, is not to express shape, but rather to relate the results of particle size measurements which have been obtained by several different methods (1). Consequently, it is possible to have different particulate solids with quite different characteristic shapes, but which all possess a similar value of a given shape factor. Further complications result when average values are used to describe particulate variables without regard for the deviation of individual values from the mean.

The present work is intended to give quantitative information on the effects of particle shape on segregation and mixing in idealized systems where an intuitive appraisal of shape is possible. Such idealized systems, which are made up of regularly shaped particles (spheres, paired spheres, cubes, rods, and hexagonal rods), have the advantage that they may be described exactly as to shape which is uniform from particle to particle. For purposes of comparison, crushed quartz and pyrite were also studied.

Results indicate that substantial differences in bulk behavior can result from relatively minor changes in particle shape. Particle size is also shown to influence the change in rate of segregation and mixing with a change in agitation intensity.

EXPERIMENTAL

Materials—Chrome steel balls of the type and grade commonly employed in the manufacture of commercial ball bearings were used. Paired balls were prepared by spot welding two similar sized balls together. The effective distance of separation of the centers of mass was reduced by approximately 1% by the welding operation. Steel cubes and cylinders of circular and hexagonal cross section were made of cold rolled steel and case hardened in

Segregation Kinetics of Particulate Solids Systems IV. Effect of Particle Shape on Energy Requirements

By E. G. RIPPIE, M. D. FAIMAN*, and M. K. PRAMODA

The relative energy requirements of the processes of segregation and mixing, which occur in systems of particulate solids, are shown to be a function of the shape and size of the particles. These energy requirements, as reflected by agitation coefficients, have been determined for several idealized systems. Granular solids, as represented by crushed quartz and pyrite, were found to behave in conformity with predictions based on the idealized systems.

PARTICLE SHAPE is known to exert a marked influence on the behavior of particulate solids. This is true, moreover, when powdered or granular material is either in a dynamic state of flow or is at rest. Little is presently known regarding the specific cause and effect relationships between bulk behavior and particle shape, a situation which arises because of difficulties in expressing the latter as a single scalar quantity.

The problem is frequently approached by the use of shape factors as a quantitative expression of the average shape of particles in a system. The function of shape factors, however, is not to express shape, but rather to relate the results of particle size measurements which have been obtained by several different methods (1). Consequently, it is possible to have different particulate solids with quite different characteristic shapes, but which all possess a similar value of a given shape factor. Further complications result when average values are used to describe particulate variables without regard for the deviation of individual values from the mean.

The present work is intended to give quantitative information on the effects of particle shape on segregation and mixing in idealized systems where an intuitive appraisal of shape is possible. Such idealized systems, which are made up of regularly shaped particles (spheres, paired spheres, cubes, rods, and hexagonal rods), have the advantage that they may be described exactly as to shape which is uniform from particle to particle. For purposes of comparison, crushed quartz and pyrite were also studied.

Results indicate that substantial differences in bulk behavior can result from relatively minor changes in particle shape. Particle size is also shown to influence the change in rate of segregation and mixing with a change in agitation intensity.

EXPERIMENTAL

Materials—Chrome steel balls of the type and grade commonly employed in the manufacture of commercial ball bearings were used. Paired balls were prepared by spot welding two similar sized balls together. The effective distance of separation of the centers of mass was reduced by approximately 1% by the welding operation. Steel cubes and cylinders of circular and hexagonal cross section were made of cold rolled steel and case hardened in

molten potassium cyanide. All dimensions of these three forms were 0.125 in.

Natural quartz and pyrite were crushed and sieved through U. S. Standard sieves. Following sieving, the quartz was purified by washing with 5% HCl after soaking overnight in the acid. The material was oven dried following a distilled water wash. The crushed pyrite was washed with distilled water and oven dried. After drying, both materials were again sieved before use.

Procedure—Equipment and procedure were essentially as reported previously (2–4) with regard to particle size analysis, calculation of system standard deviation, and computation of the rate constants for segregation and mixing. Agitation coefficients are defined as the slope of a plot of the natural logarithm of the rate constant for a given process *versus* the square of the reciprocal of the velocity imparted to the particles by the shaker.

The particulate systems were subjected to a vertical sine wave agitation in brass cylinders of 1-in. internal diameter which were hard chrome plated, when used with quartz and pyrite, to resist abrasion. Amplitudes and frequencies of agitation motion were held to within ±0.001 in. and ±5 c.p.m. of the stated values, respectively.

Systems comprised of steel particles were 304 Gm. in total weight and those of quartz and pyrite were 92 Gm. and 150 Gm., respectively.

RESULTS AND DISCUSSION

Agitation coefficients, as defined earlier, represent proportionality constants between the natural logarithm of the rate constant under consideration and the reciprocal of the energy imparted to the particles by the shaker. Large values of agitation coefficients indicate a high degree of dependency of the rate process on agitation and, therefore, a relatively high energy requirement for the process.

No well defined trend is apparent between the particle size ratio, V_r, (the ratio of particulate volumes of the two components) and the agitation coefficients of segregation and mixing, as shown on lines 4–7 in Table I. It is apparent, however, that the equilibrium agitation coefficients of these same systems tend to decrease with a decrease in the average particle size.

Paired Spheres—Unexpected results were obtained for the mixtures of single and paired balls, and are shown on lines 8 and 9 of Table I. The energy requirements for both segregation and mixing are less than in the same systems containing no paired particles, as shown on lines 6 and 7.

In addition to the results reported in Table I, binary mixtures of $^3/_{32}$-in. paired spheres and $^7/_{32}$-in. paired spheres, and $^3/_{32}$-in. paired spheres and $^7/_{32}$-in. single spheres were agitated at an amplitude of 0.141 in. and a frequency of 1030 c.p.m. The data indicated that segregation either had not occurred, or that the rate was immeasurably small. In contrast, binary systems of the same size single balls (Table I, line 7) segregate fairly rapidly. Binary mixtures of single and paired balls of similar size ($^3/_{32}$-, $^5/_{32}$-, and $^7/_{32}$- in.) exhibited no tendency to segregate.

It appears, from these observations, that in a binary mixture where the smaller component was paired, segregation of the system either decreased or did not occur. When the larger component only was paired, segregation was found to occur. This is consistent with the theory that the large and small components compete for void space created by particulate motion.

TABLE I—AGITATION COEFFICIENTS FOR IDEALIZED BINARY SYSTEMS

System	V_r	Segregation Coeff.	Mixing Coeff.	Equilibrium Coeff.
$^1/_{16}$-in. cube	15.3	21	...	...
$^1/_{16}$-in. hex.	14.3	24	...	...
$^1/_{16}$-in. cyl.	12.0	36	...	...
$^1/_{16}$-in.–$^1/_8$-in.	8.0	41	84	−42
$^1/_{16}$-in.–$^5/_{32}$-in.	15.6	46	74	−28
$^3/_{32}$-in.–$^5/_{32}$-in.	4.6	79	106	−27
$^3/_{32}$-in.–$^7/_{32}$-in.	12.7	51	46	5
$^3/_{32}$-in.–$^5/_{32}$-in.[a]	9.3	42	45	−3
$^3/_{32}$-in.–$^7/_{32}$-in.[a]	25.4	34	31	4

[a] Paired balls.

Nonspherical Particles—Over-all segregation of systems containing particles other than spheres or paired spheres showed an atypical pattern. A typical graph of such a system undergoing segregation is shown in Fig. 1, which represents a mixture of $^1/_{16}$-in. steel balls and $^1/_8$-in. steel cubes agitated at an amplitude of 0.141 in. and a frequency of 1030 c.p.m. The standard deviation is seen to increase, decrease, and then increase again. Similar results occurred with binary mixtures of $^1/_{16}$-in. spheres with both of the other nonspherical shapes studied.

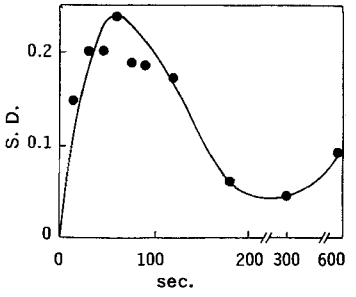

Fig. 1—Standard deviation as a function of agitation time for a 1:1 w/w mixture of $^1/_{16}$-in. steel balls and $^1/_8$-in. steel cubes agitated at a frequency of 1030 c.p.m. and an amplitude of 0.141 in.

The reason for this anomalous behavior became apparent when a Lucite cylinder was used, permitting the process to be viewed. It was found that the angular particles, when originally mixed with the balls, had a random orientation. After a short period of segregation in which the angular particles migrated to the top, they were found to orient themselves with their flat surfaces to the sides of the cylinder and to move in a reverse direction down the sides. In effect, convection currents were set up which accounted for the cycling behavior of the standard deviation. This behavior was not observed for systems other than those containing angular particles.

Segregation rate constants were obtained for these systems by fitting a quadratic equation to the data

TABLE II—AGITATION COEFFICIENTS FOR CRUSHED QUARTZ AND PYRITE

System 12/14–70/80 Mesh	Segregation Coefficients	Mixing Coefficients	Equilibrium Coefficients
Quartz	19	2	17
Pyrite	50	49	1

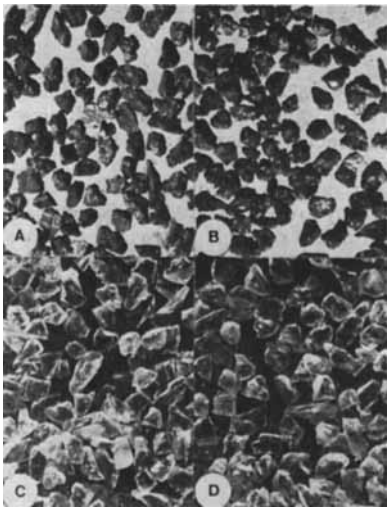

Fig. 2—Key: A, 12/14 mesh pyrite; B, 70/80 mesh pyrite; C, 12/14 mesh quartz; D, 70/80 mesh quartz. Materials are magnified to the same apparent size to show their characteristic particle shapes.

over the initial period of segregation. The coefficient of the linear term in the equation is thus proportional to the initial segregation rate and can be used to compute the segregation agitation coefficients. These are listed on lines 1–3 in Table I.

This coefficient can be seen to increase as the particles become more nearly spherical. The volumes of the angular particles lie between those of the $^1/_8$ and $^5/_{32}$-in. balls so that comparisons can be made among the first 5 lines of Table I. The lower energy apparently required for segregation of the systems containing the more angular particles cannot be explained on the basis of the data at hand.

The agitation coefficients for the equilibrium values in the last column of Table I can be seen to be the numerical difference between the agitation coefficients for segregation and mixing. Apparent discrepancies are due to rounding to a reasonable number of significant figures.

Results of studies on two granular systems, crushed quartz and pyrite, are presented in Table II. These data agree qualitatively with those relating to the angular shapes. While no attempt was made to measure shape, it was readily apparent (Fig. 2) that crushed quartz of a given mesh size is more angular than pyrite of the same size. The higher values of the agitation coefficients of pyrite for both segregation and mixing can be expected on the basis of data in Table II.

TABLE III—AGITATION AMPLITUDES AND FREQUENCIES EMPLOYED AND THEIR CORRESPONDING PARTICULATE VELOCITIES

Amplitude, in.	Frequency, c.p.m.	Particle Velocities, in./sec.
0.200	1030	10.18
0.195	1030	9.89
0.174	1030	8.68
0.174	925	7.43
0.141	1238	8.64
0.141	1119	7.58
0.141	1030	6.71
0.141	935	5.66
0.141	856	4.63
0.100	1400	6.84
0.100	1030	4.04

Conditions under which the foregoing data were obtained are summarized in Table III. With the exception of the data on lines 6 and 7 of Table I which were determined from studies at all 11 agitation conditions, agitation coefficients were calculated from data obtained under the three conditions represented by lines 1, 7, and 11 in Table III.

SUMMARY

A useful indication of the relative energy requirements for the processes of segregation and mixing, as they occur in idealized particulate systems of the type studied here, may be obtained from the determination of agitation coefficients. Such coefficients are somewhat analogous to activation energies for molecular processes but possess certain important fundamental differences from the latter as indicated previously (4).

The energy requirements of both segregation and mixing have been shown to depend on the shape and relative size of the particles involved. Two granular systems possessing different particulate characteristics were found to behave in conformity with predictions based on the idealized systems. The general method appears to be applicable to the study of other particulate variables as they influence diffusive segregation and mixing.

Field Screening Test for Lysergic Acid Diethylamide

By JAMES LOOK

A rapid and sensitive field screening test for lysergic acid diethylamide (LSD), which requires little manipulation and equipment, is described. The method is only a presumptive test, and the sample must be taken back to the laboratory for confirmatory tests. (The method is also applicable as a screening test for other psychotomimetic drugs such as dimethyltryptamine, diethyltryptamine, bufotenin, serotonin, and psilocybin.)

THE CLASSICAL Van Urk test is specific for α- or β-unsubstituted indoles (1). In the presence of strong acid these indoles condense with *p*-dimethylaminobenzaldehyde to form colorless, violet-red, and blue compounds, the relative amounts depending on the concentration of reagents and the presence or absence of oxidizing agents (1–6).

This procedure has been modified to provide a sensitive rapid field screening test for LSD which requires no oxidizing agent other than air. In addition, several observations have been made which support the reaction scheme and structures previously proposed by other workers (2–4).

PROCEDURE

Reagents—Filter paper (*e.g.*, Whatman No. 1) saturated with a solution of 2% *p*-dimethylaminobenzaldehyde in 95% alcohol, then air-dried, cut into strips, and stored in a tightly capped amber glass bottle.

Screening Test—The amount of LSD found in a dosage form usually varies from 75 to 250 mcg. A quantity equivalent to one-tenth of the dosage gives a strong, rapid test.

Macerate a portion of the sample with sufficient alcohol to provide some liquid extract. Keep the volume of the liquid extract to a minimum in order to keep the presumed concentration of LSD high. Transfer the extract to a strip of the prepared filter paper and allow the alcohol to evaporate. Add 1 drop of concentrated hydrochloric acid and let the paper stand, supporting it in such a way that the acidified spot does not touch any surface. A violet-red or violet-blue spot develops if LSD or other psychotomimetic agents of indole derivatives are present; the color slowly diffuses to the edge of the spot to form a colored ring.

The test can be applied directly by placing a portion of the crushed suspected material directly on the prepared paper and then adding a drop of concentrated hydrochloric acid. A violet-red or violet-blue color will develop if LSD or other psychotomimetic indole derivative is present, but the color may or may not edge out to form a ring.

The test can be applied to aqueous solutions if several mcg. of LSD is present in a few drops of the solution. Apply a few drops of the liquid to the filter paper, let it air-dry, and proceed as above. The reaction occurs slowly if the paper is not allowed to dry thoroughly before the hydrochloric acid is added. If the suspected material is in a dilute aqueous solution, make a portion alkaline with a drop or two of concentrated ammonium hydroxide. Add 1–3 ml. chloroform (or enough to provide some liquid extract without greatly lowering the LSD concentration) and shake well in a stoppered vial. Place a tight wad of cotton on the mouth of the vial, quickly invert it, and let the chloroform extract settle into the cotton. Place a few drops of the chloroform extract on a piece of the prepared filter paper, let the paper dry, and add a drop of concentrated hydrochloric acid to the spot.

DISCUSSION

Screening Test—This test as given in the procedure is convenient, requires little equipment, is completed in a few minutes, and is sensitive to as little as 1 mcg. LSD. The *p*-dimethylaminobenzaldehyde-saturated paper is stable for several months.

Concentrated hydrochloric acid is found to give a rapid test and a clearly defined ring. However, 1:1 hydrochloric acid solutions in water or alcohol are also satisfactory developing agents. More dilute acid solutions are unsatisfactory. When they are used, the reaction is very slow, and the color remains diffused throughout the spot rather than migrating and concentrating on the edge of the spot to form a ring.

The color changes observed in the usual air atmosphere depend on which reagent is present in excess (Scheme I). Usually, *p*-dimethylaminobenzaldehyde is in excess and in less than 1 min. a violet-red or violet-blue color develops; however, on standing, the initially formed ring loses its violet tinge and the color becomes less intense but bluer; then it gradually fades through a series of color changes: pale blue, pale blue-gray, and pale green. Another drop of hydrochloric acid regenerates the violet-blue color; upon standing, this fades again through the same sequence of colors. This observation is consistent with the expected dependence of acid concentration on the interconversion of IV and V. The color can be restored many times by the addition of more acid, but it is fainter each time. The color changing phenomena observed depend on the concentration of LSD, proportion of reagents, temperature, and other variables.

Since positive tests are obtained for any compound containing an indole ring with an open α or β position, any positive results should be tested for possible confirmation in the laboratory by thin-layer (7–9) or paper (10) chromatography or by ultraviolet and infrared spectrophotometry.

Chemistry of the Test—The reaction scheme and color assignments given in Scheme I have been generally agreed upon by previous workers (2–4), and we have made certain qualitative observations with lysergic acid which support the reaction sequence. In the first step of the scheme, the reagents condense in a 1:1 mole ratio to form a base

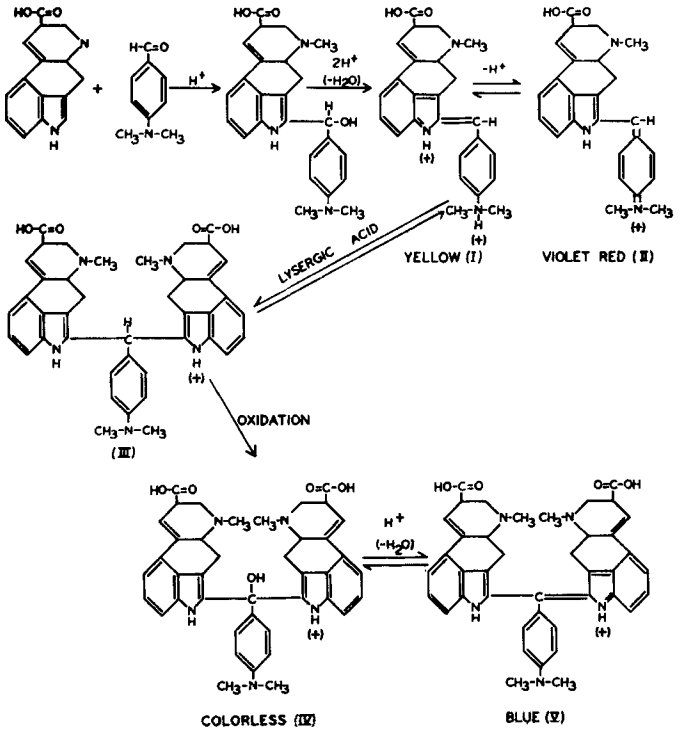
Accepted for publication August 2, 1967.

The author thanks Dr. Frederick R. Jensen, San Francisco District, Food and Drug Administration, for his advice on this project.



Scheme I

which has a protonated yellow form (I) and a violet form (II). If excess lysergic acid is present, further condensation occurs to give III which is colorless. However, III is oxidized very readily to yield IV (colorless) or its ionic form (V) (intense blue) depending on acid concentration.

Under a helium atmosphere (nonoxidative conditions), the following observations were made.

(*a*) In the presence of excess *p*-dimethylaminobenzaldehyde, a strong violet color is instantly obtained, which is in accord with the expected formation of II under these conditions.

(*b*) With excess lysergic acid, the reaction mixture is initially colorless but slowly turns slightly violet, which supports the postulated predominant formation of III under these conditions.

(*c*) The observed colors are consistent with the proposal that regardless of which reagent is present in excess, compound II is formed and not V. The formation of II is rapid with an excess of aldehyde and slow with an excess of lysergic acid.

On addition of NH_4OH to compounds II and V, the intense colors disappear. These colors can be restored by adding excess concentrated HCl to the compounds.

Interferences—In the present procedure, any α- or β-unsubstituted indole gives a color reaction. The psychotomimetic drugs dimethyltryptamine, diethyltryptamine, bufotenin, serotonin, and psilocybin also give a color reaction, but the color which develops is more red than violet-red or violet-blue. Experience with this test procedure allows one to tentatively distinguish these compounds from LSD.

Chemistry of the Ephedrine Spot Test Based on Its Pyrolytic Oxidation to Acetaldehyde by Sodium Bismuthate

By LESTER CHAFETZ, MILTON ELEFANT, and PRAMOD R. AMIN

The presence of acetaldehyde in the pyrolysis products resulting from heating ephedrine with sodium bismuthate can be explained by a hydramine fission reaction or a periodate-type α-aminoalcohol mechanism. Model experiments using gas chromatographic analysis indicate that the reaction is analogous to a periodate oxidation.

FEIGL AND SILVA (1) described a sensitive and selective spot test for ephedrine based on the detection of acetaldehyde produced by heating the alkaloid or its salts with sodium bismuthate. They rationalized the reaction as a hydramine fission of the phenethanolamine to methylamine and propiophenone catalyzed by the alkalinity of the bismuthate reagent (Scheme I) followed by oxidation of the latter to acetaldehyde by excess bismuthate. The authors have found that propiophenone responds to the ephedrine spot test with a detection limit of less than 3 mcg., which lends credence to their explanation of the reaction route; however, an alternative explanation is possible.

$$\phi CHOHCH(NHCH_3)CH_3 \rightarrow \phi COCH_2CH_3 + CH_3NH_2$$

Scheme I

Rigby (2) described the use of sodium bismuthate in acid solution for the facile cleavage of 1,2-glycols to aldehydes and ketones and for related reactions analogous to those effected by lead tetraacetate and periodic acid. The periodate oxidation of ephedrine was first reported by Wickstrøm (3), who identified the products as benzaldehyde, acetaldehyde, and methylamine (Scheme II). He showed that the oxidation was highly dependent on pH,

$$\phi CHOHCH(NHCH_3)CH_3 \rightarrow \phi CHO + CH_3CHO + CH_3NH_2$$

Scheme II

proceeding quantitatively in minutes at room temperature at pH 7.5, but at an immeasurably slow rate at pH 6 or lower. Chafetz (4) indicated that periodate oxidation of phenethanolamines appears to require the availability of an unshared electron pair on the amine nitrogen. Assuming that the bismuthate and periodate reactions proceed by analogous mechanisms, one would not expect the acidic reagent described by Rigby to react with ephedrine; however, the spot test is performed with dry sodium bismuthate, an aqueous suspension of which gives a strongly alkaline reaction.

The problem of discriminating between the alternative reaction routes resolves itself to a matter of determining whether benzaldehyde or propiophenone is produced by the reaction of ephedrine with bismuthate. The experiments described here were designed to provide elucidation.

EXPERIMENTAL

Equipment and Supplies—Ephedrine HCl N.F., sodium bismuthate, propiophenone, benzaldehyde, isooctane, methylene chloride, and 2,4-dinitrophenylhydrazine were the best available laboratory grades used without further purification. A Beckman DK-2 recording spectrophotometer was used with 1-cm. silica cells for U.V. measurements. A Perkin-Elmer model 801 gas chromatograph was employed using the following experimental parameters.

Column: a 2 M. glass helix of 0.25 in. o.d. packed with 3% HI-EFF 8 BP on 100/120 mesh Gas Chrom Q (Applied Science Laboratories, Inc., State College, Pa.); injector temperature: 200°; helium flow: 40 ml./min.; hydrogen flow: 30 ml./min.; column temperature: 80°, programmed immediately after injection at 10°/min. to a final temperature of 150°; sample collection: a Perkin-Elmer 008-0525 sample collector chilled in a Dewar flask of dry ice–acetone was used with a collection ratio of 4 parts effluent to the collector and 1 part to the flame ionization detector.

Reaction of Ephedrine with Aqueous Bismuthate—A solution of 2.0 mg. of ephedrine HCl in 5.0 ml. of water was mixed with a suspension of 330 mg. of sodium bismuthate in 1 ml. of water and 20.0 ml. of isooctane in a 50-ml. glass-stoppered centrifuge tube. The stoppered mixture was heated 30 min. in a boiling water bath and cooled at the tap. The isooctane layer was filtered through Whatman No. 1 paper, and its ultraviolet spectrum was scanned from 300 to 205 mμ *versus* solvent. The extent of conversion of ephedrine to benzaldehyde was calculated from the ratio of the molar absorptivity obtained in this experiment to the molar absorptivity of benzaldehyde in isooctane determined concomitantly.

A mixture of 2 Gm. of ephedrine HCl and 3.5 Gm. of sodium bismuthate was heated at reflux with 5 ml. of water in a round-bottom flask for 15 min. The cooled mixture was extracted with ether twice, and the ether was allowed to evaporate. The residue was taken up in 20 ml. of alcohol and treated with 10.0 ml. of 2,4-dinitrophenylhydrazine reagent prepared by dissolving 800 mg. of 2,4-dinitrophenylhydrazine in 4 ml. of concentrated sulfuric acid to which 6 ml. of water and 10 ml. of alcohol are added after cooling. The resulting 2,4-dinitrophenylhydrazone was recrystallized from alcohol. Its melting point was determined by the capillary method in a Thomas-Hoover apparatus and compared with that of authentic benzaldehyde 2,4-dinitrophenylhydrazone.

Pyrolysis and Gas Chromatography Experiments—Pyrolysis was effected in a test tube fitted with a sidearm. The vapors were collected through a pipet secured with rubber tubing in 1 ml. of methylene chloride in a second test tube. The pyrolysis tube was heated with a free flame until the vapors were observed to have been driven into

Received April 17, 1967, from the Pharmaceutical Research and Development Laboratories, Warner-Lambert Research Institute, Morris Plains, NJ 07950
Accepted for publication July 31, 1967.

the collection tube (no more than 5 min.). The following mixtures were pyrolyzed: 500 mg. of ephedrine HCl and 1.65 Gm. sodium bismuthate, 200 mg. propiophenone and 800 mg. sodium bismuthate, 500 mg. ephedrine HCl and 1.5 Gm. sodium hydroxide pellets, 0.5 ml. acetaldehyde and 1.5 Gm. sodium bismuthate, 0.5 ml. acetaldehyde and 1.5 Gm. sodium hydroxide pellets.

The methylene chloride solutions obtained were injected into the gas chromatograph, using 5-μl. volumes. Peaks with retention times corresponding to benzaldehyde and propiophenone were collected, and the trapped fractions were washed into 1-cm. cells with methanol and scanned in the ultraviolet range with the recording spectrophotometer.

RESULTS AND DISCUSSION

Ephedrine Reaction with Aqueous Bismuthate—A conversion of 2% of the ephedrine to benzaldehyde was obtained under the conditions used. The low yield is not unexpected, for the bismuthate is both insoluble and unstable in aqueous medium. The ultraviolet spectra of benzaldehyde and propiophenone are closely similar, and for this reason the identity of the product was checked by derivative formation. The 2,4-dinitrophenylhydrazone obtained in the second experiment melted at 236°. Authentic benzaldehyde 2,4-dinitrophenylhydrazone melted at 236°, and the mixed melting point was not depressed. The literature (5) melting point for benzaldehyde 2,4-dinitrophenylhydrazone is 237°, while the propiophenone derivative melts at 191°. The reaction in aqueous medium appears analogous to periodate oxidation, and it might be expected to proceed by a similar mechanism.

Pyrolysis Experiments—Dry-heating ephedrine with sodium bismuthate led to six major peaks. The peak with the retention time of benzaldehyde (4.0 min.) constituted 13.8% of the total detector response as determined by the internal normalization technique. The methanol solution of the isolated peak showed an absorption maximum at 244 mμ, and its spectrum corresponded with that of benzaldehyde in methanol. Other peaks were found with retention times of 2.4, 2.8, 6.0, 7.5, 8.4, 12.4, 14.4, and 16.0 min. The major peak, which amounted to nearly 75% of the total response, had a retention time of 12.4 min. It was not identified. The peak which eluted at 7.5 min. amounted to 2.5% of the total and eluted at about the same time as propiophenone. However, its ultraviolet spectrum after elution did not correspond with propiophenone; it had an absorption maximum at 270 mμ. Sodium bismuthate is a very alkaline material, and complex aldol and Cannizzaro products might well be expected. Heating ephedrine with sodium hydroxide led to a typical pyrolysis chromatogram with a large number of peaks and no major components. Pyrolysis of propiophenone with sodium bismuthate leads to a positive test for acetaldehyde under the Feigl and Silva conditions; however, the gas chromatogram showed no peak corresponding to benzaldehyde. This indicates that propiophenone is not an intermediate in the formation of benzaldehyde from ephedrine. Heating acetaldehyde with either sodium hydroxide or sodium bismuthate led to only minor amounts of products.

SUMMARY AND CONCLUSIONS

The Feigl and Silva rationalization of the spot test they described for ephedrine (1), detection of acetaldehyde after pyrolysis of the alkaloid with sodium bismuthate, was hydramine fission to propiophenone and methylamine followed by oxidation of propiophenone to acetaldehyde and other products. No propiophenone was detected in the reaction of ephedrine with bismuthate either during heating in aqueous medium or under pyrolytic conditions, which militates against acceptance of the hydramine fission explanation for the reaction. An alternative rationalization is presented: periodate-type cleavage of the ethanolamine side chain of ephedrine to benzaldehyde, acetaldehyde, and methylamine. Evidence supporting the alternative explanation includes the analogous behavior of bismuthate with periodate on glycols, identification of benzaldehyde as a product of oxidation of ephedrine by bismuthate under both aqueous and pyrolysis conditions, and the absence of benzaldehyde as a pyrolysis product of propiophenone with bismuthate. Gas chromatographic analysis of the ephedrine pyrolyzate showed it to be a complex mixture of products, of which benzaldehyde amounted to 14% and a major component accounted for nearly 75% of the total detector response.

Rapid Analysis of Chlorinated Hydantoin by Gas Chromatography

By ARVIN P. SHROFF and R. E. HUETTEMANN

Gas chromatographic separation of a number of chlorinated hydantoins has been carried out using a split column. A quantitative method for the determination of 3-trichloromethylthio-5-(1-ethylamyl)hydantoin (chlordantoin) in suppositories has been developed. The accuracy of the method and results of the assay are reported.

A NUMBER OF trichloromethylthio derivatives of the phthalimide and hydantoin series have been investigated (1, 2) for their microbiological activity. Kupferberg and Doscher (2) found one of these hydantoin compounds, 3-trichloromethylthio-5-(1-ethylamyl)hydantoin (chlordantoin) to be the most active topical agent against *C. albicans* infections. A simple and rapid method of chemical analysis was required for this compound formulated in suppositories.

Hydantoins have been quantitated volumetrically in tablets by either compleximetric or precipitation techniques (3, 4). Borkowski and Dluzniewska (5) have used spectrophotometric procedures in biological fluids. These methods are sensitive but they lack the specificity required in the presence of other hydantoins.

Gas–liquid chromatography was considered as a desirable technique for estimating these halogenated hydantoins because it offered quantitation with concurrent fractionation. Chlorinated compounds used in pharmaceutical, pesticide, and fumigant areas have successfully been subjected to gas–liquid chromatography using either flame ionization or electron capture detectors (6–15).

The work reported here describes an analytical method utilizing a preliminary solvent extraction followed by a direct gas chromatographic determination using a flame ionization detector.

EXPERIMENTAL

Apparatus—A modified F and M model 1609 gas chromatograph equipped with flame ionization detector was used throughout this study. (The injection port was modified by F and M Scientific to eliminate the potential for inlet sample splitting.) The column used was a 12 in. long and 1/4 in. o.d. copper tube, half of which (injection port end) was packed with 4% Carbowax 20M on Gas Chrom Z, 100/120 mesh, and the other half with 2% phosphoric acid on Diatoport S, 60/80 mesh. The injection port and detector temperatures were approximately 250° and 235°, respectively. The column was conditioned at 210° and operated at 130° and 190°. Nitrogen was used as a carrier gas with a flow rate of 45 ml. per minute. Hydrogen and oxygen flow were maintained at approximately 45 and 400 ml. per minute, respectively. The attenuation and range throughout the determinations were at 32 and 10, respectively. The chart speed was maintained at 15 in. per hour.

Analytical Procedure—Two 100-ml. standard solutions containing 25 mg./ml. of chlordantoin and 3 mg./ml. of 9-anthraldehyde, respectively, were prepared in chloroform. A 2.0-ml. aliquot of the standard chlordantoin solution was evaporated in a 10 dr. vial and 2.95 Gm. of suppository base was added. To this and another vial containing two suppositories (equivalent to 50 mg. chlordantoin) were added 5.0 ml. of distilled pentane and 10.0 ml. of nitromethane. The mixture was shaken to effect complete solution followed by centrifugation for 2 min. A 5.0-ml. aliquot of the nitromethane solution from each vial was transferred to two other vials and evaporated. One milliliter of standard 9-anthraldehyde solution (internal standard) was added to each vial, mixed, and a 3-μl. injection was made into the gas chromatograph. The retention times for chlordantoin and 9-anthraldehyde were 1 and 2 min., respectively. The concentration of chlordantoin in each suppository was obtained as follows:

$$\text{mg. of chlordantoin/suppository} = \frac{A_s}{B_s} \times \frac{S_b}{S_a} \times 25$$

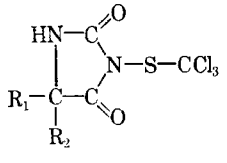
where

A_s, peak height of chlordantoin in sample,
B_s, peak height of 9-anthraldehyde in sample,
S_a, peak height of chlordantoin in standard,
S_b, peak height of 9-anthraldehyde in standard,
25, milligram of chlordantoin in standard.

RESULTS AND DISCUSSION

Table I gives the retention times of a number of hydantoins at 130°. It can be seen that the increase in bulkiness of the alkyl groups at C_5 does not correspondingly increase the retention time. Theoretically, any hydantoin in Table I can serve as an internal standard for chlordantoin (No. 4). However, because of the unavailability of these hydantoins and the time it would take to carry out each determination (130°), we chose to use an internal standard from another chemical series, namely 9-anthraldehyde, and carry out the determination at 190°. This speeds up the determination by a factor of four and is quite useful for control purposes.

TABLE I—RETENTION TIME OF HYDANTOINS AT 130°



No.	R_1	R_2	Time, min.
1	CH_3	C_2H_5	3.05
2	CH_3	i-C_3H_7	2.95
3	CH_3	i-C_4H_9	3.80
4	H	$CH(C_2H_5)(C_4H_9)$	14.00
5	H	$CH_2CH(CH_3)(CH_2)_3CH(CH_3)_2$	3.05

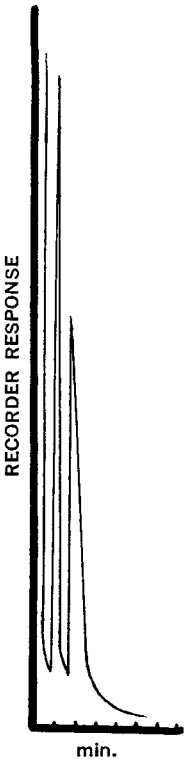

Fig. 1—A typical gas chromatogram for a mixture of chlordantoin and 9-anthraldehyde.

The analytical procedure utilizes extraction by two organic solvents, namely pentane and nitromethane. Thus, a modified extraction *p*-value determination (fractional amount of a solute partitioning into the nonpolar phase of an equal volume two-phase system) for chlordantoin was carried out. According to the procedure of Bowman and Beroza (16), *p*-values are determined by analysis of the nonpolar solution of the solute before and after extraction. However, we determined the *p*-value by analyzing both the polar and nonpolar phase and found it to be 1.0 in the nitromethane. Next the "binding" of chlordantoin to the suppository base was investigated in the same manner as the determination of *p*-value with different proportions of the suppository base in the pentane. It was found by analyzing the polar phase that there was a definite amount of retention in the pentane layer containing the base. This observation necessitated the addition of a fixed amount of base to the standard solution for the sake of relative comparison of available chlordantoin in samples.

Figure 1 illustrates a typical gas chromatogram of chlordantoin containing 9-anthraldehyde. The ratio of peak heights obtained for various concentrations of hydantoin in the standard solutions is given in Table II. A plot of these data is a straight line. The means for a series of injections of extracted samples containing 25 mg. of chlordantoin were ±1.5% (Table III) with a standard deviation of ±0.26 mg. (Table IV). This procedure affords a rapid means of comparative assay for chlordantoin.

TABLE II—CONCENTRATION *Vs.* RATIO OF PEAK HEIGHT

No.	Chlordantoin, mg.	Ratio of Peak Ht.
1	20	0.854

Peptides Synthesis: Coupling of Pentachlorophenyl Active Esters of *N*-Carbobenzoxy Amino Acids and Peptides to the Pentachlorophenyl Active Ester Hydrochlorides of Amino Acids

Sir:

Pentachlorophenyl active esters afford a satisfactory method for the synthesis of peptides and polypeptides with the ordered sequence of amino acids (1–3). One of the main advantages in the use of pentachlorophenyl esters is their relatively higher melting points which lead to easy crystallization and purification. The other very significant advantage lies in the fact that pentachlorophenyl esters are stable to controlled hydrogenation conditions, thereby allowing the selective removal of the *N*-carbobenzoxy protecting group (3). During the course of our work for the synthesis of biologically active peptide hormones, we extended the use of pentachlorophenyl esters by directly coupling them with amino acids which were C-protected by suitable salt formation. The aim in mind was to develop a procedure whereby aqueous alkaline treatment and the problems brought about by it could be avoided. The alkaline hydrolysis which is usually employed for the removal of methyl or ethyl C-protection in peptides is associated with a number of problems, *e.g.*, racemization (4), transpeptidation (3, 5), and formation of urea and hydantoin derivatives from the carbobenzoxy protecting group (6). In addition, hydrolysis becomes more difficult as the number of amino acids increases in the peptide chain (7).

We recently reported that *N*-carbobenzoxy amino acid or peptide pentachlorophenyl esters couple in good yields with amino acids which are C-protected by salt formation with dicyclohexylamine (8). The salt protection from the resulting peptides was removed by mild acid treatment, thereby avoiding the alkaline treatment. Stepwise lengthening of the peptide chain was achieved by using the combination of mixed anhydride and pentachlorophenyl active ester methods.

We now wish to report an interesting reaction sequence which we have found to be very rewarding as a complementary approach to the method previously described (8). Using the new approach, we have been able to couple pentachlorophenyl active esters of amino acids or peptides with pentachlorophenyl active ester hydrochlorides of amino acids in satisfactory yields. The advantage of this approach is significant since all the amino acids or peptides used in the coupling reaction are in the form of their pentachlorophenyl esters; therefore, as mentioned above, they are crystalline derivatives and easily purified (3). The outlines of the reaction conditions for the synthesis of *N*-carbobenzoxy-glycyl-serine pentachlorophenyl ester[1] are given below.

To a solution of *N*-carbobenzoxy-glycine pentachlorophenyl ester, (0.02 mole) and a catalytic amount (0.2–0.3 Gm.) of 2-hydroxypyridine in 75 ml. of methylene chloride, was added one equivalent of triethylamine. A suspension of serine pentachlorophenyl ester hydrochloride (0.02 mole) in 10 ml. of methylene chloride was added to the above solution over a period of 1 hr. After 24 hr. of stirring at room temperature, the reaction mixture was freed from solvents under reduced pressure. The residue was taken up in ethyl acetate and extracted with 1 *N* hydrochloric acid, 5% aqueous sodium bicarbonate, and water. From the ethyl acetate solution Z-Gly-Ser-OPCP was isolated in 75% yield after crystallization from methanol, m.p. 160–161°.

Anal.—Calcd. for $C_{19}H_{15}Cl_5N_2O_6$: C, 41.87; H, 2.75; N, 5.15. Found: C, 41.73; H, 2.69; N, 5.21.

Z-Gly-Ser-OPCP was coupled following the above conditions with alanine pentachlorophenyl ester hydrochloride to afford Z-Gly-Ser-Ala-OPCP, in 69% yield, m.p. 169–170°.

Anal.—Calcd. for $C_{22}H_{20}Cl_5N_3O_7$: C, 42.91; H, 3.5; N, 6.83. Found: C, 43.12; H, 3.46; N, 6.78.

In order to further establish the usefulness of the above method, we selected a tripeptide active ester, *N*-carbobenzoxy-γ-*tert*-butyl-glutamyl-alanyl-γ-*tert*-butyl-glutamic acid pentachlorophenyl ester which was previously synthesized using the conventional methods (3). The yields for each step in Scheme I were above 62%.

The tripeptide (V) had melting point and ele-

Assay of Chlorpromazine Glucuronides in Human Urine

Sir:

Recently we reported a routine assay for conjugated and unconjugated chlorpromazine metabolites in human urine (1). The group of conjugated chlorpromazine metabolites was assayed by passing a small volume of urine through an ion-exchange resin to remove unconjugated drug metabolites and some contaminating endogenous urinary constituents. The eluate was then made up to 50% sulfuric acid content, and the conjugated drug metabolites were estimated spectroscopically. The procedure was satisfactory for conditions of chronic drug administration of 100 to 1400 mg. chlorpromazine per day. However, studying the excretion of chlorpromazine glucuronides in patients during the initial 4 days of low dosage chlorpromazine therapy (300 mg. or less per day), the method was found lacking in specificity and therefore inaccurate. In a typical determination, *i.e.*, with adequate amounts of chlorpromazine glucuronides, a certain amount of endogenous urinary chromogens can be compensated for by the background cancellation technique. At a starting level of 300 mg. chlorpromazine per day, an adequate urinary level of chlorpromazine glucuronides was reached only after about 1 week. A more selective assay was needed to measure the initial low levels of chlorpromazine glucuronides in the presence of excessive amounts of endogenous urinary chromogens. The following modification of the original procedure was found satisfactory.

Instead of adding 5 ml. of concentrated sulfuric acid to 5 ml. of effluent from the ion-exchange column, as previously specified, it was found practical to add 5 ml. of 50% sulfuric acid solution containing 75 mcg. $FeCl_3 \cdot 6H_2O$ per ml., in a 10-ml. volumetric flask immersed in an ice water bath. After thorough mixing under cooling, the solution was removed from the ice water bath, made up to volume with 25% H_2SO_4, and the absorption spectrum recorded between 400 and 700 mμ, when the mixture had reverted to room temperature. Maximum absorption was read as previously specified, at 550 mμ against a standard calibration curve prepared from 7-methoxychlorpromazine.

Sharper maxima, cleaner purple colors, and lower background readings were obtained by this modification of color development which lowered the over-all acidity from the previously specified 50% to 25%. Maximum color development was completed at 5 min., and colors remained stable for 60 min., the longest period tested.

The modification was therefore adopted for de-

Proper Identification of the *n*-Alkane from *Arctostaphylos patula*

Sir:

In a recent phytochemical investigation reported in *J. Pharm. Sci.*, an *n*-alkane was isolated from *Arctostaphylos patula* Greene (*Ericaceae*) which was tentatively identified as *n*-nonacosane (1). This identification was made on the basis of solubility characteristics and a sharp melting point of 64° for the isolate. Since this report was published, we have gained additional information on the identity of this subtance, which is the subject of this communication.

In order to obtain an exact molecular weight for the isolate, it was subjected to mass spectral analysis and was found to be a mixture of nine *n*-alkanes.[1] All members of the C_{25}–C_{33} series were present with the odd carbon atom compounds being predominant. This finding is in agreement with recent extensive studies on plant *n*-alkanes reported by others (2–4).

Furthermore, the sample was subjected to a gas chromatographic analysis using a Packard FID instrument fitted with a 4 mm. × 2 M. glass column and packed with 3% SE-30 on Shimalite W (80–100 mesh). Argon (60 ml./min.) was the carrier gas, and a flame ionization detector with a sensitivity setting of 1×10^{-7} was used. The column temperature was maintained at 230° and the injection port was 235°. Estimation of the concentration of *n*-alkanes in the sample was by planimeter (5).

Under these conditions, it was found that the sample separated into nine distinct peaks, each corresponding to the mass spectral data. These peaks were identified as *n*-pentacosane, $C_{25}H_{52}$ (<1%); *n*-hexacosane, $C_{26}H_{54}$ (<1%); *n*-heptacosane, $C_{27}H_{56}$ (3%); *n*-octacosane, $C_{28}H_{58}$ (4%); *n*-nonacosane, $C_{29}H_{60}$ (17%); *n*-triacontane, $C_{30}H_{62}$ (5%); *n*-hentriacontane, $C_{31}H_{64}$ (60%); and *n*-dotriacontane, $C_{32}H_{66}$ (6%); as well as *n*-tritriacontane, $C_{33}H_{68}$ (5%). No peaks representative of *iso*alkanes were observed. An infrared absorption spectrum (KBr) of the original sample was typical for *n*-alkanes, with no evidence of OH or carbonyl absorption.

The qualitative and relative quantitative distribution of *n*-alkanes in the mixture is consistent with data reported for other ericaceous species (3).

Therefore, on the basis of the data reported at this time, the material reported earlier as "*n*-nonacosane" is a mixture containing *n*-hentriacontane (60%) as the major constituent (1).

This identification was made on the basis of solubility characteristics and a sharp melting point of 64° for the isolate. Since this report was published, we have gained additional information on the identity of this subtance, which is the subject of this communication.

In order to obtain an exact molecular weight for the isolate, it was subjected to mass spectral analysis and was found to be a mixture of nine *n*-alkanes.[1] All members of the C_{25}–C_{33} series were present with the odd carbon atom compounds being predominant. This finding is in agreement with recent extensive studies on plant *n*-alkanes reported by others (2–4).

Furthermore, the sample was subjected to a gas chromatographic analysis using a Packard FID instrument fitted with a 4 mm. × 2 M. glass column and packed with 3% SE-30 on Shimalite W (80–100 mesh). Argon (60 ml./min.) was the carrier gas, and a flame ionization detector with a sensitivity setting of 1×10^{-7} was used. The column temperature was maintained at 230° and the injection port was 235°. Estimation of the concentration of *n*-alkanes in the sample was by planimeter (5).

Under these conditions, it was found that the sample separated into nine distinct peaks, each corresponding to the mass spectral data. These peaks were identified as *n*-pentacosane, $C_{25}H_{52}$ (<1%); *n*-hexacosane, $C_{26}H_{54}$ (<1%); *n*-heptacosane, $C_{27}H_{56}$ (3%); *n*-octacosane, $C_{28}H_{58}$ (4%); *n*-nonacosane, $C_{29}H_{60}$ (17%); *n*-triacontane, $C_{30}H_{62}$ (5%); *n*-hentriacontane, $C_{31}H_{64}$ (60%); and *n*-dotriacontane, $C_{32}H_{66}$ (6%); as well as *n*-tritriacontane, $C_{33}H_{68}$ (5%). No peaks representative of *iso*alkanes were observed. An infrared absorption spectrum (KBr) of the original sample was typical for *n*-alkanes, with no evidence of OH or carbonyl absorption.

The qualitative and relative quantitative distribution of *n*-alkanes in the mixture is consistent with data reported for other ericaceous species (3).

Therefore, on the basis of the data reported at this time, the material reported earlier as "*n*-nonacosane" is a mixture containing *n*-hentriacontane (60%) as the major constituent (1).

HISTORY

FOR CENTURIES the toad has been known to produce a poisonous secretion. The Roman women used the toad, although unsuccessfully, as a murdering agent for their unfaithful husbands (1). William Shakespeare, born about 400 years ago, pictured the toad as wearing a precious jewel in its head. In Macbeth, Shakespeare made the witch throw a toad into the hell-broth. It has been long believed that handling of toads causes warts. In a small area of the state of Illinois, folklore has 300 references to warts of toad origin, particularly their cures (2). These superstitions can of course be disproved by laboratory experience. Houssay (3) operated on 15,000 toads for endocrine studies and we handled more than 10,000 toads for the collection of their poisons—with no ill effects. In form of a votive animal, the toad is associated with the uterus and various gynecological diseases (4) in Central Europe. Bronze toads of the Perm culture of Northeastern Russia were among the archaeological findings dating from the middle of the 1st century A.D.

Toad medicine has been advocated all over the world. For many years the Chinese have used a preparation of toad venom, ch'an su, for the treatment of canker sores, toothache, sinusitis, and local inflammations (5). During the 15th century a European physician wrote a book, "De Venenis," in which he mentioned that the toad's blood was of value in the treatment of difficult breathing (6). Pharmacopeias and dispensatories of early dates gave the dried toad a prominent place among healing agents (7, 8). The South American Indians have made use of the skin secretion of the toad as arrow poison. These arrows are shot into game or enemies from blowtubes.

The English word "toad" is applied to several tailless amphibians, but the various species under

discussion belong to the genus *Bufo* of the *Bufonidae* family. The members of this genus all have a pair of well-defined skin glands behind the eyes, which secrete venom and are called "parotid" glands. The latter, however, have no relation to salivary glands. The longitudinal axis of the toad's parotid glands is parallel with the body axis, although that of exceptional species may be perpendicular to it—*B. peltocephalus* and *B. asper* (9, 10). Additional glands may appear on arms and legs, *e.g.*, *B. alvarius* (11). The venom can be expressed from the parotid gland between the thumb and index finger, and into a glass evaporating dish held over the toad's head. The toad has warts over the dorsal part of the body, and their secretion is difficult to obtain and may or may not be identical with the parotid secretion. Vulpian (12, 13) discovered that the toad venom had a digitalis-like action and that the toad's heart was relatively immune to its own poison. The histology of parotid glands and warts of European, South and North American toads has been documented by several workers (14–16).

Ugly and venomous, one species of toads, *B. marinus*, has saved sugar crops and other cultivated fields in the Hawaiian Islands and Puerto Rico by devouring the insects which do damage to the plantations. Although the toad is reputed to enjoy longevity, it lives in the laboratory from 8.5 to almost 16 years (17).

Attempts to isolate pharmacologically active substances from the European common toad were initiated over a half century ago (18). Abel and Macht (8) succeeded in isolating "bufagin" and epinephrine from the parotid venom of *B. marinus*. This was followed by the eventual identification of bufotalin and bufotoxin from *B. bufo bufo* by Wieland and Weil (19) and cinobufagin and cinobufotoxin from ch'an su (20). Marked advances were made at the University of Basel (21, 22), for numerous cardioactive substances were isolated from ch'an su, and later from the venoms of other species by elegant modern methods. It is now clear that the chemical composition of the venom of each species of *Bufo* differs from one another, although there are many similarities. Most species elaborate in addition, noncardiotonic sterols, indolealkylamines, and several, catecholamines.

CHEMICAL INGREDIENTS OF TOAD VENOM

Pharmacology of Bufadienolides

The cardioactive sterols are naturally the center of interest. In all instances the lactone ring is 6-membered of α-pyrone type, attached to C_{17}. They have a free secondary hydroxy group at C_3, and are known as bufagins corresponding to aglycones of plants. The structural formulas shown in Fig. 1 represent the better known substances which are chemically bufadienolides (23) and synonymous with bufagins. Because different species of toads do not synthesize identical bufadienolides, prefixes have been employed for distinction. The Japanese toad apparently can produce all of them (24). In our laboratory gamabufagin and gamabufotalin are used interchangeably.

None of the bufadienolides in the toad venom conjugates with a carbohydrate to form a glycoside, but a few couple with suberylarginine to become bufotoxins. The first bufotoxin was isolated from the European common toad (25). To distinguish it from other bufotoxins, Wieland's compound has been renamed vulgarobufotoxin (26), and a structure of 14-suberylarginine bufotalin has been proposed (22–27). Among the amphibians, *Bufo* is the only genus elaborating bufagins and bufotoxins (28). Recently it has been reported that a North African grasshopper, *Poekilocerus bufonius*, feeding on milkweeds, is capable of storing glycosides of cardenolide type (29).

Bufagins—The action of bufagins upon the heart follows almost the same pattern as that of digitalis glycosides. Perfusion by various methods with appropriate concentrations in the frog results in systolic standstill. The absorption is generally poor. The positive inotropic action is easily demonstrated in mammals, such as the cat, by slow infusion of a dilute solution of regularobufagin. Electrocardiographic changes are most instructive. Figure 2 serves as an example. The prolongation of P-R interval, bradycardia, the diphasic T-wave, the nodal rhythm, the A–V dissociation, and the idioventricular rhythm are obvious. The slowing of heart rate can be abolished by atropinization but not by vagotomy. The effect of bufagins on the heart is less cumulative than that of digitoxin, being more like that of ouabain. There is a low order of absorption through the gastrointestinal tract in mammals. Thus, no more than 15% of cinobufagin is absorbed by oral administration in anesthetized cats, and 50% of bufalin (36) by intrajejunal injection in nonanesthetized dogs.

Because the chemical structures of bufagins differ from one another, their cardiac activity varies. Table I shows the potencies of 27 compounds. Their mean (geometric) lethal doses (LD's) are determined in groups of 10 or more etherized cats. It should be noted that bufota-

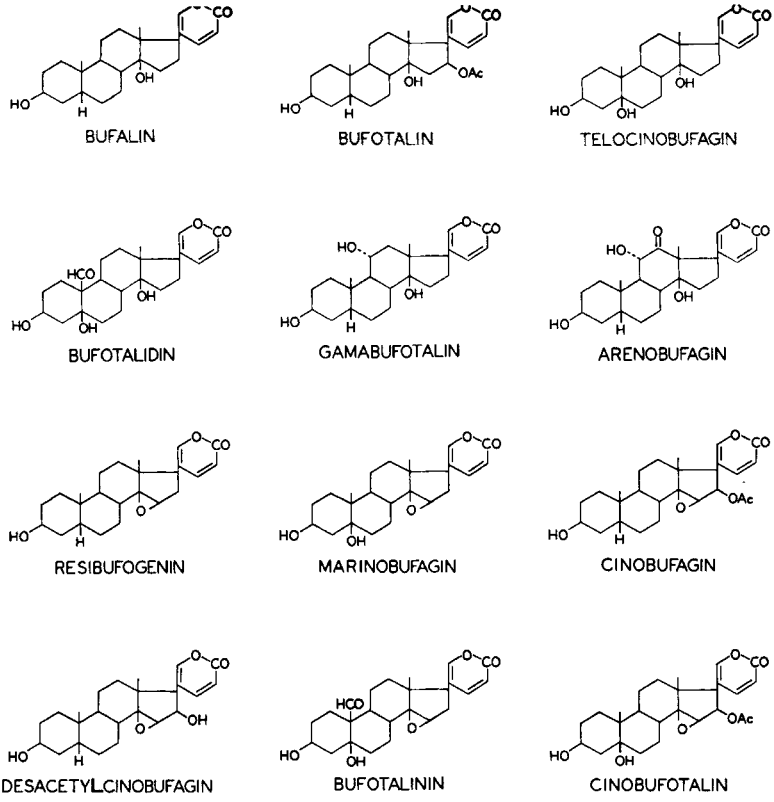

Fig. 1—Structural formulas for better known substances which are chemically bufadenolides (23) and synonymous with bufagins.

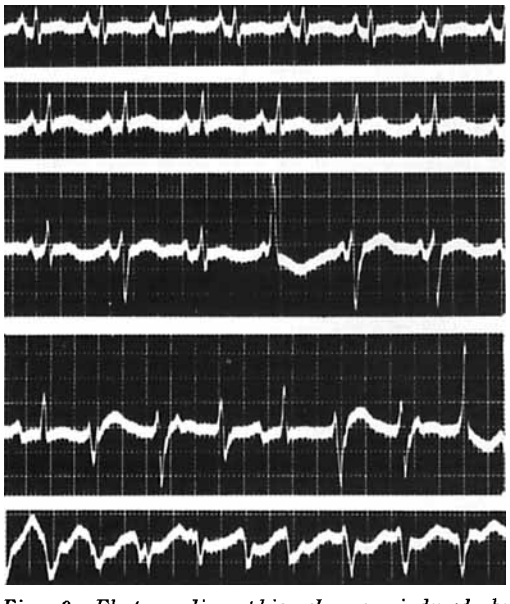

Fig. 2—Electrocardiographic changes induced by regularobufagin in a cat. Regularobufagin in percent of fatal dose (top to bottom): 0, 57, 60, 67, 99.

lidin is identical with hellebrigenin, an aglycone of the root of *Helleborus niger* (34). That toads can synthesize hellebrigenin and hellebrigenol of plant origin is exemplified by several species (37–39). When the means are converted to their reciprocals, they become the number of LD's per mg. as given in Table I, expressing the direct relationship of activity. The very high potency (toxicity) of some of these substances can be appreciated if one realizes that 1 Gm. of acetyl bufotalidin may have 15,600 cat LD's.

The contributions of the Basel scholars make it possible to arrive at certain trends of structure-activity relationship (30). If we consider bufalin the simplest bufadienolide, substitution of H with 5β-OH in telocinobufagin, or with 11α-OH in gamabufagin increases the activity (Table I). A 12-keto group in arenobufagin further enhances the activity. The presence of a free 16-OH in desacetyl bufotalin reduces the toxicity, but 16-acetyl in bufotalin brings back the potency of bufalin. In other cases, 16-desacetylation abolishes the cardiac effect of cinobufagin and cinobufotalin. 3-Acetylation of cinobufotalin, marinobufagin, and bufotalidin (hellebrigenin) has a favorable influence on the potency to various degrees, but the same reaction with cinobufagin produces the opposite effect. A surprising feature is that 14β:15β-epoxides preserve a substantial amount of cardiac activity

TABLE I—ACTIVITY OF BUFAGINS AS MEASURED BY LD'S IN CATS

Name	Mean (Geo.) LD, mg./Kg.	No. of LD's/mg.	Ref.
Arenobufagin	0.08 ± 0.01	13.0 ± 1.14	(30)
Bufotalin	0.13 ± 0.01	7.6 ± 0.40	(31)
Desacetylbufotalin	0.26 ± 0.02	3.8 ± 0.28	(32)
Cinobufagin	0.20 ± 0.02	5.0 ± 0.44	(33)
Acetylcinobufagin	0.59 ± 0.04	1.7 ± 0.11	(30)
Desacetylcinobufagin	inactive	...	(30)
Cinobufotalin	0.20 ± 0.02	5.0 ± 0.62	(33)
Acetylcinobufotalin	0.18 ± 0.01	5.6 ± 0.40	(30)
Desacetylcinobufotalin	inactive	...	(30)
Marinobufagin	1.49 ± 0.09	0.7 ± 0.03	(32)
Acetylmarinobufagin	0.95 ± 0.05	1.1 ± 0.05	(30)
12β-Hydroxymarinobufagin	3.00	0.3	unpublished
Bufotalidin (hellebrigenin)	0.08 ± 0.01	13.0 ± 0.93	(34)
Acetylbufotalidin	0.06 ± 0.00	15.6 ± 0.70	(30)
Resibufogenin	inactive	...	(30)
Acetylresibufogenin	inactive	...	(30)
12β-Hydroxyresibufogenin	4.16	0.2	unpublished
Bufalin	0.14 ± 0.01	7.3 ± 0.55	(33)
Telocinobufagin	0.10 ± 0.02	9.8 ± 0.64	(33)
Bufotalinin	0.62 ± 0.12	1.6 ± 0.31	(30)
Artebufogenin	inactive		(35)
Gamabufotalin	0.10 ± 0.01	9.9 ± 0.50	(31)
Vallicepobufagin	0.20 ± 0.02	5.0 ± 0.43	(31)
Quercicobufagin	0.10 ± 0.04	10.3 ± 0.39	(31)
Viridobufagin	0.11 ± 0.01	9.0 ± 0.66	(31)
Regularobufagin	0.15 ± 0.01	6.5 ± 0.25	(31)
Fowlerobufagin	0.22 ± 0.01	4.6 ± 0.24	(31)

as compared with their free 14β-OH analogs—marinobufagin *versus* telocinobufagin, cinobufagin *versus* bufotalin, and bufotalinin *versus* bufotalidin. It is difficult to explain the absence of activity of resibufogenin and artebufogenin (35). Telocinobufagin with a methyl group at C_{10} is less potent than the aldehyde derivative of the same structure, bufotalidin. The cardenolides of plants—digitoxigenin, periplogenin, oleandrigenin, sarmentogenin, and strophanthidin, corresponding to bufalin, telocinobufagin, bufotalin, gamabufotalin, and bufotalidin—have lower toxicities. The same order of difference has been demonstrated on the contractility of guinea pigs' auricles (40). The superiority of α-pyrone at C_{17} to the cyclobutenolide ring at the same position is unequivocal.

The nature of cardiotonic action is not yet clearly elucidated. An enormous amount of data with cardiac glycosides on tissue respiration, carbohydrate metabolism, high-energy phosphate bonds, ion equilibrium, and contractile proteins is probably also applicable to bufagins (41, 42).

Like ouabain, any of the bufagins causes vomiting in cats or pigeons following intravenous injection of one-half LD. The mechanism of action is presumably also due to the excitement of the chemoreceptor trigger zone where the impulse is mediated to the vomiting center (43).

Restlessness and convulsions occur in frogs with cinobufagin. The action appears to be on the spinal cord. Convulsant action has also been observed with acetyl cinobufagin, marinobufagin and its acetyl derivative, and bufotalinin, not only in frogs but also in cats (30).

As a class bufagins constrict arterial blood vessels and stimulate isolated rabbit's intestines and uterus (44–46). The action must be directly on the smooth muscles.

Some of the bufagins, if not all, have a local anesthetic action. Cinobufagin in 0.1–0.5% solutions produces numbness of the tongue when applied locally. With the stronger solution, sweet and bitter tastes may be lost. There is disappearance of tactile sensation. Local anesthesia can also be demonstrated on the rabbit's cornea after instillation and the guinea pig's skin following intracutaneous injections. Its action is not on nerve fibers, but is confined to sensory nerve endings. So far tested, bufalin, cinobufotalin, and gamabufagin also have a local anesthetic effect.

Bufotoxins—The principal action of a bufotoxin is also upon the heart. The electrocardiographic changes during the slow infusion of cinobufotoxin in a cat are illustrated in Fig. 3. They are similar to those with bufagins or cardiac glycosides. Their potencies are lower than those of corresponding bufagins. Thus vulgarobufotoxin is weaker than bufotalin. The data on

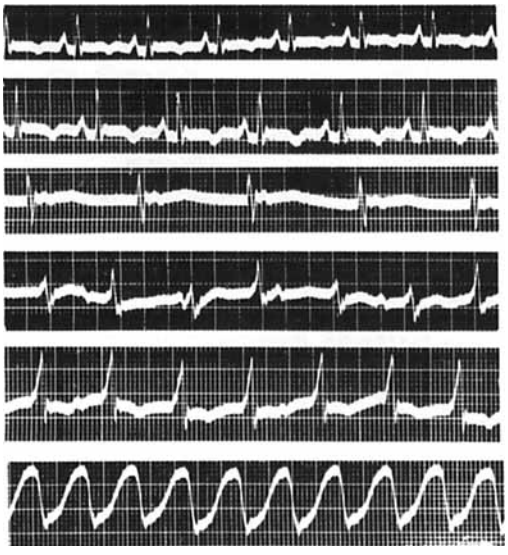

Fig. 3—Electrocardiographic changes caused by cinobufotoxin in a cat. Cinobufotoxin in percent of fatal dose (top to bottom): 0, 19, 37, 75, 77, 100.

nine bufotoxins are given in Table II. All of them are easily dissipated in the animal organism.

Extracardiac effects are repetitious of those of cardiotonic substances—emesis, stimulation of smooth muscle organs, and bitter taste when applied locally.

Clinical Trials—Because of the wide interest in the therapeutic value of toad venom in folklore, a clinical study of one of the bufadienolides was carried out. Cinobufagin can be used as a model, since it is easily available (47). Cases of auricular fibrillation are most suitable for this purpose. Indeed intravenous injection of 1 mg. slows the ventricular rate in some patients, and that of 2 mg. causes a marked fall of pulse rate. The effect lasts for about 5 hr. Nausea and vomiting occur in the majority of instances with the larger dose. It is obvious that cinobufagin offers no advantage over ouabain due to its brevity of action and frequency of side effects. In spite of such evidence, "bufomarine" has been recommended for the treatment of heart ailments of the aged (48). Aside from the curiosity, none of the toad cardiotonic principles can be justifiably employed in cardiology.

TABLE II—ACTIVITY OF BUFOTOXINS AS MEASURED BY LD'S IN CATS (31)

Name	Mean (Geo.) LD, mg./Kg.	No. of LD's/mg.
Viridobufotoxin	0.27 ± 0.01	3.70 ± 0.16
Vulgarobufotoxin	0.29 ± 0.02	3.43 ± 0.21
Cinobufotoxin	0.36 ± 0.02	2.79 ± 0.19
Gamabufotoxin	0.37 ± 0.03	2.67 ± 0.19
Arenobufotoxin	0.41 ± 0.01	2.46 ± 0.07
Marinobufotoxin	0.42 ± 0.02	2.40 ± 0.12
Regularobufotoxin	0.48 ± 0.03	2.10 ± 0.12
Alvarobufotoxin	0.76 ± 0.08	1.32 ± 0.13
Fowlerobufotoxin	0.79 ± 0.05	1.26 ± 0.09

Catecholamines

Epinephrine—The discovery of epinephrine in the venom of *B. marinus* marks the first extramedullary source of a very potent sympathomimetic amine (8). What is more remarkable is the large quantity present in a pair of parotid glands. By a pressor method in pithed cats the dried secretion contains more than 5% of this agent. Not all species of toads produce epinephrine in the venom. To date *B. marinus*, *B. bufo gargarizans*, *B. regularis*, *B. arenarum*, *B. formosus*, *B. blombergi*, and *B. peltocephalus* are known to elaborate epinephrine in the parotid glands (9, 47, 49), while *B. bufo bufo*, *B. viridis viridis*, *B. alvarius*, *B. americanus*, *B. valliceps*, *B. fowleri*, *B. quercicus*, *B. melanostictus*, and *B. asper* are devoid of it (10). The pharmacology of epinephrine is so frequently reviewed (50, 51) that it will be superfluous to give an account here.

Norepinephrine—The identification can be made on the cat's blood pressure and nictitating membrane as well as by paper chromatography. Norepinephrine occurs in the epinephrine of *B. marinus* (52, 53) in amounts of 2–5%. The *l*-isomer of this catecholamine has also been found as an impurity from the sample of epinephrine, isolated from ch'an su (54). The detection of such a small quantity cannot be achieved by using the toad venom without isolating the bulk of epinephrine (55, 56). A monograph on the pharmacology of norepinephrine is available for reference (57).

Indolealkylamines

The first indole base was isolated from the venom of *B. bufo bufo* (58). Its structure is 5-hydroxy-dimethylaminotryptamine (59). Indolethylamine derivatives occur in other species of toads (9, 10, 60). As shown in Fig. 4, cinobufotenine is the methylbetaine of bufotenine. 5-Hydroxytryptamine or serotonin and dehydrobufotenine are present in the parotid secretion of *B. marinus* (61, 62). Bufothionine occurs in the skin secretions of *B. viridis* (63).

The pressor activity in pithed cats can serve to distinguish indoleamines of different species (26). Cinobufotenine is the most potent. In fowls intravenous injection of these substances is followed by a fall of blood pressure (64). Application of the toad indoleamines stimulates

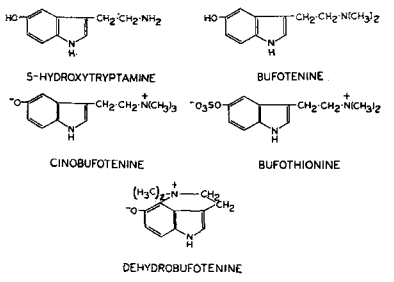

Fig. 4—Substances appearing in the parotid secretions of the toad.

the isolated uterus of the rabbit, the guinea pig, and the rat, and contracts the isolated ileum of the rabbit and the guinea pig. An extensive review on 5-hydroxytryptamine and its related indolealkylamines is available (65, 66).

Noncardiotonic Sterols

The petroleum ether fraction of the ethanol extract contains a mixture of noncardiotonic sterols.

Cholesterol—The bulk can be identified as cholesterol by melting point, spectrogram, and color reactions in addition to digitonin precipitation.

Provitamin D—An admixture of the cholesterol sample of different species of toads is a phytosterol which varies from zero to 14 parts per thousand. The spectrogram is characteristic of ergosterol and after irradiation the material causes bone healing in rachitic rats.

γ-Sitosterol—Sterols of the plant kingdom occur in the venom of toads. γ-Sitosterol has been isolated from *B. bufo bufo*, *B. formosus*, and *B. arenarum* (67).

Miscellaneous Substances—The fresh venom of the different species of toads contains an average of 51–61% of water (11). During squeezing a typical scent is emitted. After drying and extraction for active principles, the residue swells in water, suggestive of mucoproteins. Free suberic acid and arginine are identifiable. The significance of these inert products have not been explored.

USE OF THE VENOM TO THE TOAD

Protection from Enemies—The venoms of most animals are *a priori* intended for self-protection. If the toad finds it possible to introduce its poison into the enemy's bloodstream, it would be fatal to the latter. But the toad does not have teeth to bite, nor does it realize a danger by accurately squirting the venom. It blows itself up when approached by a human hand; when a dog or a cat bites a toad, prolonged salivation takes place but vomiting rarely follows (68). In our experience, one dog was induced to swallow a toad (*B. valliceps*) with complete recovery (47). Some snakes and rats feed on toads (69). The death of a little terrier from biting a toad (*B. alvarius*) was recorded (70). The bitter taste and local irritation of the nose and the eye when one comes in contact with the toad venom is well known (71, 72).

The process of regeneration of the venom is slow. If the pair of parotid glands (*B. marinus*) are manually expressed, it takes about 11 weeks for the toad to restore two-thirds of the original amount. It would be impossible for the animal to furnish large quantities of the poison repeatedly for defensive purposes.

It appears that the toad (*B. marinus*, *B. valliceps*) can dispense with the parotid glands. Surgical removal of these skin organs is compatible with the normal life of the animal. Observations of such an experiment were extended over a year (47).

Significance to Behavior—Recent work on psychopharmacology in higher mammals is centered around the amines of the brain. There is no information about the significance of 5-hydroxytryptamine and catecholamines to the toad. If a large toad, *B. marinus*, is dissected under local anesthesia for the blood supply and nerve innervation of a parotid gland, no epinephrine is demonstrable in the vein following electric stimulation of the glandular nerve which is a branch of the jugular ganglion. The result is not comparable to the splanchnic stimulation in mammals, liberating medullary epinephrine of adrenal glands. The toad's serum cholesterol averages 153 mg.%, lower than that of human adults. Is it possible that γ-sitosterol regulates it to this depressed level?

In short, toads of various species are capable of synthesizing in the parotid glands sterols of either *trans-* or *cis*-configuration, catecholamines, and indolealkylamines. All are pharmacologically active, but apparently serve little purpose to the toads.

NATURAL TOLERANCE TO CARDIAC GLYCOSIDES AND AGLYCONES

For more than a century it has been known that the toad's heart is resistant to its own venom and to digitalis. This is a distinct example of pharmacogenetics. By comparison, the frog, *Rana pipiens*, is many times more susceptible to scillaren, ouabain, cymarin, and coumingine

HCl than the toad, *B. valliceps* (73, 74). Similar differences can be demonstrated by perfusions with gamabufagin, viridobufagin, vulgarobufotoxin, or regularobufotoxin. The exact mechanism of the toad's cardiac resistance is not known, but it offers a great challenge for elucidation. A suggestion has been made that the toad resistance is not due to the fate of cardiotonic substances, but determined by the reactivity of "digitalis receptors" (75). Aside from the classical studies, certain methods employed in electrophysiology may throw light upon this subject (76, 77).

RESPONSE OF OTHER TISSUES TO DRUGS

Epinephrine on one hand and cinobufotenine and fowlerobufotenine on the other increase the tone and contraction of the frog's and the toad's heart to the same degree when perfused through the inferior vena cava (73, 78).

The central nervous system of the toad is almost equally susceptible as that of the frog to strychnine, picrotoxin, cocaine, caffeine, pentobarbital, and curare. The toad shows similar responses to gonadotropins as *Xenopus laevis* and *Rana esculenta* (79). The exhaustive investigations of Houssay (3) on the Argentine toad, *B. arenarum*, reveal more resemblance than exceptions to higher vertebrates. The natural tolerance of the toad's heart to cardiotonic steroids is unique and is only shared by rodents such as the rat. More studies to search for the reason will contribute to our understanding of this biological anomaly.

Release Rates of Solid Drug Mixtures Dispersed in Inert Matrices I

Noninteracting Drug Mixtures

By PARVINDER SINGH*, SAURABH J. DESAI*, ANTHONY P. SIMONELLI, and WILLIAM I. HIGUCHI

The theory for the simultaneous release of a mixture of two noninteracting drugs dispersed in an inert plastic matrix has been developed. Quantitative relationships based on a physical model were derived that express the diffusion-controlled rates of release of both drugs as functions of the amounts of each drug, the solubilities of the drugs, their diffusional coefficients, and the porosities and tortuosities of the tablet. The theoretical relationships were applied to the salicylic acid–benzoic acid–plastic mixture. The experimental data were found to be in close agreement with the theoretically calculated values.

RECENTLY the drug release rate of a single species dispersed in inert plastic matrices has been extensively investigated (1–4). It was felt that it would be of interest to explore the more complex situation in which more than one drug is present in the tablet matrix. This report is involved with matrices containing an ideal mixture of drugs where the presence of one drug species does not alter the physicochemical properties of the other. The salicylic acid–benzoic acid mixture was chosen to represent the nonreactive case. A subsequent paper will report the results of the benzocaine–caffeine mixture representing the reactive system.

A physical model for the simultaneous release of a mixture of two drugs embedded in an insoluble matrix is developed and theoretical equations derived from it. The equations permit the independent quantitative description of the release rates of both drugs. All the parameters operative in these equations were independently determined, and after substitution into the appropriate theory, the theoretical release rates were obtained. These were then compared with the experimentally determined release rates to test the validity of the proposed model.

Received April 14, 1967, from the College of Pharmacy, University of Michigan, Ann Arbor, MI 48104

Accepted for publication July 17, 1967.

Presented to the Basic Pharmaceutics Section, APhA Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

This research project was supported in part by grants from the Ciba Pharmaceutical Co., Summit, N. J., and Parke-Davis Co., Detroit, Mich.

THEORETICAL MODEL

The diffusion-controlled model used to develop the mixture release equations derived under the *Appendix* is shown in Fig. 1. Figure 1(a) depicts initial conditions, *i.e.*, no solvent penetration, and both drugs exist solely as solids embedded in the matrix, region 3. Figure 1(b) depicts the conditions existing at a finite time, t. The boundary of the matrix solvent interface is at $x = 0$ and separates region 0 (solvent) and region 1 which corresponds to the completely leached portion of the matrix. The solid–liquid boundary of the slower moving drug is at $x = s_1$ and separates region 1 and region 2 which contains solid drug A in equilibrium with its saturated solution and drug B solely in solution. Finally the solid–liquid boundary of the faster

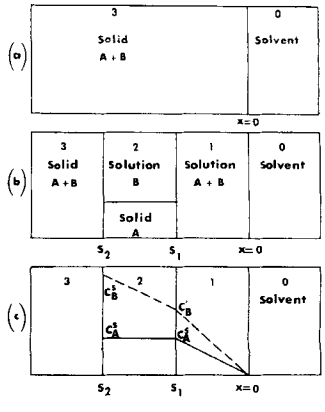

Fig. 1—The physical model that describes the release of a mixture of two noninteracting drugs from an inert matrix. Key: (a) *conditions existing at time* $t = 0$; (b) *conditions existing at finite time,* t; (c) *an illustration of the concentration gradients for all species.*

moving drug is at $x = s_2$ and separates region 2 and region 3 (solid drugs only). The concentration gradients of drugs A and B are shown in Fig. 1(c).

The relative boundary movement of drugs A and B will be a function of their solubilities, diffusion coefficients, and concentration of their solids in the matrix. If both drugs are present in equal concentrations and have equal diffusion coefficients, the more soluble drug will have the faster moving boundary. If both drugs have equal solubilities and are present in equal concentrations, the drug with the larger diffusion coefficient will move faster. Finally, if both drugs have equal solubilities and diffusion coefficients, the drug present in the smaller amount will have a faster moving boundary. It is evident from the above that the slower moving drug can be made to have a faster moving boundary by sufficiently decreasing its concentration in the matrix.

Inspection of Fig. 1 shows that the porosity and tortuosity of region 1 and region 2 will differ due to the presence of solid A in region 2 but not in region 1. The porosity of region 1 is given by the sum of the porosities due to the presence of drug A, drug B, and residual air in the matrix. The porosity of region 2, on the other hand, is given by the sum of porosity contributions of only drug B and residual air. In addition, the presence of solid drug A in region 2 will cause its tortuosity to be equal to or greater than that of region 1.

It is evident from the model that as neither solid A nor solid B is present in region 1, the release of the slower moving drug A can be described by the Higuchi equation (5):

$$\frac{dQ_A}{d(t^{1/2})} = \left[D_A \frac{\epsilon_1}{\tau_1} (2A_A - \epsilon_1 C_A^s) C_A^s \right]^{1/2} \quad \text{(Eq. 1)}$$

For the release of the faster moving drug, B, however, the following more complex equation must be utilized:

$$\frac{dQ_B}{d(t^{1/2})} = \frac{2D_B\epsilon_1}{\frac{k_A}{A_A}\tau_1} \left[\frac{\frac{\epsilon_2}{\tau_2} C_B^s}{\frac{\epsilon_2}{\tau_2} + \frac{\epsilon_1}{\tau_1} \left[\frac{\frac{k_B}{A_B} - \frac{k_A}{A_A}}{\frac{k_A}{A_A}} \right]} \right] \quad \text{(Eq. 2)}$$

Here, subscripts 1 and 2 symbolize parameters operative in regions 1 and 2, respectively, and subscripts A and B refer to the drugs A and B, respectively. The symbols used in the above equations are defined as follows: Q_i is the grams of drug i released per unit area of surface at time, t; D_i is the diffusion coefficient of the drug i in the release medium; A_i is the concentration of the drug i in the tablet; C_i^s is the solubility of the drug in the release medium; ϵ_j is the porosity of the region j and τ_j is the tortuosity of the region j. K_A is the slope of the Q_A *versus* $t^{1/2}$ plot (from Eq. 1) and K_B is the slope of the Q_B *versus* $t^{1/2}$ plot (from the *Appendix*).

The evaluation of these parameters and the application of these equations are discussed at length in later portions of the text.

EXPERIMENTAL

In previous papers the release behavior of drugs from polyethylene matrices as well as polyvinyl chloride (PVC) matrices were reported (3, 4). Both matrices provided nonideal release profiles using water as the release medium. It was found, however, that the inclusion of surfactant in the release medium provided ideal release profiles from polyethylene matrices but not for PVC matrices. The PVC matrices, on the other hand, provided ideal release profiles if previously subjected to vacuum treatment before introduction of solvent.

For these series of studies, both mutually interacting and noninteracting drug mixtures studies were anticipated. It would be highly undesirable, therefore, to include any surfactant in the release medium due to its possible direct or indirect interactions with the drug mixture systems. The use of vacuum techniques, on the other hand, always poses threats of technical difficulties.

Due to the possibility that a combination of these two plastics might lead to a matrix system that would eliminate the need for either of these treatments, a systematic series of matrices was studied in which the two plastics were mixed in different ratios from PVC: polyethylene ratios of 9:1 to 1:9 on a weight-to-weight basis. Both caffeine and potassium acid phthalate were separately used as drugs. In both instances the PVC–polyethylene ratio of 7:3 provided the most ideal matrix. The release rates in water, surfactant, and under vacuum conditions gave identical results for these drugs embedded in this matrix system. It was therefore decided to use this mixture as the inert matrix to investigate the release behavior for these series of drug mixtures.

The release rates from these matrices containing solid drug mixtures as well as solutions were studied using the techniques and the evaluation of parameters described previously (1, 2). The diffusion coefficients and solubilities of both drugs used in each mixture were determined individually as well as in the presence of each other.

For this study the simultaneous release of salicylic and benzoic acid from the above matrix was obtained by spectrophotometric assay of the release medium as a function of time at 302 mμ and 259 mμ and by solving the two simultaneous equations for their respective concentrations.

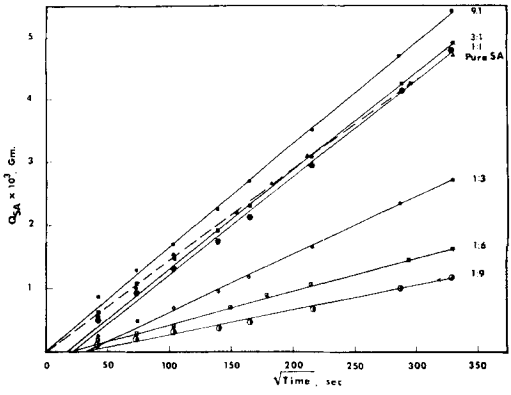

Fig. 2—Release of salicylic acid from matrices containing different ratios of salicylic acid-to-benzoic acid into 0.1 N HCl. The total amount of drug in all cases was 20% w/w, and the numbers indicate salicylic acid-to-benzoic acid ratios.

RESULTS AND DISCUSSION

Six different weight-to-weight ratios of salicylic acid and benzoic acid were homogeneously dispersed in the PVC–polyethylene 7:3 mixture and compressed. The total was maintained at 20% w/w. Release profiles were obtained in 0.1 *N* HCl to assure that both acids would exist primarily in their undissociated form. The results of these release studies are displayed in Figs. 2, 3, and 4. As predicted by the theoretical equations, a linear square root of time dependence is observed, both for the total as well as for the individual drugs when they are simultaneously released from the matrix.

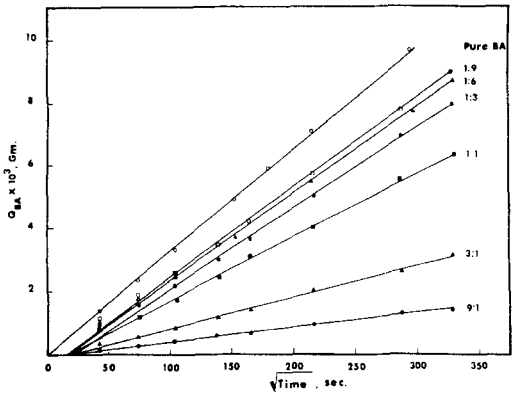

Fig. 3—Data showing benzoic acid release in the same experiments as in Fig. 2.

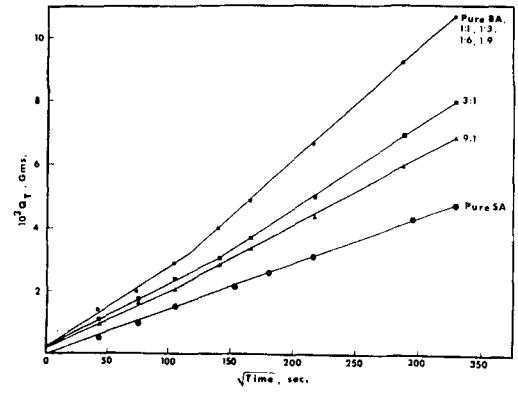

Fig. 4—The sum of the salicylic acid and benzoic acid release in the same experiments as in Figs. 2 and 3.

Examination of Fig. 1 indicates that the release profiles shown in Figs. 2 and 3 occur through region 1 for the slower moving drug and through region 2 for the faster moving drug. When $t = 0$, the relative rates of the two solid-liquid boundary movements can be given by the ratio of their respective release rates as indicated by Eq. 1; *i.e.*,

$$\frac{\text{salicylic acid boundary}}{\text{benzoic acid boundary}} = \frac{Q_{BA}/A_{BA}}{Q_{BA}/A_{BA}} = \left[\frac{D_{BA}C_{BA}A_{BA}}{D_{BA}C_{BA}A_{BA}}\right]^{1/2} \quad \text{(Eq. 3)}$$

All other factors in Eq. 1 are equal and cancel. The above indicates that both boundaries will move at an equal rate (no region 2) at a ratio of:

$$\frac{A_{SA}}{A_{BA}} = \frac{D_{BA}C_{BA}}{D_{BA}C_{BA}} = \frac{(1.16 \times 10^{-5})(2.0 \times 10^{-3})}{(1.22 \times 10^{-5})(3.6 \times 10^{-3})} = \frac{1}{1.9}$$

This analysis indicates that for ratios of salicylic to benzoic acid which are larger than 1:1.9, the benzoic acid drug–liquid boundary is moving more rapidly, but at ratios smaller than 1:1.9 it is moving more slowly.

ANALYSIS OF REGION 1 PARAMETERS

The previous discussion has indicated that Eq. 1 is valid for the release of the drug whose boundary is moving at a slower rate and therefore can be used to describe the salicylic acid release profile for drug ratios greater than 1:1.9 and for benzoic acid release at smaller ratios. The total porosity of the matrix (due to air and both drugs), the diffusion coefficient, solubility, and concentration in the matrix of the predicted slower moving drug were substituted in Eq. 1, and apparent tortuosity values, τ_1, for region 1 were calculated and tabulated in columns *7* and *8* of Table I. A similar treatment was used to calculate the tortuosity of region 1 using the parameters of the faster moving drug. Although Eq. 1 is not valid for the faster moving drug, these calculations were made only as a basis for comparison and are therefore listed in parentheses in Table I. An examination of columns *7* and *8* indicates that the bracketed values of τ are generally significantly higher when analyzing the extreme ratios and are in closer agreement as the ratio of drugs approaches the predicted ratio of equal boundary movement. This is reasonable because region 2 is relatively large at the extreme ratios and becomes smaller, completely disappearing when the boundaries move at an equal rate.

An independent test of the tortuosity values of region 1 can be made by obtaining the release profile of the completely leached matrix resaturated with a drug solution. Tortuosity values obtained in this manner are shown in column *9* of Table I. It is seen that these tortuosity values are independent of the drug mixture ratio. This would be expected as both drugs have been leached from the matrix. In addition, these values are in close agreement with those calculated using Eq. 1 for the slower moving drug and confirm the previous analysis.

ANALYSIS OF REGION 2 PARAMETERS

The drug with the faster moving boundary must diffuse both through regions 1 and 2, and it is obvious that Eq. 2 (not Eq. 1) must be used to describe its release. The porosity of region 2 is due to air and the faster moving drug. All other parameters in Eq. 2 have been independently determined except the tortuosity, τ_2, and allow its calculation. These values are listed in column *5* of Table II. To verify the above tortuosity values, an independent study of these matrices was made by obtaining release profiles of salicylic acid using saturated benzoic acid solution as the release

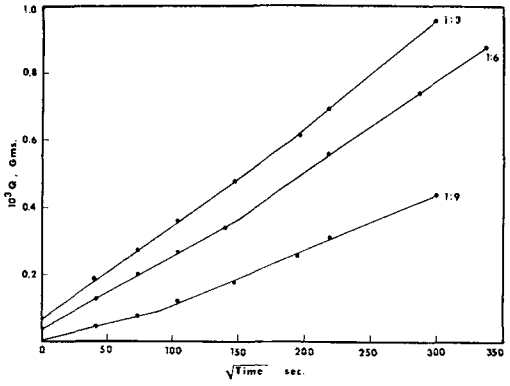

Fig. 5—Release of salicylic acid from matrices containing different ratios of salicylic acid to benzoic acid into saturated benzoic acid solutions containing 0.1 N HCl.

medium and are shown in Fig. 5. Since the benzoic acid embedded in the matrix is insoluble in this release medium, the conditions of region 2 are duplicated and permit its parameters to be determined using Eq. 1. The tortuosity values, τ_2, obtained in this manner are listed in column 4 in Table II and agree reasonably well with the values obtained using Eq. 2 and the release profiles in 0.1 *N* HCl.

The above procedure was not duplicated for benzoic acid release into saturated salicylic acid solution because of the difficulties in accurately determining small concentrations of benzoic acid in the presence of relatively high concentrations of salicylic acid. Furthermore, it was felt that the agreement between the τ_2 values obtained for the 1:9, 1:6, and 1:3 drug ratio systems sufficiently established the validity of this approach.

COMPLEMENTARY SURFACTANT AND VACUUM STUDIES

It was interesting to note, however, that the apparent tortuosity values for region 1 listed in Table I indicate an apparent tendency to increase with an increasing ratio of salicylic acid to benzoic acid. In contrast they were lower and relatively constant when obtained using the solution saturated matrices as compared to matrices containing the solid drug. The tortuosity values for region 2, on the other hand, indicate an apparent tendency to decrease rather than increase with an increasing ratio of salicylic acid to benzoic acid. Furthermore, they are relatively high for the lower ratios.

Although the potassium acid phthalate and caffeine studies indicated that there would not be any surfactant or vacuum effect when using this matrix system, the above observations prompted the study of their effect in the salicylic acid–benzoic acid system.

The surfactant effect was determined by obtaining release rates of matrices containing 20% salicylic acid in 0.1 *N* HCl solution containing 0.1% dioctyl sodium sulfosuccinate[1] (AOT) and the vacuum effect with 0.1 *N* HCl as the release medium (3, 4).

The results of these studies are presented in Fig. 6. It is noted that the release rates are increased with either treatment. Since the surfactant effect provided the faster release rates and therefore the more ideal system, the matrices containing both salicylic and benzoic acid were similarly studied.

The salicylic acid–benzoic acid mixture ratios of 1:6 and 3:1 were selected for these studies to provide examples of both drugs functioning as the faster moving drug boundary. Salicylic acid functions as

[1] Marketed as Aerosol OT by the American Cyanamid Co., Wayne, N. J.

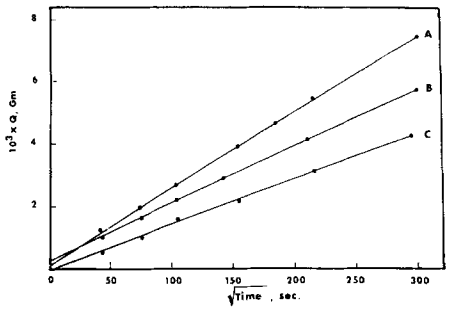

Fig. 6—Salicylic acid release experiments with matrices containing only 20% salicylic acid showing the influence of surfactant and of vacuum treatment. Key: A, *0.1* N *HCl/0.1% AOT as the release medium;* B, *0.1* N *HCl as the release medium and with vacuum treatment (4);* C, *0.1* N *HCl as the release medium.*

the faster moving boundary in the 1:6 mixture ratio but as the slower moving boundary in the 3:1 mixture ratio.

The results of these studies are reported in Table III. The presence of surfactant, as anticipated, increased all release rates. In addition the tortuosity values for region 1 were significantly decreased and remained constant for the four ratios of salicylic acid-to-benzoic acid mixtures indicating that its dependence on which drug was the slower moving boundary disappeared when surfactant was incorporated in the release medium.

The tortuosities of region 2 were also calculated using the surfactant release data for both mixture ratios by substituting the above tortuosities for region 1 in Eq. 2. They are listed in Table III and reveal that the tortuosities for region 2 are significantly decreased for the 1:6 and 3:1 mixture ratios from 34.4 and 10.0 to 6.1 and 8.4, respectively. Very significantly the tortuosity dependence on which drug is slower moving has again disappeared when surfactant is used as the two values are reasonably close.

As with previous studies the tortuosities of region 2 were confirmed by determining the release profile of a matrix containing the 1:6 salicylic acid–benzoic acid mixture into a saturated solution of benzoic acid containing 0.1 *N* HCl and 0.1% AOT. Using Eq. 1, the tortuosity was found to be 7.4 which agrees very well with the tortuosity previously calculated for region 2.

Previous work (3) has shown that the polyethylene matrix generally provides significantly higher drug release rates if surfactant is incorporated in the release medium. This was not true for the PVC matrices (4); the PVC, on the other hand, exhibited a more marked effect than the polyethylene matrix when pretreated by the vacuum technique.

Since the PVC–polyethylene matrix utilized in these studies demonstrated a markedly higher increase in the release rates when surfactant was included in the release medium as compared to the studies utilizing the vacuum treatment, it is strongly suggested that the polyethylene plastic is the controlling plastic in this matrix.

This indicates that in the compressional process the polyethylene plastic predominantly flows around the PVC plastic resulting in a discontinuous phase of PVC plastic surrounded by a continuous phase of polyethylene plastic. Comparison of the physical properties of both plastics indicates that the above is reasonable as polyethylene appears to be more plastic in nature and less rigid than the PVC plastic. In addition, the lower tortuosity values generally obtained in previous studies with the PVC matrices suggested that PVC existed as spheres in the compressed matrices, whereas polyethylene yielded higher tortuosity values in general indicating that it underwent considerable distortion with compression.

The results also indicate that salicylic acid is also predominantly surrounded by the polyethylene plastic under compression as indicated by the much higher tortuosity values obtained for region 2 when it participates as the faster moving drug in nonsurfactant solutions but exhibits a slightly lower tortuosity in the presence of surfactant. In addition, the tortuosity values of region 1 are higher when it participates as the slower moving drug in nonsurfactant solutions but not in the presence of surfactant. Finally the tortuosity of a matrix containing only salicylic acid showed a tortuosity of 12 in nonsurfactant solution but only 4.3 in the presence of surfactant.

Benzoic acid, on the other hand, exhibited consistently low tortuosities in all of the above situations, and this indicates that it is sufficiently distorted under compression to prevent it from being effectively coated in a similar manner.

APPENDIX

Derivation of Eq. 2—This derivation is based on the model previously described in Fig. 1. The equation for continuity at the boundary, s_1, is given by:

$$D_B \frac{\epsilon_1}{\tau_1}\left[\frac{dB}{dx}\right]_1 = D_B \frac{\epsilon_2}{\tau_2}\left[\frac{dB}{dx}\right]_2 \qquad \text{(Eq. 1}a\text{)}$$

Using the concentration gradients obtained from Fig. 1(c), the above yields:

TABLE III—CALCULATION OF THE TORTUOSITY OF REGION 1 AND REGION 2 USING SURFACTANT AS THE RELEASE MEDIUM

Pure SA	2.45	...	4.3	...	...	...	...

[a] Slope of the release study when the salicylic acid–benzoic acid mixture tablet is released into saturated benzoic acid solution.

$$D_B \frac{\epsilon_1}{\tau_1} \frac{C_B'}{s_1} = D_B \frac{\epsilon_2}{\tau_2} \frac{(C_B^s - C_B')}{(s_2 - s_1)} \quad \text{(Eq. 2a)}$$

The concentration of drug B at the boundary s_1 can be obtained by rearrangement of Eq. 2a to give:

$$C_B' = \frac{\frac{\epsilon_2}{\tau_2} C_B^s}{\frac{\epsilon_2}{\tau_2} + \frac{\epsilon_1}{\tau_1} \frac{(s_2 - s_1)}{s_1}} \quad \text{(Eq. 3a)}$$

The equation of continuity dictates that the rate of release of drug B, G_B, must be equal to its rate of diffusion in region 1, *i.e.*,

$$G_B = \frac{dQ_B}{dt} = D_B \frac{\epsilon_1}{\tau_1} \frac{C_B'}{s_1} \quad \text{(Eq. 4a)}$$

Rearrangement of Eq. 4a yields a second relationship for the concentration for drug B at the boundary s_1:

$$C_B' = \frac{G_B \tau_1 s_1}{D_B \epsilon_1} \quad \text{(Eq. 5a)}$$

By equating Eqs. 3a and 5a one obtains:

$$G_B = \frac{dQ_B}{dt} = D_B \frac{\epsilon_2}{\tau_1 s_1} \left[\frac{\frac{\epsilon_2}{\tau_2} C_B^s}{\frac{\epsilon_2}{\tau_2} + \frac{\epsilon_1}{\tau_1} \frac{(s_2 - s_1)}{s_1}} \right] \quad \text{(Eq. 6a)}$$

Since s_1 and s_2 do not readily lend themselves to experimental determination, it would be advantageous to replace them with functions of measurable variables.

If the amount of dissolved drug remaining in the pores is assumed negligible, as compared to the amount of drug released (true for poorly soluble drugs), then:

$$Q_A = s_1 \cdot A_A$$

For the slower moving drug, Q_A is also given by Eq. 1, and its substitution in the above equation yields the following:

$$s_1 = \frac{K_A}{A_A} t^{1/2} \quad \text{(Eq. 7a)}$$

where K_A is given by the slope of the corresponding Q_A *versus* $t^{1/2}$ plot. It would be desirable if a similar relationship could be obtained for s_2 which would then permit the integration of Eq. 6a as all parameters could then be experimentally determined.

Equation 1 cannot be used to obtain a similar expression for s_2 as it involves both regions 1 and 2 as shown in Fig. 1. It can be shown, however, that Q_B is also proportional to $t^{1/2}$. If the ratio of $(s_2 - s_1)/s_1$ is invariant and Eq. 7a is used to substitute for s_1, Eq. 6a shows that G_B is inversely proportional to the square root of time, and therefore Q_B is directly proportional to the square root of time, *i.e.*,

$$Q_B = K_1 t^{1/2} \quad \text{(Eq. 8a)}$$

where K_1 is the integration constant.

The ratio of $(s_2 - s_1)/s_1$ can be shown to be invariant by the following analysis. The equation of continuity, Eq. 2a, dictates that:

$$\frac{C_B^s - C_B'}{s_2 - s_1} = K_2 \frac{C_B'}{s_1} \quad \text{(Eq. 9a)}$$

where K_2 is a function of the porosities and tortuosities of the two regions. s_1 describes the position of the slower moving drug boundary as it moves from the matrix surface and must increase with time. Since s_2 describes the position of the faster moving drug boundary, the value of $s_2 - s_1$ must also increase with time. If C_B' increases, $C_B^s - C_B'$ would correspondingly decrease. Equation 9a, however, would then require $s_2 - s_1$ to correspondingly decrease relative to s_1 and would require the impossible situation of the supposedly slower moving boundary to be the faster one. C_B', on the other hand, cannot decrease as $C_B^s - C_B'$ would correspondingly increase and would require a positive acceleration of the movement of s_2 relative to s_1; yet its maximum acceleration must occur at $t = 0$. Since C_B' must be invariant, rearrangement of Eq. 9a shows that the ratio of $(s_2 - s_1)/s_1$ is indeed invariant and that Eq. 8a is therefore valid.

Its substitution in $Q_B = s_2 A_B$ shows that s_2 is directly proportional to the square root of time and is equal to $K_B t^{1/2}/A_B$ where K_B is the slope of the corresponding Q_B *versus* $t^{1/2}$ plot.

Substituting for s_1 and s_2 into Eq. 6a yields the desired relationship:

$$\frac{dQ_B}{d(t^{1/2})} = 2\left[\frac{dQ_B}{dt}\right] t^{1/2} = \frac{2 D_B \epsilon_1}{\tau_1 \frac{K_A}{A_A}} \times \left[\frac{\frac{\epsilon_2}{\tau_2} C_B^s}{\frac{\epsilon_2}{\tau_2} + \frac{\epsilon_1}{\tau_1} \left(\frac{K_B/A_B - K_A/A_A}{K_A/A_A} \right)} \right] \quad \text{(Eq. 10a)}$$

Release Rates of Solid Drug Mixtures Dispersed in Inert Matrices II

Mutually Interacting Drug Mixtures

By PARVINDER SINGH*, SAURABH J. DESAI*, ANTHONY P. SIMONELLI, and WILLIAM I. HIGUCHI

The equations developed to describe the release from a mixture of two noninteracting drugs was further extended to cover the case where the two drugs mutually interact with each other. All the parameters were independently determined and evaluated as before. Complexation studies were carried out and their effects on the solubilities and diffusion coefficients were also considered in the theoretical equations. The different regions existing in the tablet matrix were independently analyzed. The theoretical equations for the drug release rates were seen to predict the experimental data extremely well.

In a previous communication, the release behavior of a mixture of two noninteracting drugs dispersed in an inert, insoluble matrix has been discussed (1). As a continuation of the same work, it was decided to study the somewhat more complex system where the two drugs incorporated in the matrix mutually interact. The benzocaine–caffeine mixture provided an interesting system since solution interactions between the two drugs lead to a mutual increase of their solubilities.

The diffusion-controlled model that will be utilized is essentially similar to the one used in the salicylic acid–benzoic acid mixture study. In this system, however, solution interactions of the two drugs require equations of a different form.

The model is schematically shown in Fig. 1. Figure 1(a) shows that benzocaine and caffeine are transported both as free drugs and as complex species through region 1. In region 2, however, the slower moving drug, caffeine, is transported solely as complexes, as the entire region is saturated with respect to free caffeine. Figures 1(b) and (c) show the appropriate boundary conditions at s_1 and s_2 and the resulting concentration gradients which are fully discussed under the *Appendix*.

Mutual interactions were included in the model by utilizing the appropriate stability expressions for the three complexes, B·C, B·C$_2$, and B·C$_3$. An adequate discussion of the release parameters, tortuosity, τ, and porosity, ϵ, was given in the previous paper (1) and the same terminology is applicable here.

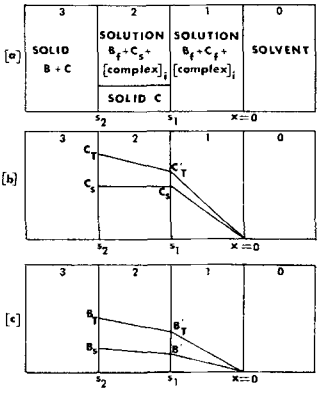

Fig. 1—The physical model that describes the simultaneous release of a mixture of two interacting drugs from an inert matrix. Key: (a) *conditions existing at finite time,* t; (b) *concentration gradients for the drug having the slower moving boundary;* (c) *concentration gradients for the drug having the faster moving boundary.*

The resulting equations are:

$$Q_B = A_B \cdot \gamma t^{1/2} \qquad \text{(Eq. 1)}$$

and

$$Q_C = \left[A_C \cdot \beta + A_B(\gamma - \beta)\left(\frac{\delta}{\alpha}\right)\right] t^{1/2} \qquad \text{(Eq. 2)}$$

where

$$\gamma = \frac{2\epsilon_1\epsilon_2 B_s \alpha}{A_B(\tau_2\epsilon_1\gamma - \tau_2\epsilon_1\beta + \tau_1\epsilon_2\beta)}$$

$$\beta = \left[\frac{2\epsilon_1 D_C C_s \alpha}{\tau_1(A_C\alpha - A_B\delta)}\right]^{1/2}$$

$$\alpha = D_B + D_{BC}K_1C_s + D_{BC_2}K_1K_2C_s^2 + D_{BC_3}K_1K_2K_3C_s^3$$

$$\delta = D_{BC}K_1C_s + 2D_{BC_2}K_1K_2C_s^2 + 3D_{BC_3}K_1K_2K_3C_s^3$$

A_i = concentration of drug i in the matrix,

Received April 14, 1967, from the College of Pharmacy, University of Michigan, Ann Arbor, MI 48104
Accepted for publication July 17, 1967.
Presented to the Basic Pharmaceutics Section, APhA Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.
This research project was supported in part by grants from the Ciba Pharmaceutical Co., Summit, N. J., and Parke-Davis Co., Detroit, Mich.
* Present address: Ranbaxy Laboratories Ltd., Okhla, New Delhi, India.

Q_i = total amount of drug i released per unit area,
D_i = diffusion coefficient of drug i,
K_i = stability constant of complex i,
C_s = solubility of uncomplexed caffeine,
B_s = solubility of uncomplexed benzocaine,
ϵ_j = porosity of region j,
τ_j = tortuosity of region j.

It should be emphasized that these equations are restricted to a system in which benzocaine exhibits the faster moving boundary. In this system the concentrations of all species are directly proportional to the concentration of free benzocaine in solution. In the reverse situation, however, the concentrations of all species must be expressed in terms of a polynomial involving the free caffeine solution concentration. This requires the solution of a cubic equation and results in a very lengthy and much more complicated set of equations.

EXPERIMENTAL

The matrix system used in these studies was a mixture of polyvinylchloride (PVC) and polyethylene in a 7:3 weight-to-weight ratio. This matrix was chosen for the study of drug release from mixtures of two drugs for reasons described previously (1).

A direct assay in the ultraviolet region for the simultaneous release of both drugs in the presence of each other was not utilized because of the strong mutual absorption at their respective maximum absorption wavelengths. Benzocaine was independently assayed using a colorimetric assay procedure involving a diazotization reaction (2), and recording its absorption at 550 mμ. The total absorption, however, due to both caffeine and benzocaine was determined at 273 mμ. The contribution from benzocaine adsorption at 273 mμ was then accounted for, allowing the determination of the caffeine concentration.

The diffusion coefficients of the pure drugs were determined experimentally by the method described earlier (3), modified by the use of a Gelman[1] Versapor filter in place of a sintered-glass disk.

Two kinds of interaction studies were carried out. In the first case, an excess amount of benzocaine (0.4 Gm.) was weighed into a series of Teflon-stoppered culture tubes and known but varying amounts of caffeine were added to them. Then, 20 ml. of distilled water was added to each tube. The samples were equilibrated in a constant-temperature tumbling water bath for 24 hr. They were then filtered through a Millipore[2] filter (0.45-μ pore size) and the samples prepared for spectrophotometric assay. In the other study, the reverse experiment was carried out where an excess amount of caffeine (1.6 Gm.) was weighed into each culture tube and known but varying amounts of benzocaine added. The samples were then equilibrated, filtered, and assayed.

RESULTS AND DISCUSSON

Interaction Studies—The results of the complexation-solubility experiments are presented in Figs. 2 and 3. As can be seen, when caffeine was added to excess solid benzocaine the total solubility of benzocaine, B_T, increased more rapidly than linearly with added caffeine (Fig. 2). In those experiments where benzocaine was added to excess solid caffeine, the total solubility of caffeine, C_T, was found to be essentially linear with total benzocaine added.

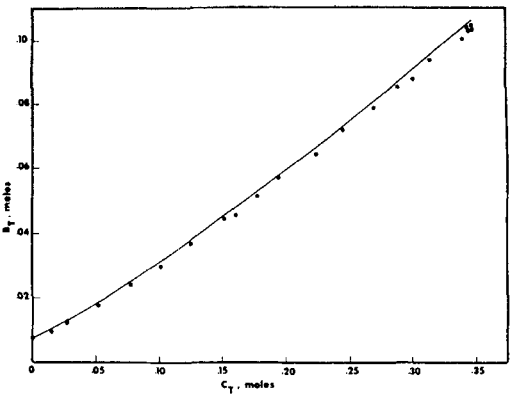

Fig. 2—Interaction study between benzocaine and caffeine using an excess of solid benzocaine and varying amounts of caffeine. The smooth curve represents the theoretical curve based on Eqs. 6 and 7 and the points represent experimental data. (See text for discussion.)

These data indicate that (*a*) for the Fig. 2 experiments, while only the 1:1 complex is important at low caffeine concentrations, there are other complexes contributing significantly to the B_T at the higher caffeine concentrations, and (*b*) in all of the complexes benzocaine probably occurs singly, *i.e.*, BC, BC_2, BC_3, BC_4, *etc.*, as suggested by the linear relationship (Fig. 3). In addition, the average stoichiometry of the complexes at the invariant point (saturation point for both phases) was found to be 2.17 with both sets of experiments. This showed that at least three complexes, the 1:1, the 1:2, and the 1:3 benzocaine–caffeine should be considered in a thermodynamic treatment of all of the data.

Thus, it was assumed that the following solution equilibria were present:[3]

$$B + C \overset{K_1}{\rightleftarrows} B\cdot C \qquad \text{(Eq. 3)}$$

$$B\cdot C + C \overset{K_2}{\rightleftarrows} B\cdot C_2 \qquad \text{(Eq. 4)}$$

$$B\cdot C_2 + C \overset{K_3}{\rightleftarrows} B\cdot C_3 \qquad \text{(Eq. 5)}$$

The stability constants were then evaluated in the following manner.

For the saturated-benzocaine experiment (Fig. 2), the total concentration of caffeine and benzocaine can be given by:

$$C_T = C_{\text{free}} + C_{\text{complexes}}$$

$$= C_i + K_1 B_s C_i + 2K_1K_2 B_s C_i^2 + 3K_1K_2K_3 B_s C_i^3 \qquad \text{(Eq. 6)}$$

and

[1] Gelman Instrument Co., Ann Arbor, Mich.
[2] Millipore Filter Corp., Bedford, Mass.

[3] The possibility is ignored that caffeine may self-associate at high caffeine concentrations as is suggested by the data of Guttman and Higuchi (4).

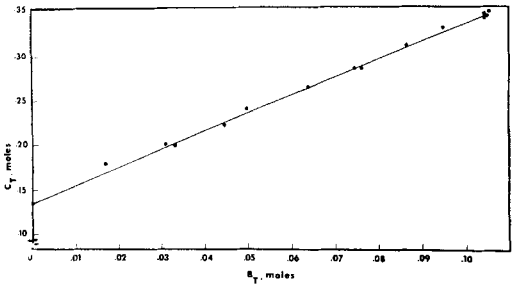

Fig. 3—Interaction study between benzocaine and caffeine using an excess of solid caffeine and varying amounts of benzocaine. The smooth curve represents the theoretical curve based on Eqs. 8 and 9 and the points represent experimental data. (See text for discussion.)

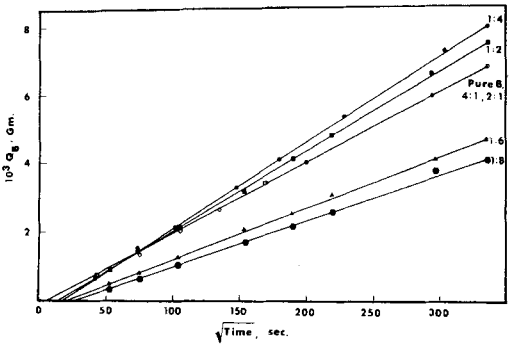

Fig. 4—Release af benzocaine from matrices containing different ratios of benzocaine to caffeine to water. The total amount of drug in all cases was 20% w/w, and the numbers indicate benzocaine-to-caffeine ratios.

$$B_T = B_{\text{free}} + B_{\text{complexes}}$$

$$= B_s + K_1B_sC_i + K_1K_2B_sC_i^2 + K_1K_2K_3B_sC_i^3 \qquad \text{(Eq. 7)}$$

For the saturated-caffeine experiments (Fig. 3) the corresponding expressions will be:

$$C_T = C_s + K_1B_iC_s + 2K_1K_2B_iC_s^2 + 3K_1K_2K_3B_iC_s^3 \qquad \text{(Eq. 8)}$$

and

$$B_T = B_i + K_1B_iC_s + K_1K_2B_iC_s^2 + K_1K_2K_3B_iC_s^3 \qquad \text{(Eq. 9)}$$

For the saturated-caffeine experiments (Fig. 3) where a straight line is obtained we have:

$$C_T = \text{slope} \times (B_T) + \text{intercept}$$

Then, using Eq. 8 and Eq. 9, we obtain:

$$K_2K_3 = \frac{2 + K_1C_s}{K_1C_s^3} \qquad \text{(Eq. 10)}$$

Now K_1 may be determined from the initial slope of the Fig. 2 data. Then K_2 and K_3 can be solved by using Eq. 6 and Eq. 7. The calculated values for K_1, K_2, and K_3 were found to be 34.4, 3.2, and 24.1, respectively.

Using these calculated values for K_1, K_2, and K_3, both curves were reproduced theoretically and these results are given in Figs. 2 and 3 as the smooth curves. It can be seen that these calculated values for the stability constants give an extremely close fit to the experimental data and thereby confirm our hypothesis that, in the benzocaine–caffeine system, a consideration of these three complexes may adequately describe the system.

It should be pointed out that only this set of K_1, K_2, and K_3 values gave a good fit to the data. Thus, ignoring the terms involving K_3 did not give a satisfactory fit of the theory to the data.

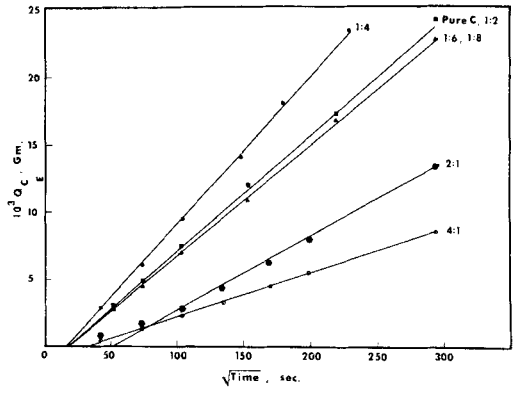

Fig. 5—Data showing caffeine release in the same experiments as in Fig. 4.

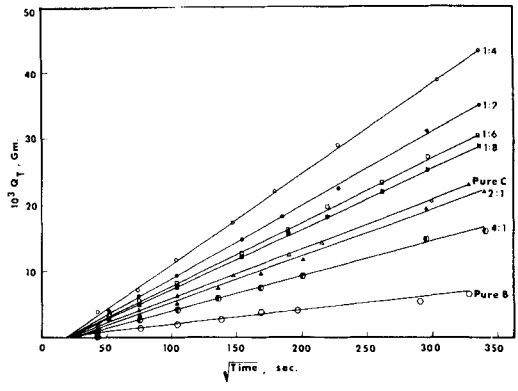

Fig. 6—The sum of the benzocaine and caffeine release in the same experiments as in Figs. 4 and 5.

Release Studies—The release profiles of benzocaine and caffeine as they are simultaneously released in water are presented in Figs. 4 and 5 for various weight-weight ratios of the two drugs in the tablet. Figure 6 shows the sum of benzocaine and caffeine release as a function of the square root of time. It is seen that the square root of time dependence, as predicted by the T. Higuchi equation (5), is observed in all cases. The data also show that for the total release as well as for the release of the individual drugs the 1:4 mixture ratio yields the highest release rate.

This 1:4 critical mixture ratio is in accordance with that predicted by the following relationship which is analogous to Eq. 3 of the previous com-

munication (1), and describes the relative rates of boundary movement for benzocaine and caffeine:

$$\frac{\text{boundary movement for caffeine}}{\text{boundary movement for benzocaine}} = \frac{Q_C/A_C}{Q_B/A_B} = \left[\frac{D_{C(eff.)}C_T A_B}{D_{B(eff.)}B_T A_C}\right]^{1/2}$$

assuming all other factors constant for both systems. Here, $D_{B(eff.)}$ and $D_{C(eff.)}$ are the effective diffusion coefficients for the total transport of benzocaine and caffeine, respectively, when diffusion of both solutes takes place from the solution saturated with respect to both drugs. Thus, when the two boundaries move at the same rate, the lefthand side of the above equation will be unity, and we have:

$$\frac{A_C}{A_B} = \frac{D_{C(eff.)}C_T}{D_{B(eff.)}B_T} = \frac{(6.94 \times 10^{-6})}{(7.08 \times 10^{-6})} \cdot \frac{(6.71 \times 10^{-2})}{(1.73 \times 10^{-2})} = 3.8$$

which is in close agreement with the experimental 1:4 ratio.

The values for the effective diffusion coefficients $D_{B(eff.)}$ and $D_{C(eff.)}$ were estimated from the following equations:

$$D_{B(eff.)} = \frac{D_B(B_s) + D_{BC}(K_1B_sC_s) + D_{BC_2}(K_1K_2B_sC_s^2) + D_{BC_3}(K_1K_2K_3B_sC_s^3)}{B_s + K_1B_sC_s + K_1K_2B_sC_s^2 + K_1K_2K_3B_sC_s^3}$$

and

$$D_{C(eff.)} = \frac{D_C(C_s) + D_{BC}(K_1B_sC_s) + 2D_{BC_2}(K_1K_2B_sC_s^2) + 3D_{BC_3}(K_1K_2K_3B_sC_s^3)}{C_s + K_1B_sC_s + 2K_1K_2B_sC_s^2 + 3K_1K_2K_3B_sC_s^3}$$

The diffusion coefficients for benzocaine and caffeine and the stability constants were determined experimentally, and the diffusion coefficients for the complexes were estimated from the Stokes-Einstein relation (6). That the Stokes-Einstein estimations were reasonable was verified by an experimental determination of the effective diffusion coefficient for benzocaine which was done by diffusing a solution saturated with both caffeine and benzocaine into a solution saturated only with caffeine. (See Table I.)

Analysis of Region 1 Parameters—To test the proposed model, both region 1 and region 2 need to be independently analyzed. The tortuosity value of region 1 cannot be obtained from the experiments as was done in the salicylic acid–benzoic acid problem using the T. Higuchi equation (5) since the total solution concentrations of benzocaine and caffeine at the boundary s_1 are unknowns in this problem. For this reason, a different approach was used. Equation 8*a* (from the *Appendix*) is:

$$G_C = \frac{\epsilon_1}{\tau_1 s_1} D_C \cdot C_s + G_B \frac{\delta}{\alpha} \qquad \text{(Eq. 8a)}$$

s_1 can be substituted for by Eqs. 21*a* and 22*a*, G by $dQ/2t^{1/2}d(t^{1/2})$, and after rearrangement, τ_1 can be expressed as:

$$\tau_1 = \frac{2\alpha\epsilon_1 D_C C_s}{\beta[(Q_C/t^{1/2})\alpha - (Q_B/t^{1/2})\delta]} \qquad \text{(Eq. 11)}$$

Since this model only describes the case where caffeine has the slower moving boundary, the tortuosity values that can be obtained by this method are restricted to the data for benzocaine–caffeine ratios of 1:4, 1:6, and 1:8. These are presented in Table II.

Tortuosity values for region 1 have also been determined independently by liquid leaching experiments (7) and are listed in Table II. The agreement between the two sets of tortuosity values obtained by these separate experiments is generally good. These findings alone lend strong support to the validity of the proposed model.

Analysis of Region 2 Parameters—In order to evaluate the tortuosity factor in region 2, benzocaine release data (see Fig. 7) were obtained with the tablets in media saturated with caffeine, a procedure employed previously (1). The data then may be evaluated directly by means of the following equation:

$$Q_B = \left[\frac{2\epsilon_2 A_B}{\tau_2}(D_B B_s + D_{BC}K_1C_sB_s + D_{BC_2}K_1K_2B_sC_s^2 + D_{BC}K_1K_2K_3B_sC_s^3)t\right]^{1/2} \qquad \text{(Eq. 12)}$$

which was derived using Eq. 9*a* with the boundary conditions that $s_1 = 0$ for all t, and B = 0 and C = C_s at $x = 0$ for all t. The ϵ_2 entering in Eq. 12 is given by:

$$\epsilon_2 = \frac{A_B}{\rho_B} + A_B\frac{G_C'}{G_B\rho_C} + \epsilon_{air} \qquad \text{(Eq. 13)}$$

where ρ_B and ρ_C are the densities of benzocaine and caffeine and ϵ_{air} is the porosity contribution due to air. The second term of Eq. 13 represents the porosity contribution due to the caffeine loss from the tablet resulting from the diffusion of the complexes through the matrix and out of the tablet (see Eq. 10*a* under *Appendix*).

Table III gives the calculated ϵ's and τ_2 values obtained from the experiments (Fig. 7) in saturated caffeine solutions using Eqs. 12 and 13. The stability constants determined in the solubility studies and the diffusion coefficients given in Table I were used.

Test of the Model Using All Parameters—Having obtained all of the matrix parameters (ϵ_1, ϵ_2, τ_1, τ_2) and the interaction parameters (K_1, K_2, K_3, C_T, B_T, and the diffusion coefficients), it was then possible to carry out a composite test of the model proposed

Table I—Diffusion Coefficients of the Different Benzocaine and Caffeine Species Involved in This Study

Drug Species	Diff. Coeff. × 10^6 cm.²/sec.
Benzocaine	9.86[a]
Caffeine	7.53[a]
[B·C]	7.84[b]
[B·C_2]	6.85[b]
[B·C_3]	6.20[b]
Total benzocaine species $D_{B(eff.)}$	= 5.94[a]
$D_{BB(eff.)}$	= 7.08[b]
Total caffeine species $D_{C(eff.)}$	= 6.94[b]

[a] Experimental values. [b] Calculated values, based on the Stokes-Einstein relation.

TABLE II—PARAMETERS INVOLVED IN THE DETERMINATION OF TORTUOSITY OF THE OUTER REGION 1

B:C Ratio	ϵ_1[a]	$10^5 Q_B/t^{1/2}$ Solid Release	$10^5 Q_C/t^{1/2}$ Solid Release	$10^5 Q/t^{1/2}$ Liquid Release[b]	τ_1 from Solid Release (Eq. 11)	τ_1[b] from Liquid Release
Pure B	0.313	1.85	...	1.52	3.2	2.0
4:1	0.312	2.08	3.50	1.38	...	2.2
2:1	0.311	2.20	5.50	1.39	...	2.1
1:2	0.299	2.30	8.70	1.26	...	3.0
1:4	0.295	2.53	11.0	1.15	2.5	2.8
1:6	0.283	1.49	8.0	1.13	3.3	2.6
1:8	0.278	1.34	7.8	1.04	3.8	3.0
Pure C	0.289	...	8.25	1.04	3.0	3.2

$\epsilon_1 = \epsilon_{total} = \epsilon_{benz.} + \epsilon_{caff.} + \epsilon_{air}$. [b] For these experiments, $C_0 = 2.6\%$ caffeine solution (see *Reference 7*).

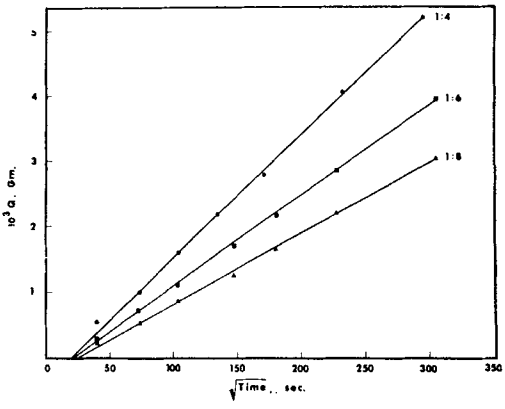

Fig. 7—Release of benzocaine from matrices containing different ratios of benzocaine to caffeine into saturated caffeine solutions.

tion of these equations is based on the model presented in Fig. 1 for the case when benzocaine has the faster moving solid–liquid drug boundary. Since the benzocaine–caffeine system forms more than one complex at stoichiometrically different ratios, the reverse situation of benzocaine having the slower boundary would require different equations.

It has been shown that benzocaine and caffeine interact to form three soluble complexes as represented below:

$$B + C \rightleftharpoons B\cdot C$$
$$B\cdot C + C \rightleftharpoons B\cdot C_2$$
$$B\cdot C_2 + C \rightleftharpoons B\cdot C_3$$

The corresponding stability constants are expressed as:

$$K_1 = \frac{(B\cdot C)}{(B)\,(C)}$$

TABLE III—PARAMETERS INVOLVED IN THE DETERMINATION OF TORTUOSITY OF THE INNER REGION 2

B:C Ratio	$\epsilon_{benz.}$	$\epsilon_{caff.}$[a]	ϵ_{air}	ϵ_2 (Eq. 13)	$10^5 Q/t^{1/2}$	τ_2
1:4	0.037	0.061	0.136	0.234	1.07	7.7
1:6	0.027	0.044	0.121	0.192	1.40	6.6
1:8	0.021	0.035	0.118	0.174	1.88	6.2

[a] $\epsilon_{caff.}$ value for the second term in Eq. 13.

TABLE IV—COMPARISON OF THE EXPERIMENTAL AND THEORETICAL RELEASE RATES

B:C Ratio	Exptl. $10^5 Q/t^{1/2}$ B	Exptl. $10^5 Q/t^{1/2}$ C	Theoret. $10^5 Q/t^{1/2}$ B	Theoret. $10^5 Q/t^{1/2}$ C
1:4	2.53	11.0	2.83	10.8
1:6	1.49	8.00	2.00	10.37
1:8	1.34	7.80	1.45	9.34

in this paper. This was done by substituting the values for all of these parameters into Eqs. 1 and 2, calculating the theoretical rates of drug release for both benzocaine and caffeine, and then comparing these to the experimental values.

Table IV shows the close agreement of experiment with theory for both drugs and for the three mixture ratios.

APPENDIX

Derivation of Theoretical Equations When Benzocaine is the Faster Moving Boundary—The derivation of these equations is based on the model presented in Fig. 1 for the case when benzocaine has the faster moving solid–liquid drug boundary. Since the benzocaine–caffeine system forms more than one complex at stoichiometrically different ratios, the reverse situation of benzocaine having the slower boundary would require different equations.

It has been shown that benzocaine and caffeine interact to form three soluble complexes as represented below:

$$B + C \rightleftharpoons B\cdot C$$
$$B\cdot C + C \rightleftharpoons B\cdot C_2$$
$$B\cdot C_2 + C \rightleftharpoons B\cdot C_3$$

The corresponding stability constants are expressed as:

$$K_1 = \frac{(B\cdot C)}{(B)\,(C)}$$

$$K_2 = \frac{(B\cdot C_2)}{(B\cdot C)\;(C)}$$

$$K_3 = \frac{(B\cdot C_3)}{(B\cdot C_2)\,(C)}$$

The boundary conditions for the two drugs at s_1 and s_2 can be given in terms of K_1, K_2, K_3, and uncomplexed drug concentrations.

At the boundary s_1, the concentration expressions are:

$$(C) = C_s$$
$$(B) = B'$$
$$(B\cdot C) = K_1 B' C_s$$
$$(B\cdot C_2) = K_1 K_2 B' C_s^2$$
$$(B\cdot C_3) = K_1 K_2 K_3 B' C_s^3$$

and at the boundary s_2, they are:

$$(C) = C_s$$
$$(B) = B_s$$

$$(B\cdot C) = K_1 B_s C_s$$
$$(B\cdot C_2) = K_1 K_2 B_s C_s^2$$
$$(B\cdot C_3) = K_1 K_2 K_3 B_s C_s^3$$

where B' is the concentration of benzocaine at the boundary s_1. The other parameters have been defined earlier.

The equations of continuity for region 1 yield the following relationships for the net movement of all species:

$$G_B = \frac{\epsilon_1}{\tau_1}\left[D_B\frac{d(B)}{dx} + D_{BC}\frac{d(BC)}{dx} + D_{BC_2}\frac{d(BC_2)}{dx} + D_{BC_3}\frac{d(BC_3)}{dx}\right] \quad \text{(Eq. 1a)}$$

and

$$G_C = \frac{\epsilon_1}{\tau_1}\left[D_C\frac{d(C)}{dx} + D_{BC}\frac{d(BC)}{dx} + 2D_{BC_2}\frac{d(BC_2)}{dx} + 3D_{BC_3}\frac{d(BC_3)}{dx}\right] \quad \text{(Eq. 2a)}$$

where G_i is the rate of movement of species i, D_i is the diffusion coefficient of species i, and di/dx is the concentration gradient for species i.

Integration of Eq. 1a from $x = 0$ to $x = s_1$ yields:

$$G_B\cdot s_1 = \frac{\epsilon_1}{\tau_1}B'\alpha \quad \text{(Eq. 3a)}$$

where

$$\alpha = (D_B + D_{BC}K_1C_s + D_{BC_2}K_1K_2C_s^2 + D_{BC_3}K_1K_2K_3C_s^3) \quad \text{(Eq. 4a)}$$

Rearrangement of Eq. 3a gives:

$$B' = \frac{G_B s_1 \tau_1}{\epsilon_1 \alpha} \quad \text{(Eq. 5a)}$$

Integration of Eq. 2a similarly yields:

$$G_C s_1 = \frac{\epsilon_1}{\tau_1}(D_C\cdot C_s) + \frac{\epsilon_1}{\tau_1}B'\delta \quad \text{(Eq. 6a)}$$

where

$$\delta = (D_{BC}K_1C_s + 2D_{BC_2}K_1K_2C_s^2 + 3D_{BC_3}K_1K_2K_3C_s^3) \quad \text{(Eq. 7a)}$$

On substituting for B' from Eq. 5a, Eq. 6a then becomes:

$$G_C = \frac{\epsilon_1}{\tau_1\cdot s_1}(D_C\cdot C_s) + G_B\frac{\delta}{\alpha} \quad \text{(Eq. 8a)}$$

The equations of continuity for region 2, on the other hand, are:

$$G_B = \frac{\epsilon_2}{\tau_2}\left[D_B\frac{d(B)}{dx} + D_{BC}\frac{d(BC)}{dx} + D_{BC_2}\frac{d(BC_2)}{dx} + D_{BC_3}\frac{d(BC_3)}{dx}\right] \quad \text{(Eq. 9a)}$$

and

$$G_C' = \frac{\epsilon_2}{\tau_1}\left[D_C\frac{d(C)}{dx} + D_{BC}\frac{d(BC)}{dx} + 2D_{BC_2}\frac{d(BC_2)}{dx} + 3D_{BC_3}\frac{d(BC_3)}{dx}\right] \quad \text{(Eq. 10a)}$$

It is to be noted that G_C' is equal to the rate of transport of total caffeine from region 2. Since region 2 contains a saturated solution with respect to free caffeine, this rate must only involve the movement of caffeine complexes and therefore is different from G_C which includes the diffusion of free caffeine as well as the complexes.

On integrating Eq. 9a from $x = s_1$ to $x = s_2$ one obtains:

$$G_B(s_2 - s_1) = \frac{\epsilon_2}{\tau_2}(B_s - B')\alpha \quad \text{(Eq. 11a)}$$

again, where α is given by Eq. 4a. Equation 5a is substituted for B', yielding:

$$G_B = \frac{\epsilon_2\alpha}{\tau_2(s_2 - s_1)}\left[B_s - \frac{G_B s_1 \tau_1}{\propto \epsilon_1}\right] \quad \text{(Eq. 12a)}$$

Integration of Eq. 10a, on the other hand, gives:

$$G_C' = \frac{\epsilon_2\cdot\delta}{\tau_2(s_2 - s_1)}(B_s - B') \quad \text{(Eq. 13a)}$$

where δ is given by Eq. 7a.

The above equations cannot be solved as there are more variables than equations. Another set of equations, however, can be obtained by considering the amount of each drug released, determined on the basis of the amount incorporated in the tablet matrix and both drug boundary movements. In this way equivalent expressions for G_B and G_C can be obtained. Examination of Fig. 1 shows that the total amount of drug B released, Q_B, is a function of the distance its boundary has moved out, and therefore,

$$Q_B = s_2\cdot A_B \quad \text{(Eq. 14a)}$$

neglecting the amount of drug remaining as solution in the matrix. This condition is met when $C_s <<< A$. Then, differentiating Eq. 14a,

$$G_B = \frac{dQ_B}{dt} = A_B\frac{ds_2}{dt} \quad \text{(Eq. 15a)}$$

The total amount of drug C released, Q_C, on the other hand, is a function of the distance both boundaries have moved and can be expressed as:

$$Q_C = s_1A_C + (s_2 - s_1)A_B\frac{G_C'}{G_B} \quad \text{(Eq. 16a)}$$

where s_1A_C describes the total amount of caffeine released from region 1, and the second term describes the total amount released from region 2. Since caffeine is released solely in the form of complexes from region 2, its amount will be directly proportional to the amount of benzocaine released from region 2 $[(s_2 - s_1)A_B]$. The proportionality constant obviously is given by the ratio of the caffeine and benzocaine rates of release from that region.

The ratio of Eqs. 11a and 13a yield:

$$\frac{G'_C}{G_B} = \frac{\delta}{\alpha}$$

Substitution of the above in Eq. 16a and differentiating provides another expression for G_C:

$$G_C = A_C\frac{ds_1}{dt} + A_B\frac{\delta}{\alpha}\left[\frac{ds_2}{dt} - \frac{ds_1}{dt}\right] \quad \text{(Eq. 17a)}$$

Equating the expressions for G_C, given by Eqs. 8a and 17a:

$$A_C\frac{ds_1}{dt} + A_B\frac{\delta}{\alpha}\left[\frac{ds_2}{dt} - \frac{ds_1}{dt}\right] = \frac{\epsilon_1}{\tau_1 s_1}(D_C \cdot C_s) + G_B\frac{\delta}{\alpha} \quad \text{(Eq. 18a)}$$

Substituting for G_B from Eq. 15a gives:

$$A_C\frac{ds_1}{dt} - A_B\frac{\delta}{\alpha}\frac{ds_1}{dt} = \frac{\epsilon_1 D_C C_s}{\tau_1 s_1} \quad \text{(Eq. 19a)}$$

or

$$s_1\frac{ds_1}{dt} = \frac{\epsilon_1 \cdot D_C \cdot C_s}{\tau_1(A_C - \frac{\delta}{\alpha}A_B)} \quad \text{(Eq. 20a)}$$

Equation 20a can be integrated to yield:

$$s_1 = \beta t^{1/2} \quad \text{(Eq. 21a)}$$

where

$$\beta = \left[\frac{2\epsilon_1 D_C C_s \alpha}{\tau_1(A_C\alpha - A_B\delta)}\right]^{1/2} \quad \text{(Eq. 22a)}$$

As expected, the movement of boundary s_1 has a square root of time dependence.

Similarly, Eqs. 12a and 15a for G_B can be equated. After rearranging, the following expression is obtained:

$$G_B = A_B\frac{ds_2}{dt} = \frac{\epsilon_1\epsilon_2 B_s \alpha}{\tau_2\epsilon_1(s_2 - s_1) + \epsilon_2 s_1 \tau_1}$$

and

$$\frac{ds_2}{dt} = \frac{\epsilon_1\epsilon_2 B_s \alpha}{A_B s_1\left[\tau_2\epsilon_1\frac{(s_2 - s_1)}{s_1} + \epsilon_2\tau_1\right]} \quad \text{(Eq. 23a)}$$

The ratio of $(s_2 - s_1)/s_1$ has been shown to be invariant (1). Equation 21a can be substituted for s_1. Integration of Eq. 23a then shows that:

$$s_2 = \gamma\, t^{1/2} \quad \text{(Eq. 24a)}$$

$$\gamma = \frac{2\epsilon_1\epsilon_2 B_s \alpha}{A_B(\tau_2\epsilon_1\gamma - \tau_2\epsilon_1\beta + \tau_1\epsilon_2\beta)} \quad \text{(Eq. 25b)}$$

Equations When Both Boundaries Move at the Same Rate—It can be seen from Eqs. 3a and 6a that when both boundaries recede at the same rate, we may write:

$$G_B \cdot s_1 = \frac{\epsilon_1}{\tau_1}B_s\alpha \quad \text{(Eq. 26a)}$$

and

$$G_C \cdot s_1 = \frac{\epsilon_1}{\tau_1}D_C \cdot C_s + \frac{\epsilon_1}{\tau_1}B_s\delta \quad \text{(Eq. 27a)}$$

As, for this case, $s_1 = s_2$:

$$G_B = A_B\frac{ds_1}{dt} \quad \text{(Eq. 28a)}$$

and

$$G_C = A_C\frac{ds_1}{dt} \quad \text{(Eq. 29a)}$$

Then these equations may be solved as before to give:

$$Q_B = \left[\frac{2\epsilon_1 A_B}{\tau_1}(D_B B_s + D_{BC}K_1 C_s B_s + D_{BC_2}K_1K_2B_sC_s^2 + D_{BC_3}K_1K_2K_3B_sC_s^3)t\right]^{1/2} \quad \text{(Eq. 30a)}$$

and

$$Q_C = \left[\frac{2\epsilon_1}{\tau_1}A_C(D_C C_s + D_{BC}K_1C_sB_s + 2D_{BC_2}K_1K_2B_sC_s^2 + 3D_{BC_3}K_1K_2K_3B_sC_s^3)t\right]^{1/2} \quad \text{(Eq. 31a)}$$

These equations may also be written as:

$$Q_B = \left[\frac{2\epsilon_1 A_B D_{B(\text{eff.})} B_T t}{\tau_1}\right]^{1/2} \quad \text{(Eq. 32a)}$$

and

$$Q_C = \left[\frac{2\epsilon_1 A_C D_{C(\text{eff.})} C_T t}{\tau_1}\right]^{1/2} \quad \text{(Eq. 33a)}$$

where $D_{B(\text{eff.})}$ and $D_{C(\text{eff.})}$ are the effective diffusion coefficients for the total transport rates of benzocaine and caffeine, respectively.

Equations When Caffeine Is the Faster Moving Boundary—As was done for the first case and considering the continuity relations at the boundaries we obtain the following equations that are analogous to Eqs. 3a, 6a, 11a, and 13a:

For region 1,

$$G_B s_1 = \frac{\epsilon_1}{\tau_1}[D_B B_s + D_{BC}K_1B_sC' + D_{BC_2}K_1K_2B_s(C')^2 + D_{BC_3}K_1K_2K_3B_s(C')^3] \quad \text{(Eq. 34a)}$$

and

$$G_C s_1 = \frac{\epsilon_1}{\tau_1}[D_C C_s + D_{BC}K_1B_sC' + 2D_{BC_2}K_1K_2B_s(C')^2 + 3D_{BC_3}K_1K_2K_3B_s(C')^3] \quad \text{(Eq. 35a)}$$

and, for region 2,

$$G_B'(s_2 - s_1) = \frac{\epsilon_2}{\tau_2}D_{BC}K_1B_s(C_s - C') + D_{BC_2}K_1K_2B_s[C_s^2 - (C')^2] + D_{BC_3}K_1K_2K_3B_s[C_s^3 - (C')^3] \quad \text{(Eq. 36a)}$$

and

$$G_C(s_2 - s_1) = \frac{\epsilon_2}{\tau_2}D_C(C_s - C') + D_{BC}K_1B_s(C_s - C') + 2D_{BC_2}K_1K_2B_s[C_s^2 - (C')^2] + 3D_{BC_3}K_1K_2K_3B_s[C_s^3 - (C')^3] \quad \text{(Eq. 37a)}$$

Here C' is the caffeine concentration and s_1 and G_B' represent the rate of benzocaine movement in region 2. All other symbols are the same as before.

In addition to these equations we have the relations,

$$G_C = \frac{dQ_C}{dt} = A_C\frac{ds_2}{dt} \quad \text{(Eq. 38a)}$$

and

$$G_B = \frac{dQ_B}{dt} = A_B\frac{ds_1}{dt} + A_C\frac{G_B'}{G_C}\left[\frac{ds_2}{dt} - \frac{ds_1}{dt}\right] \quad \text{(Eq. 39a)}$$

As in the first case we now have six equations in six unknowns—G_B', G_B, G_C, C', s_1, and s_2. While in principle the problem can therefore be solved, one finds that the algebra becomes extremely complicated due to the occurrence of an equation cubic in C'.

Penicillin G Interactions with Deoxycholic Acid Polymer-Like Structures

By F. ALHAIQUE, C. BOTRÉ, G. LIONETTI, M. MARCHETTI, and F. M. RICCIERI

Conductivity, activity coefficient, and ultraviolet absorption data have shown that an interaction occurs between deoxycholate helical complexes (DCA) and sodium benzylpenicillin (P). The mechanism of this interaction is still unknown, but a merely electrostatic interpretation can be ruled out. Experimental data seem to be consistent with the stereospecific nature of this interaction. The presence of DCA helical complexes increases benzylpenicillin resistance to the hydrolytic activity of penicillinase. No interaction and therefore no decrease in the hydrolytic activity of penicillinase has been found with different derivatives, *i.e.*, dimethoxyphenyl- and α-aminobenzylpenicillin. At the same time dehydrocholic acid sodium salt (NaDHCA), which in no case forms helical complexes, shows no effect upon P, whereas sodium salt of cholic acid (NaCA) still exerts a protective action upon P but to a lesser degree.

THE FORMATION of a helical complex of macromolecular dimension from sodium deoxycholate has been previously described by Rich and Blow (1, 2). Under appropriate conditions sodium deoxycholate aggregates in solution to form a gel which behaves in many ways like a polymer of high molecular weight. The fibers, which can be drawn from the solutions, showed an X-ray diffraction pattern which is characteristic of a helical aggregate (2). In a previous work (3) the influence of cation dimensions, hydration, and hydrogen bonds on the thermal stability of deoxycholic acid (DCA) "polymer-like" structure was discussed. It was shown that the thermal stability of deoxycholate aggregates is cationic species dependent.

In this paper the possibility of an interaction between DCA or related molecules and antibiotics has been studied. Even if the micelle-forming properties of deoxycholate could account for some of the observed phenomena, the formation of huge micelles with a regular or "crystalline" (2) internal structure seems to be responsible for effects which occur only when a specific system of hydrogen bonding is established within the micelle.

Conductivity, activity coefficient, and ultraviolet absorption data gave evidence that a specific interaction takes place between DCA polymer-like structure and benzylpenicillin (P). The mechanism of this interaction is still unknown, but an interpretation of the experimental data on merely electrostatic grounds can be ruled out.

It seemed sound to suppose that this interaction should somehow affect the biological activity of P, namely, its resistance to the penicillinase hydrolytic activity.

An inclusion, already demonstrated in the case of fatty acids (4, 5), could be proposed as an explanation for the observed decrease of penicillinase activity which has been chosen as reference. At the same time it could be suggested that the other molecular species present in the solution during the formation of the complex, could be attached to the outside of the helical steroid core, as are amino acids and peptides (2).

It cannot be overlooked that the study of this kind of interaction can lead to a more detailed knowledge of the mechanism of action of this class of antibiotics at the level of biomembranes.

EXPERIMENTAL

Materials—Deoxycholic acid (DCA), dehydrocholic acid (DHCA), and cholic acid (CA) Merck were further crystallized from alcohol before use. Different DCA salts were prepared by neutralizing DCA with solutions of different hydroxides. The DCA salt solutions were then lyophilized. The same procedure was used in preparing DHCA and CA salts.

Quaternary nitrogen bases were prepared by exchanging the corresponding iodides through an ionic exchanger, *i.e.*, Ionenaustauscher III Merck. The solution was then titrated with a standard HCl solution. The absence of halogens from these solutions was checked. A penicillin G sodium salt (P) sample, whose purity was determined by a spectrophotometer (Hitachi Perkin-Elmer model 139) according to a method described elsewhere (6), was used. Penicillinase (Baltimore Biological Laboratory) was a sample containing 2×10^6 units/ml.

All reagents used were of analytical grade.

Procedure—The different DCA salts were prepared by dissolving DCA with an amount of the corresponding hydroxide solution slightly less than that required. The excess of acid was then removed by filtration. The solution was then lyophilized and the DCA salt recovered. Conductivity measurements were carried out in a thermostatic bath, regulated within 0.01°. The complete filling and closing of the cell avoided the evaporation of the solution. A WTW bridge (model LF3) was employed for such measurements.

The pH values were controlled by means of a pH meter (Radiometer pH M4). The activity coefficients were determined by potentiometric titration carried out by means of a coupled permselective membrane electrode system extensively described elsewhere (7). The activity of sodium ions was calculated by means of a calibration curve, which allowed conversion of the recorded E.M.F. values into the activities. This was done stepwise by diluting a sodium chloride solution, recording the E.M.F. at each step, and plotting it against the logarithm of Na^+ ion activity. A linear plot was obtained. The a_{Na^+} values of the solution were calculated from the measured E.M.F. by interpolating the calibration curve. This was done assuming that $\gamma_{Na^+} = \gamma_{\pm NaCl}$ in the calibration solution (8). The penicillinase activity on P was evaluated with the manometric method described by Henry and Housewright (9) and modified by Pollock (10). Each time 3 ml. of a diluted penicillinase solution, corresponding to 300,000 units, was added to 0.5 ml. of different solutions of P in 0.0177 *N* $NaHCO_3$ as a buffer. The temperature was 30° ± 0.01° and the reading of CO_2 development was done every 2 min. All determinations were checked against a blank containing penicillinase inactivated with boiling water.

The ultraviolet absorption measurements were performed by means of a Hitachi Perkin-Elmer apparatus (model 139).

RESULTS AND DISCUSSION

In order to prove that a real interaction occurs between DCA and P, three sets of measurements were carried out, *i.e.*, conductivity, activity coefficient, and ultraviolet absorption. In Fig. 1, specific conductivity χ is plotted against the concentration of the different compounds considered.

Plot A refers to a solution of NaDCA, plot B to a solution of tetrabutylammonium deoxycholate (TBADCA), and plot C to a solution of P. The trend of the resulting plots is linear. In order to correlate the prerequisite of a polymer-like structure of DCA, TBADCA has been chosen because this DCA salt has proved to form no helical complexes in the range of temperatures of the experiments (3).

In Fig. 2 specific conductivity χ is plotted against the concentration of DCA salts in the presence of P (molar ratio 1:1). Plot A refers to a solution containing NaDCA + P in a molar ratio 1:1. Plot B refers to a solution containing TBADCA + P in a molar ratio 1:1. In both sets of measurements the temperature was 25° ± 0.01°.

Plot A of Fig. 2 shows a break point. It is to be noted that even if DCA concentration is the same in both plots, the stability of aggregates is cationic species dependent, as already discussed (3). In order to prove that this discontinuity is due to a

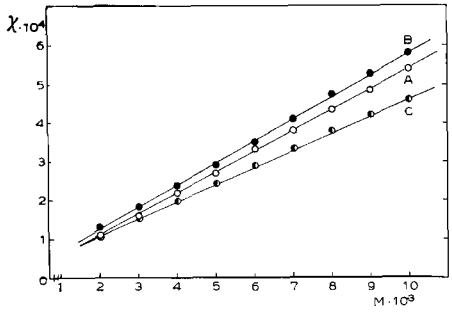

Fig. 1—No discontinuity is detected by conductivity measurements in solutions of different DCA salts. Specific conductivity χ is plotted as a function of the molar concentration of different deoxycholates. Key: A, *a solution of NaDCA;* B, *a solution of TBADCA;* C, *a solution of P.*

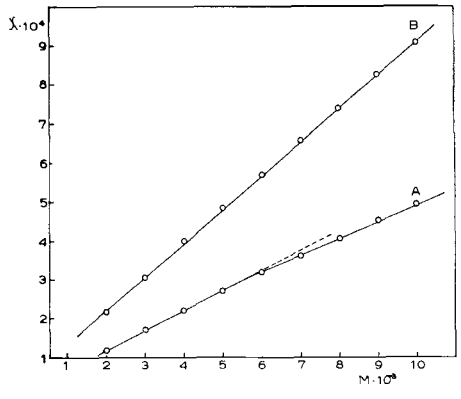

Fig. 2—DCA polymer-like structure interacts with P. No discontinuity is detected when polymer-like structures cannot take place. Specific conductivity χ is plotted against the concentration of DCA salts in the presence of P. Key: A, *NaDCA + P (molar ratio 1:1);* B, *TBADCA + P (molar ratio 1:1). The temperature was 25° ± 0.01°.*

real interaction between P and NaDCA, the activity coefficient of cations in solution was measured through a permselective membrane electrode system described elsewhere (7). The resulting plots are shown in Fig. 3, where plot A refers to a P solution, plot B to a NaDCA solution, and plot C to a NaDCA + P (molar ratio 1:1) solution.

Even in this case the trend of the plot shows a critical point which falls at the same concentration and proves interaction between NaDCA and P.

The increase in cationic activity shown by the complex NaDCA + P would tend to suggest that P interferes with sites of the helical complex, where electrostatic interactions with sodium ions take place. Possibly due to the conformation of the structure there must be a specific nonelectrostatic interaction which results in an increase of cationic activity if compared with that shown by P and DCA, respectively.

Further evidence of a specific interaction was found in extinction coefficient data at a wavelength of 264 mμ. The resulting data are reported in Fig. 4.

As might be expected, the trend of the plots of P and NaDCA taken singularly are linear, whereas

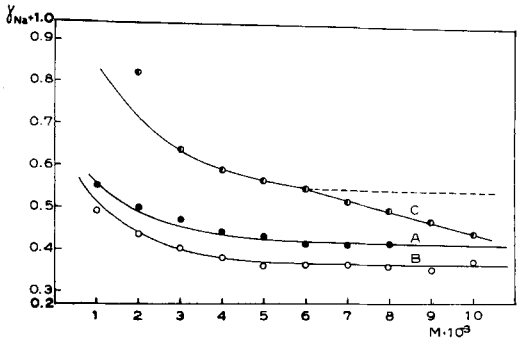

Fig. 3—Activity coefficient measurements show that a real interaction occurs. Activity coefficient γ_{Na^+} is plotted as a function of the molar concentration of a P solution (A), *a NaDCA solution* (B), *and a NaDCA + P solution in a molar ratio 1:1* (C). *The temperature was 25° ± 0.01°.*

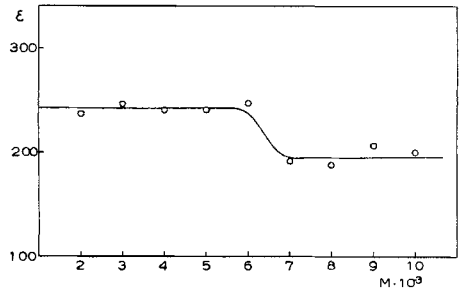

Fig. 4—Ultraviolet absorption data give evidence that DCA polymer-like structure interacts with P at the same value of NaDCA concentration where the transition is observed in both conductivity and activity coefficient measurements. Molar extinction coefficient ε at the wavelength of 264 mμ is plotted as a function of the concentration of a NaDCA + P solution in a molar ratio 1:1. The temperature was 25° ± 0.01°.

the plot referring to NaDCA + P shows a "jump" at the same value of NaDCA concentration where the transition was observed in both conductivity and activity coefficient measurements. The hyperchromic effect is such that the ε value of a diluted solution of NaDCA + P is nearly coincident to that of a penicillin solution when DCA concentration is lower than the transitional value (see Fig. 2). It can then be assumed that the structural changes which occur in deoxycholate complexes are such that no more interaction takes place between NaDCA and P. The same measurements were repeated with different DCA salts. Only the data referring to TBADCA have been reported, but constantly whenever temperature, pH, and ionic strength were such that no helical complex could be established (1–3) no singular points were detected by means of activity coefficient, conductivity, and spectrophotometric measurements. When DCA is replaced with DHCA (dehydrocholic acid), no interaction occurs in a number of concentrations ranging from those of DCA (see Fig. 5). At the same time CA (cholic acid) has the same effects as those for DCA, but the transition occurs at much higher values of concentration. (NaCA concentration was about 2×10^{-2} *M*.) In the attempt to elucidate the mechanism of this interaction, the same kind of measurements were carried out on some derivatives of 6-aminopenicillanic acid. On the assumption that the mechanism would be mainly of a steric nature, a molecule whose structure would ensure a higher degree of rigidity was chosen. In this sense the well known 2,6-dimethoxyphenylpenicillin seemed to be suitable. At the same time in order to find out in which way the total absence of a side chain or the presence of a polar group in it would influence the interaction, the authors took into consideration the α-aminophenylacetyl derivative (ampicillin) and the 6-aminopenicillanic acid itself.

All these compounds show the same behavior, and in the case of ampicillin the resulting data are given in Fig. 6. The plots prove that no interaction takes place. It seems reasonable then to suppose that the interaction between DCA and P is probably of a steric nature.

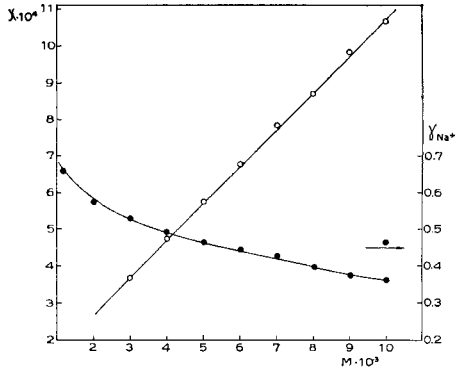

Fig. 5—No interaction occurs in the case of a NaDHCA + P solution. Activity coefficient γ_{Na^+} (●, right ordinate) and specific conductivity χ (○, left ordinate) are plotted against the molar concentration of a NaDHCA + P solution in a molar ratio 1:1. The temperature was 25° ± 0.01°.

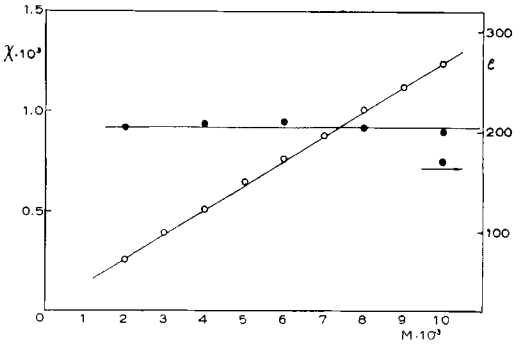

Fig. 6—No singular point can be detected by means of specific conductivity and ultraviolet absorption measurements when benzylpenicillin is replaced with ampicillin. Specific conductivity χ (○, left ordinate) and molar extinction coefficient ε (●, right ordinate) are plotted as a function of the molar concentration of a NaDCA + ampicillin solution in a molar ratio 1:1. The temperature was 25° ± 0.01°.

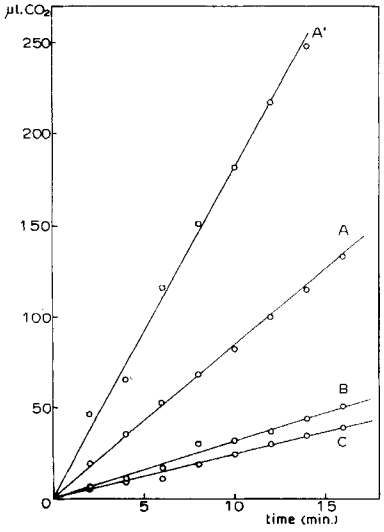

Fig. 7—A protecting action upon benzylpenicillin against hydrolytic activity of penicillinase is shown by DCA polymer-like structures and to a lesser extent by CA. Carbon dioxide volume (μl.) is plotted as a function of time (min.) for a solution of P 1.20 × 10^{-2} M (A), for a solution of NaCA + P 1.20 × 10^{-2} M, respectively (B), for a solution of NaDCA + P 1.20 × 10^{-2} M, respectively (C), and for a solution of NaDHCA + P 1.20 × 10^{-2} M, respectively (A'). The temperature was 30° ± 0.01°. All solutions were buffered with 0.0177 N $NaHCO_3$ (pH = 8.5).

The above described interaction between DCA polymer-like structure and P results in a decrease of penicillinase hydrolytic activity. If the interaction can take place only when DCA has acquired its polymer-like structure, it can be foreseen that there will be a decrease of penicillinase hydrolytic activity only when experimental conditions are such that the formation of a helical complex of macromolecular dimension is possible.

In Fig. 7 the amount of carbon dioxide (μl.) liberated by penicillinase is plotted as a function of time. Plot A refers to a solution of P 1.2 × 10^{-2} *M*. Plot B refers to a solution of NaCA + P 1.2 × 10^{-2} *M*, respectively. Plot C refers to a solution of NaDCA + P both at a concentration of 1.2 × 10^{-2} *M*. In each measurement the temperature was 30° ± 0.01° and the pH = 8.5. The volume of CO_2 developed in the case of NaDCA + P solution is much smaller than for a solution of P. NaCA still exerts a protective action upon P but to a lesser degree. On the other hand, if experimental conditions are such that no interaction can occur, there is no decrease of penicillinase activity as shown in Fig. 8. Here plot C refers to a solution of NaDCA + P both at a concentration of 2.37 × 10^{-3} *M*. Plot B refers to a solution of NaCA + P both at a concentration of 2.37 × 10^{-3} *M* and plot A refers to a solution of P 2.37 × 10^{-3} *M*.

Even if the micelle-forming properties of bile

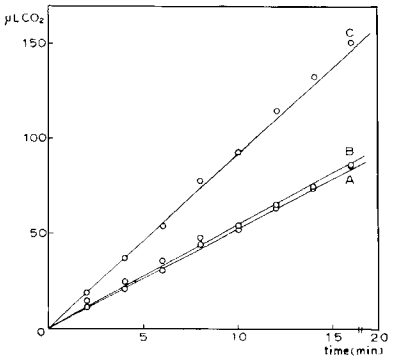

Fig. 8—No protecting action is shown when DCA concentration is lower than the transitional value or when DCA is replaced with CA. Carbon dioxide volume (μl.) is plotted as a function of time (min.) for a solution of P 2.37 × 10^{-3} M (A), for a solution of NaCA + P 2.37 × 10^{-3} M, respectively (B), and for a solution of NaDCA + P 2.37 × 10^{-3} M, respectively (C). The temperature was 30° ± 0.01°. All solutions were buffered with 0.0177 N $NaHCO_3$ (pH = 8.5).

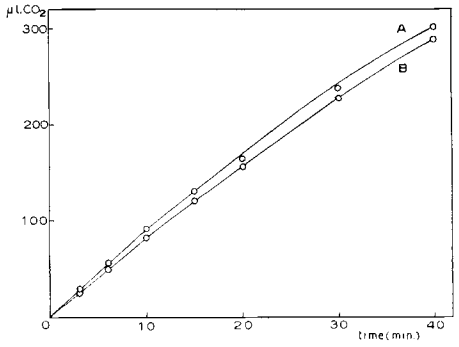

Fig. 9—No variation in penicillinase hydrolytic activity is shown when benzylpenicillin is replaced with ampicillin in a solution of DCA. Carbon dioxide volume (μl.) is plotted as a function of time (min.) for a solution of ampicillin 1.20 × 10^{-2} M (A) and for a solution of ampicillin + NaDCA 1.20 × 10^{-2} M, respectively (B). The temperature was 30° ± 0.01°. All solutions were buffered with 0.0177 N $NaHCO_3$ (pH = 8.5).

salts can account for the observed phenomena (11), nevertheless the ability of deoxycholate to give huge micelles with a regular or crystalline internal structure (2) seems to be responsible for effects which differ in their entity and specificity.

The formation of helical complexes of macromolecular dimension produces a large increase in viscosity which is the outstanding feature of this phenomenon. In the study of changes in viscosity of deoxycholate solutions at different concentrations, Ekwall (12) and Rich and Blow (2) found a number of concentration ranges separated by discontinuities in various properties. These discontinuities are ascribed to changes in the type of micelles. The assumption can be made that the type of DCA structure which corresponds to the range of concentrations indicated by conductivity, UV absorption, and ionic activity measurements interacts with penicillin G. In this respect CA and DCA seem to have almost the same effect upon penicillinase activity (see Fig. 7, plots B and C), but experimental conditions, namely pH = 8.5, suggest that DCA is probably hindered in forming its characteristic complexes which would give a more enhanced effect. In the case of CA, micelle formation and inclusion can be considered as being responsible for the data. This interpretation is consistent with the experimental results which showed that CA interacts with P in a range of concentrations much higher than those of DCA.

At the same time a comparison of the hydrolytic activity of penicillinase upon ampicillin in the presence or absence of DCA helical complexes shows (Fig. 9) that the lack of interaction brings no decrease in the development of CO_2.

In Fig. 8, in the case of a solution of NaDCA + P, where NaDCA concentration is lower than the transitional value, there is an increase in the quantity of CO_2 development if compared with that of a P solution at the same concentration.

We assume that, where no helical complex occurs, the presence of DCA results in an activation of the enzyme, possibly due to Van der Waals interactions with hydrophobic sites of the protein. This effect, of course, is always present, but when helical complexes take place, steric interactions become prevalent. This is further confirmed by the plot A′ of Fig. 7 where NaDHCA, which in no case forms helical complexes (2), shows the same effect upon penicillinase. A solution containing DCA helical complexes can be related on electrostatic grounds to a solution containing chain molecules with high densities of ionized groups.

According to Morawetz (13–15), the electrostatic potentials in the neighborhood of the polyion can be such to induce wide variation in the local concentration of mobile ions. If this is the case, then the presence of DCA helical complexes should have an effect exactly opposite to the one experimentally found on P. Therefore, the polymer-like structure must interact with P molecules through a mechanism which, still unknown, must not be of a merely electrostatic nature.

In conclusion if we choose those experimental conditions defined by that part of the plot of Fig. 2 which is above the break point, we will constantly have a decrease of penicillinase activity and therefore a protective action upon benzylpenicillin.

Spectrophotometric Analyses of Ribose and 2-Deoxy-D-ribose Alone and in Mixtures

By EDWARD R. GARRETT, JAIME BLANCH, and JOACHIM K. SEYDEL*

The rates of production of the chromophore for ribose (R) and the maximum absorbance of the chromophore for 2-deoxy-D-ribose (DR), produced under thermal and acidic conditions are directly related to their sugar concentrations. These factors are the bases for qualitative and quantitative analysis of these sugars. The $\lambda_{max.}$ 261 mμ chromophore of degraded DR is stable for at least 15 hr. after 5 hr. of treatment at 80.0° with 1.0 *M* HCl. The $\lambda_{max.}$ 277 mμ chromophore of degraded R increases continuously during the same period at an apparent zero-order rate. These phenomena serve as bases for a sensitive spectrophotometric assay of both sugars, alone and in mixtures. These acid-generated chromophores when made alkaline generate other absorption bands with specific properties which permit additional methods of differentiation between the sugars.

Analyses of sugars in mixtures constitute a broad field of investigation. Sugar mixtures have been separated by paper or column chromatography with further analyses of the effluents (1–3). Methods of separation by gas chromatography of methylated sugars are available (4, 5). Differences in color development after reaction with specific reagents have been another approach (6). Dialysis based on differential kinetics (7) and combinations of different methods (8) have been proposed. However, some of these techniques are nonselective and are insensitive to small sugar concentrations.

The phenomenon of chromophore production when sugars are heated with mineral acids is well known. Correlations between absorbances of those chromophores and the sugar concentration have served as bases for sugar analyses (9–11). Limited attempts have been made to analyze sugars in mixtures by these procedures. The extremely strong conditions in acid concentration and temperature which have been used sometimes do not permit the attainment of reproducible results and are not specific for individual sugars.

If a sugar is subjected to well-defined and mild conditions of acid concentration, temperature, and time, definite chromophores with well-defined properties can result (12–14). For example, when 2-deoxy-D-ribose (DR) is heated 5 hr. in 1.0 *M* HCl at 80.0°, a chromophore $\lambda_{max.}$ 261 mμ (12) is produced as shown in Fig. 1 and is stable under those conditions for at least 15 hr. (Fig. 2). Ribose (R) under the same conditions generates a chromophore $\lambda_{max.}$ 277 mμ (Fig. 1) which increases continuously during the same period at an apparent zero-order rate (Fig. 2). Such differences can provide sensitive assay methods for these sugars, alone and in mixtures. The properties of these acid-generated chromophores were also investigated.

EXPERIMENTAL

Materials and Equipment—D-Ribose (R) and 2-deoxy-D-ribose (DR) were obtained from Calbiochem (analytical reagent grade) and furfural from the Fisher Scientific Co. (reagent grade). All other chemicals used were of analytical reagent grade. A Beckman model DU spectrophotometer, slit width 0.1 mm., was used. Complete absorption spectra were obtained on a Cary model 15 spectrophotometer.

Spectrophotometric Procedures for Calibration Curves of 2-Deoxy-D-ribose (DR)—A calibration curve for DR was prepared using concentrations between $1 \times 10^{-4}M$ and $7 \times 10^{-4}M$ in 1.0 *M* HCl.

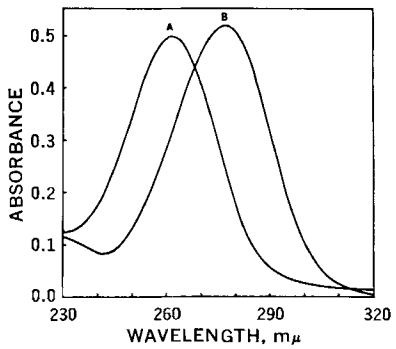

Fig. 1—Ultraviolet spectrum of the products of sugar degradation in 1.0 M HCl at 80.0°. Curve A is for 3.75 × 10⁻⁴ M 2-deoxyribose after 5 hr. of degradation. Curve B is for 8.00 × 10⁻⁴ M ribose after 6.5 hr. of degradation and is also the spectrum of furfural in 1.0 M HCl.

This investigation was supported in part by an institutional grant to the University of Florida by the American Cancer Society, and in part by grant GM-09864-03,04,05 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

Abstracted in part from a thesis submitted by Jaime Blanch to the Graduate School, University of Florida, Gainesville, in partial fulfillment of Master of Science degree requirements.

* Present address: Borstel Research Institute, Borstel, Germany.

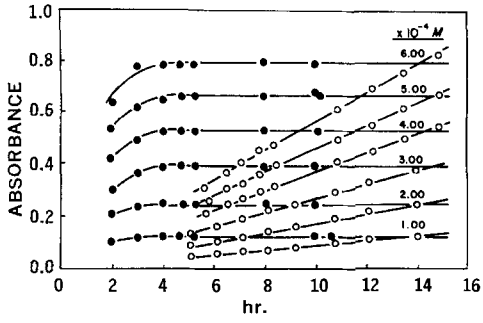

Fig. 2—Effect of time on the absorbances of (○) *1.0* M *HCl acid-degraded ribose measured at 277 mμ, and* (●) *deoxyribose measured at 261 mμ, at 80.0°.*

The samples were maintained at 80.0° in a thermostatted bath. Aliquots were taken between 5 and 20 hr. of degradation. On cooling, the absorbances were read at $\lambda_{max.}$ 261 mμ. A plot of these absorbances against the respective sugar concentration resulted in the calibration curve for DR as shown in Fig. 3.

Calibration Curves of D-Ribose (R)—Samples of R between $1 \times 10^{-4}M$ and $6 \times 10^{-4}M$ were degraded under the same conditions as specified for DR. Samples were taken between 5 and 20 hr. of degradation. The cooled aliquots were read at 277 mμ against a blank solution of 1.0 *M* HCl. The plots of absorbances against time for each R concentration are given in Fig. 2. The apparent zero-order rate constants, the slopes of such lines, are plotted against the respective R concentration in the calibration curve for R (Fig. 3).

Assay of Ribose and 2-Deoxy-D-ribose—Solutions of the sugars were prepared so that the absorbance between 200 and 400 mμ did not exceed 1.50 after heating at 80.0° for 20 hr. in 1.0 *M* HCl. For greater absorbances the solution may be diluted with known volumes of 1.0 *M* HCl. To assay DR, the absorbance at 261 mμ was measured between 5 and 20 hr. of degradation. This value was used to obtain the DR concentration from Fig. 3, the calibration curve. To assay R, samples between 5 and 20 hr. were removed from the reaction flask, and the absorbances of the cooled aliquots were measured at 277 mμ. A plot of absorbance against time was made and the apparent rate constant was measured. This value was used to obtain the R concentration from Fig. 3, the calibration curve. Seven or eight aliquots at 1.0 or 1.5 hr. intervals will provide an accurate value for the rate constant. However, two measurements at 5 and 20 hr. are sufficient to estimate the apparent zero-order rate constant for any R concentration.

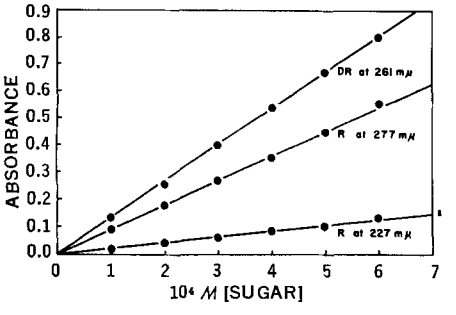

Fig. 3—Calibration curves for the spectrophotometric analyses of acid-degraded ribose and deoxyribose. The ordinate represents the absorbance after 5 hr. for deoxyribose (DR) and the rate constants in 10 × absorbance units/hr. at 277 mμ for ribose (R) as obtained at 80.0° in 1.0 M *HCl.*

Anaylsis of Ribose and 2-Deoxy-D-ribose in Mixtures—Solutions containing the mixture were degraded in 1.0 *M* HCl at 80.0°. Samples were taken between 5 and 20 hr. of degradation. The absorbances at 261 mμ and 277 mμ were measured and plotted against time. In the plot at 277 mμ, the slope was determined and the R concentration obtained from the calibration curve, Fig. 3. The intercept of the plot of absorbances of the mixtures at 261 mμ against time corresponds to the absorbance due to degraded DR. The pertinent DR concentration was read from its calibration curve, Fig. 3.

Investigation of Properties of Furfural—The spectrum of furfural was obtained in 1.0 *M* HCl and followed as a function of time in 0.25 *M* NaOH at 45.0°. The extraction of furfural and the chromophore of acid-degraded ribose from 1.0 *M* HCl by equal volumes of chloroform was followed by observing the decreases in the $\lambda_{max.}$ 277 mμ absorbance in the aqueous phases.

RESULTS AND DISCUSSION

Kinetic Studies—When 2-deoxy-D-ribose (DR) is degraded in 1.0 *M* HCl at 80.0° a chromophore at 225 mμ is generated by an apparent first-order process. The apparent first-order rate constants are proportional to the hydrogen ion activity, a_{H^+}, at a given temperature (12). The compound with this chromophore is the precursor of 5-methyl-3(2*H*)-furanone (13) with a $\lambda_{max.}$ 261 mμ (Fig. 1) which is also generated by an apparent first-order process. The 261 mμ absorbance reaches a constant value A_∞ after 5 hr. of heating in 1.0 *M* HCl, which is maintained for at least 15 hr. (Fig. 2). The A_∞ is directly proportional to DR concentration, and the apparent first-order rate constants are also proportional to the hydrogen ion activity. A complete discussion of the properties of acid-degraded DR, 5-methyl-3(2*H*)-furanone and the chemical nature of the degraded products has been reported (12, 13).

When ribose (R) is degraded under the same conditions, a chromophore at $\lambda_{max.}$ 277 mμ is generated (Fig. 1). After a slight induction period, this chromophore appears at apparent zero-order rates between 5 and 25 hr. after initiation of the degradation (Fig. 1). However, the over-all reaction may not be strictly a zero-order process. As the degradation proceeds, the rate of appearance of the 277 mμ absorbance band decreases, but this deviation from zero order is not significant until after 25 hr. A final absorbance $\lambda_{max.}$ 277 mμ with an apparent molar absorptivity of 7,160 based on the initial ribose concentrations is obtained after 200 hr. at 80.0° in 1.0 *M* HCl.

Concomitant with the appearance of the 277 mμ absorbance band, another at 227 mμ $\lambda_{max.}$ is also observed to arise by an apparent zero-order rate process. The 227 mμ chromophore is not preferred for analytical purposes due to its lessened absorptivity.

The effect of the R concentration on the rate of generation of the chromophores was studied. Concentrations of R ranging from $1 \times 10^{-4}M$ to $6 \times 10^{-4}M$ were degraded in 1.0 M HCl at 80.0°. The resultant absorbances, A, were measured at 227 and 277 mμ and plotted against time, t, as shown in Fig. 2 for the 277 mμ values. The values for the slopes, k_o, of the lines between 5 and 20 hr. of degradation were obtained (Fig. 1) in accordance with the equation:

$$A = k_o t \qquad \text{(Eq. 1)}$$

The apparent intercepts are not significantly different from zero for ribose concentrations less than $6 \times 10^{-4}M$. The k_o values are directly related to the ribose concentration as shown in Fig. 3 where:

$$k_{277} = \alpha_{277}\,\mathrm{R};\ \alpha_{277} = 2.49 \times 10^{-2}\ \text{absorbance units} \times \text{L./mole/sec.} \qquad \text{(Eq. 2)}$$

where the percent of standard deviation of α_{277} is 1.8% and the standard deviation of k_{277} about regression on R is 1.87×10^{-7}, so that at $3.5 \times 10^{-4}M$ ribose the percent of standard deviation of k_{277} is 2.1%. The percent of standard deviation is often referred to as the coefficient of variation Also,

$$k_{227} = \alpha_{227}[\mathrm{R}];\ \alpha_{227} = 5.92 \times 10^{-3}\ \text{absorbance units} \times \text{L./mole/sec.} \qquad \text{(Eq. 3)}$$

The dependency of the apparent zero-order rate constant, k_{277}, at 277 mμ on the HCl concentration was also studied for $1 \times 10^{-3}M$ ribose solution degraded at 80.0°. The values of k_{277} were determined (Table I) and plotted against the respective hydrogen ion activity, $a_{H+} = f[\mathrm{HCl}]$, where f is the activity coefficient obtained from the literature (15). From the plot of k_{277} against a_{H+} (Fig. 4), at 80.0° at $10^{-3}M$ ribose:

$$k_{277} = k_{H+}a_{H+};\ k_{H+} = 3.2 \times 10^{-5}\ \text{absorbance units} \times \text{L./mole/sec.} \qquad \text{(Eq. 4)}$$

Alternatively, in terms of HCl concentration:

$$k_{277} = k_{\mathrm{HCl}}[\mathrm{HCl}];\ k_{\mathrm{HCl}} = 2.3 \times 10^{-5}\ \text{absorbance units} \times \text{L./mole/sec.} \qquad \text{(Eq. 5)}$$

Thus, at 80.0°:

$$\alpha_{277} = [\beta_{277}]_{H+}a_{H+} = (k_{277}/[\mathrm{R}])\,a_{H+};\ [\beta_{277}]_{H+} = 3.2 \times 10^{-2}\ \text{absorbance units} \times \text{L.}^2/\text{mole}^2/\text{sec.} \qquad \text{(Eq. 6)}$$

$$\alpha_{277} = [\beta_{277}]_{\mathrm{HCl}}[\mathrm{HCl}] = (k_{277}/[\mathrm{R}])[\mathrm{HCl}];\ [\beta_{277}]_{\mathrm{HCl}} = 2.3 \times 10^{-2}\ \text{absorbance units} \times \text{L.}^2/\text{mole}^2/\text{sec.} \qquad \text{(Eq. 7)}$$

For a given hydrogen ion activity or HCl concentration, the appropriate value at 80.0° can be determined for the 277 mμ absorbance of degraded ribose (Eqs. 6 and 7). Knowledge of the experimental zero-order rate constant at that acid concentration or hydrogen ion activity permits calculation of the ribose concentration from the rearranged Eq. 2.

The rate dependency on the absolute temperature, °C. + 273, was determined from the appropriate plot (Fig. 5, curve A) of the Arrhenius equation from data obtained at several temperatures (Table I) for $10^{-3}M$ ribose in 1.0 M HCl:

$$\log k_{277} = -(\Delta H_a/2.303\ \mathrm{R})\,1/T + \log P \qquad \text{(Eq. 8)}$$

The apparent heat of activation calculated from the slope of this plot was $\Delta H_a = 28.6$ Kcal./mole, and the log P value was 13.1. Since $k_{\mathrm{HCl}} = k_{277}$ at 1.0 M HCl (Eq. 5), the Arrhenius parameters are the same for log k_{HCl} at 277 mμ. Also, the Arrhenius parameters for log $[\beta_{277}]_{\mathrm{HCl}}$ are $\Delta H_a = 28.6$ Kcal./mole and log $P = 10.1$ so that $[\beta_{277}]_{\mathrm{HCl}}$ may be calculated for various temperatures from the Arrhenius equation (Eq. 8). Substitution of this value and a given HCl concentration in Eq. 7 determine the α_{277} value to be used in Eq. 2 for determining ribose concentration.

Assay of Ribose and 2-Deoxy-D-ribose in Mixtures—The 261 mμ absorbance of degraded DR increases to a stable value after 4 hr., whereas the 277 mμ absorbance of degraded R continues to increase linearly with time (Fig. 6). When a mixture of R and DR is subjected to thermal acid degradation the apparent zero-order rates of increase of the absorbances in the region of 277 mμ after 5 hr. are identical with the rates for the same concentration of ribose alone under the same conditions of acid and temperature (Figs. 2, 3, and

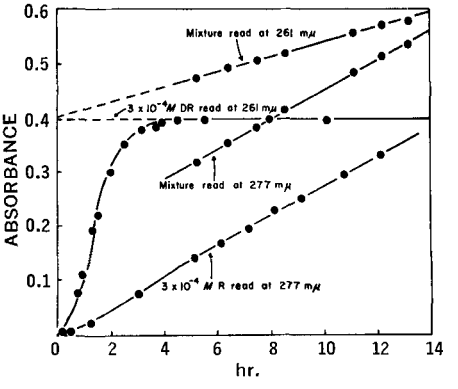

Fig. 6—Examples of analyses of mixtures of ribose (3×10^{-4} M) *and deoxyribose* (3×10^{-4} M) *degraded in 1.0 M HCl at 80.0°. The combined absorbances are read at 261 mμ to determine the intercept value related to the deoxyribose concentration which is obtained by extrapolation of the linearity observed after 5 hr. The combined absorbances are read at 277 mμ to determine the linear slope after 5 hr. which is related to the ribose concentration. The absorbances with time at these* $\lambda_{max.}$ *values are also given for the acid degradation of the separate sugars.*

6). The slope of the absorbance *versus* time plot after 5 hr. for such a mixture is a function only of the R concentration which can be obtained from the calibration curve for R (Fig. 3). The zero time intercept for this linear segment after 5 hr. when absorbance at 261 mμ is plotted against time is only due to the absorbance of the degraded DR (Fig. 6). This intercept is related to the concentration of DR present in the mixture by the appropriate calibration curve (Fig. 3).

This technique was applied to the resolution of several mixtures of both sugars in the concentration ranges from $1 \times 10^{-4}M$ to $6 \times 10^{-4}M$. The results are given in Table II. The estimated percent of standard deviations of each assay in such mixtures is 1.87% for deoxyribose and 2.93% for ribose.

Alkaline Degradation of the Acid-Generated Chromophore of Ribose—The 261 mμ chromophore of acid-degraded DR can be destroyed in mildly alkaline solutions. The 261 mμ absorbance upon alkalinization shifts to a $\lambda_{max.}$ 293 mμ, which absorbance band disappears rapidly by a first-order process (12). When acid-degraded ribose is made alkaline by addition of NaOH, the $\lambda_{max.}$ 277 mμ absorbance is lost by a first-order process to a small residual absorbance (Fig. 7). The loss in absorbance is accompanied by a gradual hypsochromic shift to a residual absorbance with a $\lambda_{max.}$ about 260 mμ. Concomitant with the 277 mμ absorbance disappearance, a band $\lambda_{max.}$ 324 mμ arises by an apparent first-order process and approaches an asymptotic value. This band subsequently disappears by an apparent first-order process (Fig. 7). The initial isosbestic point at 302 mμ indicates a 1:1 transformation for the first reaction in the apparent sequence, *i.e.*, $A \rightarrow B$, with an apparent first-order rate constant k'_{277}. The subsequent slower transformation, $B \rightarrow C$, of an apparent first-order rate constant k_{324} is accompanied by a loss of the isosbestic point. The respective k'_{277} and k_{324} values at various temperatures and concentrations of alkali are given in Table III. These apparent rate constants at 45.0° when plotted against the respective NaOH concentrations show a linear dependency (Fig. 8) and:

$$k_i = k_{NaOH}[NaOH] \qquad \text{(Eq. 11)}$$

where k_{NaOH} for the disappearance of the 277 mμ chromophore and appearance of the 324 mμ chromophore at 45.0° is 2.58×10^{-4} L./mole/sec., and the k_{NaOH} for the disappearance of the 324 mμ chromo-

31.0	0.20	1.40	0.666
25.0	0.20	0.852	...

phore is 1.92×10^{-5} L./mole/sec. The Arrhenius parameters, (Eq. 8) ΔH_a and log P, for the apparent first-order rate constants for the transformation of the acid-degraded ribose chromophores in 0.20 *M* NaOH were 16.5 Kcal./mole and 7.0 for the loss of the $\lambda_{max.}$ 277 mμ and 21.3 Kcal./mole and 9.1 for the loss of the resultant $\lambda_{max.}$ 324 mμ.

Correlation of the Chromophore of Acid-Degraded Ribose with Furfural—It is well-known that furfural is the major product of acid degradation of ribose (16). The ultraviolet spectrum of furfural in 1.0 *M* HCl is exactly that of acid-degraded ribose (Fig. 1). The bands at $\lambda_{max.}$ of 277 mμ and 227 mμ have a ratio of absorbances for furfural A_{277}/A_{227} = 3.78, whereas the spectrum of acid acid-degraded ribose of an equivalent absorbance, $A_{277} = 1.5$, has a ratio of absorbances of 3.68. Furfural in 0.28 *M* NaOH at 45.0° loses its chromophore at 277 mμ with a slight hypsochromic shift. Concomitantly a less intense band at $\lambda_{max.}$ 324 mμ arises with a clear isosbestic at 301 mμ. These are exactly the properties of the chromophore of acid-degraded ribose (Fig. 7). The molar absorptivity of furfural ϵ_f at 277 mμ is 14,962 in agreement with the literature value of 14,800 (17). Thus the ultimate yield of furfural after 200 hr. from acid degradation of ribose at 80.0° in 1.0 *M* HCl is 7,160/14,962 = 47.8%.

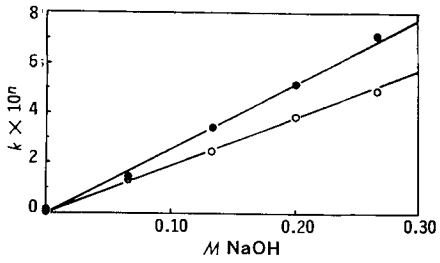

Fig. 8—Dependence of the apparent first-order rate constant, k in sec.$^{-1}$, on the NaOH concentration for the disappearance of the chromophores of the products of acid-degraded ribose at 45.0° where n = 5 for $\lambda_{max.}$ 277 mμ (●) and n = 6 for $\lambda_{max.}$ 324 mμ (○).

Both furfural and the chromophore of acid-degraded ribose are readily extracted from 1.0 *M* HCl by chloroform. When equal volumes of chloroform and 1.0 *M* HCl were used, 94.4% of the 277 mμ absorbance was extracted from the aqueous phase as compared to 94.5% of the 277 mμ absorbance of acid-degraded ribose.

Solubility Profiles for Antipyrine and Aminopyrine in Hydroalcoholic Solutions

By ANTHONY N. PARUTA

The solubilities of antipyrine and aminopyrine have been determined in binary mixtures of ethanol and water of known dielectric constants. The solubility curves produced in this solvent system were compared with the solubility curves found in dioxane–water mixtures. The dielectric requirements (DR's) are apparently not correlatable in these two solvent systems, and the constancy of DR's may be questioned. The solubility ratios of these 2 solutes in the binary mixtures studied is also discussed. In addition, the dielectric constants of the saturated solutions were determined and compared to the dielectric constants of the binary mixtures. It is felt that these data may lead to a consideration of "solute" or "inherent" polarity for these materials.

IT HAD BEEN shown previously (1) that antipyrine and aminopyrine produced rather unique solubility curves in dioxane–water mixtures. The highly water-soluble antipyrine was characterized by a solubility curve running asymptotically to pure water, whereas aminopyrine was characteristic of an ideal semipolar solute having only one maximum in the solvent mixture. The attributed variation in polarity between antipyrine and aminopyrine was felt to be due to the dimethylamino group in aminopyrine causing both a decrease in the magnitude of solubility and a substantially lower DR, or a shift to lower polarity. This rather large difference, while perhaps not too surprising, was somewhat perplexing. Thus, it was felt judicious that these two solutes should be tested in another solvent system, and in this case, ethanol–water mixtures were chosen. It was also expected that the DR's should also correlate and that the nature of the curves should be essentially similar.

Since it had also been observed (2) that the highly water-soluble antipyrine caused substantial dielectric constant changes in syrup vehicles, the dielectric constants of the saturated solutions were also determined. It is hoped that some useful information might be gained from a knowledge of these values.

EXPERIMENTAL

Materials—The solutes used in this study were aminopyrine USP[1] and antipyrine USP.[2] The solvents used were freshly boiled demineralized distilled water and absolute ethanol USP–NF.[3]

Methods—The protocol used in the analysis of solubility data has already been described (1). No pretreatment of the solutes was considered necessary, and they were used directly. The reported results are the averages of at least 4 runs on each material. Each run was internally averaged for both gravimetric and spectrophotometric procedures. Dielectric constant values were determined from calibration curves as previously described (2).

Equipment—A WTW DK-06 multidekameter was used for dielectric constant determinations, a Bantam demineralizer, model BD-1 with mixed resin bed; Bausch & Lomb Spectronic 505, and a Mettler automatic balance, type H 6T, heated vacuum desiccator.[4] A water bath and attendant temperature controls were used for equilibration media.

RESULTS AND DISCUSSION

Solubility—In Fig. 1, the solubility of antipyrine in mg./ml. is plotted *versus* the dielectric constants of the binary mixture indicated. The solubility of aminopyrine in ethanol–water and dioxane–water mixtures (1) is also shown in Fig. 1.

The data for ethanol–water mixtures are from the present work, whereas that for the dioxane–water system has been taken from a previous communication (1). The dielectric requirement (DR) is seen to have a value of about 55 for antipyrine and about 35 for aminopyrine in ethanol–water mixtures. In dioxane–water mixtures, there may be a slight "shouldering" at a dielectric constant value of about 55 for antipyrine.

It was also shown in another communication (3) that changes, *i.e.*, "appearance" of shoulders, could occur upon changing the composition scale coordinate to a dielectric constant scale coordinate. Although this appearance allows for the correlation of the binary systems in the case of antipyrine, this correlation is considered to be vague. This is especially notable in the case of antipyrine in ethanol–water mixtures where a change in the plotting coordinate does not effect a change in the DR value for this solute.

The solubility curve for aminopyrine in dioxane–water mixtures does not indicate the occurrence of a shoulder, although one can "force" this occurrence, it is deemed as noncorrelation of the DR in these solvent mixtures for this solute.

Since the dielectric constants of the saturated solutions in ethanol–water mixtures were deter-

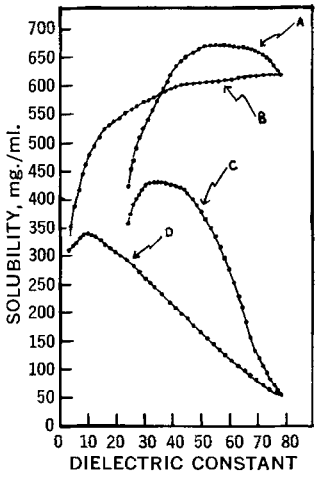

Fig. 1—A plot of the solubilities of antipyrine and aminopyrine in mg./ml. at 25° versus *the dielectric constants of the solvent mixtures. Curves* A *and* C *are for antipyrine and aminopyrine in ethanol–water mixtures. Curves* B *and* D *are for antipyrine and aminopyrine in dioxane–water mixtures.*

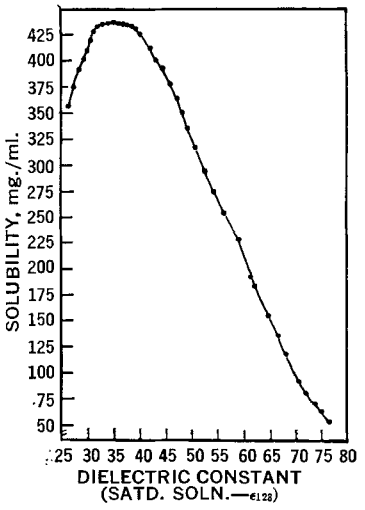

Fig. 3—The solubility of aminopyrine in mg./ml. at 25° versus *the dielectric constant values of the respective saturated solutions.*

mined, it was felt instructive that the solubility curves be plotted *versus* these values. As expected, the solubility curves obtained from this treatment were essentially the same as the curves produced when only the dielectric constants of the solvent mixtures (ϵ_{12}) were used. The solubilities of antipyrine and aminopyrine are plotted *versus* the dielectric constants of the saturated solutions (ϵ_{123}) and are shown in Figs. 2 and 3.

If it were found that the ϵ_{123} and the ϵ_{12} curves were plotted as a function of concentration and these dielectric curves intersected, it would imply that the dielectric constant of the solute might occur at this point of intersection. In other words, the addition of solute to a given composition does not change the dielectric constant of the solvent mixture. Furthermore, were the point of intersection to lie close to the dielectric requirement, where maximum solubility occurs, it would further indicate that solute polarity and solvent polarity were equal in magnitude. This would probably indicate the essential embodiment of either the solubility parameter or dielectric requirement approaches since solubility is maximized when there is no difference in the polarity of the solute and solvent mixture. This is seen to be the case for antipyrine (Fig. 4) and for aminopyrine (Fig. 5) having points of intersection for antipyrine and aminopyrine at 51–53 and 35, respectively, whereas the dielectric requirements were 53–55 and 35, respectively. At any point away from the intersection, one observes either an increase or decrease in the dielectric constant of the saturated solution relative to the solvent system.

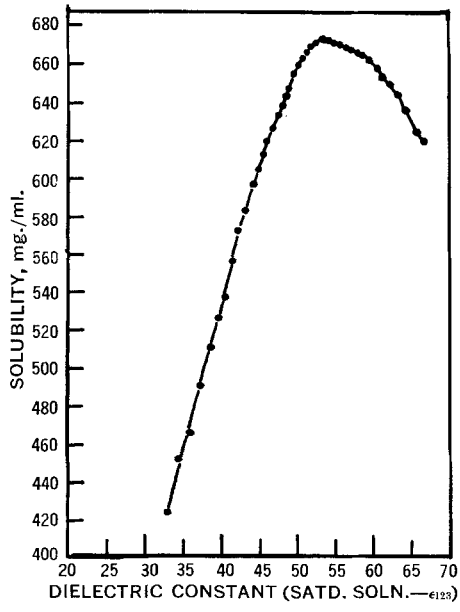

Fig. 2—The solubility of antipyrine in mg./ml. at 25° versus *the dielectric constant values of the respective saturated solutions.*

Since the dielectric constants and solubilities were known, it would then be possible to calculate the approximate change in the dielectric constant of the solvent system/mg. of solute added. Although it should be realized that the addition of 1 unit or mg. of a solute to a given solvent composition may not change the dielectric increment in a linear fashion when more units or mg. are added up to saturation, it may be assumed that on the average this linearity may be approximately correct.

In Tables I and II, the values for the dielectric constants of the binary solvent system and the saturated solutions are listed in columns 2 and 3. The dielectric increment, $\Delta\epsilon$, the solubilities, and the dielectric constant change/mg. of solute are listed in columns 4, 5, and 6.

In Table I, the data for antipyrine are given and several interesting observations can be made. Whereas antipyrine in pure water at a concentration of 620 mg./ml. decreases the dielectric constant substantially (11.8 units), the same concentration

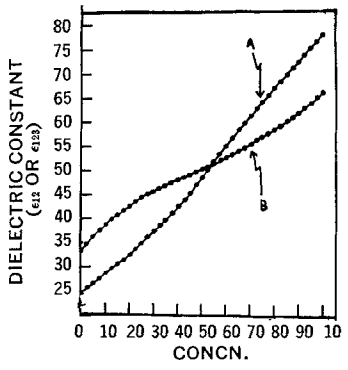

Fig. 4—A plot of the dielectric constants of the solvent mixture (curve A) and saturated solutions (curve B) of antipyrine versus the composition of the solvent mixtures.

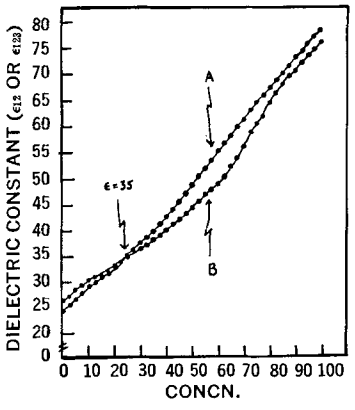

Fig. 5—A plot of the dielectric constants of the solvent mixture (curve A) and saturated solutions (curve B) of aminopyrine versus the composition of the solvent mixtures.

in 70% w/w ethanol–water raises the dielectric constant by 8.5 units.

This may indicate that at these high concentrations of solute, antipyrine and its inherent polarity dominates, and the effect would be one of altering or changing its environment to conform more closely to its own nature.

The dielectric constant increment/mg. of solute has been plotted *versus* the dielectric constant of the solvent system and is shown in Fig. 6 for antipyrine (A) and aminopyrine (B).

In Table II, the data for aminopyrine are given in the same fashion as above, and again there are several interesting observations. It can be seen that although the dielectric increment caused by aminopyrine in pure water is only −2.2 units, the dielectric increment/mg. is 0.042 units which is greater than twice the dielectric increment/mg. for antipyrine which has a value of only 0.019 units. One can also observe that the magnitude of solubility for antipyrine is almost 12 times that of aminopyrine, and thus, the effective dielectric increment of aminopyrine is about 24 times that of antipyrine. The dimethylamino group present in aminopyrine, while causing a diminution of solubility, may also,

because of spacial requirements "thrust" into the hydrogen bonded structure of water more effectively and cause the larger decrease in the dielectic constant. From a mechanistic point of view, one can conceive of the solute "melting," and the liquid produced being miscible with water to a certain extent. Thus, this second "liquid" should lower the dielectric constant of water depending upon its own magnitude. If it is assumed that aminopyrine as the second liquid has an approximate polarity value or dielectric constant of about 35, it should have a

more decided effect of lowering the dielectric constant of water relative to antipyrine which has a value of about 53–55. This would be analogous to the case of adding 2 solvents of differing polarity or dielectric constants. Therefore, methanol should be more effective in lowering the dielectric constant of water, having a dielectric constant value of 33, than glycerin with a value of about 43 at the same concentration. It can be presumed that aminopyrine may be operating through two mechanisms: the first by having an inherent polarity lower than antipyrine, and the second by the side chain thrust into the bonded structure of water.

Although antipyrine is more effective in reducing the dielectric constant of water and ethanol–water mixtures up to about 40% w/w ethanol, antipyrine is also far more effective in increasing the polarity or dielectric constant of ethanol and water–ethanol mixtures up to about 20% w/w water. The dielectric increment/mg. of solute has been summarized in Table III. In this case, the composition for the binary mixtures is given in the first column. The dielectric increment/mg. solute and the ratios of the increments, where their value is greater than unity, are also shown. It can then be seen that the polarity adjustment for any given solvent composition by a given solute probably depends on the inherent polarity of that solute.

Magnitude of Solubility—There are several ways in which the solubilities of these compounds in 2 solvent mixtures can be viewed. The solubility of antipyrine and aminopyrine in each solvent mixture at common dielectric constant values is shown in Tables IV and V. In this case, the solubilities of the solutes in mg./ml. for dioxane–water and ethanol–water is given in the first 2 columns. The last column shows the solubility ratio, the solubility of the solute in ethanol–water mixtures relative to dioxane–water mixtures.

In Table IV, the data for antipyrine illustrate that ethanol–water mixtures over the dielectric constant range of 35–75 are more efficient cosolvents but only to the extent of 5–10%. Furthermore, at dielectric constant values below 35, dioxane–water mixtures are more efficient cosolvents.

However, in Table V, the aminopyrine data show that ethanol–water mixtures possess far greater cosolvency than dioxane–water mixtures. This greater cosolvency is also seen to occur over the given range of dielectric constant values, 25–75. The increase in solubility caused by the ethanol–water cosolvents is seen to span a range of 22–230%.

This would then lead to the consideration of the ratio of solubility of antipyrine relative to aminopyrine in the 2 binary solvent systems studied. These data are shown in Table VI, where at various dielectric constant values the ratio of the solubility of antipyrine relative to aminopyrine is given for dioxane–water and ethanol–water mixtures. The

far greater cosolvency effect of ethanol–water on aminopyrine is seen in the smaller ratios in this solvent mixture.

SUMMARY

It can be observed from Fig. 1 that in both cases the polarity of antipyrine is greater than aminopyrine by virtue of possessing both higher DR's and magnitude to solubility. Furthermore, the solubility curve for aminopyrine moves closer with respect to both DR and magnitude in the solvent mixture of higher polarity. It would be interesting to note how these differences in DR and magnitude would change by the use of more polar binaries such as methanol–water mixtures and less polar binaries such as propanol–water mixtures.

It may be assumed for this particular pair of solutes in the systems studied that from the differences in the position of the DR's and the concomitant magnitude that antipyrine is inherently more polar than aminopyrine. This is further substantiated by the characterization of solute polarity from dielectric constant studies of saturated solutions.

The rather obvious noncorrelation of DR in the 2 solvent systems for aminopyrine and the vague correlation in the case of antipyrine may imply that the concept of DR agreement, irrespective of the solvent system, is suspect.

Although previous publications (4, 5) had assumed that this concept was true, and at times tenuously true, it is now reasonable to postulate that the solubility profiles and respective DR(s) may be considered unique unto themselves in any given solvent system, a situation previously reported (6–9).

It is felt that this does not obviate either the usefulness or application of this knowledge, and that the cosolvency phenomena relative to dielectric constants has been amply illustrated. It is hoped that continuing studies on solutes of pharmaceutical interest relative to the above points will allow amplification and reinterpretation of past experiences in this area.

Presently, the author's research interests are concerned with the parabens and barbiturates, and these will be the subject of future communications.

Pharmaceutical Heterogeneous Systems I

Hydrolysis of Aspirin in Combination with Tablet Lubricants in an Aqueous Suspension

By S. S. KORNBLUM and M. A. ZOGLIO

The chemical mechanism that explains the accelerated hydrolysis demonstrated by aspirin when in combination with an alkali stearate, *i.e.*, calcium stearate, in a solid dosage form has been elucidated by employing a suspension technique. The mechanism primarily involves a reaction of the alkali cation with aspirin in a solution to form a salt of aspirin which, in the presence of solvated aspirin, comprises a buffer system at a pH detrimental to the stability of aspirin. Using the kinetic data obtained from the suspension study, an attempt was made to predict aspirin stability in a solid dosage form. There is evidence presented to support the concept that stearic acid will serve as a medium for aspirin degradation at temperatures slightly above room temperature.

PREVIOUS RESEARCHERS (1–4) studying the hydrolysis of aspirin in either a homogeneous or heterogeneous aqueous system have demonstrated that decomposition is a function of water content, pH, and temperature. An aspirin tablet can be identified as a heterogeneous system. One may compare an aspirin tablet with an aqueous aspirin suspension in order to facilitate an explicit definition of the hydrolysis phenomena. The effect of antacids in mixtures with aspirin has been studied in the presence of moisture and has been demonstrated to increase decomposition rate (5, 6). Some substances employed as tablet lubricants can effectively act as antacids, *e.g.*, stearate salts. The purpose of this study was to evaluate the commonly used tablet lu-

bricants as to their effect on the stability of aspirin and define the chemical mechanisms that lead to an accelerated hydrolysis in mixtures of aspirin and alkali stearates.

EXPERIMENTAL

Aqueous Aspirin Suspensions—Mixtures of equal quantities (200 mg.) of aspirin crystals (USP) and various tablet lubricants: talc, stearic acid, hydrogenated vegetable oil,[1] calcium stearate, magnesium stearate, and aluminum stearate were prepared. Excess lubricant was employed in an attempt to insure saturation throughout the experiment. The weighed powders were transferred into glass vials of 18.5 ml. capacity and exactly 10 ml. distilled water was added to form a suspension. To prevent leakage the vials were sealed with aluminum foil before securing with Bakelite caps. The vials were then attached to a rotating circular disk in a constant-temperature bath which permitted continuous agitation at 30°. Appropriate aliquots were withdrawn at various time intervals for pH and free salicylic acid determinations. The amount of free salicylic acid formed was determined by adding to an exact volume of the suspension filtrate 4 ml. of 2% ferric chloride solution with subsequent dilution to 100 ml. with distilled water. Exactly 3 min. was permitted for the color development before reading at 540 mμ employing the Perkin-Elmer 202 spectrophotometer. The validity of the salicylic acid assay was demonstrated by adherence to the Beer-Lambert law over the concentration range studied. pH values were obtained by using a Metrohm E 300.

Determination of Aspirin Species in Suspension Filtrate—Total aspirin content was determined by withdrawing a 1-ml. aliquot of the suspension filtrate and diluting to 100 ml. with a 0.2 *M* sodium acetate–acetic acid buffer solution (pH 6.09). The spectrophotometric reading was taken at 268 mμ.

Calcium aspirin content was determined by withdrawing a 5-ml. aliquot of the suspension filtrate and diluting with distilled water to 150 ml. The pH of this solution was adjusted to 12.0–12.5 using 1 *N* sodium hydroxide solution. Hydroxynaphthol blue A.R. was employed as the indicator in a 0.2–0.3 Gm. quantity. The solution was titrated with 0.05 *M* disodium EDTA solution to a clear blue color. Each milliliter of 0.05 *M* disodium EDTA solution is equivalent to 2.0064 mg. of calcium ion.

Free aspirin contained in the suspension filtrate was calculated from the following equation:

$$\text{free aspirin} = \text{total aspirin} - \text{aspirin as calcium aspirin}$$

Effect of Reducing the Water Content in an Aqueous Aspirin–Calcium Stearate Suspension—A study was performed in order to establish the effect of decreasing the water content of the suspension from 10 to 0.1 ml. Below 1 ml. glass beads were placed in the reaction vials to insure uniform agitation. When less than 5 ml. was employed, the suspension was diluted at the time of withdrawal for analysis to contain 10 ml. of water.

Effect of Stearic Acid on Aspirin Degradation in a Solid Mixture Study—Aspirin crystals were dissolved in molten stearic acid USP in a 1:80 ratio at 75°. Equal quantities of the melt were transferred into glass vials and tightly sealed. The melt was quickly cooled by immersion in an ice bath. Samples were then kept in an oven at 40 ± 0.5° and routinely assayed after exact weighing of approximately 800 mg. of the solidified melt. The solidified melt was dissolved and diluted with chloroform to a volume of 200 ml. The solution was spectrophotometrically read in the UV at 310 mμ.

Aspirin crystals containing approximately the same amount of moisture as the stearic acid melt were stored at 40° and used as a control. Moisture present in the samples was determined by Karl Fischer titration. The analytical method employed for the aspirin crystals is outlined in the next section.

Aspirin–Stearic Acid Capsule Study—The following samples were prepared and stored at room temperature, 40°, and 50°: (*a*) aspirin–stearic acid powder blend (20:1 ratio), aspirin–stearic acid capsules[2] (20:1 ratio), (*c*) aspirin crystals, 40 mesh, (*d*) aspirin capsules.[2]

The samples were assayed for salicylic acid after dissolving a quantity equivalent to 200 mg. of aspirin in 10 ml. of chloroform. The solution was transferred to a diatomaceous earth[3] column which had been previously moistened with 2% ferric chloride solution. The column was washed with chloroform until the purple zone migrated to the lower portion of the column. These washings were discarded. Subsequently the column was washed with 10 ml. of 10% acetic acid–chloroform followed by 1% acetic acid–chloroform until the purple zone was eluted. These washings were concentrated to 50 ml. and read spectrophotometrically at 310 mμ. Moisture content of the samples studied was determined by Karl Fischer titration.

Aspirin Degradation in Aspirin–Calcium Stearate Tablets—Tablets were manufactured containing aspirin crystals and calcium stearate (1:1 ratio). The tablets were stored at 30° for 60 days. At the time of assay the tablets were comminuted and a quantity of 400 mg. of the powder was dissolved in 20 ml. chloroform and mixed for less than 1 min. This was rapidly passed through a Millipore membrane into a separator and aqueous washings followed to remove any calcium aspirin. The chloroform solution was passed through a diatomaceous earth column. From this point the analysis proceeds as described under *Aspirin–Stearic Acid Capsule Study*.

RESULTS AND DISCUSSION

The kinetics observed for the hydrolysis of aspirin in the presence of tablet lubricants is depicted in Fig. 1. The reaction rates appear to follow a zero-order reaction law with the exception of the initial rates for the aspirin–calcium stearate and the aspirin–magnesium stearate suspensions. The linear portion of the decomposition curves for each of the aspirin–lubricant combinations was accompanied by a relatively static hydrogen ion concentration for the 30-hr. period studied. A summary of pH values and reaction rate constants for the apparent zero-

order degradation is given in Table I. The order of magnitude of the reaction rates for aspirin–calcium stearate and aspirin–magnesium stearate suspensions suggested that something other than saturation solubility had manifested the relatively high pH during decomposition. The possibility existed that perhaps a reaction between aspirin and the stearate salt had taken place. If so, then a high concentration of magnesium or calcium aspirin could be expected in solution. The aspirin salt would exert a buffering effect in combination with aspirin in the solvate portion of the suspension. In order that this theory could be verified the quantity of calcium transferring into solution was followed as a function of time during the 30-hr. reaction period. Figure 2 demonstrates that the quantity of calcium ion in solution very quickly exceeds its aqueous saturation solubility (0.02 mg./ml.) in the presence of aspirin and rises radically during the initial 3-hr. period. The period of constant pH is established

TABLE I—PERTINENT DATA FOR ASPIRIN SUSPENSIONS STUDIED[a]

Compn.	Constant pH (Arithmetic Mean)[b]	Apparent Zero-Order Rate Constant, mg. of Free Salicylic Acid/hr.
Aspirin	2.60	0.123
Aspirin + stearic acid	2.62	0.133
Aspirin + hydrogenated vegetable oil	2.68	0.123
Aspirin + talc	2.71	0.133
Aspirin + aluminum stearate	3.16	0.281
Aspirin + calcium stearate	3.75	0.986
Aspirin + magnesium stearate	4.14	1.314

[a] All aspirin suspensions contained exactly 10 ml. distilled water. [b] The arithmetic mean has been determined from a minimum of 6 pH values.

during the first 10 hr. in the aspirin–calcium stearate suspension studied and is thereafter followed by a relatively unchanging calcium ion concentration. The information obtained supports the existence of a buffer system composed of calcium aspirin and aspirin which appears to be controlling the pH from the 10th to 30th hr. of the reaction. Figure 3 establishes the fact that there does exist approximately a 2:1 ratio of calcium aspirin to aspirin in the buffer system. The amount of aspirin shown in Fig. 3 at the 5th hr. is representative of the saturation solubility for aspirin at 30° in the suspension system. This concentration of aspirin is henceforth maintained throughout the 30-hr. time interval studied.

The initial S-shaped portion of Fig. 1 for the aspirin–calcium stearate and aspirin–magnesium stearate systems can be explained by analyzing the data for pH (Fig. 4) and species of aspirin in solution (Fig. 3) *versus* time. Figure 4 depicts a sharp increase in pH for the aspirin–calcium stearate system which then rises to a peak after about 3 hr. and then reverses to establish a constant pH. Observation of Fig. 3 makes it possible to explain the initial rise in pH as a result of the rapid formation of the calcium salt of aspirin. However, the dissolution rate of aspirin falls short of maintaining the saturation of aspirin during the initial stage of the salt-forming reaction. After 1.5 hr. the concentration of aspirin diminishes thus allowing the pH of the solution to be further elevated by the predominance of calcium aspirin. When the reaction has progressed for 3.5 hr., the dissolution rate of aspirin catches up with the utilization of aspirin in the salt formation. By virtue of the lower saturation pH of aspirin in solution (pH = 2.66), as compared with calcium aspirin in solution (pH = 4.2), the system stabilized to a buffer pH at 3.75 and remained constant over the 30-hr. period studied.

Experiments were performed where the amount of water employed in the suspensions was reduced in order to approach that found in a solid dosage

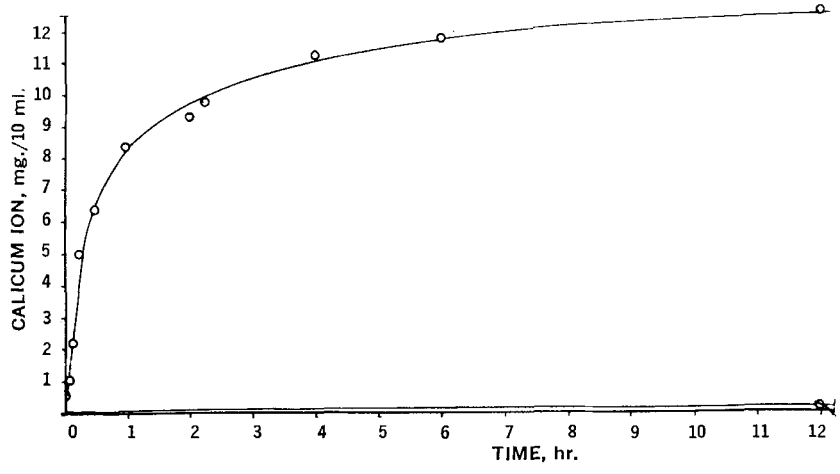

Fig. 2—Calcium ion concentration in solution during the initial segment of the aspirin–calcium stearate suspension study.

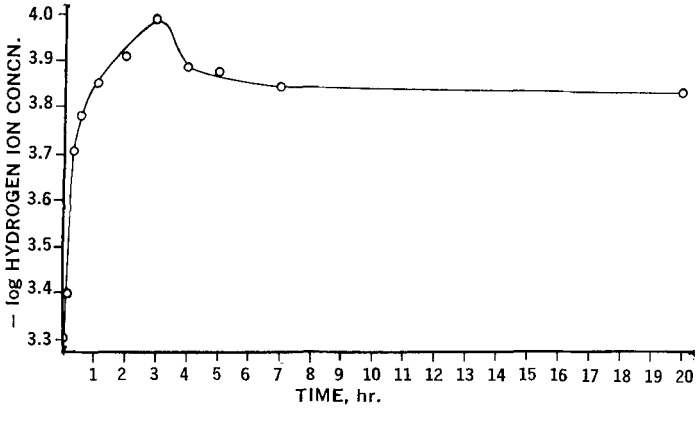

Fig. 4—pH changes occurring during the aspirin–calcium stearate suspension study (each sample contained 10 ml. water).

form. The ultimate aim was the achievement of data that would permit subsequent extrapolation to the tablet or capsule dosage form. Zero-order rate constants for the aspirin-calcium stearate aqueous suspensions were determined as a function of water content, and the data have been plotted in Fig. 5. The curve fortunately appears to be linear in the region of low water content enabling

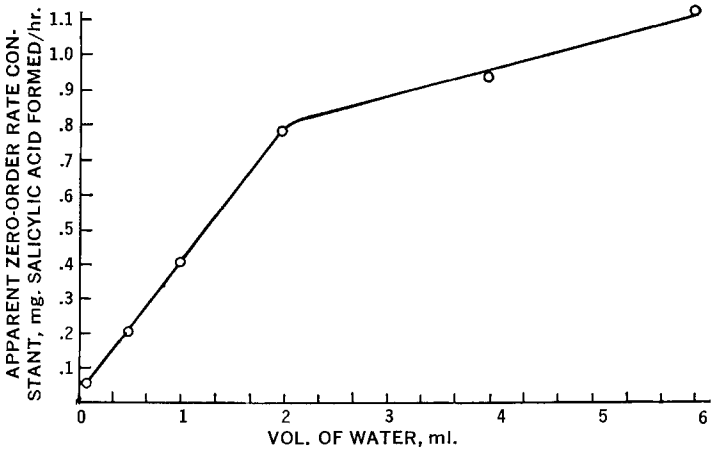

Fig. 5—Relationship of the rate of salicylic acid formation to the volume of water contained in the aspirin–calcium stearate suspension

a correlation with the solid dosage form data. The change of slope above 2 ml. is most likely due to insufficient amounts of calcium aspirin in the system to accomplish saturation. When the aqueous solubility of calcium–aspirin (0.165 Gm./ml.) is used to estimate the volume of water at this change in slope, 0.8 ml. would be indicated. The higher value in Fig. 5 indicates the solubility of calcium aspirin to be considerably lower in the system studied. Table II shows that the pH of the suspensions possessing minimal water content ascends until the pH reaches the saturation pH of calcium aspirin which is 4.2 at 2 ml. It is assumed that the linearity experienced at volumes less than 2 ml. is a result of the saturation of the water with calcium aspirin and the maintenance of the pH observed at 2 ml. The predictive aspects of the results are limited, since the reactions were only studied for a 30-hr. period. From observing Fig. 6, one can see that the pH for a period longer than 30 hr. is not a constant as was true in the suspensions studied. As the degradation products accumulate, the pH declines, until after 8 days a constant pH does exist. The data from Fig. 5 prove valuable in predicting maximum decomposition to be expected in a solid dosage form. This is true even though the reaction rate studies with the suspensions were conducted at pH values more detrimental to aspirin stability than those observed with an extended study (Fig. 6). Aspirin–calcium stearate (1:1 ratio) powder blend and tablets of the same composition were prepared. Both were stored for a 2-month period at 30°.

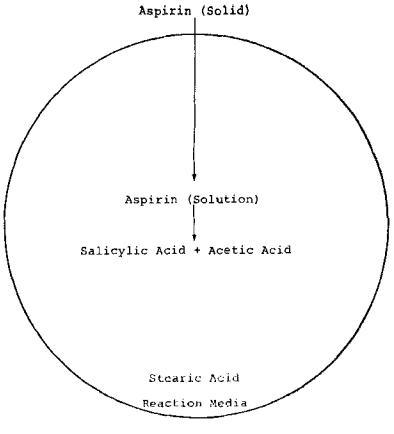

Fig. 12—Anhydrous aspirin degradation in the presence of stearic acid at 40°.

Table III reveals that data obtained from suspension studies can be satisfactorily compared with solid state information, thus enabling one to predict the extent of decomposition in the solid state from suspension data.

The data provided in Figs. 1 through 6 and Tables I and II substantiate the explanation, (Figs. 8–11), of the mechanism involved for the aspirin–calcium stearate system. The presence of moisture in the dosage form results in a solution of the aspirin and the stearate salt as illustrated in Fig. 8 (Figs. 2 and 3). In Fig. 9 calcium stearate and aspirin are shown reacting to form calcium aspirin and stearic acid (Figs. 2 and 3). Initially the buffer system (Fig. 10)

is mainly composed of calcium aspirin and aspirin which establishes a pH value detrimental to aspirin stability. In Fig. 11 the calcium–aspirin and aspirin in solution are shown undergoing hydrolysis (Fig. 1). The decomposition products being more acidic in nature than the aspirin–calcium aspirin system eventually overcome the capacity of the buffer system and lower the pH (Fig. 6). Again the pH levels at a lower value than the initial buffer pH but is still detrimental to aspirin stability.

The evaluation of the lubricants from the results in Fig. 1 indicate stearic acid and hydrogenated vegetable oil to be suitable for use in aspirin tablets. Although stearic acid does not demonstrate a pH effect, it apparently can serve as a medium for aspirin decomposition (Fig. 12). This can be demonstrated by comparing the stability of aspirin with aspirin–stearic acid in powder and capsule forms that have been stored at 22°, 40°, and 50° (Table IV).

Free salicylic acid content is significantly higher in the capsules than in the powder, most likely as a result of the water content in the gelatin. Figure 7 shows the degradation effect more dramatically when aspirin is suspended in molten stearic acid and stored at 40°.

CONCLUSION

From the kinetic data obtained with the aspirin–lubricant combinations it appears feasible that the suspension technique employed may be useful in solid dosage form stability predictions, lubricant evaluation, and as a basic method for elucidation of the chemical mechanism for other solid state decomposition.

Figure 1 illustrates the relative acceptability from a stability standpoint of tablet lubricants for combination with aspirin. The order is as follows: hydrogenated vegetable oil, stearic acid, talc, and aluminum stearate. This study has revealed that stearate salts should be avoided as tablet lubricants, if the active component is subject to hydroxyl-ion catalyzed degradation and if there is contained in the dosage form an ingredient which can react with the stearate salt to form a soluble basic species. Aluminum stearate appears to be the most suitable of the alkali stearate salts for combination with aspirin. This seems to be a result of the poor water solubility of aluminum aspirin thus limiting the total aspirin present in solution. Aside from the pH effect, the major factor influencing degradation when aspirin is combined with calcium or magnesium stearate in suspension is the high solubility of calcium aspirin and magnesium aspirin in an aqueous medium.

Talc possesses trace amounts of oxide impurities that affect the pH of the suspension initially, thus causing a slight increase in the amount of salicylic acid formed. However, this does not influence the over-all reaction rate (Table I). Talc can be used with mixtures of stearic acid and hydrogenated vegetable oil, but is not usually employed solely as a tablet lubricant due to its low ratio of efficiency.

Stearic acid appears to be suitable from the suspension studies. However, it has been noted that stearic acid may function as a medium for aspirin degradation at temperatures slightly above room temperature.

Kinetics and Mechanisms of Action of Drugs on Microorganisms VII

Quantitative Adherence of Sulfonamide Action on Microbial Growth to a Receptor-Site Model

By EDWARD R. GARRETT and OLGA K. WRIGHT

The lag time between sulfonamide addition to a balanced growth culture of *Escherichia coli* B/r and the observation of action on microbial growth is 5.5 ± 0.5 generations. It is independent of temperature and the degree of growth inhibition by simultaneously added chloramphenicol. The apparent first-order growth rate constants of *E. coli* in the subsequent drug-affected steady state can be rigorously defined as $k_{app.} = k_0 - k_0K_1K_2S/(1 + K_1K_2S)$ where k_0 is the rate constant in the absence of a sulfonamide concentration, S; K_1 is the steady-state equilibration of sulfonamide between the nutrient medium and the biophase; K_2 is the drug-receptor site association constant; and k_0 and K_1K_2 have been defined as functions of absolute temperature. The death rate of completely sulfonamide-inhibited organisms is independent of sulfonamide concentrations. The ΔH values of $1/K_1K_2$ differ for sulfisoxazole (15.9 Kcal./mole), sulfathiazole (4.3 Kcal./mole), and from the k_0 (24 Kcal./mole). The techniques provide sensitive and reliable estimates of differences in sulfonamide activities. The derived $1/K_1K_2$ values for sulfisoxazole are directly proportional to the growth rate constant in its absence but in the presence of rate-inhibiting chloramphenicol. This indicates that the numbers of receptor sites available for sulfonamide action are directly proportional to the microbial growth rate. The apparent first-order growth rate constant of *E. coli* in the presence of simultaneously added sulfonamide (S) and chloramphenicol (C) concentrations can be rigorously defined as $k_{app.} = [k_0' - k_cC][1 + K_1K_2(S - 1)]/(1 + K_1K_2S)$, where k_0' is the growth rate constant in the absence of chloramphenicol and sulfonamide and k_c is the determined inhibitory constant for chloramphenicol. Variations of sulfonamide concentrations after the lag phase demonstrate that reversibility exists and the ultimate $k_{app.}$ is in accordance with the cited predictive equation. Dilution of organisms but maintenance of sulfonamide concentrations maintains the steady-state growth rate. Addition or dilution of sulfonamide concentrations show a time-dependent re-equilibration. These facts are consistent with a competitive receptor site model for sulfonamide and a generation rate-dependent metabolite which produces modified metabolites that are stored during drug-free balanced growth.

THE VARIATION of the time-course of drug distribution in a complex organism when considered with the concomitant time-course of pharmacological activity can give insight into the properties and nature of the biophase in contact with the drug receptors. Operational models of the complex biological organism are needed to correlate drug–receptor interaction and availability at sites of action. Multicompartmental models can be established to consider and quantitatively define the kinetics of drug absorption, distribution, and biological effectiveness (1). If dosage regimens are varied, deduced compartmental capacities and rate-limiting parameters of the drug distributive processes that result in observed biological activities may functionally define the transport processes and the affinity constants of drug–receptor interaction. Unfortunately, valid quantitative and continuous measurements of pharmacological activity in a complex organism are difficult to obtain.

This paper describes the pharmacokinetic approach to the study of the action of sulfonamides on microbial growth rates in a highly reliable and reproducible system. The kinetic dependencies will be defined as functions of sulfonamide concentrations, variations in such concentrations, temperatures, and numbers of organisms, and will be related to receptor site concepts. Similar studies have been given previously with respect to the action of the chloramphenicols and the tetracyclines on microbial growth rates (2–8).

Kohn and Harris (9, 10) initiated some studies of a kinetic nature on sulfonamide action on microbial growth and made many astute observations from technologically limited data. The variability of pH observed was undesirable since sulfonamide transport and microbial growth rates are claimed to be functions of pH (11, 12).

Received April 6, 1967, from the College of Pharmacy, University of Florida, Gainesville, FL 32601
Accepted for publication August 3, 1967.
Presented in part to the Medicinal Chemistry Section, APhA Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.
The technical assistance of George L. Perry and rewarding discussions with Professor Arthur L. Koch are acknowledged.

It is not clear from their cited evidence (9, 10) if the inoculum was in balanced growth (13, 14) so that the organisms would be statistically distributed among the phases of the growth cycle. If this were not so, it is difficult to dissociate sulfonamide action on microbial growth from accelerating rates of microbial growth in the transition from the induction period to the logarithmic growth phase (2). A rigorous rate constant dependence on sulfonamide concentration was not demonstrated (9, 10).

Modern technological advances with the Coulter counter permit rigorous kinetic analyses of large amounts of data of high reliability and the obtaining of numbers of total intact organisms, live and dead. These can be compared with the numbers of viable organisms obtained by colony count techniques. Coincidence of such numbers of total and viable counts during antibacterial action clearly defines inhibition (5–8).

MATERIALS AND METHODS

The *Escherichia coli* B/r strain was used as the test organism throughout the investigation. The sodium sulfathiazole (Nutritional Biochemicals Corp., Cleveland, Ohio) and sulfisoxazole (Hoffmann-LaRoche Laboratories, Nutley, N. J.) were the drugs studied.

Media—The culture media (15) consisted of 7.00 Gm. K_2HPO_4, 3.00 Gm. KH_2PO_4, 2.0 Gm. glucose, 1.0 Gm. $(NH_4)_2SO_4$, 0.50 Gm. sodium citrate, 0.10 Gm. $MgSO_4 \cdot 7H_2O$, 10.0 Gm. vitamin-free casamino acids (Difco Laboratories, Detroit, Mich.), and 1 L. of distilled deionized water. This medium was filtered twice through a 0.45-mm. Millipore filter and autoclaved at 15 lb. of pressure for 20 min. The pH was 6.90 and did not change throughout the studies. This medium was optimum for the studies in that the time for each study was minimized and the pH maintained constancy throughout the measured growth range. When an inorganic salt–glucose medium was used, the rates of microbial growth were too slow for convenient kinetic studies.

Growth—Replicate slants were prepared from a single colony of *E. coli*, strain B/r, that was isolated from a culture on an agar plate. These slants were frozen and a separate one was used for each experiment. A broth culture was allowed to grow at 37.5° for 16 hr. A sample was then diluted tenfold in fresh broth and the growth was followed by the Coulter counter, model B, (Coulter Electronics Co., Hialeah, Fla.) until it reached an organism concentration of 1×10^8 organisms/ml. in the logarithmic growth phase. Samples were diluted into 5 or 6 replicate 50-ml. volumes of fresh broth in 125-ml. loosely-capped conical flasks to achieve the desired organism concentration. The replicate cultures were maintained at a constant temperature in a 50-gal. constant-temperature water bath equipped with a shaker.

Total Count Method—Appropriate small volume aliquots of each culture were transferred at 40-min. intervals to sterilized vials containing 1 drop of formaldehyde to kill the organisms (5). The samples were appropriately diluted with properly filtered and sterilized 0.9% saline solution so that the total organism count per 50 μl. would not exceed 35,000. The coincidence error was thus less than 0.5% on the Coulter counter model B equipped with a 30-μ orifice. The mean of 3 total counts was obtained on each sample (5–7).

The Coulter counter with this orifice size is able to count particles above 0.5 μ in diameter without significant interference from background noise (Coulter Counter Manual, model B, 4th ed., August 1966). There are negligible numbers of *E. coli* with a volume less than 0.5 μ^3 (14) or a diameter less than 1 μ (16) at our generation rates. Operational counting of *E. coli* has been clearly shown to be effective (5, 14) and in agreement with colony counts. This was also true in the many instances where only bacterial growth inhibition was manifested (5–8).

Viable Count Method—The growing culture, 0.5 ml., was diluted appropriately with 0.9% saline so that 60 to 100 colonies per plate would result. One milliliter of this solution was pipeted onto each of 5 replicate agar plates. The plates were incubated for 48 hr. at 37.5° and the colonies were counted (3–5). Bacto antibiotic medium 3 (Difco Laboratories, Detroit, Mich.) was used for broth cultures and plate counts.

Effect of Drug Concentration on Growth Rates—Six 49-ml. volumes of fresh broth in the constant-temperature baths at 37.5° were inoculated with 1-ml. aliquots of appropriately diluted culture growing in the logarithmic growth phase. The organism population was 10^4 organisms/ml. The cultures were allowed to grow for 80 min. to a population of 10^5 organism/ml. At 80 min., 0.5 ml. of appropriately diluted drug was added to the cultures to produce final concentrations of 1.0, 2.0, 3.0, 4.0, 5.0, and 20.0, 50.0, 75.0, and 100.0 mcg./ml. Samples

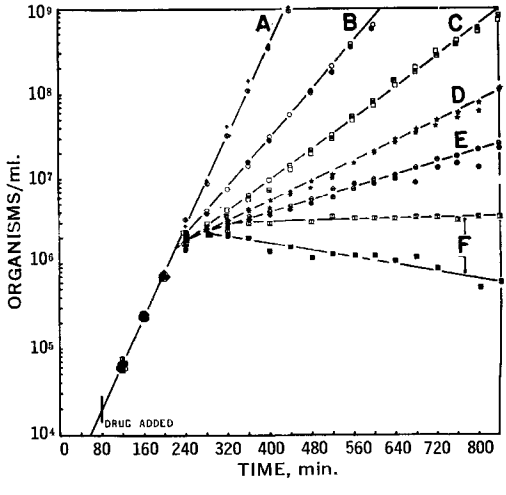

Fig. 1—Typical generation rate curves of E. coli *B/r at 37.5° in the presence of various concentrations of sulfisoxazole. The curves and mcg./ml. concentrations of sulfisoxazole were, respectively:* A, *0.0;* B, *1.0;* C, *2.0;* D, *3.0;* E, *4.0;* F, *20.0. Both viable and total counts were coincident except for the curves* F *where the viable counts (lower curve,* F*) diverged from the total counts (upper curve,* F*).*

were taken every 40 min. and were counted by the Coulter counter method as well as by the method of colony counts (Fig. 1). Sulfisoxazole was tested by both methods. Sodium sulfathiazole was tested only by total counts. A control culture without added drug was also studied to determine the growth rate in the absence of drug.

Effect of Organism Population on Drug-Affected Growth Rates—A series of experiments was conducted at 37.5° in order to check the effect of organism population at the time of drug addition on the bacteriostatic action of sodium sulfathiazole. For each experiment 6 replicate 49-ml. volumes of broth were inoculated with 1 ml. of appropriately diluted culture growing in its logarithmic phase. Experiments were run where the zero time populations were 10^2, 10^3, 10^4, and 5×10^4 organisms/ml. At 80 min. after inoculation, sodium sulfathiazole (0.5 ml. of appropriately diluted master solution) was added to 50 ml. of the cultures to achieve final concentrations of 1.0, 2.0, 3.0, 4.0, and 5.0 mcg./ml. One of the 6 replicates had no drug. The organism populations at the time of drug addition were, 10^3, 10^4, 10^5, and 5×10^5 organisms/ml. Samples were taken every 40 min. and the total count per milliliter was obtained on the Coulter counter.

Reversibility of Drug Action—A 100-ml. volume of broth in a 125-ml. conical flask was inoculated with *E. coli* to a concentration of 10^3 organisms/ml. (curve A in Fig. 2). The culture grew logarithmically at 37.5° for 80 min. to a population of about 10^4 organisms/ml. For this and the subsequent variations unless specified otherwise, samples were analyzed for total Coulter count every 20 min. At 80 min. a 1.0-ml. aliquot of an appropriately diluted solution (in fresh broth) of sulfisoxazole was added to the culture to give 1.0 mcg./ml. (curve B) and 5.0 mcg./ml. (curve C). At 340 min., after the culture of curve B (Fig. 2) had well-settled to a new logarithmic growth, 25 ml. of this culture was transferred to a sterile 125-ml. conical flask containing enough sulfisoxazole to increase the drug concentration to 5 mcg./ml. (curve D). The growth of this new culture (curve D, Fig. 2) was followed by total Coulter counts every 40 min. for 960 min.

At 280 min., when the culture of curve C (Fig. 2) growth curve was emerging from the lag period and had not yet reached the new steady state of logarithmic growth, a 5-ml. aliquot of the culture was diluted with 20 ml. of fresh broth in a 125-ml. flask (curve E, Fig. 2).

At 600 min. two 5-ml. aliquots of the culture treated with 5 mcg./ml. sulfisoxazole at 80 min. (curve C, Fig. 2) were diluted with 20 ml. of fresh broth. The final drug concentration of one of the new cultures (curve F, Fig. 2) was thus 1 mcg./ml. Enough drug was added to the second culture to maintain the 5 mcg./ml. drug concentration (curve G, Fig. 2).

Effect of Temperature on Drug-Affected Growth Rates—The inhibitory actions of sodium sulfathiazole and sulfisoxazole on the population growth of *E. coli* were studied at 24.7°, 26.0°, 29.3°, 32.0°, 34.7°, 37.5°, and 39.5°. Logarithmic-phase cultures at 4 concentrations of each drug of 1.0, 2.0, 3.0, and 4.0 mcg./ml., and one culture without drug, were studied by the Coulter count method at each temperature.

Combined Action of Sulfa Drugs and Chloramphenicol—Replicate 50-ml. *E. coli* cultures in the logarithmic growth phase at 37.5° were treated with all combinations of 3 concentrations of chloramphenicol and 4 concentrations of sulfisoxazole. The chloramphenicol concentrations were 0.33, 0.67, and 1.00 mcg./ml. The sulfisoxazole concentrations were 1.0, 2.0, 3.0, and 4.0 mcg./ml.. The drugs were added 80 min. after inoculation of the cultures in the logarithmic growth phase. The Coulter count method was used.

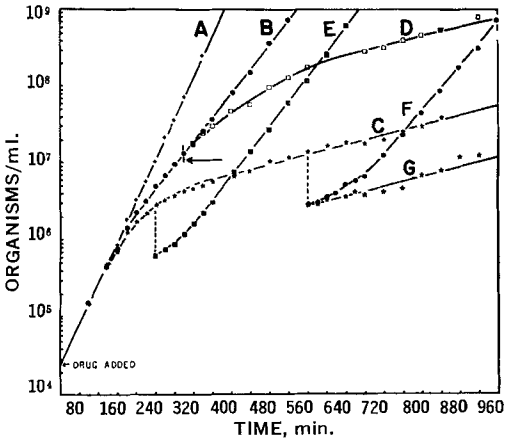

Fig. 2—Generation rate curves of E. coli *B/r at 37.5° on addition and dilution of sulfisoxazole. The population on initial drug addition was 1.6 × 10^4 organisms/ml. The curves, final mcg./ml. concentrations of sulfisoxazole, and apparent steady-state growth rate constants, $k_{app.}$, in sec.$^{-1}$, were:* A, *0.0, 50.2 × 10^{-5};* B, *1.0, 30.2 × 10^{-5};* C, *5.0, 6.29 × 10^{-5};* D, *5.0, 6.00 × 10^{-5};* E, *1.0, 30.9 × 10^{-5};* F, *1.0, 27.6 × 10^{-5};* G, *5.0, 6.28 × 10^{-5}. Arrow on curve* B *denotes more drug added to total 5 mcg./ml.*

RESULTS

Effect of Drug Concentration on Growth Rates—The number of organisms per ml. is plotted against time on semilogarithmic paper for various amounts of sulfa drugs. The example given in Fig. 1 is for sulfisoxazole. A lag period of approximately 120 min. existed before there was any significant effect of any concentration of drug on the population growth of *E. coli* in the logarithmic growth phase at 37.5°. The lag time was the same for both sulfisoxazole and sodium sulfathiazole. Subsequent to the deviation of drug-affected population growth from the control curve, a new linearity in logarithmic growth was attained. At a dosage of 20.0 mcg./ml. that produced complete inhibition of microbial population growth (line F, Fig. 1) and apparent death (line F, Fig. 1) there was an intermediate period of 40–60 min. duration before the new steady-state drug-affected growth curve was established.

At higher dosages of 50.0, 75.0, and 100.0 mcg./ml. the growth curves were superimposable and independent of the dose. Subsequent to the lag period for these higher dosages, the rate of growth decreased, and the maximum value in the number of organisms was obtained 50 min. after the deviation from the initial growth period. A slowly accelerating decay rate in viable organisms was then ob-

[a] Sulfisoxazole and chloramphenicol added to 10^5 organisms/ml. [b] The $k_{app.}$ values in sec.$^{-1}$ prior to the addition of chloramphenicol 0.33, 0.67, and 1.00 mcg./ml. were 5.10, 5.12, and 5.17 × 10^{-4}, respectively. [c] These values were obtained from the slope and intercept of the plot $S/(k_0 - k_{app.})$ *versus* S in accordance with the expression: $S/(k_0 - k_{app.}) = 1/k_a + (k_b/k_a)\,S$. [d] Reciprocal of slope of such a plot. [e] Ratio of slope to intercept of such a plot.

served for 120 min. Subsequently, the logarithmic decay of the numbers of viable organisms was constant with time for these doses with an apparent first-order rate constant of 9.75×10^{-5} sec.$^{-1}$.

The total count technique showed a decreasing rate of increase in total numbers over 120 min. after the deviation from the initial growth curve. At that time and for 400 subsequent min., there was a negligible change in the total number of organisms.

Apparent population growth rate constants, $k_{app.}$ in sec.$^{-1}$, were obtained from the slopes of these new linear logarithmic growth curves in accordance with the apparent first-order expression:

$$\log N = (k_{app.}/2.303)t + \text{constant} \quad \text{(Eq. 1)}$$

where t is time and N is the number of organisms/ml. The $k_{app.}$ values for various concentrations of sodium sulfathiazole and sulfisoxazole under varied conditions are given in Tables I–IV.

When the $k_{app.}$ values are plotted against the concentrations of the sulfa drugs, the curves are nonlinear and demonstrate that the $k_{app.}$ is not a linear function of the concentrations of the sulfa drugs. However, when the reciprocal of the differences between the population growth rate constant in the absence of drug, k_0, and the $k_{app.}$ values for population growth in the presence of drug are plotted against the reciprocal of the concentration of the sulfa drug, S in mcg./ml., excellent linearity is obtained (Fig. 3 for sulfisoxazole) in accordance with the expression:

$$1/(k_0 - k_{app.}) = (1/k_a)\,(1/S) + k_b/k_a \quad \text{(Eq. 2)}$$

where k_a and k_b are constants.

Similarly, when Eq. 2 is multiplied through by the concentration of the sulfa drug, this concentration divided by the difference between the population growth rate constants in the presence and absence of sulfa drug is a linear function of sulfa drug concentration, S, as in Fig. 4 for sulfathiazole:

$$S/(k_0 - k_{app.}) = 1/k_a + (k_b/k_a)S \quad \text{(Eq. 3)}$$

The intercepts, $1/k_a$, and slopes, k_b/k_a, derived from such plots are also given in Tables I–IV.

Effect of Temperature on Drug-Affected Growth Rates—The data for the effect of sulfonamide drugs on the steady-state growth of *E. coli* (Tables II and III) were analyzed by application of Eqs. 2 and 3 for each temperature studied, and the parameters k_a/k_b and k_b were determined from the slopes and intercepts of the plots in accordance with these equations (Figs. 3 and 4). The k_a and k_b parameters reasonably fit the Arrhenius or Van't Hoff equation for the dependence of reaction rate or equilibrium constants upon temperature (Fig. 5):

$$\log k = \log P - (\Delta H/2.303\,R)\,(1/T) \quad \text{(Eq. 4)}$$

where R is 1.987 Kcal./mole and T is in degrees Kelvin. The apparent ΔH values for k_b are −15.9 Kcal./mole for sulfisoxazole and −4.3 Kcal./mole for sodium sulfathiazole. For both sulfonamide studies, the apparent heat of activation for the derived k_a/k_b was 24 Kcal./mole. Similar plots for the k_0 values, *i.e.*, the population growth rate constants at the various temperatures in the absence of any sulfonamide were parallel to the plots for the k_a/k_b values and thus of the same apparent ΔH values.

The interval from the time of addition of sulfonamide to the time when the population growth rate

demonstrates a deviation to a drug-affected rate is termed the lag time (Fig. 1). This lag time is inversely proportional to the growth rate constant in the absence of sulfonamides for all temperatures studied. The linearity of the plot of lag time *versus* $1/k_0$ is demonstrated in Fig. 6. At any temperature, this lag time corresponded to 5.5 ± 0.5 generations.

Effect of Chloramphenicol on Sulfonamide-Affected Growth Rate—Chloramphenicol and sulfisoxazole were added simultaneously to a growing culture of *E. coli* at 10^6/ml. The chloramphenicol caused an almost instantaneous change in the rate of growth, but the sulfonamide effect was not observed until after a definitive lag time. Subsequent to this lag time, a drug-equilibrated growth rate was observed which was an apparent function of sulfisoxazole concentration. A typical semilogarithmic plot of such growth curves is given in Fig. 7 for 0.666 mcg./ml. chloramphenicol and 0.0 to 4.0 mcg./ml. sulfisoxazole.

The lag time from the time of addition of both drugs to the time when sulfonamide action was demonstrated was inversely proportional to the growth rate constant in the absence of sulfonamide (Fig. 6). At any chloramphenicol concentration used this lag time corresponded to 5.5 ± 0.5 generations.

The data for the effect of combined sulfonamide and chloramphenicol drugs on the steady-state growth rate constants for *E. coli* after the lag time are given in Table IV. These data were consistent with Eqs. 2 and 3 as demonstrated in the plot given in Fig. 8. The k_0' values chosen were those values in the presence of chloramphenicol but in the absence of sulfisoxazole. The slopes and intercepts of the curves are also given in Table IV.

The population on the addition of both drugs was 10^5 organisms/ml. Curve* A *is for the growth rate in the absence of both drugs and curve* B *is for 0.666 mcg./ml. of chloramphenicol. The other curves were for 0.666 mcg./ml. of chloramphenicol and the following mcg./ml. of sulfisoxazole:* B, *0.0;* C, *1.0;* D, *2.0;* E, *3.0;* F, *4.0.*

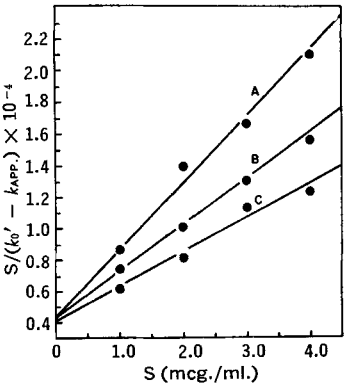

Fig. 8—Quantitative relations between apparent E. coli *growth rate constants, $k_{app.}$, and sulfisoxazole concentrations, S, at various chloramphenicol concentrations at 37.5°. The curves are plotted in accordance with the expression $S/(k'_0 - k_{app.}) = 1/k_a + (k_b/k_a)S$ where the growth rate constant in the absence of chloramphenicol and sulfisoxazole, k_0, is related to the growth rate constant, k_0', in the presence of chloramphenicol by $k_0' = k_0 + k_cC$ where C is the concentration of chloramphenicol in mcg./ml. and $k_c = 2.68 \times 10^{-4}$ ml./mcg./sec. The curves and respective concentrations in mcg./ml. of chloramphenicol are:* A, *1.00;* B, *0.67;* C, *0.33.*

Effect of Organism Population on Drug-Affected Growth Rates—The apparent growth rate constants for *E. coli*, $k_{app.}$, obtained in the presence of various concentrations of sodium sulfathiazole at various inoculum sizes at time of drug addition are listed in Table I. The values were obtained from the slopes of the curves of the logarithm of the total organism count *versus* time after the steady state attributed to sulfa drug effects had resulted as demonstrated in Fig. 1. There were no large differences in the $k_{app.}$ values obtained for the various organism population sizes on addition of a given concentration of sodium sulfathiazole for the particular *E. coli* culture used

(Table I). The variations were greatest for higher organism and sulfa drug concentrations. These facts imply that it is best to do comparative studies of sulfonamide action on *E. coli* growth at as constant a population as is possible. For this reason, sulfonamide was added at about 10^6 organisms/ml. Similar studies were also performed with different *E. coli* B/r cultures. In many of these cases, organism population had a greater effect on drug-equilibrated growth rates than with the specific culture used throughout these experiments.

Reversibility of Drug Action—As previously stated, the addition of sulfonamide to an inoculum demonstrated no immediate effect on the microbial growth rate (curves A and B, Fig. 2). It takes 5.5 generations for a drug effect on the microbial growth rate to be observed. At the lower concentrations of drug (curve B, Fig. 2), the transition period to the new steady-state growth rate can be considered as small and is 20–30 min. for 1.0 mcg./ml. of sulfisoxazole. At the higher concentrations of drug (curve C, Fig. 2), the transition period to the new steady-state growth rate is larger and is 140–160 min. for 5.0-mcg./ml.-affected growth rate (curve D). The ultimate steady-state growth rate achieved is independent of whether the total sulfisoxazole is added to the initial culture (curve C), or added stepwise (curves B and D), or the drug-affected culture is diluted and sufficient drug is added to maintain the same concentration (curves C and G). The growth rate constant, $k_{app.}$, was the same in all these instances when steady state was attained.

When the culture in the drug-affected growth period is diluted so that the sulfisoxazole concentration is diminished, the growth rate increases (curve C to E and to F) to achieve a new steady-state rate of growth. The increase in rate appears to occur immediately after dilution, but 100–130 min. must elapse before the new steady-state rate of growth is achieved. The ultimate growth rate is equivalent to that which would have been ultimately achieved with the same concentration of drug added to fresh inoculum.

DISCUSSION

The action of sulfonamide on drug-equilibrated microbial growth in the individual cell may be explained by the simple model:

$$S \underset{K_1}{\overset{}{\rightleftharpoons}} S' + R \underset{\frac{k_2}{K_2}}{\overset{k_1}{\rightleftharpoons}} (S'R) \quad \text{(Eq. 5)}$$

This model assumes an equilibrated partitioning of the sulfonamide concentration S in the media with the concentration S′ in the cell which is available to the unreacted receptor sites, R. The fact that the growth rate is constant for a given sulfonamide in the drug-equilibrated steady state implies that the two equilibria characterized by K_1 and K_2 are achieved in that state.

If θ is the fraction of receptor sites reacted with drug, the metabolic rate, $d\,M/dt$, may be proportional to the fraction, $1 - \theta$, of receptor sites that are unreacted with drug:

$$d\,M/dt = k_m\,(1 - \theta) \quad \text{(Eq. 6)}$$

An implicit assumption in this postulate is that the number of receptor sites in a single bacterium are constant and independent of the mass of the cell or time. Possible cases where this was not assumed have been discussed previously (7).

The equilibrium constant, K_2, for the drug–site interaction of Eq. 5 may be defined by:

$$K_2 = k_2/k_1 = (S'R)/[R_t - (S'R)]\,(S') = (S'R)/(S')(R) \quad \text{(Eq. 7)}$$

where $(S'R)$ is the number of sulfonamide-reacted sites, R is the number of unreacted sites, and R_t is the total number of sites whether reacted or unreacted. The fraction θ of sites reacted with drug may be obtained from rearrangement of Eq. 7:

$$\theta = (S'R)/R_t = K_2S'/(1 + K_2S') \quad \text{(Eq. 8)}$$

Thus, Eq. 6 on substitution becomes:

$$d\,M/dt = k_m - k_mK_2S'/(1 + K_2S') \quad \text{(Eq. 9)}$$

where k_m is the steady-state rate of metabolism in the absence of sulfonamide.

The concentration of sulfonamide, S′, in the cell is related to the concentration, S, in the media by:

$$S' = K_1S \quad \text{(Eq. 10)}$$

It follows that the rate of metabolism in the steady state of a single bacterium is related to the sulfonamide concentration, S, in the media by:

$$d\,M/dt = k_m - k_mK_1K_2S/(1 + K_1K_2S) \quad \text{(Eq. 11)}$$

If it is postulated that the rate of population increase of N organisms is proportional to this rate of metabolism and to the number of organisms in the balanced growth culture, it follows that:

$$d\,N/dt = q(dM/dt) \times N \quad \text{(Eq. 12}a\text{)}$$

$$d\,N/dt = [qk_m - qk_mK_1K_2S/(1 + K_1K_2S)]N \quad \text{(Eq. 12}b\text{)}$$

$$d\,N/dt = [k_0 - k_aS/(1 + k_bS)] \times N \quad \text{(Eq. 12}b\text{)}$$

$$d\,N/dt = k_{app.} \times N \quad \text{(Eq. 12}c\text{)}$$

where $k_0 = qk_m = k_a/k_b$, $k_a = qk_mK_1K_2$, $k_b = K_1K_2$ and:

$$k_{app.} = k_0 - k_aS/(1 + k_bS) \quad \text{(Eq. 13)}$$

where $k_{app.}$ is the apparent first-order steady-state growth rate constant in the presence of a constant sulfonamide concentration, S.

On integration, Eq. 12c becomes Eq. 1, and the $k_{app.}$ values were obtained from the slopes of semilogarithmic plots of drug-equilibrated growth (Figs. 1, 2, and 7; Tables I–IV).

The Eq. 13 can be rearranged into the forms of Eqs. 2 and 3, from which by appropriate plotting (Figs. 3, 4, and 8) the k_a and k_b values and related parameters were obtained (Tables I–IV).

The adherence of the data to Eqs. 2 and 3 demonstrates the validity of the model of Eq. 5 to explain the action of sulfonamide on microbial growth. The metabolic rate in the drug-affected steady state that results in microbial growth is proportional to the number of receptor sites unreacted with or unbound by sulfonamide. These receptor sites may be enzymes that are needed in the metabolic pathway (17–22) or an actual and constant amount of

substrate needed in the metabolic sequence that is inactivated by the sulfonamide (23, 24).

It has been argued (17–24) that certain sulfonamide antagonists such as *p*-aminobenzoic acid (PABA) and the sulfonamide compete for such receptor sites, and PABA reaction is necessary in the metabolic sequence. If this is true, the experimental confirmation of Eq. 5 demonstrates that all available receptor sites are occupied either by sulfonamide or PABA and the relative degree of occupation is determined competitively.

It is implied by the experimental verification of Eqs. 5–13 that total reaction of sulfonamide with the total number of receptor sites, R_t, is necessary for complete cessation of microbial growth. This should mean that the obtained $k_a/k_b = gk_m$ (Eqs. 2, 3, 12, and 13) should have the same magnitude as k_0, the apparent growth rate constant in the absence of sulfonamide. This is not exactly true as is evidenced by the values given in Tables II and III. For sulfisoxazole, $k_0 = 0.90\ k_a/k_b$, and for sodium sulfathiazole, $k_0 = 0.82\ k_a/k_b$, with average deviations of 0.03. These facts imply that it is only necessary to affect 82% or 90% of the available receptor sites to obtain the asymptotic cessation of microbial growth by these sulfonamides. The detailed analysis of this concept has been given previously (7).

Although the major action of sulfonamides is inhibitory, microorganism death is observed at high sulfonamide concentrations. Viable and total organism counts are coincident for 0.0 to 4.0 mcg./ml. of sulfisoxazole and demonstrate that microbial growth inhibition is the effective process in this range (Fig. 1). However, at much higher doses of sulfisoxazole, which included 20.0, 50.0, 75.0, and 100.0 mcg./ml., the constancy of the drug-equilibrated total microbial count with time (curve F, Fig. 1) implied completely inhibited growth. The loss of viables by a first-order process of dying must be assigned to the death of growth-inhibited microorganisms. In studies with 50.0, 75.0, and 100.0 mcg./ml., the viable count with time did not vary among these sulfisoxazole concentrations and went through a maximum after the lag period. The same ultimate, first-order kill rate was observed at 37.5° for all these concentrations. These observations imply that the nongrowing, sulfonamide-affected microorganism does not lose its viability as a function of sulfonamide concentration. It is probable that the metabolic limitations placed on the organisms by saturation of receptor sites with sulfonamide results in a statistical probability of death demonstrated by a first-order rate of dying.

It has been shown previously (7) that a plot of the logarithm of the microbial growth rate constant against the reciprocal of the absolute temperature is reasonably linear for drug-free *E. coli* cultures in the temperature range 25° to 39° and that ΔH values can be determined from the slopes of such plots in accordance with Eq. 4. This reasonable adherence to the Arrhenius or Van't Hoff Eq. 4 implies that one step, or several steps with similar temperature dependencies, in the metabolic processes of the organism may be rate limiting in this temperature range. The coincidence of the apparent ΔH values, 24 Kcal./mole for the derived k_a/k_b values from the sulfonamide studies (Tables II and III) and the observed k_0 values in the absence of sulfonamide indicate that these constants represent the same processes.

The derived parameter most descriptive of the quantitative action of a sulfonamide on microbial growth is $k_b = K_1K_2$ (Tables II–IV). Unfortunately, this product cannot be kinetically dissociated into the partition coefficient or transfer process for drug across the cell membrane, K_1, and the affinity constant, K_2, for sulfonamide reaction with receptor site. The product of these two equilibrium constants is temperature dependent (Fig. 5) and is reasonably in accordance with the Arrhenius or Van't Hoff Eq. 4 over the temperature range studied. The ΔH from this equation is not the same for sulfisoxazole and sulfathiazole. In terms of dissociation constants, $1/K_2$, and partition coefficient for the ratio of concentrations in the media to that within the cell, *i.e.*, $1/K_1$, the ΔH of $1/K_1K_2$ is 15.9 Kcal./mole for sulfisoxazole and 4.3 Kcal./mole for sulfathiazole. These values are significantly different from the ΔH of 24 Kcal./mole for microbial growth in the absence of sulfonamide, and are significantly different from each other. These facts imply that a fundamental difference exists between the reactivities and/or transport of these two sulfonamides into the cell.

Heats of diffusion are generally small, about 2–5 Kcal./mole. Thus, if partition or transport of the sulfonamide into the cell is a diffusion-controlled passive process, large ΔH values would indicate that definitive heats of reaction may be assigned to drug–receptor site interaction since:

$$\ln K_1K_2 = \ln P_{K_1K_2} - \Delta H_{K_1K_2}/RT = \ln K_1 + \ln K_2 = \ln P_{K_1}P_{K_2} - (\Delta H_{K_1} + \Delta H_{K_2})/RT \quad \text{(Eq. 14)}$$

so that:

$$\Delta H_{K_1K_2} = \Delta H_{K_1} + \Delta H_{K_2} \quad \text{(Eq. 15)}$$

For example, the $\Delta H_{K_1K_2}$ values for these two sulfonamides may imply that the receptor site–drug interaction or active transport processes have greater significance in the sulfisoxazole case than in the sulfathiazole case.

Several mechanisms of sulfonamide action have been proposed. One that has had wide acceptance is that these drugs act competitively with essential metabolites such as *p*-aminobenzoic acid, PABA, in a process which is necessary for growth (17–24). This can be competition for an enzyme in a vital enzymatic transformation (17–22), or is actually a competitive chemical reaction involving a vital metabolite in a necessary metabolic sequence (23, 24). To be consistent with our experimentally verified Eqs. 13 and 14, acceptance of these concepts implies that all receptor sites in Eq. 5 (whether enzymatic *or* chemical) are occupied by or reacted with either the sulfonamide or the available PABA in the drug-affected steady state. The number of sulfonamide-unreacted sites or substrates, *i.e.*, R are really PABA-reacted sites or PABA-reacted substrates and the rate of metabolism linked to growth is proportional to this R.

The lag time is the interval from the time of addition of sulfonamide to the time when the population growth rate demonstrates a deviation to a drug-affected rate (9, 25). This lag time is now shown to be inversely proportional to the growth

rate constant before sulfonamide affects the growth rate for all temperatures studied, and when chloramphenicol was added concomitantly with the sulfonamide (Fig. 6). At any chloramphenicol concentration and for any temperature, this lag time corresponded to 5.5 ± 0.5 generations. The 5.5 ± 0.5 generations after sulfonamide addition and before an observed deviation in microbial growth rate imply that cellular division is primarily responsible for the conditions necessary for sulfonamide action or microbial growth to be observed. This could be assigned to the depletion of PABA-derived metabolite [or folic acid precursor (22, 26–28)] storage in a single cell, in agreement with the arguments of Kohn and Harris (9, 10) and Rose and Fox (29). As long as these compounds are in excess, the metabolic pipeline can be maintained full and the rate of microbial growth dependent on a delivered quantity of metabolite per unit of time is invariant. The limiting factor in microbial growth may be the size of this pipeline. In more conventional terms, this would be equivalent to the saturation value of a compartment, tissue, enzyme, or process. It also follows that a standard excess of PABA metabolite and PABA is produced in the balanced growth culture.

Evidence for this is provided by the variation in the dose-response of sulfonamide action on drug-affected steady-state microbial growth as a function of inoculum size. Although this was of little significance in the inoculum ranges with the particular culture used in this paper, many other cultures (30–32), including other strains of *E. coli* B/r that were investigated, showed this effect in varying degrees. In general, for these other strains the greater the number of organisms on drug addition, the more sulfonamide was needed to give the same inhibition of microbial growth, or the greater the antagonism to sulfonamide action. If each organism in a balanced growth culture produced an excess of PABA or PABA-derived metabolites which "leaked" into the nutrient media, the response to sulfonamide would obviously be a function of the numbers of such organisms prior to the inhibition of production of PABA or PABA-derived metabolite.

Ultimately, a situation results where the amounts of stored PABA metabolites per unit cell are insufficient to saturate the pipeline and a gradual decrease in rate of microbial growth occurs to the new drug-affected steady state. This gradual change in rate also may be attributed in part to cellular division and thus to depletion of PABA metabolites in a single cell. The new drug-affected steady state then may be assigned to the competition of PABA from its new steady-state production and the cellular sulfonamide concentration. They compete for all available receptor sites and the production of PABA metabolites depends on the results of this competition.

An alternative or concomitant possibility is the diminution of available receptor sites (or enzymes) in the new steady state (27). Since depletion of stored PABA metabolites explains the lag period (9, 10, 29), lowered rates of PABA production and/or decreased numbers of receptor sites due to the feedback from metabolites' inhibition by sulfonamide are plausible. As first approximations, the rate of PABA production and/or the numbers of available receptor sites may be assumed to be proportional to the microbial growth rate.

The greater the sulfonamide concentration of the balanced growth culture (Fig. 1), the longer the time to achieve the new drug-affected steady state. This may imply time-dependent processes either for equilibration of sulfonamide in the culture media with the biophase concentration, or for diminution of rates of PABA production, or for transfer of PABA into the biophase.

The sulfonamide concentration was reduced by dilution of the culture with nutrient media or was increased by adding more sulfonamide (Fig. 2). This was done after the lag phase, both before and during the drug-affected steady-state growth process. There were gradual transitions to the new steady-state microbial growth rate characteristic of the new sulfonamide concentration. Since PABA-derived metabolites were already depleted, this may be assigned to either one or a combination of the following: (*a*) a time interval is necessary to rejuvenate or inhibit PABA production to its new steady state; (*b*) a finite time interval is necessary to equilibrate receptor sites with sulfonamide and/or PABA; (*c*) the equilibration between sulfonamide in the biophase surrounding the receptor sites and the sulfonamide in the culture media is a time-dependent process; (*d*) the biophase compartment is removed from the PABA generation site and the distributive processes for PABA are time-dependent; (*e*) there is a lag in transfer of the PABA-derived metabolite to or in the metabolic pathway that results in metabolism and growth.

The authors have previously made the statement that, as first approximations, the rate of PABA production and/or the numbers of receptor sites (*e.g.*, folic acid synthesizing enzymes) may be assumed to be proportional to the microbial growth rate. These postulates would explain the appearance of a new drug-affected steady state of microbial growth where the new rate of PABA production and the sulfonamide in the cell would compete for available receptor sites. Thus, the numbers of sulfonamide-unaffected sites, R in Eq. 5, that give rise to metabolism and growth, are PABA-reacted and would be direct functions of PABA production. It follows from Eq. 7 that the sulfonamide–receptor site dissociation constant, $1/K_2$ is directly proportional to this number of receptor sites, R, and thus should be directly proportional to the microbial growth rate. The same reasoning results if a feedback mechanism is operative (27) and the numbers of folic acid synthesizing enzymes are reduced with a reduced microbial growth rate.

Evidence in support of these statements is provided by the studies of microbial growth on simultaneous addition of chloramphenicol and sulfisoxazole (Table IV, Fig. 7). Confirmation of the adherence of the data to Eqs. 2, 3, 12, and 13 is demonstrated by the plots of Fig. 8. The derived parameters are listed in Table IV. It is apparent that the obtained K_1K_2 values, all at 37.5°, vary as a function of the chloramphenicol concentration, C, as do the k_0 values. Consistent with previous studies (3–8) the data of Table IV show that:

$$k_0 = k_0' - k_c\mathrm{C} \qquad \text{(Eq. 16)}$$

where $k_0' = 5.10 \times 10^{-4}$ sec.$^{-1}$ is the first-order growth rate constant in the absence of chloramphenicol and $k_c = 2.68 \times 10^{-4}$ ml./mcg./sec. is the inhibitory constant where C is in mcg./ml.

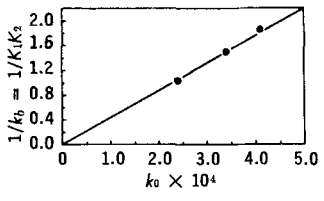

Fig. 9—The product ($1/K_1K_2$) of sulfonamide partition constant ($1/K_1$) and the sulfonamide-receptor site dissociation constant ($1/K_2$) as a function of the growth rate constant k_0 in the presence of chloramphenicol at 37.5°.

The action of chloramphenicol on microbial growth has been assigned to the inhibition of the function of messenger RNA in protein synthesis by blocking its attachment to ribosomes through competition for ribosomal binding sites (33). The differences in the kinetics in regard to lag period, reversibility, and concentration dependence are indicative that chloramphenicol and sulfonamide mechanisms of action differ.

Since $1/K_2$ is directly proportional to R and if the numbers of receptor sites, R, are a function of the microbial growth rate, it follows that $1/K_1K_2$ should be a linear function of k_0, the growth rate constant in the presence of chloramphenicol and in the absence of sulfisoxazole. Since the data (Table IV) are at constant temperature, the partition constant, K_1, should be invariant.

The plot of the data in Fig. 9 confirms this reasoning since it demonstrates that a linear relation with an intercept of zero exists and:

$$1/K_1K_2 = mk_0 \qquad \text{(Eq. 17)}$$

where $m = 0.440$.

For predictive purposes, we can describe the number of microorganisms at any time, t, when chloramphenicol and sulfonamide are administered simultaneously as:

$$N = N_1 e^{k_{app.}(t - t_1)} \qquad \text{(Eq. 18)}$$

where N_1 is the number of *E. coli* in balanced growth at time t_1, where within the first 5.5 generations $k_{app.}$ is defined by k_0 in Eq. 16. When the new sulfonamide-affected steady state is achieved, $k_{app.}$ is defined from consideration of Eqs. 12, 13, and 16 as:

$$k_{app.} = \frac{[k_0' - k_cC][1 + K_1K_2(S - 1)]}{1 + K_1K_2 S} \qquad \text{(Eq. 19)}$$

where k_0, k_c, K_1, and K_2 have been shown in this paper and others (7, 8) to conform to the Arrhenius–Van't Hoff relation over a considerable temperature range:

$$k = P_e - \Delta H/RT \qquad \text{(Eq. 20)}$$

For a given temperature where m in Eq. 17 is known, Eq. 19 can be written as:

$$k_{app.} = k_0 - 1/(m + S/k_0) \qquad \text{(Eq. 21)}$$

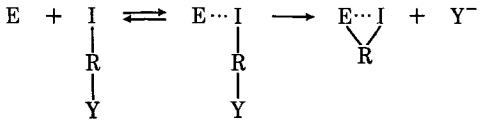
Enzyme Inhibitors XXI

Hydrophobic and Hydroxylic Binding Sites of Adenosine Deaminase

By HOWARD J. SCHAEFFER and CHARLES F. SCHWENDER

Recent studies have shown that the *ortho* and *para*-isomers of 9-(bromoacetamidobenzyl)adenine are good irreversible inhibitors of adenosine deaminase. In an attempt to prepare other types of irreversible inhibitors of this enzyme, a series of 9-(ω-bromoacetoxyalkyl)adenines were synthesized. However, none of these compounds were active as irreversible inhibitors although they were reversible inhibitors of this enzyme. Thus, it appears that the alkyl chain of the 9-(ω-bromoacetoxyalkyl)adenines does not complex with the enzyme in a manner identical to the 9-substituent of 9-(*p*- or *o*-bromoacetamidobenzyl)adenine. When the 9-(ω-hydroxyalkyl)adenines were evaluated as reversible inhibitors of adenosine deaminase, it was found that as the alkyl chain was lengthened, the compounds became initially more potent inhibitors, then less potent, and finally more potent again as the alkyl chain was lengthened to octyl. These results can be rationalized by assuming two different modes of binding. The short chain compounds bind to a hydroxyl binding site whereas the long chain compounds bind to a hydrophobic region which based on other data appears to extend approximately seven or eight carbons from the 9-position of adenine.

One of the prime requirements of an active-site-directed irreversible inhibitor is that the enzyme and inhibitor (1) form a reversible complex prior to the reaction in which the irreversible inactivation occurs (see Scheme I).



Scheme I

Thus, knowledge concerning types of binding sites on the enzyme required for reversible complexation are essential for the design of active-site-directed irreversible inhibitors. It has previously been shown that adenosine deaminase has both a polar and a nonpolar area that are important in binding certain substituents of a 9-substituted adenine (2). A successful attempt to utilize the hydrophobic region of adenosine deaminase for the preparation of active-site-directed irreversible inhibitors resulted in the synthesis of some 9-benzyl- and 9-phenethyladenines in which the benzene ring carried an alkylating agent (3–6). In order to determine if certain 9-alkyladenines bearing an alkylating group on the alkyl substituent could irreversibly inhibit adenosine deaminase, the authors decided to prepare some 9-(ω-bromoacetoxyalkyl)adenines where the alkyl group varies from ethyl to octyl. The present paper describes the synthesis and enzymic evaluation of these compounds as well as a study of the hydrophobic and hydroxyl binding sites of adenosine deaminase with some 9-(ω-hydroxyalkyl)adenines.

DISCUSSION

An examination of Table I reveals that the compounds prepared for this study were capable of causing reversible inhibition of adenosine deaminase. However, when the potential irreversible inhibitors (VII–XI) were incubated with the enzyme for periods of 5 hr. at 37°, no irreversible inactivation was observed. The incubations were performed with concentrations of inhibitors such that the amount of the reversible E· · ·I complex was at least 0.5 E_t. Under similar conditions, 9-(*p*-bromoacetamidobenzyl)adenine caused extensive irreversible inactivation of adenosine deaminase (3, 4). Comparison of the rates of reaction of VII–XI with iodoacetamide using 4-(*p*-nitrobenzyl)pyridine as the nucleophilic reagent revealed that VII–XI were approximately 4–5 times more reactive than iodoacetamide. Thus, VII–XI exhibit approximately the same rates of reaction as do 9-(*p*- and *o*-bromoacetamidobenzyl)adenines (XIII and XIV) with 4-(*p*-nitrobenzyl)pyridine (3–5).

[a] None of these compounds served as substrates of adenosine deaminase. [b] The concentration of adenosine in all experiments was 0.066 mM. In no experiment of reversible inhibition did the concentration of inhibitor exceed 0.12 mM. In those cases where a higher concentration is shown for 50% inhibition, the value was obtained by extrapolation of a plot of V_0/V *versus* (*I*). [c] Average deviation. [d] Data taken from *Reference 2*. [e] Ratio of the rates of reaction of the various 9-(ω-bromoacetoxyalkyl)adenines to iodoacetamide with 4-(*p*-nitrobenzyl)pyridine.

The fact that VII–XI form reversible complexes with adenosine deaminase and possess good alkylating activity but nevertheless are not irreversible inhibitors of the enzyme is evidence that the 9-substituent of these compounds does not complex with the enzyme in a manner identical to the 9-substituent of XIII and XIV. In addition, it was found that 9-(2-bromoacetoxypropyl)adenine was a poor reversible inhibitor and did not cause irreversible inactivation of adenosine deaminase. Moreover, when the stability of the bromoesters to phosphate buffer was evaluated, it was found that less than 10% of the alkylating ability of these compounds was lost during a 2-hr. incubation at 37°. The lack of irreversible inactivation of adenosine deaminase by VII–XI substantiates the selectivity that one may obtain with active-site-directed irreversible inhibitors (1). An examination of molecular models reveals that VII–XI may assume several conformations identical with XIII or XIV. Even though all of these compounds form reversible complexes with the enzyme and have nearly equal alkylating activity, only 9-(*o*- and *p*-bromoacetamidobenzyl)adenines and 9-(*m*-bromoacetamidophenethyl)adenine are good irreversible inhibitors of adenosine deaminase.

An interesting phenomenon was observed when a comparison was made of the reversible inhibition of adenosine deaminase by some 9-(ω-hydroxyalkyl)adenines and some 9-alkyladenines (see Fig. 1). As the alkyl chain of the 9-alkyladenines is lengthened, the ability of the inhibitor to form a complex with the enzyme is increased. It was on these data that we previously concluded that the hydrophobic area of adenosine deaminase extends from approximately three to seven carbon atoms (2). The authors have recently prepared 9-nonyl- and 9-decyladenines which unfortunately were not

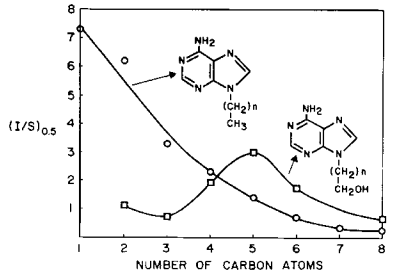

Fig. 1—A plot of the index of inhibition vs. *the number of carbons in the 9-substituent of some 9-(alkyl)- and 9-(hydroxyalkyl)adenines.*

sufficiently water-soluble to allow an accurate measurement of their inhibition index. Nevertheless, when these compounds were evaluated as inhibitors of adenosine deaminase in phosphate buffer containing 40% dimethylsulfoxide, they were weaker inhibitors than was 9-octyladenine evaluated under the same conditions. From these data, it would appear that the hydrophobic area on adenosine deaminase does terminate at a length of approximately seven or eight carbon atoms. However, an examination of a plot of $(I/S)_{0.5}$ *versus* chain length for a number of 9-(ω-hydroxyalkyl)adenines reveals that as the alkyl group is lengthened, the inhibitors become more potent, then less potent, and finally more potent again. The authors believe that these data conclusively demonstrate that two types of forces are involved in the formation of a complex with the 9-substituent of 9-(ω-hydroxyalkyl)adenines. When the 9-position of adenine bears either a 2-hydroxyethyl or a 3-hydroxypropyl group, both

the hydroxyl site and the hydrophobic region on the enzyme are making a contribution to binding. It has previously been shown that the hydroxyl site and the large hydrophobic site are not related to each other in an unbranched manner; *i.e.*, a straight carbon chain compound, such as 2-hydroxyheptyl, cannot bridge to both sites (7). This observation is further supported by the study of the compound with a 4-hydroxybutyl group at the 9-position of adenine. In this case, the 9-substituent cannot bind to both areas on the enzyme at the same time. When the butyl group binds to the hydrophobic region of the enzyme, there is some repulsion caused by proximity of the terminal hydroxyl group to the nonpolar area. However, by extensive folding of the butyl chain which is energetically unfavorable, it is possible for the alcohol function to bind to its hydroxyl binding site. The repulsive factor on the one hand is almost equally balanced by the second binding site so that the inhibition caused by III is almost equal to that caused by 9-butyladenine. The substituent of 5-hydroxypentyl represents a case where the hydroxyl group apparently does not make a contribution to binding. In fact, its major effect is a repulsion from the hydrophobic region. Finally, in the case of the 6-hydroxyhexyl and especially in the case of 8-hydroxyoctyl, the hydroxy group has essentially lost its repulsive effect. This occurs because the hydrophobic region has a length of only seven or eight carbon atoms. Thus, when the octyl group of 9-(8-hydroxyoctyl)adenine is complexed with the enzyme, the hydroxyl group extends beyond the hydrophobic region and is no longer repelled. Consequently, 9-octyladenine and 9-(8-hydroxyoctyl)-adenine approach each other in their inhibitory properties. Finally, a plot of $(I/S)_{0.5}$ *versus* the number of carbons in the alkyl chain of the 9-(ω-bromoacetoxyalkyl)adenines reveals a reasonably smooth curve with the inhibition becoming greater as the chain is lengthened. We interpret these data to mean that there is only one type of interaction important in binding the 9-substituent of the 9-(ω-bromoacetoxyalkyl)adenines and that this type of interaction is mainly hydrophobic.

CHEMISTRY

The synthesis of 9-(6-hydroxyhexyl)adenine was accomplished by a modification of a procedure (8) in which adenine was alkylated with 6-chloro-1-hexanol in dimethylacetamide in the presence of potassium carbonate. 9-(8-Hydroxyoctyl)adenine was synthesized by condensing 8-hydroxy-1-octanol with 5-amino-4,6-dichloropyrimidine. The resultant substituted pyrimidine was cyclized with trimethyl orthoformate to the desired 6-chloro-9-(8-hydroxyoctyl)purine which on treatment with methanolic ammonia gave 9-(8-hydroxyoctyl)adenine.

Several procedures were investigated to prepare the 9-(ω-bromoacetoxyalkyl)adenines using bromoacetyl bromide and bromoacetic anhydride, but the yields were consistently low. Finally, it was found that the bromoacetoxy derivatives could best be prepared by simple esterification of the hydroxyl group with bromoacetic acid catalyzed by ethanesulfonic acid. In this way 9-(ω-bromoacetoxyalkyl)adenines were prepared where the alkyl group was ethyl, propyl, butyl, hexyl, and octyl. In addition 9-(2-bromoacetoxypropyl)adenine was prepared by this general procedure.

EXPERIMENTAL[1]

9-(6-Hydroxyhexyl)adenine (V)—A mixture of 9.92 Gm. (58.0 mmoles) of adenine dihydrate, 15.8 Gm. (116 mmoles) of 6-chloro-1-hexanol, and 8.01 Gm. (58.0 mmoles) of anhydrous potassium carbonate in 40 ml. of dimethylacetamide was heated at 125° for 43 hr. under an atmosphere of nitrogen. The reaction mixture was filtered, and the filtrate was evaporated *in vacuo* to a residual solid, 6.01 Gm., which was placed on a column (35 × 900 mm.) of 450 Gm. of neutral alumina and eluted with a methanol–chloroform mixture collected in 100-ml. fractions. The desired material was obtained from fractions 51–66 (4% methanol in chloroform). Removal of the volatile material *in vacuo* gave a crude solid, 3.64 Gm. (37.4%), m.p. 184–187°, which was shown by TLC on silica gel to be one component, R_f 0.67 (20% methanol in chloroform).

8-Amino-1-octanol—To a stirred suspension of 19.9 Gm. (125 mmoles) of 8-aminooctanoic acid in 250 ml. of absolute ethanol at 0°, was slowly added 16.7 Gm. (140 mmoles) of thionyl chloride. The mixture was then refluxed for 8 hr. The reaction mixture was evaporated *in vacuo* and gave crude solid ethyl 8-aminooctanoate hydrochloride in a quantitative yield. The crude material was dissolved in 150 ml. of chloroform and washed with cold 5% sodium hydroxide solution (3 × 10 ml.). After the chloroform solution had been dried with anhydrous magnesium sulfate, the chloroform was evaporated *in vacuo* and gave the crude ethyl 8-aminooctanoate, 16.5 Gm. (71.2%). To a suspension of 10.6 Gm. (280 mmoles) of lithium aluminum hydride in 1 L. of anhydrous ether was added 16.5 Gm. of crude ethyl 8-aminooctanoate in 1 L. of ether. The reaction mixture was refluxed for 6 hr. and then water (45 ml.) was added to the cooled mixture. The resulting suspension was filtered, and the residual solid was washed with chloroform (500 ml.). The filtrates were combined and evaporated *in vacuo;* yield, 13.4 Gm. of crude 8-amino-1-octanol, m.p. 54–57°. Recrystallization of the material from benzene–hexane gave the pure white product; yield, 11.6 Gm. (63.8%), m.p. 54–59°. ν in cm.$^{-1}$ (KBr): 3450 (OH); 3300, 1550 (NH).

Anal.[2]—Calcd. for $C_8H_{19}NO$: C, 66.17; H, 13.19; N, 9.64. Found: C, 66.26; H, 13.11; N, 9.87.

This compound has previously been prepared by a different procedure and a m.p. 45° was reported (9).

5-Amino-4-chloro-6-(8-hydroxyoctylamino)pyrimidine—A mixture of 692 mg. (4.23 mmoles) of 5-amino-4,6-dichloropyrimidine, 644 mg. (4.44 mmoles) of 8-amino-1-octanol, and 504 mg. (5.00 mmoles) of triethylamine in 35 ml. of 1-butanol was heated at reflux for 23.5 hr. under nitrogen. The mixture was evaporated *in vacuo* and gave a residual syrup which was crystallized from a mixture of ethanol and water; yield, 940 mg. (81.0%), m.p. 80–85°. Recrystallization of the material from

[1] The infrared spectra were determined on a Perkin-Elmer model 137 spectrophotometer; the ultraviolet spectra were determined on a Perkin-Elmer model 202 spectrophotometer; the enzyme studies were done on a Gilford instrument model 2000 spectrophotometer. The melting points, unless otherwise noted, were taken in open capillary tubes on a Mel-Temp apparatus and are corrected.

[2] The analyses reported in this paper were performed by Galbraith Microanalytical Laboratories, Knoxville, Tenn.

9-(8-Hydroxyoctyl)adenine Hydrochloride (VI)—A mixture of 5.34 Gm. (19.6 mmoles) of 5-amino-4-chloro-6-(8-hydroxyoctylamino)pyrimidine, 268 mg. (2.43 mmoles) of ethanesulfonic acid, and 25 ml. of trimethyl orthoformate was stirred at room temperature for 23.5 hr. The reaction mixture was evaporated *in vacuo* to give a syrup which would not crystallize. The crude 6-chloro-9-(8-hydroxyoctyl)purine (17.6 mmoles) was heated at 80° with 60 ml. of methanolic ammonia solution in a steel bomb for 66 hr. The reaction mixture was cooled and a solid which precipitated was collected by filtration; yield, 3.68 Gm. (79.7%), m.p. 186–192°. For purification the product was converted into the hydrochloride salt which was recrystallized from methanol–ether.

9-(ω-Bromoacetoxyalkyl)adenines—These materials were prepared by the same general procedure. Therefore, only one procedure will be presented. The physical constants and analytical data for these compounds are given in Table II.

9-(6-Bromoacetoxyhexyl)adenine (X)—A mixture of 258 mg. (1.10 mmoles) of 9-(6-hydroxyhexyl)-adenine, 3.06 Gm. (22.0 mmoles) of bromoacetic acid, and 138 mg. (1.25 mmoles) of ethanesulfonic acid in 20 ml. of chloroform was heated at reflux for 23 hr. The chloroform volume was increased to 40 ml. and then washed with a saturated sodium bicarbonate solution (8 × 1 ml.). The chloroform phase was dried with anhydrous magnesium sulfate and evaporated *in vacuo* to a residual solid. The crude material after recrystallization from acetone–hexane gave 322 mg. (82.3%) of crude X, m.p. 174–177° dec. Further recrystallizations from acetone–hexane gave the analytical product; yield, 128 mg (32.7%), m.p. 173–178° dec.

CHEMICAL REACTIVITY OF THE ALKYLATING AGENTS

The procedure has previously been described (5) and is a modification of a literature procedure (10–12).

ENZYME ASSAY AND REAGENTS

Adenosine deaminase (type I, calf intestinal mucosa) was purchased from the Sigma Chemical Co. The assay procedure for reversible inhibitors is a modification of the method developed by Kaplan (13).

The method used to study the irreversible inactivation of adenosine deaminase at 37° has been described (5) and is a modification of the general procedure of Baker (14).

Modified Hofmann Degradation for the Analysis of *n*-Alkylbenzyldimethylammonium Chlorides by Gas Chromatography I

C_{14}- to C_{18}-Alkyl Compounds

By E. C. JENNINGS, JR., and H. MITCHNER*

The Hofmann degradation of quaternary ammonium compounds has been studied for *n*-alkylbenzyldimethylammonium chlorides. Gas chromatography of the reaction products provides resolution of the benzyldimethylamine and the corresponding alkene. Quantitative analysis of quaternary content and qualitative evaluation of impurities have been obtained for a number of commercial products.

Of the methods for splitting of C—N bonds in amines, such as the von Braun with cyanogen bromide (1), the Hofmann degradation by pyrolysis of quaternary ammonium hydroxides (1), the Emde reduction of quaternary ammonium salts with sodium amalgam (2), and catalytic hydrogenation (2, 3), only the Hofmann and catalytic hydrogenation methods lend themselves readily to the analysis of *n*-alkylbenzyldimethylammonium chlorides. Warrington (3) has determined the alkyl distribution in benzalkonium chloride by the gas chromatographic analysis of the amines produced by catalytic hydrogenation. The determination of impurities was not feasible by this method, and the quantitative assay of the benzalkonium chloride was not afforded. Metcalfe (4) attempted the analysis of long chain quaternary ammonium compounds by a Hofmann degradation with direct injection on an alkaline treated gas chromatographic column. The reaction did not follow the expected course, and the results were not sufficiently precise for quantitative assay. Changing of the column with use also altered the alkyl distributions.

The Hofmann degradation for the analysis of *n*-alkyltrimethylammonium halides (5), and the catalytic hydrogenation of *n*-alkylbenzyldimethylammonium chloride (6, 7) have been reported in connection with gas chromatography for the determination of the long chain alkyl group. It has been suggested that in the Hofmann degradation (5) a disproportion reaction results, giving rise to both alkenes-1 and the corresponding alkanols, although this was not established by quantitative data.

Catalytic hydrogenation requires special equipment and does not afford a ready means of quantitatively determining volatile impurities. The Hofmann reaction suggested a simpler analytical approach. This work was directed toward determination of optimum reaction conditions with subsequent gas chromatography analysis of the reaction products. Assay of volatile impurities prior to Hofmann degradation combined with analysis of the products of the reaction provided a means of complete assay of commercial C_{14} to C_{18} alkylbenzyldimethylammonium chlorides.

APPARATUS AND REAGENTS

An F&M 810R-12 gas chromatograph equipped with a linear temperature programmer and dual hydrogen flame ionization detectors was employed with dual columns, 5 ft. × 1/8 in. (0.101 in. i.d.),

Modified Hofmann Degradation for the Analysis of *n*-Alkylbenzyldimethylammonium Chlorides by Gas Chromatography I

C_{14}- to C_{18}-Alkyl Compounds

By E. C. JENNINGS, JR., and H. MITCHNER*

The Hofmann degradation of quaternary ammonium compounds has been studied for *n*-alkylbenzyldimethylammonium chlorides. Gas chromatography of the reaction products provides resolution of the benzyldimethylamine and the corresponding alkene. Quantitative analysis of quaternary content and qualitative evaluation of impurities have been obtained for a number of commercial products.

Of the methods for splitting of C—N bonds in amines, such as the von Braun with cyanogen bromide (1), the Hofmann degradation by pyrolysis of quaternary ammonium hydroxides (1), the Emde reduction of quaternary ammonium salts with sodium amalgam (2), and catalytic hydrogenation (2, 3), only the Hofmann and catalytic hydrogenation methods lend themselves readily to the analysis of *n*-alkylbenzyldimethylammonium chlorides. Warrington (3) has determined the alkyl distribution in benzalkonium chloride by the gas chromatographic analysis of the amines produced by catalytic hydrogenation. The determination of impurities was not feasible by this method, and the quantitative assay of the benzalkonium chloride was not afforded. Metcalfe (4) attempted the analysis of long chain quaternary ammonium compounds by a Hofmann degradation with direct injection on an alkaline treated gas chromatographic column. The reaction did not follow the expected course, and the results were not sufficiently precise for quantitative assay. Changing of the column with use also altered the alkyl distributions.

The Hofmann degradation for the analysis of *n*-alkyltrimethylammonium halides (5), and the catalytic hydrogenation of *n*-alkylbenzyldimethylammonium chloride (6, 7) have been reported in connection with gas chromatography for the determination of the long chain alkyl group. It has been suggested that in the Hofmann degradation (5) a disproportion reaction results, giving rise to both alkenes-1 and the corresponding alkanols, although this was not established by quantitative data.

Catalytic hydrogenation requires special equipment and does not afford a ready means of quantitatively determining volatile impurities. The Hofmann reaction suggested a simpler analytical approach. This work was directed toward determination of optimum reaction conditions with subsequent gas chromatography analysis of the reaction products. Assay of volatile impurities prior to Hofmann degradation combined with analysis of the products of the reaction provided a means of complete assay of commercial C_{14} to C_{18} alkylbenzyldimethylammonium chlorides.

APPARATUS AND REAGENTS

An F&M 810R-12 gas chromatograph equipped with a linear temperature programmer and dual hydrogen flame ionization detectors was employed with dual columns, 5 ft. × 1/8 in. (0.101 in. i.d.),

TABLE I—RELATIVE RETENTION DATA FOR CALIBRATION COMPOUNDS

Carbon No.	n-Alkanes		1-Alkenes		n-Alkanols	
	Rel. Tr[a]	RRT[b]	Rel. Tr	RRT	Rel. Tr	RRT
12	0.85	0.58	0.89	0.69	1.50	2.5
14	1.02	1.10	1.08	1.22	1.67	3.0
16	1.20	1.64	1.26	1.77	1.78	3.4
18	1.39	2.16	1.43	2.28		3.8

[a] With respect to BDMA = 1.00, Tr = 135°. [b] With respect to BDMA = 1.00, tr = 7.4 min. Benzylmethylamine gave a rel. Tr = 1.15 and RRT = 1.44. Benzylamine gave a rel. Tr = 1.60 and RRT = 2.8.

316 stainless steel, packed with 20% Carbowax 20M on polyvinylpyrrolidone (1%) coated support (Chromosorb W, 60/80 mesh). A total packing of 3.06 to 3.08 Gm. was obtained using only moderate vibration from a hand vibrator.[1] Hydrogen was supplied with an Elhygen generator[2] and tank nitrogen was used as carrier gas. Air for combustion was taken from the laboratory supply line after regulation to 23 psig and filtration through 13X molecular sieve. Samples were injected with a 10-μl. syringe (Hamilton 701 NW/G). A glass insert was placed within the injector chamber to confine the caustic solutions used to the area of this disposable glass liner and to protect the syringe needle from damage by striking any metal tubing. These glass liners were prepared from 3 mm. × 11 cm. glass tubing and were given a slight flare at the septum end. The liners were slotted 1.5 cm. from the flared end to allow entry of carrier gas. An emery disk of a Dremel Moto-Tool[3] was used for slotting.

The chromatograms were recorded with a Honeywell, model 16, recorder equipped with a Disc integrator, model 227.[4]

Even numbered compounds from C_{12} to C_{18} inclusive were obtained in 99% purity from Matheson, Coleman, and Bell for the homologous series of alkanes, alkenes-1, and alkanols and used without further purification.

Benzyldimethylamine was fractionally redistilled before use. Benzylmethylamine and benzylamine were used without further treatment. Reagent grade silver oxide and potassium hydroxide were used as received.

Glass ampuls (5 ml.), Pasteur disposable pipets, 5-ml. gas tight syringe (Hamilton 1005), and an ampul sealing torch (Matheson Scientific) were the only other items that may not be standard supplies in all laboratories.

PROCEDURE

Parameters for Programmed Temperature Gas Chromatography—The injection port temperature was set at 180°, and the oven was given a lower limit of 100°. A post-injection dwell time of 1 min. was used. The temperature was programmed to an upper limit of 240°, at a rate of 6.0°/min. An upper limit dwell time of 8 min. was held prior to the automatic recycling and resetting of initial conditions. All compounds of interest for the determination of the alkyl group distribution were eluted within 20 min. The program provided sufficient time to ensure that higher boiling impurities found in most quaternary ammonium salts had been eluted prior to the next run.

The hydrogen pressure was set at 13–15 psig which gave a flow of 40 to 48 ml./min. The nitrogen pressure was set at 60 psig, and flow through each column was adjusted at the upper temperature limit to balance the columns for column bleed. The measuring column had a flow of 25 ml./min., and the reference column a flow of 20 ml./min. The air pressure to the detector was set at 23 psig which gave a flow of 340 ml./min.

Gas Chromatography of Reference Compounds—With 5.0-μl. injections of solutions containing 10 mg./ml. of each reference compound a range of 100 and an attenuation of 128 were used. The relative retention data of all compounds were taken with respect to benzyldimethylamine (BDMA). The detector responses in micrograms per disk unit of integration (mcg./DU) were calculated for a range of 10 and an attenuation of 1×. (Table I.)

Determination of Optimum Hofmann Reaction Conditions—Initially the Hofmann degradation with silver oxide was studied. A modification of the Hofmann degradation, using 4 *N* KOH, was used for a replicate set of experiments. Equal volumes of 8 *N* KOH and aqueous quaternary ammonium salt solution were pipeted into ampuls to provide a final concentration of 4 *N* KOH and 25 mg./ml. of the quaternary ammonium chloride. Ampuls were heated to 110°, and samples were analyzed at 1, 2, and 4 hr.

Determination of Impurities—Injections of the aqueous solutions of the quaternary ammonium compounds were made prior to running Hofmann reactions. Clean glass injection port liners were used in each run to obviate residual alkali from previous experiments that could give rise to a Hofmann degradation. The injector port temperature was reduced to a practical minimum of 180° to minimize thermal pyrolysis of the quaternary ammonium chlorides. Three alkylbenzyldimethylammonium chlorides, C_{14}-alkyl, C_{16}-alkyl, and C_{18}-alkyl, were studied.

From gas chromatographic runs the major volatile impurities were isolated using an effluent splitter at a ratio of 1:1. The impurities were collected directly on a 13-mm. Millipore filter disk, type TH (8). Infrared spectra of isolates were obtained by scanning the Millipore disks on a Beckman IR-8 spectrophotometer. A clean disk was used in the reference beam.

Isolation of impurities was also made by processing a chloroform solution of the quaternary ammonium chloride on a chromatographic column of silicic acid (19 mm. × 100 mm.). The total loading of the column was 2.0 Gm. of quaternary ammonium

chloride. Development of the column was made with chloroform. During the washing of the column with solvent, the eluate was observed in ultraviolet light (366 mμ), and fraction cuts were made where it appeared that a change in fluorescence could be seen. Finally the column was washed with methanol to remove the quaternary ammonium chloride when the column fluorescence was not further reduced by the chloroform washing. The solvent from each fraction collected was evaporated and the residues were examined (*a*) by microscopy at 100× in polarized light, (*b*) by IR spectroscopy, and (*c*) by gas chromatography of a chloroform solution of the residue. The residues were compared by these methods to known compounds. In the case of the C_{18}-alkyl compound crystals of a major impurity separated from the initial aqueous solution used for the Hofmann reaction. These were subjected also to the foregoing methods of identification.

RESULTS AND DISCUSSION

Preliminary experiments with Hofmann degradation and gas chromatographic studies of the reaction products indicated the possible presence of alkanes and alcohols, as well as the expected alkenes and

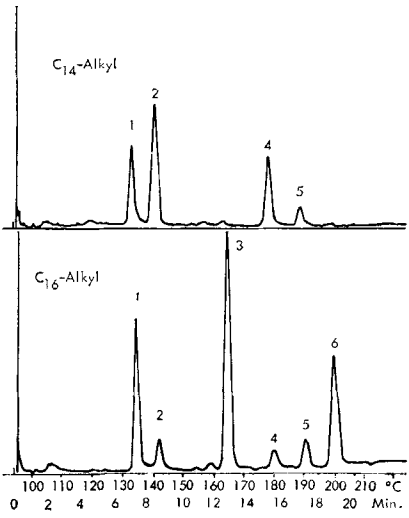

Fig. 2—Hofmann degradation in 4 N *KOH, 1 hr. 105°; 5-µl. injection, range 10, attenuation 32×. Key:* 1, *BDMA;* 2, *1*-$C_{14}H_{28}$; 3, *1*-$C_{16}H_{32}$; 4, n-$C_{18}H_{38}$; 5, *1*-$C_{18}H_{36}$; 6, n-$C_{12}H_{25}OH$.

benzyldimethylamine. To identify the products and to ascertain that the materials were being resolved, reference compounds of C_{12} to C_{18} straight chain alkanes, alcohols, and alkenes were obtained and synthetic mixtures chromatographed (Fig. 1). Relative retention data to benzyldimethylamine was used for comparison and identification. (Table I.) Retention data were also obtained for benzylmethylamine and benzylamine considered as possible impurities. Programmed chromatograms resolved all compounds.

For determinations of optimum conditions to conduct the Hofmann degradation, a C_{16}-alkylbenzyldimethylammonium chloride was reacted at several time periods in the presence of silver oxide. With increasing reaction time the composition of products changed. When 4 *N* KOH was substituted for silver oxide, constant composition results were obtained as shown in Table II. All subsequent studies used 4 *N* KOH with 1.0 hr. reaction time in sealed ampuls. Chromatograms for the C_{14}- and C_{16}-alkyl quaternaries after Hofmann degradation are shown in Fig. 2.

The relative retention data for the major impurities in the C_{16}-alkyl compound were consistent with that for the C_{12} and C_{16} straight chain alcohols and the C_{16}-alkane. Some monomethylbenzylamine was present, as was some C_{18}-alkene, the latter attributable to the presence of some C_{18} quaternary in the original product. The C_{12} and C_{16} alcohols from the C_{16}-alkyl compound were also isolated by column chromatography on silicic acid and positively identified. The composition of the volatile components from the gas chromatograms were calculated from the detector sensitivities of the individual components of reference compounds (Table III). The alkyl distribution and quaternary assay for the C_{16}-alkylbenzyldimethylammonium chloride is given in Table IV. The material was approximately 50% quaternary ammonium compounds and 50% impurities, the latter primarily lauryl and cetyl alcohols. A C_{14}-alkyl compound, a second C_{16}-alkyl compound, and a C_{18}-alkyl compound were also subjected to a purity study. The data for these materials are shown in Table V. Based on the total material injected, the total recovery of volatile materials was about 90%, and the total quaternary ammonium content ranged from 59% to 67%. About 10% of the material injected was of a non-

volatile nature and probably represented inorganic salts that occur in such commercial materials.

It has been reported (5) that a Hofmann reaction can result in a disproportionation reaction with both the alkene and its corresponding alcohol appearing as reaction products. The C_{14}-alkylbenzyldimethylammonium chloride, purified by silicic acid absorption chromatography, was used to study this possibility. Pre-Hofmann chromatograms showed that C_{14} alcohol was absent in the purified material. Following degradation in 4 *N* KOH no C_{14} alcohol was produced. Results are shown in Table VI.

SUMMARY

It has been shown that the various commercial *n*-alkylbenzyldimethylammonium chlorides are mixtures of two or more quaternary ammonium compounds and that impurities of higher alkanes, C_{16} to C_{18}, and higher alcohols, C_{12} to C_{18}, are significant. The compounds investigated contained from 50% to 70% quaternary ammonium chlorides.

The modified Hofmann degradation is a relatively simple procedure and provides for the determination of alkyl distribution, quaternary ammonium salt content, and impurities. Standard deviations obtained show good precision for this type of procedure. Quantitative assay is dependent upon the amount of BDMA formed by the reaction and is directly proportional to the total quaternary ammonium chloride present.

Modified Hofmann Degradation for the Analysis of *n*-Alkylbenzyldimethylammonium Chlorides by Gas Chromatography II

Benzalkonium Chloride

By H. MITCHNER* and E. C. JENNINGS, JR.

The modified Hofmann degradation with gas chromatography of degradation products has been applied to a study of benzalkonium chloride. Quantitation is possible to 0.05 percent and the determination of alkyl group distribution is simultaneously possible. A good correlation was found between the Hofmann degradation and the USP catalytic hydrogenation for determination of alkyl ratios.

BENZALKONIUM CHLORIDE is a germicide and preservative which has found increasingly greater use. Its germicidal effectiveness is based on its content of a mixture of *n*-alkyl dimethylbenzylammonium chlorides, the most important of which are the C_{12} and C_{14}. The United States Pharmacopeia requires compendia labeled material to contain not less than 40% of the C_{12}-alkyl, and that C_{14} be not less than 20% of the total alkyldimethylammonium chloride content with the sum of the C_{12} and C_{14}-alkyls not less than 70% of the total (1).

The analysis of the alkyl substituent in benzalkonium chloride poses a difficult analytical problem. For the official analysis the USP applies a gas chromatographic assay following an Emde degradation. This allows a determination of alkyl group ratios but is not quantitative and requires specialized hydrogenation equipment. A new gas chromatographic approach to the analysis of *n*-alkyl dimethylbenzalkonium chlorides employing a modified Hofmann degradation (2) was found applicable to the analysis of benzalkonium chloride.

The modified Hofmann degradation was applied directly to several commercial benzalkonium chloride preparations. The catalytic hydrogenation procedure utilized in the benzalkonium chloride monograph of the USP (1), which is essentially the procedure of Warrington (3) and the special apparatus of Southworth (4), was compared with the Hofmann degradation procedure with similar results.

APPARATUS AND REAGENTS

In addition to the apparatus employed previously in this study (2), special adaptation of the Parr hydrogenation apparatus for microsamples was used.

For further calibration of the F&M 810R-12 gas chromatograph, pure alkyldimethylamines with even numbered alkyl groups C_8 to C_{18} were obtained from Matheson, Coleman, and Bell. These compounds were used as received and corrections for minor alkyldimethylamines were made, based on gas chromatograms of these materials.

Samples of benzalkonium chloride[1] from several manufacturers and a standard benzalkonium chloride from the USP reference standards,[2] as distributed by the United States Pharmacopeial Convention, Inc., were obtained.

PROCEDURE

Based on the label assay of the commercial benzalkonium chloride preparations, aqueous concentrations of 100 mg./ml. were prepared. For the modified Hofmann degradation, 1.8 ml. of the benzalkonium chloride solution was transferred with a Pasteur disposable pipet actuated with a 5-ml. Hamilton syringe. An equal volume of 8 *N* KOH was added to give final concentrations of 50 mg./ml. of benzalkonium chloride in 4 *N* KOH. Ampuls were sealed and heated 1.0 hr. at 110°. After cooling the ampul under tap water and shaking to thoroughly remix any separated phases, the ampul was opened, and 5 μl. was injected into the chromatograph. All conditions of operation were the same as used in the previous study (2).

For the catalytic hydrogenation, 2.0 ml. of the benzalkonium chloride solution was transferred to the micro glass reaction flask and 35 mg. of palladium chloride (10%) on charcoal was added. After initial evacuation of the reaction flask, hydrogen was introduced to a final pressure of 35 psig and the reaction was allowed to proceed until no further pressure drop was obtained. The procedure of the USP (1) was continued for the recovery of the alkyldimethylamines formed.

The calibration runs on the gas chromatograph

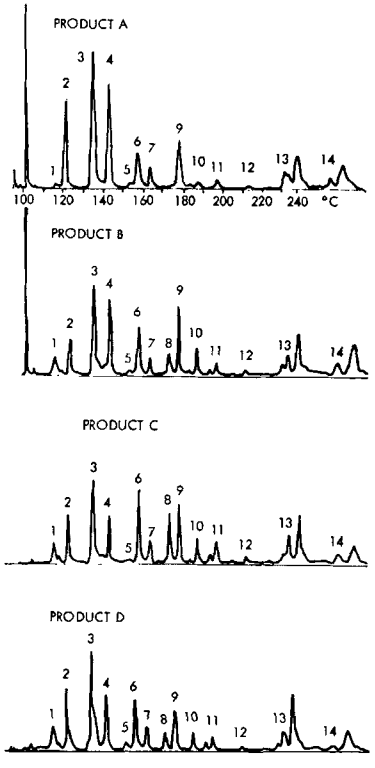

Fig. 2—Hofmann degradation of four commercial benzalkonium chlorides. Key: 1, n-$C_{12}H_{26}$; 2, *1-*$C_{12}H_{24}$; 3, *BDMA;* 4, *1-*$C_{14}H_{28}$; 5, *BMA;* 6, n-$C_{16}H_{34}$; 7, *1-*$C_{16}H_{32}$; 8, n-$C_{18}H_{38}$; 9, $C_{10}H_{21}OH$; 10, *1-*$C_{18}H_{36}$; 11, $C_{12}H_{25}OH$; 12, $C_{14}H_{29}OH$; 13, $C_{16}H_{33}OH$; 14, $C_{18}H_{37}OH$.

were temperature programmed runs (6°/min.) from 100–240° and linear plot of relative elution temperature to benzyldimethylamine for all alkanes, alkenes-1, and alkanols found in the modified Hofmann degradation against carbon number in the various homologous series gave straight line relationships. The same operating conditions were used also for the analysis of the catalytic hydrogenation products.

The relative elution temperature and average detector response in micrograms per disk unit of integration (mcg./DU) for the alkanes and alkanols have been previously reported (2). Table I shows the relative retention characteristics of alkyldimethylamines with respect to lauryldimethylamine under similar conditions.

TABLE III—ALKYL DISTRIBUTION OF FOUR BENZALKONIUM CHLORIDES BY THE MODIFIED HOFMANN DEGRADATION

Alkyl Group	Product *A*	Product *B*	Product *C*	Product *D*[a]
C_{12}	25.8	24.8	34.9	36.1
C_{14}	47.0	47.4	34.1	37.5

C_{18}	12.1	18.4	16.6	12.0
	100.0	100.0	100.0	100.0

[a] Prepared from the 93.5% concentrate.

RESULTS AND DISCUSSION

Alkyl Distribution Studies—To determine the applicability of the modified Hofmann degradation in conjunction with gas chromatography for the analysis of alkyl distribution of a mixture, such as benzalkonium chloride, a synthetic mixture was prepared from samples of C_{14}-alkyl-, C_{16}-alkyl-, and C_{18}-alkylbenzyldimethylammonium chlorides, previously analyzed by the same technique (2). As shown in Fig. 1, good resolution of all peaks was obtained, and reasonable replication of alkyl distribution between samples was achieved. (Table II.)

[a] Based on detector responses given in Table I. [b] Based on detector responses given in Table I for BDMA and distributed molecular wt. of quaternary ammonium chlorides.

Four different commercial benzalkonium chlorides were analyzed after Hofmann degradation. Qualitatively similar chromatograms were obtained (Fig. 2), but analysis of peak areas showed considerable variation in the alkyl ratio distribution (Table III). This study was expanded to evaluate possible lot to lot variations in a commercial product used for an extended time and samples of benzalkonium chloride (product *D*) as received over a period of 2 years were analyzed for their alkyl distribution. Constant alkyl ratios were obtained (Table IV). Two lots of product *A* were also analyzed with similar good agreement for alkyl distribution between lots (Table V).

Impurities in Benzalkonium Chlorides—In addition to the expected alkenes, samples of benzalkonium chlorides showed the presence of impurities of alkanols, alkanes, and benzylmethylamine. Many of these impurities have been previously characterized (2) and can be identified in chromatograms by their retention data. Considerable variation in the amounts of the impurities between different benzalkonium chlorides were noted. An analysis of the peak areas of the major impurities in the chromatograms from Fig. 2 is shown in Table VI. The volatile impurities were a significant contribution to the content of the products and were from 30–53%. No evaluation of nonvolatile impurities was made.

Quantitation—The use of the modified Hofmann degradation approach for quantitative results is based on the formation of benzyldimethylamine by any of the quaternaries present, irrespective of the alkyl substituents. The ratios of the alkenes found allows an assignment of the amount of the particular quaternary. Quantitation was possible to a lower limit of 0.05%.

Comparison of Catalytic Hydrogenation and Hofmann Degradation—The official USP method for the determination of alkyl distribution in benzalkonium chloride requires specialized hydrogenation equipment in addition to a temperature programmed gas chromatograph (1). In the chemical work-up after hydrogenation and before analysis, many of the impurities possibly present in the original compounds or created with hydrogenation are eliminated by the USP procedure. The ratio of the amines resulting from the hydrogenation of the benzalkonium chloride are obtained from the chromatograms. A comparison of the USP procedure with the modified Hofmann degradation was made for two lots of product *A* (Table V) and for a USP reference standard (Table VII). The results obtained by both methods showed that the differences between methods were within the limits of variation for either method on a single sample.

N-Aralkyl-*N*-methylaminoethyl Carbanilates as Hypocholesteremic Agents

By WILLIAM J. ROST, BLAINE M. SUTTON, BENJAMIN BLANK, FRANCIS R. PFEIFFER, WILLIAM L. HOLMES, NICHOLAS W. DITULLIO, and EDWIN B. INGRAM

A group of aralkylaminoethyl esters and ureas of substituted carbanilic acids was prepared and studied for hypocholesteremic activity in eucholesteremic mice. Biological results indicated that modification of either terminal aromatic ring altered the activity of the resultant compound. The *meta* and *para* methyl substituted carbanilates of aralkylmethylaminoethanol consistently exhibited the most desirable effect. In the dicarbanilate series of aralkyl or aryl substituted iminodiethanols, no appreciable activity was seen.

A previous publication (1) reported on the preparation of a series of *N*-aralkyl-*N*-methylaminoethyl carbanilates and their local anesthetic activity. Since that report, additional biological testing revealed that certain members of the series possessed hypocholesteremic activity in experimental animals. The novelty of this activity as well as the potential value of a safe effective agent exhibiting these properties prompted the study of this type of compound in greater detail. This paper describes preparation of additional examples in this class of compounds, their effect on cholesterol metabolism in the mouse, and chemical structure-biological function relationships in the series.

Received April 25, 1967, from the School of Pharmacy, University of Missouri at Kansas City, Kansas City, MO 64110
Accepted for publication August 15, 1967.
Presented to the Medicinal Chemistry Section, APhA Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

EXPERIMENTAL

Chemical

Preparation of N-Aralkyl-N-methylaminoethyl Carbanilate Hydrochlorides—The compounds listed in Tables I, II, and III were prepared from the appropriate alcohol and substituted phenyl isocyanate in the manner previously described by Barnes and Rost (1).

Preparation of N-Benzyliminodiethyl Dicarbanilates—The compounds listed in Table IV were prepared from *N*-benzyliminodiethanolamine and substituted phenylisocyanate in the same manner as that described for *N*-benzyliminodiethyl di-*p*-chlorophenylcarbanilate by McKay and Hatton (2).

Preparation of N-m-Tolyliminodiethyl Dicarbanilates—The compounds in Table V were prepared from *m*-tolyliminodiethanol and the appropriate substituted phenyl isocyanate in the same manner as the *N*-benzyliminodiethyl dicarbanilates previously described.

Preparation of N_1-(N-Benzyl-N-methylaminoethyl)-N_3-p-chlorophenylurea—The compound was prepared by dissolving 3.25 Gm. (0.02 mole) of *N*-benzyl-*N*-methylaminoethylamine in 10 ml. of toluene and adding 3.2 Gm. (0.022 mole) of *p*-chlorophenylisocyanate which was dissolved in 10 ml. of toluene. After refluxing 1 hr., the mixture was permitted to stand overnight. The crystals which formed were filtered off and recrystallized from acetone. The 3.4 Gm. yield (53%) melted at 118–120°.

The compounds listed in Table VI were prepared in the same manner as that described for N_1-(*N*-benzyl-*N*-methylaminoethyl)-N_3-*p*-chlorophenylurea.

Preparation of N-Benzyl-N-methylaminoethyl-N'N'-dimethylcarbamate Hydrochloride—A mixture of 15.2 Gm. (0.1 mole) of β-chloroethyl dimethylcarbamate (3) and 24.2 Gm. (0.2 mole) of benzylmethylamine was heated at 100° for 1 hr. After cooling, the solid reaction mixture was extracted with ether, the combined extracts concentrated, and the residue fractionally distilled to give 15.1 Gm. (64%) of ester, b.p. 110–120°/0.25 mm. The ester was dissolved in anhydrous ether and precipitated as the hydrochloride salt by the addition of an ethereal solution of hydrogen chloride. The resultant oil crystallized on standing and was recrystallized from an ether–alcohol mixture. The product melted at 146°.

Anal.—Calcd. for $C_{13}H_{21}ClN_2O_2$: C, 57.24; H, 7.76. Found: C, 56.93; H, 7.19.

Preparation of N-Benzyl-N-methylaminoethyl-N'-butylcarbamate Hydrochloride—The compound was prepared as noted in the carbanilate series (1). The product melted at 122–123° and was obtained in 58.5% yield.

Anal.—Calcd. for $C_{15}H_{25}ClN_2O_2$: C, 59.88; H, 8.38. Found: C, 60.11; H, 8.05.

Preparation of N-α-Methylbenzyl-N-methylaminoethanol—1-Bromoethylbenzene was reacted with *N*-methylaminoethanol as described previously (1) to give *N*-α-methylbenzyl-*N*-methylaminoethanol (67%), b.p. 131–133°/5 mm.

Preparation of N-o-Chlorobenzyl-N-methylaminoethanol—*o*-Chlorobenzyl chloride was reacted with *N*-methylaminoethanol as previously described (1) to give *N*-*o*-chlorobenzyl-*N*-methylaminoethanol (85%), b.p. 112–120°/1.5 mm.

Preparation of N-Benzyl-N-methylaminoethylamine—Benzylmethylamine was reacted with ethyleneimine according to the method of Coleman and Callen (4) to give *N*-benzyl-*N*-methylaminoethylamine (73%), b.p. 80–93°/2 mm.

Biological Assay

Each compound was evaluated for its hypocholesteremic activity in male, Swiss Webster mice. Ten mice, weighing between 28–34 Gm., were used for each test compound. The mice were maintained on a fat-supplemented, cholesterol-free diet.[1] Test compounds were administered orally in a tragacanth suspension at a dose of 25 mg./Kg. b.i.d. At the end of the 11-day treatment period, animals were sacrificed and pooled tissue cholesterols[2] were determined by the Nury-Smith method (5). Percent change from controls was obtained by comparison with values obtained in an untreated control group of animals carried simultaneously in the experiment. Decreases in plasma or liver total cholesterol greater than 20% from control values without an increase of 8% in either end point, or decreases of 12% or greater in both end points were considered desirable biosignificant results.[3]

DISCUSSION

The types of compounds reported here have not been previously described as exhibiting hypocholesteremic activity in experimental animals. In this study their effect on both plasma and liver cholesterol is reported. It is considered desirable to lower cholesterol levels in one or both of these tissues without increasing either before concluding that a material has produced a desirable effect.

It is difficult if not impossible to ascribe the variable activities of the different members of this series to any specific portion of the molecule, but certain observations might be significant. As seen in Table VII, the presence of an aralkyl substitution seems advantageous, but it can be varied considerably. The *N*-benzyl, *N*-phenethyl, and *N*-phenpropyl amines show activity in lowering plasma and liver cholesterol (groups *A*, *B*, and *C*). However, the branching of the aralkyl group (group *D*) and substitution in the aralkyl group (group *E*) appear detrimental.

Substitution in the carbanilate ring markedly affects activity in this series of compounds. *Meta* and *para* substitutions produce compounds with a more consistent desirable activity than *ortho* substitution. Methyl substitution appears more favorable than the chloro or methoxy. Analogous ureas (group *I*) did not exhibit patterns similar to the carbanilate series. Here only the *p*-methoxy compound (53) appeared interesting. Even the aromatic ring was not essential, as seen by the activity of the butylcarbamate (48).

Increasing the bulk of the molecule to compounds of the dicarbanilate type (groups *F* and *G*) did not yield useful agents.

The results of this biological study indicate that both terminal portions in the molecules of the compounds reported contribute to the type of activity produced by them. Although several of these compounds do block *in vitro* biosynthesis of cholesterol from mevalonate (7), their mechanism of hypocholesteremic action *in vivo* is unknown. If they should be acting by inhibiting cholesterol biosynthesis, it is tempting to suggest that the enzymatic site of activity has two or more foci of attachment. Such an implication has been suggested by Kraml *et al.* (8) when describing the hypocholesteremic activity of *N,N'*-dibenzylethylenediamine and related compounds.

[1] Vitamin free casein, 24%; sucrose, 45%; Alphacel, 4%; salt mixture (USP XIV), 4%; dextrin, 20%; vitamin fortification mixture, 2%; ethyl linoleate, 1%.

[2] It was found more convenient to use pooled rather than individual samples in this work because of the large number of assays necessary. The authors have found previously in groups of ten animals that the mean of ten individual assays did not differ measurably from the result obtained with a pooled sample.

[3] Triparanol tested under these conditions decreased serum cholesterol 17.8% and liver cholesterol 37.6%. Gas chromatography of tissue extracts of triparanol treated animals shows accumulation of desmosterol (6). No abnormal sterols were observed in the tissue extracts of the animals treated with the compounds of this report.

Dermatitic Effect of Nonionic Surfactants II

Changes in Phospholipid and in Deoxyribonucleic Acid Content of Rabbit Epidermis *In Vivo*

By MICHAEL MEZEI* and R. W. SAGER

A hypothesis, namely, that the site of action of surfactants is in the biological membranes, was investigated with an indirect method. One representative member from each of 3 major types of nonionic surfactants was tested. Sorbitan trioleate, polysorbate 85, and polyoxyethylene ether 96 were incorporated, 10 percent in concentration, in white petrolatum and applied to rabbit skin daily. Measurements of lipid phosphorus indicated a considerable increase in the phospholipid content of the 0.1 mm. thick skin samples representing mainly the epidermis. Two reference standards were used: the wet weight and the deoxyribonucleic acid (DNA) content. After 4 days of treatment with polysorbate 85, sorbitan trioleate, and polyoxyethylene ether 96 preparations, the increase in phosphorus was found to be 23–56 percent, 28–73 percent, and 46–90 percent, respectively, on the basis of wet weight and 26–53 percent, 27–58 percent, and 47–81 percent, respectively, if DNA content was used as the reference standard. After 10 days of treatment, the increase in phosphorus was considerably smaller if calculated on the basis of DNA present in the sample, but did not differ much if wet weight was used as the reference. A comparison of the two reference standards demonstrated that the DNA content also increased after 10 days of treatment. The smaller spread in results indicated that DNA content may be more reliable as a reference standard, but the wet weight still can be used as a practical and useful standard of reference especially if the DNA content is also influenced by the test.

THE DERMATITIC effects of nonionic surfactants have been the subject of much research (1–7). All of these studies, however, have been limited to surfactants present in household cleaners or in aqueous solutions. Most of these investigations employed *in vitro* and/or patch test techniques, which were based upon experimental procedures that were empirical in nature and arbitrary in evaluation; they relied on gross observations and on microscopic evaluations. These evaluation methods can reveal little or nothing about the biochemical changes at the cellular level which probably initiate the morphological changes observed.

The aim throughout the present investigation has been to design and apply more definitive and rational test procedures. In contrast to the *in vitro* and patch test techniques, attempts were made to reproduce the frequent application of dermatological and cosmetic preparations, which may contain these surfactants, by the general public. Besides macroscopic and microscopic observations, attempts were made to investigate biochemical changes by standard and well-accepted assay methods. Measurements and observations regarding morphological changes (on both the macroscopic and microscopic level) and of oxygen consumption were reported as a first part of the study (8). This presentation is mainly concerned with the measurement of quantitative changes in the phospholipid content of the rabbit epidermis induced by surfactant applied to the skin in the form of an ointment. The DNA content was also determined with the intention of using a more reliable reference standard than the wet weight of sample is believed to be.

MATERIALS AND METHODS

Thirteen New Zealand white rabbits of both sexes, 6–12 weeks old, were used as experimental animals. They were housed in hanging screen-bottom cages and were maintained on Purina rabbit chow and water *ad libitum*. The trunk of each rabbit was clipped free of hair with an electric hair clipper (Oster model A2, size 40), and was divided into 6 areas. Harness-type restrainers (9) were used for restraining rabbits with a minimum amount of stress.

One representative member from each of 3 major types of surfactant was selected. Sorbitan trioleate,[1] polysorbate 85,[2] and polyoxyethylene ether 96[3] were incorporated in white petrolatum USP in 10% concentration and were applied to the center of the designated areas of rabbit skin daily. The other three areas on the rabbits' back were reserved for controls: (*a*) untreated skin *A*, (*b*) untreated skin *B*, and (*c*) skin treated with the ointment base only. Untreated skin *B* was used as a control to determine

whether the surfactant which penetrated into the skin influenced the extraction of lipids and DNA, which could also be a reason for finding different amounts of lipids and perhaps DNA in control and treated skin. To this control area one of the surfactant preparations was applied only once: 15 min. before the sample was taken. This single application provided some surfactant in the skin homogenate, but did not induce any measurable biological changes. The sites of control and treated areas were randomly selected from different animals to exclude any influence of body area. After 4 or 10 days of treatment, the animals were killed by fracturing the neck. The test areas were quickly washed with cotton soaked in ether to remove not only the substances applied previously, but also the surface lipids. Skin samples were taken with the aid of the Castroviejo keratotome (10) set to cut a 0.1-mm. thick skin slice. The samples were immediately dipped in liquid nitrogen, and kept there until the wet weight was determined on an analytical balance. The weight of each sample was around 100 mg. The elapsed time between removing and weighing the samples was not more than 20–30 min. Immediately after weighing, the skin samples were homogenized in a glass homogenizer and extracted with 2.0 ml. of chloroform–methanol (2:1) after the method of Folch *et al.* (11). The residue was set aside for DNA extraction. Nonlipid contaminants were removed from the chloroform–methanol extracts with 0.2 vol. of 0.05% $CaCl_2$ solution. The phospholipid content of the lipid extracts was determined by the method of Bartlett (12). The residue obtained after the extraction of lipids was extracted for the determination of DNA content by the method of Santen and Agranoff (13).

RESULTS AND DISCUSSION

In studies involving skin lipid analyses the greatest problem has been to provide skin samples in chemically unaltered form with well-defined anatomical structure. Skin lipid samples have usually been divided into 3 categories (14): (*a*) epidermal lipid samples; (*b*) lipid samples from various sebaceous type glands, or from the dermis and, (*c*) lipid samples from the skin surface.

There have been only indirect methods reported for the determination of lipid composition of human epidermis (14–18). In these studies the separation of epidermis from the dermis was achieved by chemical and physical methods (19, 20). In the present investigation, in order to avoid any artifact induced by these separation techniques, 0.1 mm. thick skin slices were cut from rabbits. Microscopic examinations revealed that these samples contained mainly the epidermis, and occasionally a trace of dermis (Fig. 1). The surface lipids were extracted with ether before cutting off the skin slices. This technique provided a well-isolated and chemically unaltered epidermis sample for lipid analysis.

The total phospholipid content of control and treated rabbit skin after 4 days of treatment is shown by Tables I and II. Using DNA content as the reference standard, it was found that the phosphorus (P) content of the control skin samples (untreated skin *A* and *B*) was within the range of 7.44–10.84 mcg. P/100 mcg. of DNA. In skin samples which were treated with the ointment base only,

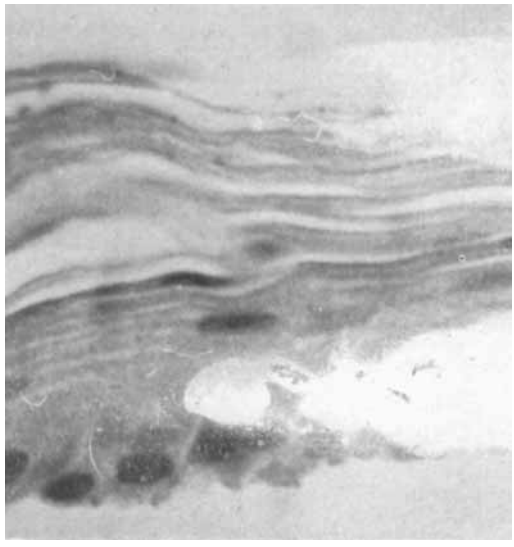

Fig. 1—Photomicrograph of skin sample obtained with the aid of the Castroviejo keratotome set to cut 0.1 mm. thick skin slices.

which were also considered as controls, the range was somewhat higher, 9.26–11.24 mcg. P/100 mcg. DNA. Among the treated skin samples the one which was treated with polyoxyethylene ether 96 (10% in petrolatum) showed the largest increase in phosphorus content; the range was 11.52–17.31 mcg. P/100 mcg. DNA, which represented a 47–81% increase as illustrated by Fig. 2.

Treatment with polysorbate 85 and sorbitan trioleate also produced a considerable increase in phosphorus content, 26–53% and 27–58%, respectively. If the phosphorus content is referred to the wet weight of the sample, it is found that the same pattern exists (see Fig. 3 and Table II). The phosphorus content of treated skin samples also showed an increase, but the spread in the results was somewhat larger. The increase of phosphorus, calculated according to the wet weight for samples treated with petrolatum, polysorbate 85, sorbitan trioleate, and polyoxyethylene ether 96, was within the range of 1–15%, 23–56%, 28–73%, and 46–90%, respectively.

Tables III and IV show the results of a similar treatment but for a longer period of time. After 10 days of treatment with polysorbate 85, sorbitan trioleate, and polyoxyethylene ether 96, the increase in phosphorus was found to be 19–38%, 18–35%, and 22–33% (Fig. 2), respectively, on the basis of DNA content, and 40–66%, 24–67%, and 46–76%, respectively, on the basis of wet weight of sample (Fig. 3). The increase of phospholipid phosphorus was considerably smaller than that found after 4 days of treatment, if calculated on the basis of DNA present in the sample, but did not differ much if wet weight was used as the reference. A probable explanation could be that the DNA content was also increased; consequently, the reference standard became greater in the case of DNA, and probably changed nothing in case of the wet weight.

The wet weight is generally used with caution as a reference standard in biological studies, especially

when the tissue studied is heterogeneous in nature. An attempt was made in this study to use samples with uniform structure. Skin samples of 0.1-mm. thick slices could, however, contain different proportions of the four layers of epidermis (stratum germinativum, stratum spinosum, stratum granulosum, and stratum corneum). In order to find a more reliable reference standard than the tissue wet weight is believed to be, the DNA content of each sample was determined. DNA content is used to indicate the number of viable cells. On the basis of DNA content the results of lipid phosphorus determinations show patterns similar to those found when the wet weight was used as a reference. There were, however, 2 distinct differences between the results, calculated on the basis of the two refer-

ence standards. Using DNA as a reference, the range of these percentages is narrower than if wet weight is used as a reference standard. The second difference is apparent with the results of the 10 day treatment. Here not only the range is narrower but the increase of phosphorus is also smaller when using DNA as a reference. The smaller spread in results indicates that DNA may be more reliable as a reference standard, but the wet weight still can be used as a practical and useful standard of reference, especially if the DNA content is also influenced by the test.

Table V shows the comparison of the 2 reference standards. DNA content, as related to wet weight of the sample, shows an increase after 10 days of treatment. This might be due to irritation of the skin, caused by the surfactant treatment which could initiate a higher metabolic and mitotic activity. An increased rate in cell proliferation, and hyperplasia of the epidermis, are often paralleled with an increased rate of DNA synthesis and an increase in DNA content (21–24).

It was postulated (8) that the effect of nonionic surfactants on the respiratory metabolism of rabbit skin is partly an indirect one and may be due to permeability changes of cell membranes.

The structure of biological membranes is based upon a lipid–protein positional relationship. The classical Danielli-Davson (25) model of the membrane and the more recent "unit membrane" hypothesis of Robertson (26) have suggested a bimolecular phospholipid leaflet as the backbone of membrane structure. Recent reports and reviews (27–32) describe the structure and function of membranes in a more detailed manner. All of these descriptions are highly speculative in nature; there is no proven theory for the exact nature of membranes at the molecular level.

On the basis of these hypotheses it can be stated, however, that a qualitative and/or quantitative change in the lipid composition of a tissue might indicate structural changes in the membranes, especially if these changes were induced by substances which more likely act on the membranes.

Surfactants, due to their hydrophilic–lipophilic character, generally possess a particular affinity for membranous structures. As a result of this affinity, a nonionic surfactant can (*a*) interact by hydrophobic bonding, being a macromolecule itself; (*b*) interact by hydrogen bonding, because of the strong hydrogen bonding affinity of the ether oxygens of the polyoxyethylene chains; (*c*) disturb the micellar structure of phospholipids, forming micelles, or replacing phospholipid molecules in the continuous lipid micelles; and (*d*) interact with water molecules participating in these micelles. These are only a few possibilities which may result in alterations of membrane structure and, consequently, functional changes and metabolic disorders.

On the basis of the postulation that the primary site of action of surfactants is in the biological membranes, it was decided to seek ways to test this possibility. It was apparent that proving this hypothesis with direct methods would be difficult, since there is no way at the present time to study membrane structures at the molecular level. The determination of quantitative changes of phospholipids, an indirect method, was intended to investigate and to support this hypothesis.

The probable reason for the increase of phospholipids is that the surfactants damaged the biological membranes by either rupturing the membranes or replacing certain phospholipid molecules in the continuous phospholipid micelles present in the membranes. To repair this damage, a higher rate in the biosynthesis of certain phospholipids should be expected, in order to regenerate the original membrane structure. Phospholipid molecules present in ruptured membranes and those that are possibly replaced by surfactants are measured along with the newly formed molecules during the analysis of skin tissue.

An investigation of the effects of polysorbate 80 on the *in vitro* metabolism of cells, reported by Kay (33), should be mentioned here to support this hypothesis. Treatment with polysorbate 80 induced a marked increase in cell permeability in preparations of Ehrlich-Lettré ascites cells. An extraordinary increase (up to almost 300%) in the incorporation of ^{32}P into phospholipid fractions was also observed in cell preparations containing 1% polysorbate 80.

The above phenomena might also be explained by the assumption that the increase in permeability is due to structural changes (disruption of membranes). The rapid incorporation of ^{32}P into phospholipids after the surfactant treatment suggests a reconstitution of cell membrane material.

A further study of the rate of biosynthesis of phospholipids in rabbit and in human skin treated with surfactant preparations should prove the above hypothesis.

Another well-known phenomenon, namely, that surfactants generally increase percutaneous absorption of various substances (34), could be explained partly by permeability changes, due to structural changes in skin "barrier" membranes.

The results reported here are in accordance with the authors' previous findings regarding gross and microscopic changes in rabbit skin induced by surfactants. It is apparent that the polyoxylene ether-type surfactants have the highest capacity to pro-

duce dermal reactions: severe erythema, hyperkeratinization, and desquamation with marked induration and fissuring on the macroscopic level; inflammation with a number of polymorphonuclear and round cells in the dermis and acanthosis with hyperplasia and various degrees of necrosis in the epidermis on the microscopic level; and the highest increase in lipid phosphorus content.

Reaction Gas Chromatography III

Recognition of Tropane Structure in Alkaloids

By CZESLAWA RADECKA and ISHWAR C. NIGAM

The technique of "reaction gas chromatography" involving dehydrogenation of heterocyclic compounds by a platinum-firebrick catalyst was applied to alkaloids possessing the tropane moiety in their structures. The reaction chromatogram of 3-tropanol, from which most of these alkaloids may be considered to be derived, exhibited several peaks, among which were those due to pyrrole, methylpyrrole, pyrrolidine, pyridine, piperidine, and toluene. These products were also produced by atropine, homatropine, scopolamine, ecgonine, and cocaine when these alkaloids were examined under similar experimental conditions. Atropine, homatropine, and scopolamine exhibited some additional peaks which were correlated with their structures.

APPLICATIONS OF reaction gas chromatography involving catalytic dehydrogenations, to alicyclic and heterocyclic compounds in general and to monoterpenoids in particular, were described in earlier publications from this laboratory (1, 2). The success achieved in experiments with heterocyclic compounds (1) prompted the authors to extend the technique to bases belonging to the tropane group of alkaloids. The present communication reports the results of the investigations. It was observed that these alkaloids as well as tropine, the alcohol from which they are derived, suffered pyrolytic dehydrogenation when they were passed through a reactor packed with 5% platinum on base-washed firebrick. Structures of the substances examined could be meaningfully correlated with the products of reaction and the technique may be employed for the detection of tropane moiety in natural and synthetic alkaloids.

Received April 5, 1967, from the Research Laboratories, Food and Drug Directorate, Department of National Health and Welfare, Ottawa, Ontario, Canada.
Accepted for publication August 8, 1967.
Presented to the Thirteenth Canadian Conference on Pharmaceutical Research, Saint John, New Brunswick, Canada, August 16, 1966.
The authors are thankful to Dr. Leo Levi for his interest in these investigations.

Previous paper: Mizrahi, I., and Nigam, I. C., *J. Chromatog.*, **25**, 230(1966).

EXPERIMENTAL

Apparatus—*Gas Chromatograph*—Burrell Kromotog K-2 equipped with thermal conductivity detector and gas valves for directing the carrier gas to the chromatographic column directly or *via* the reactor, as required.

Column—Glass tube (225 cm. long, 6 mm. i.d.)

packed with 20% Carbowax 20M on base-washed firebrick and maintained at 140 ± 1°.

Carrier Gas—Helium, 75 ml./min.

Reactor—Construction of the reactor has been described (1). It was filled with 0.7 Gm. of the catalyst and maintained at 280 ± 5° with the help of an external heating jacket. A thin platinum wire was inserted into the tapered end of the reactor leading into the column in order to prevent deposition of less volatile products.

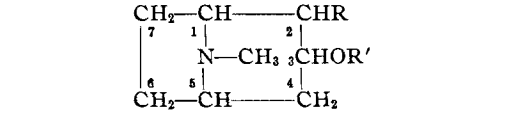
Catalyst—Five percent platinum on base-washed firebrick (30–60 mesh) prepared as described before (1).

Procedure—Ethanolic solutions of the substances were employed. Aliquots containing 1–3 mg. of the samples were used for injections. Substances existing in the liquid state at room temperature were used without solvent. The chromatographic peaks were tentatively identified by comparison of retention times with those of pure reference standard. Identifications of compounds possessing chromophoric groups were confirmed by collecting the corresponding effluent fractions in ethanol and recording the ultraviolet spectra.

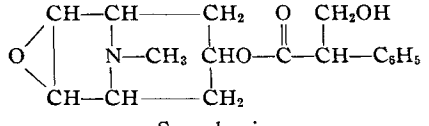
RESULTS AND DISCUSSIONS

Tropane alkaloids are derivatives of 3-tropanol formed by esterification of the hydroxyl group and/or by substitutions on other carbon atoms. The formulas of compounds used in the present investigations are shown in Table I. It may be

TABLE I—TROPANE DERIVATIVES



Compd.	R	R′
3-Tropanol	H	H
Atropine	H	—C(=O)—CH(CH₂OH)—C₆H₅
Homatropine	H	—C(=O)—CH(OH)—C₆H₅
Ecgonine	—COOH	H
Cocaine	—COOCH₃	—C(=O)—C₆H₅



Scopolamine

expected that the products of pyrolytic dehydrogenation of tropanol would be present among the products derived from the alkaloids. It was, therefore, considered worthwhile first to study the degradation of tropanol and then to employ the data for interpretation of results obtained by dehydrogenation gas chromatography of the alkaloids.

Tropanol—The reaction gas chromatogram of tropanol exhibited several peaks (Fig. 1,A). Apparently the fused ring system of tropanol had suffered cracking under the experimental conditions, leading to the formation of smaller molecules. This was confirmed by identification of some of the reaction products. The first step of the reaction may be the dehydration of tropanol to tropidine (3). Degradation of tropidine may then proceed *via* rupture of C—N or C—C bonds as indicated in Scheme I. The rupture of a C—N bond on passage of vapors of tropane over a palladium-asbestos catalyst at 300° was reported by Ehrenstein and Marggraff (4). Under more drastic conditions—*viz.*, fusion with alkali—the nitrogen atom was completely detached in the form of methylamine (3, 5). The rupture of C—C bonds of the tropane skeleton has also been observed. Thus when tropidine was dehydrogenated with bromine, 3,5-dibromopyridine, ethylene dibromide, and methyldibromopyridine were formed (6). Although the presence of pyrrole derivatives among the products of the above degradations was not reported, their formation under conditions of drastic degradation is quite likely to take place since it would involve only rupture of C—C bonds without affecting the N—CH_3 group (4). The rupture of the fused ring system of tropanol may, therefore, give rise to three types of monocyclic systems: a five-membered heterocyclic ring, a six-membered heterocyclic ring, and a seven-membered carbocyclic ring.

As expected, *N*-methylpyrrole, pyridine, and pyrrole were readily identified among the products as peaks No. 4, 5, and 9, respectively. (Table II.) Peak No. 3 was generated by toluene. This aromatic hydrocarbon must have been formed by isomerization of tropilidine produced, presumably, by detachment of the N—CH_3 bridge from the molecule of tropidine (or tropanol). Isomerization of tropilidene to toluene has been the subject of several recent publications (7–12). Under the present experimental conditions hydrogen transfer reactions may also take place. Thus peaks No. 1 and 2 were assigned to pyrrolidine and piperidine. Peaks No. 6 and 7 appeared to be due to partially dehydrogenated piperidines. Peaks at the same retention times were observed along with the peaks of pyridine and unchanged piperidine, when the latter was passed through the reactor under the same experimental conditions. Highly volatile products, *e.g.*, methane, ethylene, methylamine, *etc.*, were presumably eluted within the first 2 min., and their peaks were masked by those generated by ethanol, the solvent employed for injecting the samples.

Atropine and Homatropine—Atropine and homatropine are esters of tropanol with tropic and mandelic acids. Pyrolysis of these substances would be expected to yield tropidine and the corresponding acids, which products would undergo further degradation to simpler molecules. Thus the reaction chromatograms of these alkaloids (Fig. 1,B and C) exhibited all the peaks generated by tropanol. In addition atropine showed a peak (No. 8) which, according to ultraviolet spectral analysis, may be assigned to styrene. This product was also obtained when tropic acid was passed through the reactor under the same experimental

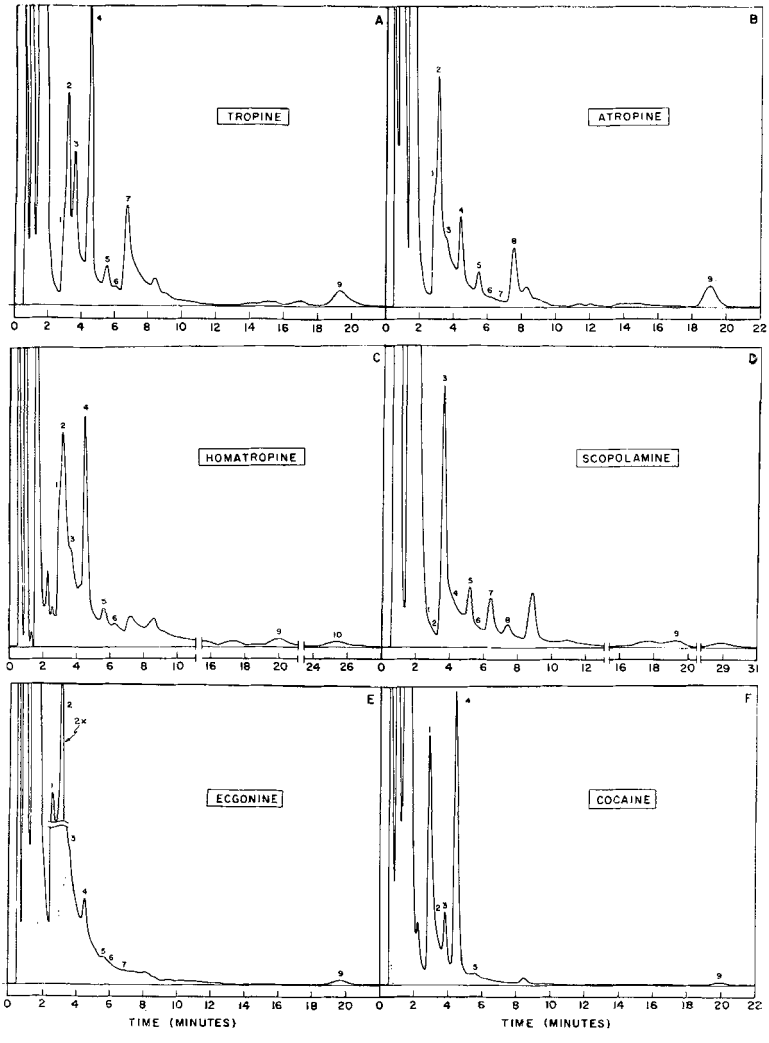


Fig. 1—Reaction chromatograms of tropanol and tropane alkaloids. (See Table II for assignment of peaks.)

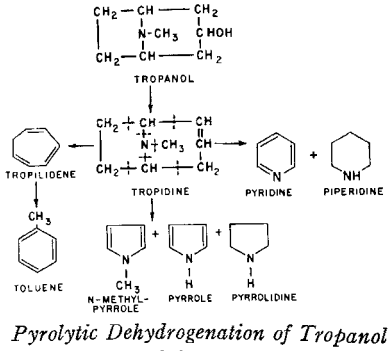

Pyrolytic Dehydrogenation of Tropanol
Scheme I

conditions. The reaction chromatogram of homatropine exhibited a peak due to benzaldehyde, formed by degradation of mandelic acid moiety in the alkaloid. This was confirmed by injecting mandelic acid in the reactor, when benzaldehyde was observed to be the main product of reaction.

$$C_6H_5CH(COOH)CH_2OH \rightarrow C_6H_5CH{=}CH_2$$
$$C_6H_5CH(OH)COOH \rightarrow C_6H_5CHO$$

TABLE II—ASSIGNMENT OF PEAKS IN REACTION CHROMATOGRAMS

Peak No.[a]	Relative Retention Time[b]	Assignment
1	0.64	Pyrrolidine
2	0.71	Piperidine
3	0.82	Toluene
4	1.00	*N*-Methylpyrrole
5	1.25	Pyridine
6	1.38	Partially dehydrogenated piperidines
7	1.52	
8	1.68	Styrene
9	4.55	Pyrrole
10	5.83	Benzaldehyde

[a] See Fig. 1. [b] Reference standard: *N*-methylpyrrole.

Scopolamine—Scopolamine is an epoxy-atropine. On pyrolytic dehydrogenation it yielded products many of which were the same as those produced by atropine (see Fig. 1,D). However, the peaks due to *N*-methylpyrrole, pyrrole, and pyrrolidine

were comparatively smaller presumably due to further oxidative degradation of the five-membered heterocyclic ring carrying the epoxy group.

Ecgonine and Cocaine—Ecgonine is a carboxy derivative of tropanol, while cocaine is a carbomethoxy derivative of tropanyl benzoate. Although these compounds would be expected to yield the same products of degradation, the yield of six-membered heterocyclic compounds was in fact, very poor (Fig. 1,E and F). Presumably these compounds do not decarboxylate easily and are retained by the basic support.

CONCLUSIONS

The experimental data reported above demonstrate that the described technique should prove of value in establishing the identity of tropane alkaloids as well as in recognizing the tropane carbon skeleton in alkaloids of unknown structure.

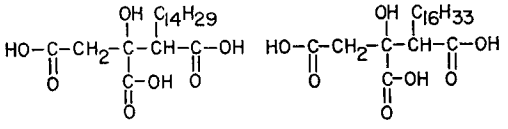
Pharmacologic Study of Norcaperatic and Agaricic Acids

By RICHARD A. CARRANO* and MARVIN H. MALONE

In rats norcaperatic acid produced delayed onset, dose-related effects of mydriasis, skeletal muscle weakness, and central nervous system depression similar to those induced by its homolog, agaricic acid. Agaricic acid was a nonspecific potentiator of furtrethonium in isolated rat jejunum. Both acids produced a slow onset of leiomyotonic effects on isolated guinea pig ileum. This effect could be blocked by papaverine but was not affected by high concentrations of atropine, pyribenzamine, or by a depolarized muscle. Tonic activity could also be produced in a K^+ deficient muscle. Both norcaperatic acid and agaricic acid were competitive inhibitors of the enzyme aconitase with norcaperatic acid being slightly more potent. The potentially toxic properties of *Cantharellus floccosus* due to the presence of norcaperatic acid may be related to the structural chemical relationships of this substance to citric acid.

CANTHARELLUS FLOCCOSUS Schw. has been reported to cause serious delayed gastrointestinal disturbances in individuals (1). Miyata *et al.* (2) isolated and characterized the active principle as norcaperatic or α-tetradecylcitric acid ($C_{20}H_{36}O_7$). Agaricic acid ($C_{22}H_{40}O_7$), an isolate from the mushroom *Polyporus officinalis* Fr., is a homolog of norcaperatic acid and has been included in this study (I and II).



NORCAPERATIC ACID I

AGARICIC ACID II

The isolation of norcaperatic acid from *C. floccosus* marked its first reported occurrence in nature, although agaricic acid had been isolated and studied by various investigators and classified as an anhydrotic and parasympatholytic agent (3–5). The literature reports do not satisfactorily settle whether the mechanism of action on smooth muscle is musculotropic or neurotropic. This study hoped to clarify this problem and to study the possible mechanisms by which these agents could induce mushroom poisoning.

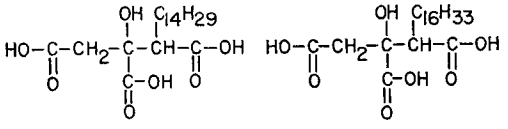
Miyata *et al.* (2) isolated and characterized the active principle as norcaperatic or α-tetradecylcitric acid ($C_{20}H_{36}O_7$). Agaricic acid ($C_{22}H_{40}O_7$), an isolate from the mushroom *Polyporus officinalis* Fr., is a homolog of norcaperatic acid and has been included in this study (I and II).



NORCAPERATIC ACID I

AGARICIC ACID II

The isolation of norcaperatic acid from *C. floccosus* marked its first reported occurrence in nature, although agaricic acid had been isolated and studied by various investigators and classified as an anhydrotic and parasympatholytic agent (3–5). The literature reports do not satisfactorily settle whether the mechanism of action on smooth muscle is musculotropic or neurotropic. This study hoped to clarify this problem and to study the possible mechanisms by which these agents could induce mushroom poisoning.

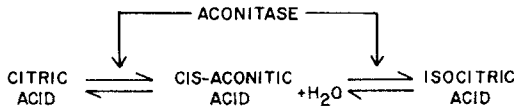
EXPERIMENTAL

In Vivo Hippocratic Screening—Nonfasted albino rats of either sex (Wistar strain, 150–250 Gm.) were injected intraperitoneally with various log-doses of the test drugs suspended in 0.25% agar according to the gross observational method of Malone and Robichaud (6). All required observations were made using the standard worksheet at +5, 10, 15, 30, and 60 min. postinjection, +2, 4, and 24 hr. postinjection, and +2, 4, and 7 days postinjection.

Isolated Rat Jejunum—Using the methods of Ariëns (7), van Rossum (8), and van Rossum and van den Brink (9), cumulative concentration-response curves were recorded with furtrethonium used as the reference agonist. Tyrode's solution oxygenated with 95% oxygen and 5% carbon dioxide and containing the calcium disodium salt of ethylenediaminetetraacetic acid (1×10^{-5} Gm./ml.) was the perfusion media. The rat jejunum section was mounted in a 50-ml. bath (37.5°) using a modified Magnus technique. All drug concentrations were calculated in terms of drug base.

Isolated Guinea Pig Ileum—The ileum wa mounted in the bath (37.5°) using a modified Magnus technique. In the protective studies a submaximal concentration of reference agonist was followed by: a specified concentration of test drug, a specified incubation period, and a repeat of the same concentration of reference agonist. In the antagonism studies a specified dose of experimental drug producing a suitable response was followed by: a specified concentration of prototype antagonist, a specified incubation period, and a repeat of the same concentration of experimental drug. In the K^+ deficient studies, KCl was omitted from the Tyrode's solution and replaced with an equivalent weight of NaCl. In the K^+ excess studies, KCl was added to the Tyrode's solution until the final concentration of potassium ion was 47 m*M*.

Enzymatic Studies—Aconitase was prepared from fresh pig hearts and diluted to a concentration giving workable activity (10). The reaction was studied in a Beckman DU spectrophotometer by following the change in light absorption (240 mμ and 25°) caused by the appearance or disappearance of *cis*-aconitic acid (Scheme I). The reaction was



Scheme I

started by the addition of substrate. Total cell volume was kept at 3.0 ml. by varying the amount of 0.05 *M* phosphate buffer. To assure initial reaction rates, the changes in extinction values (240 mμ at 25°) were recorded at intervals between start and +45 sec., checked for proper kinetics, and calculated as change in absorbance units/min. Experimental drugs were incubated with the enzyme preparation for 3–5 min. prior to activation with substrate. A control rate for a specific concentration of substrate was determined prior to testing the inhibitor's effect on that rate. All drug concentrations were calculated in terms of drug base and were made in 0.05 *M* phosphate buffer, pH 7.4 (10–12).

RESULTS AND DISCUSSION

In Vivo Hippocratic Screening—The whole powdered mushroom of *C. floccosus* and the 70% ethanol extractive obtained from the Drug Plant Laboratory, University of Washington, Seattle, were toxic and showed definite dose-related activity beginning at a dose of 50 mg./Kg. Mydriasis, skeletal muscle weakness, and central nervous system depression accompanied by hypothermia were among the symptoms. Although parasympatholytic activity appeared to be indicated, the presence of lacrimation without salivation, a delayed onset of all activity, and a profound and progressive loss in body weight suggested a more complicated mechanism of action. The extract, as expected, was considerably more toxic and showed more pronounced symptoms. The marc was also studied and was shown to contain residual amounts of activity indicating that the 70% ethanol extraction did not entirely exhaust the active components of the mushroom.

The hippocratic profiles for the samples of agaricic acid and norcaperatic acid were qualitatively identical to that of the mushroom preparations (CNS depression, hypothermia, mydriasis, lacrimation, *etc.*). Fine body tremors were also apparent as a delayed effect. In general, these gross *in vivo* studies suggested a parasympatholytic (hyoscine-like) mechanism. However, the complicating symptomatology, the delayed onset of all effects, and the progressive loss of body weight all suggested metabolic blockade.

Isolated Rat Jejunum—Figure 1 shows the cumulative log-concentration curves of furtrethonium obtained in the presence of agaricic acid. In general, a potentiating effect was seen. Longer incubation resulted in a greater effect. When agaricic acid was incubated with the tissue for 30 min. and washed for 10 min., a significant decrease in the intrinsic activity but not in the affinity of the furtrethonium to the receptor was seen. Apparently, while agaricic acid could be washed out, the muscle or one of its components had been physically changed by the drug. Agaricic acid alone increased both the tone and spontaneous activity of the jejunum. After incubation for about 5 min., a small contrac-

tion would result. A musculotropic (nonspecific) mechanism of action could explain these results.

Isolated Guinea Pig Ileum—Both agaricic and norcaperatic acids (1–5 × $10^{-5}M$) caused a delayed onset, slow, persistent contraction of the guinea pig ileum when the tissue was attached to a lightly loaded isotonic lever system. This leiomyotonic contraction had musculotropic rather than neurotropic characteristics in that it did not begin immediately upon introduction of the drugs but was seen only after about a 3-min. wait. The effect was also very slow (5–6 min. to reach maximum) and did not fade away as is the case with most neurotropic agents (*e.g.*, acetylcholine). The contraction could not be blocked by atropine (1 × $10^{-5}M$), pyribenzamine (1 × $10^{-5}M$), or by previously depolarizing the muscle by increasing the potassium ion concentration to 47 mM. It was still present in the absence of potassium ion in the perfusate. Papaverine, a nonspecific antagonist, could block the effect. These results indicated that the mechanism of action for the test drugs would have to be musculotropic in nature. Dose-related activity is one of the basic prerequisites for true drug activity. Figure 2 depicts the dose-response curve obtained when agaricic acid was accumulated in the bath.

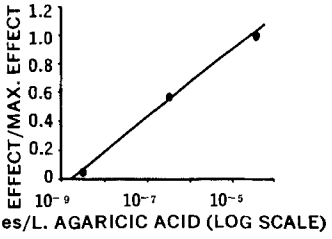

Fig. 2—Cumulative log-concentration curve of agaricic acid. Guinea pig ileum.

Enzymatic Studies—The musculotropic action on smooth muscle when considered along with the noted *in vivo* effects of loss of body weight and delayed onset of toxic activity strengthens the hippocratic diagnosis of metabolic blockade. The structural resemblance of these agents to citric acid initiated a study to determine the effect of these acids on the activity of the enzyme aconitase. Figures 3 and 4 show that agaricic acid and norcaperatic acid (1 × $10^{-4}M$) are competitive inhibitors of aconitase. In these experiments *cis*-aconitic acid was used as the substrate. As substrate concentration was increased, the inhibition caused by the test drugs was overcome. Finally, all of the enzyme surface was occupied by the substrate and the reaction velocity was only dependent on substrate concentration. The K_m for *cis*-aconitic acid was 3.3 × $10^{-4}M$. The K_i for agaricic acid was 4.3 × $10^{-4}M$ and for norcaperatic acid, 3.0 × $10^{-4}M$.

Figures 5 and 6 show the results of a similar study in which *dl* + allo, trisodium isocitric acid was used as the substrate for aconitase. The test agents were confirmed to be competitive inhibitors of the enzyme. The K_m for *dl* + allo, trisodium isocitric acid is 6.9 × $10^{-3}M$, while the K_i for agaricic and nor-

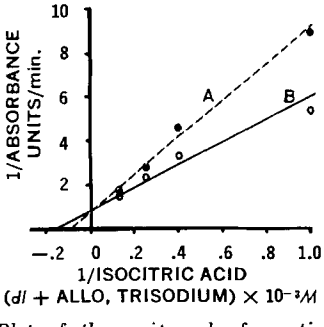

Fig. 6—Plot of the reciprocal of reaction velocity versus *the reciprocal of the* dl + *allo, trisodium isocitric acid concentration. Key:* A, *reaction in the presence of 1* × 10^{-3} M *of norcaperatic acid;* B, *control.*

caperatic acids are 3.0×10^{-3} and $2.4 \times 10^{-3}M$, respectively. Norcaperatic acid seemed to have a greater affinity to the enzyme than either of the substrates or agaricic acid. The order of decreasing affinities to aconitase was: norcaperatic acid, *cis*-aconitic acid, agaricic acid, and *dl* + allo, trisodium isocitric acid.

A chemical-steric relationship exists between the test acids and fluorocitric acid. Peters (13) states that fluorocitric acid is a competitive inhibitor of aconitase. *In vivo* it produces effects similar to those seen with agaricic and norcaperatic acids.

The basic concepts of enzyme action and steric requirements have been discussed by Koshland (14) and Ogston (15, 16) and a three-point attachment of citric acid to aconitase has been postulated. The citric acid is the correct size and shape to bind to the enzyme surface at three points as the conformation of the enzyme changes to accommodate it. In this natural situation, the proper alignment of bonds needed for catalytic activity is formed. It may be that when the bulky molecule of norcaperatic acid (citric acid with a $C_{14}H_{29}$ substituted for a H atom) approaches and attaches to the enzyme surface, it is bound; but because of its size, the proper formation of the catalytic bonds is prevented (steric hindrance). Agaricic acid and fluorocitric acid could act in the same manner since a $C_{16}H_{33}$ group or a F atom is also sterically much larger than a H atom. Moreover norcaperatic, agaricic, and fluorocitric acids all contain two asymmetrical carbon atoms, while citric acid does not. This makes four stereoisomeric forms possible for each structure. These forms would each have varying abilities to form enzyme and/or receptor attachments (affinity). In conclusion, the two naturally occurring acids studied here may be useful biochemical tools—especially for seeking antidotes, since the gross symptoms of certain toxic mushrooms have been shown here to be due, at least in part, to subcellular activity.

Effect of Tris(hydroxymethyl)aminomethane on Removal of Urea by Peritoneal Dialysis

By W. M. MCLEAN, D. M. POLAND, M. S. COHON, S. C. PENZOTTI, and A. M. MATTOCKS*

From earlier *in vitro* studies it was thought that tris(hydroxymethyl)aminomethane (tromethamine) might accelerate diffusion of substances across the peritoneal membrane by a mechanism other than causing ionization of a weak acid in the dialysis fluid. This concept was tested by measuring the rate of dialysis of urea in rabbits, urea being essentially nonionized at the pH of the tromethamine fluid. Blood and dialysate concentrations were measured following intravenous injection of tagged urea and following incorporation of tagged urea in the dialysis fluid (reverse dialysis). Dialysis rates were calculated. It was found that tromethamine increased the dialysis rate two to threefold. It is concluded that tromethamine accelerates dialysis by an unknown mechanism.

SEVERAL WORKERS have reported on the use of tris(hydroxymethyl)aminomethane (tromethamine)[1] in peritoneal dialysis (1–6). These have dealt with the use of tromethamine to remove salicylates, barbiturates, and urate, the theory being that the alkalinity of the dialysis fluid would cause ionization of the drug in the peritoneum and thus maintain a higher concentration gradient of unionized drug across the dialyzing membrane. It is important that the mechanism by which tromethamine exerts its effect on dialysis be understood in order that a search for other more effective substances be facilitated.

In a study conducted in these laboratories, it was found that both ionized and unionized pento-

Effect of Tris(hydroxymethyl)aminomethane on Removal of Urea by Peritoneal Dialysis

By W. M. MCLEAN, D. M. POLAND, M. S. COHON, S. C. PENZOTTI, and A. M. MATTOCKS*

From earlier *in vitro* studies it was thought that tris(hydroxymethyl)aminomethane (tromethamine) might accelerate diffusion of substances across the peritoneal membrane by a mechanism other than causing ionization of a weak acid in the dialysis fluid. This concept was tested by measuring the rate of dialysis of urea in rabbits, urea being essentially nonionized at the pH of the tromethamine fluid. Blood and dialysate concentrations were measured following intravenous injection of tagged urea and following incorporation of tagged urea in the dialysis fluid (reverse dialysis). Dialysis rates were calculated. It was found that tromethamine increased the dialysis rate two to threefold. It is concluded that tromethamine accelerates dialysis by an unknown mechanism.

SEVERAL WORKERS have reported on the use of tris(hydroxymethyl)aminomethane (tromethamine)[1] in peritoneal dialysis (1–6). These have dealt with the use of tromethamine to remove salicylates, barbiturates, and urate, the theory being that the alkalinity of the dialysis fluid would cause ionization of the drug in the peritoneum and thus maintain a higher concentration gradient of unionized drug across the dialyzing membrane. It is important that the mechanism by which tromethamine exerts its effect on dialysis be understood in order that a search for other more effective substances be facilitated.

In a study conducted in these laboratories, it was found that both ionized and unionized pento-

[1] Tham.

barbital and salicylate diffused rapidly and at almost equal rates across isolated rabbit mesentery (7). This agreed with other work (8–10) which demonstrated the diffusion of rubidium and phosphate ions across the isolated membrane. These findings suggest that the effect of tromethamine in accelerating dialysis might be something other than simple change of pH of the peritoneal fluid. On the other hand, it remains to be shown that the isolated membranes truly represent the diffusion characteristics of the live organ; thus *in vivo* tests are required.

One approach to determine whether tromethamine has an effect other than that of causing ionization of the compound in the peritoneum is to measure its effect on the dialysis of a substance which is not ionized at the pH of the tromethamine dialysis fluid or that of the blood. Urea is such a substance, having a pKa of 0.18, and it was selected for this study.

At the outset it was recognized that the rate of dialysis of a substance at any time would be a function of the blood (and extracellular fluid) concentration at that instant. The blood level, in turn, is affected not only by dialysis of the drug into the peritoneal fluid, but also by excretion and metabolism. Thus evaluation of dialysis rate simply by the amounts in dialysis fluid at intervals of time would be subject to errors resulting from different rates of metabolism and excretion by different animals. To avoid these variations experiments were designed to measure the blood and dialysate levels throughout the procedure. Results could then be calculated in terms of rate constants which are independent of the other variables.

MATERIALS AND METHODS

Healthy, mature male albino rabbits were selected as the experimental animal. No general anesthesia was used. A urinary catheter was inserted and an intravenous injection of 1 Gm. of ^{14}C-tagged urea (200 mg./ml.) was administered. Twenty to thirty minutes were allowed for the distribution of the drug throughout the body fluids before beginning dialysis, then 150 ml. of dialysis fluid was introduced into the peritoneum by means of a pediatric size peritoneal catheter. Blood samples were taken from the marginal ear vein. Dialysate samples were withdrawn through the peritoneal catheter, taking care to return contents of the outlet tubing and catheter after removal of the sample. Samples of blood and peritoneal fluid were removed at 10–15-min. intervals over periods up to 200 min. Urine samples were taken also but are not used in this analysis and are not presented here.

Several tests of "reverse dialysis" were performed, wherein the tagged urea was placed in the dialysis fluid prior to its injection into the peritoneum. In these cases 2 ml. of the urea-^{14}C injection was mixed with 150 ml. of dialysis fluid just prior to injection, and samples of dialysate and blood were taken at 5–8-min. intervals over periods up to 120 min.

The urea injection was prepared by dissolving aseptically 1.2 mg. of urea-^{14}C (specific activity 3.67 mc./mmole) in 50 ml. of a sterile solution containing 200 mg. urea/ml. and 0.9% benzyl alcohol as a preservative. The injection was stored in the refrigerator.

The control dialysis fluid was a standard hospital formula containing: dextrose, 1.5%; sodium chloride, 0.62%; sodium lactate, 0.39%; calcium chloride monohydrate, 0.026%; and magnesium chloride hexahydrate, 0.015%. Tromethamine-I fluid was the same solution to which was added 18.17 Gm. (150 mmoles) tromethamine/liter. This fluid, although equivalent to control in content of dextrose and salts, was more hypertonic, and it is possible that an effect observed might be partially due to withdrawal of fluid by osmosis. Thus, a second fluid, tromethamine-II, was prepared containing 18.17 Gm. tromethamine/L. and sodium chloride 0.40%, no dextrose, and the same quantities of calcium chloride, magnesium chloride, and sodium lactate as the control solution. This solution was measured on an osmometer and found to have the same osmolality as the control (0.351). The dextrose and lactic acid used were USP; all other chemicals were analytical or reagent grade. The reagent grade of tromethamine is of such purity as to be commonly used as a primary standard in acidimetry.

Measurements of concentration in blood and dialysate were made by standard radioactive counting methods. Blood was prepared for counting in two ways, which were shown to give equal values: (*a*) 0.5 ml. of serum was added to 1 ml. of a solubilizer[2] and the mixture was allowed to stand 24 hr. Then 0.1 ml. concentrated hydrochloric acid and 10 ml. of dioxane phosphor counting solution were added. (*b*) Approximately 0.5 ml. of blood was drawn directly into a graduated centrifuge tube containing 1 ml. of 6% trichloroacetic acid; the volume was recorded and the contents shaken thoroughly. The tube was then centrifuged, and an aliquot of the clear colorless supernatant was added to 10 ml. of dioxane counting solution. The latter method was preferred, since no quenching was observed with this procedure. A 0.5-ml. portion was added with dialysate samples directly to the dioxane counting solution. An accurate dilution of the injection was used as a standard, which was counted with each set of samples. This was also used as the internal standard whenever quenching corrections were required. The dioxane counting solution consisted of 7 Gm. PPO (2,5-diphenyloxazole), 0.05 Gm. POPOP [(1,4-bis-2,5-phenyloxazolyl) benzene], and 50 Gm. naphthalene in sufficient spectro quality dioxane to make 1 L. All samples were counted at least 3 times in a Packard 314-X Tri-Carb liquid scintillation counter.

RESULTS AND TREATMENT OF THE DATA

Data on dialysis with control and the 2 tromethamine fluids are presented in Table I. Typical curves for blood and dialysate concentrations are shown in Figs. 1 and 2. As one might anticipate,

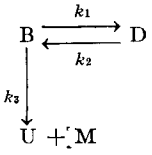
the blood levels and dialysate levels varied from one animal to another due to differences in metabolism and excretion rates. On the other hand, the more rapid rate at which the dialysate curves approach the blood curves in the case of tromethamine is obvious in most instances. As has been mentioned, the impression formed from such an observation might be quite misleading, since the reason for blood and dialysate curves approaching one another rapidly may be due to rapid rate of excretion or metabolism rather than rapid dialysis. For this reason it is necessary to compute dialysis rates to make a meaningful comparison.

The data on reverse dialysis are presented in Table II, and curves of dialysate concentrations are shown in Figs. 3 and 4. In Fig. 3 it is seen that the 2 tromethamine fluids lost urea at a consistently faster rate than the control. In Fig. 4 the tromethamine curve is quite close to control, the difference being mainly in curvature. As is shown later, the analysis yields higher rate constants in this case, since the rate constant reflects the differences in curvature between initial and final portions of the curve. The rate is slower in this instance, however, and may not be significant.

Several methods were utilized to analyze the data, all giving approximately the same results. The one judged to be most generally acceptable is presented in this paper. Rather than use equations relating total amounts in compartments which requires estimates of distribution volumes (11, 12), equations relating concentrations in the compartments were used.

The distribution of exogenous urea after an initial period for mixing throughout the body fluids may be depicted as follows:



(Eq. 1)

where B is blood or equivalent body fluid, D is dialysate in the peritoneum, and U and M represent urinary excretion and metabolites. Equations for treating this type of system may be found in Rescigno and Segre (13) and in Rodiguin and Rodiguina (14). The equation for dialysate concentration may be stated as follows:

$$X_2 = \frac{X_0 k_1}{m_2 - m_1}(e^{-m_1 t} - e^{-m_2 t}) = A(e^{-m_1 t} - e^{-m_2 t}) \quad \text{(Eq. 2)}$$

where X_2 is concentration in dialysate, X_0 is concentration in blood at time dialysis is begun, m_1 and m_2 are the roots of the auxiliary equation (13, 15). The equation for the concentration in blood is:

$$X_1 = \frac{X_0}{m_2 - m_1}[(k_2 - m_1)e^{-m_1 t} + (m_2 - k_2)e^{-m_2 t}] = B_0 e^{-m_1 t} + C_0 e^{-m_2 t} \quad \text{(Eq. 3)}$$

where X_1 is the concentration in blood, and other constants are the same as in Eq. 2. If t is zero at the time of starting dialysis, the concentration in blood at that time becomes B_0 plus C_0, and this sum may be taken as X_0 in subsequent calculations.

The dialysate curve is far more sensitive to the magnitude of k_1, since the blood concentration is

affected less than 10% by the amount diffused into dialysate, hence the dialysate curve and Eq. 2 were used to calculate the values of m_1 and m_2, while the blood curve and Eq. 3 were used to obtain values of X_0. Equation 2 was solved on an analog computer, and the values of m_1 and m_2 were put into Eq. 3 on the computer to be certain that they fit the blood curve as well. This is easily and rapidly done with the analog computer and a modern *x-y* plotter. The rate constant was then calculated from an expression derived from Eq. 2:

$$k_1 = \frac{A}{X_0}(m_2 - m_1) \qquad \text{(Eq. 4)}$$

Values obtained for k_1 are presented in Table III.

With reverse dialysis the dialysis curve was again used for evaluation of m_1 and m_2 and for the values X_{20} and D of the following equation, which is the one applicable for the condition where the drug is administered in the dialysis fluid (13):

$$X_2 = \frac{X_{20}}{m_2 - m_1}\left[(D - m_1)e^{-m_1 t} + (m_2 - D)e^{-m_2 t}\right] \qquad \text{(Eq. 5)}$$

where X_2 is concentration in dialysate, X_{20} is its initial value, D is k_1 plus k_3, m_1 plus m_2 equals the sum of k_1, k_2, and k_3, the k's having the same meaning as in Eq. 1. The value of k_2, representing transport from the dialysate to the blood, was calculated as $m_1 m_2 - D$. The values obtained for k_2 are shown in Table III.

It is seen from Table III that an increased rate of dialysis was observed with tromethamine rather consistently. One control was as high as 2 of the tromethamine solutions, but it was high for a control solution. The average rate with tromethamine was more than twice that of controls. Tromethamine-I and tromethamine-II fluids showed no difference, thus all tromethamine values were averaged together.

DISCUSSION AND CONCLUSIONS

The blood curves for urea showed greater deviations than one might generally expect for a typical drug or injected substance. These variations were the subject of much laboratory study, and a number of variations in assay were attempted in an effort to obtain better uniformity. It did not appear that the variation was due to assay procedure, or that urea was entrapped in protein precipitates since results were nearly identical when several methods were used, including those not requiring protein precipitation on the same set of samples. It is believed that these variations result from traces of radioactive carbon dioxide present in the blood and tissues following metabolism of urea, removal of this metabolite being a slow and nonuniform process.

TABLE III—RATE CONSTANTS, k_1 AND k_2, FOR DIALYSIS OF EXOGENOUS UREA

	18	3.96	4.1

The fitting of the dialysate curve to the data points is reasonably precise. A change in values of curve parameters of 5% or more will not yield a satisfactory fit. Furthermore, a variation in one constant tends to be corrected for in another; for example, if one uses too large a value for m_1 a correspondingly higher value for m_2 is required, making the difference $m_2 - m_1$ about the same. Thus, the values for A, m_1, and m_2 appear to be within 5%. The greatest error in calculating k_1 results from the estimation of X_0, initial blood level. This value is restricted, however, by the requirement that m_1 and m_2 of the dialysis curve must also apply to the blood curve.

Reverse dialysis was run with the aim of determining whether tromethamine might have a uni-directional effect on dialysis. One possible mechanism for its action might be the formation of a tromethamine–urea complex which is nondiffusible or slowly diffusible, thus increasing the effective blood to dialysate concentration gradient. If this were the mechanism, then in reverse dialysis the presence of tromethamine in the peritoneum would cause a much slower transport from fluid to blood than would be observed in controls. Since the tromethamine actually accelerated transport in 2 of 3 cases, this hypothesis for tromethamine action was rejected. The reason for a less significant effect in one case of reverse dialysis (Fig. 4) is not clear, but since the failure to retard dialysis answered the purpose of the experiment, this was not investigated further.

The values of dialysis rate constants, which are independent of individual variations in blood levels, excretion, and metabolism rates, clearly demonstrate that the diffusion of exogenous urea across the peritoneal membrane is accelerated by the presence of tromethamine. In these experiments the pH of the

tromethamine dialysate was found to change to a variable degree. The original fluid was pH 9.7, and it dropped rapidly after injection to 8.0–8.2, then more slowly as it approached the pH of body fluids. This drop occurs as a result of neutralization in the abdomen and due to absorption of tromethamine (5). One might expect the dialysis rate constant to vary with these changes, but a single constant was found to give acceptable fit to the data throughout the dialysis period.

The rate constants obtained in this work are based only on exogenous urea which may be considered to diffuse from one compartment to another quite independently of all other molecules. The constants themselves should be applicable to any urea present in the animal, but the total amounts of urea in the various compartments in the animals studied cannot be deduced without having measurements of specific activity. Since this work was designed to evaluate the rates for the added urea only, specific activities in the various fluids were not measured. Thus, by following only the exogenous urea the complexities of analysis and errors in measurement of total urea were avoided. If one treats the kinetics of endogenous urea, the biosynthesis of urea must be taken into account, and an equation of form similar to that of Teorell (11) for amount of drug in tissues with 3 exponential terms would be required. Obviously a direct comparison of blood and dialysate concentrations would not reflect the dialysis rates. This greater complexity of the system, coupled with the relatively low urea levels found in normal animals, probably accounts for the failure to detect the effect of tromethamine on urea dialysis by other workers, such as Knochel and Mason (6) where urea diffusion was followed.

The acceleration of urea dialysis by tromethamine cannot be attributed to a pH effect on ionization since urea is essentially nonionized under all conditions of the experiments. The mechanism of the tromethamine effect in this case is unknown, but it is certainly worthy of further investigation, particularly with the aim of finding other more effective substances. Some possible mechanisms are: (*a*) a wetting effect to improve contact between the membrane and dialysis fluid, especially where fatty deposits are present on the membrane, (*b*) a direct chemical effect on the peritoneal membrane to increase membrane permeability, (*c*) improved circulation of the extracellular fluid to the membrane. Some preliminary tests of these possibilities have been made. Measurements of protein content of dialysates showed the tromethamine fluids to have extracted no more protein than the control solutions. Examination of the membranes after dialysis revealed no gross visible changes, except a possibility that the membranes have less fatty film. Knochel *et al.* (1) reported no gross changes in the membrane with tromethamine fluids. Three tests with isolated membrane in the manner used by Shenouda and Mattocks (7) indicated only small increases in permeability with tromethamine. Further studies are in progress to define the nature of the tromethamine effect.

Although this work suggests the possibility of the use of tromethamine in dialysis for uremia, it should be noted that tromethamine is rapidly absorbed from the dialysis fluid (5) and is primarily eliminated *via* the kidneys. In the uremic patient elimination may be extremely slow, resulting in rapid accumulation in the body. Thus, the toxicity in the uremic patient may be much greater than in the normal. Additional studies with nephrectomized animals are needed to define the safe and effective ranges of the procedure before application in the clinic. Such experiments are being undertaken in this laboratory.

Pharmacopeial Standards and Specifications for Bulk Drugs and Solid Oral Dosage Forms

Similarities and Differences

By W. N. FRENCH, F. MATSUI, DENYS COOK, and LEO LEVI

Tests for tablet weight variation, drug content, and disintegration time described in the "United States Pharmacopeia," "The National Formulary," the "British Pharmacopoeia," the "Pharmacopée Française," the "State Pharmacopoeia of the U.S.S.R.," and the "Nordic Pharmacopoea" are compared with regard to methodology, apparatus, scope, and compliance. Similarities and differences characterizing these standards are discussed. Comparable appraisals are made of assays for bulk drugs and compressed tablets included in the United States Pharmacopeia, the National Formulary, the British Pharmacopoeia, and the State Pharmacopoeia of the U.S.S.R. Discrepancies of sufficient magnitude exist between these tests and specifications to warrant closer cooperation among pharmacopeial agencies. Such cooperation should ensure greater uniformity of drug testing, encourage wider drug trade, and promote better public health throughout the world. These objectives are actively pursued by the World Health Organization.

PHARMACOPEIAL STANDARDS have been developed in many countries. Realizing their value as mutually acceptable criteria of pharmaceutical quality control and their commercial importance, some countries have come to agree on common standards and specifications. The Nordic Pharmacopoea, official in Denmark, Finland, Iceland, Norway, and Sweden, may be cited as an example, and the European Pharmacopoeia—aiming to encourage and facilitate drug trade between countries of the European Common Market—likewise reflects this trend. Yet a great deal of work remains to be done to establish truly international standards as reference criteria, *i.e.*, standards that can be used conveniently anywhere and mean the same thing to analysts working in their national laboratories throughout different parts of the world.

It is the purpose of this paper to point out certain differences and similarities which exist between pharmacopeial tests and specifications applied in the quality control of bulk drugs and

Received May 15, 1967, from the Research Laboratories, Food and Drug Directorate, Department of National Health and Welfare, Ottawa, Ontario, Canada.
Accepted for publication September 1, 1967.
The authors express their appreciation to Dr. Lloyd C. Miller, the United States Pharmacopeia; Dr. Edward G. Feldmann, the National Formulary, Dr. T. C. Denston, British Pharmacopoeia Commission; Professor M. D. Mashkovsky, Ministry of Health, U.S.S.R., and Dr. Kjeld Ilver, Farmakopékommissionens Laboratorium, Copenhagen, Denmark, for courteously reviewing the manuscript. They are also indebted to Dr. D. F. Bray, Statistical Services Division, Food and Drug Directorate, for valuable discussions.

tablet preparations, and to emphasize the need for greater interpharmacopeial uniformity.

GENERAL STANDARDS APPLICABLE TO SOLID ORAL DOSAGE FORMS

Weight Variation

Pharmacopeial standards and specifications have been established to provide limits for permissible variations in the weights of individual dosage forms, expressed in terms of the allowable deviation from the average weight of a representative sample. Separate procedures and limits are described in most reference compendia for uncoated tablets, capsules, and sterile solids.

United States Pharmacopeia, National Formulary, and British Pharmacopoeia—USP XVII (1), NF XII (2), and B.P. 1963 (3) specify that 20 whole tablets be weighed individually, the average weight calculated, and the variations compared with specifications. Samples meet requirements if weight variations observed are not greater than those shown in Table I.

The British Pharmacopoeia allows performance of this test on 10 tablets also, specifying that in this case not more than *one* tablet may deviate from the average weight by a percentage greater than that shown in the table, and none of the tablets differ from the average by more than double that percentage.

Pharmacopée Française VIII (Codex Médicamentarius Gallicus) (4)—This compendium specifies that 10 tablets be weighed individually from a batch of homogeneous manufacture, the average weight determined, and the variations compared with specifications. Samples meet the requirements if weight variations observed are not greater than those shown in Table II.

State Pharmacopoeia U.S.S.R. IX (5)—This compendium specifies that 10 tablets be weighed collectively and the average weight calculated. Another 10 tablets are to be weighed individually (each to within 10 mg.) and the variations compared with specifications. Samples meet requirements if weight variations observed are not greater than those shown in Table III.

Pharmacopoea Nordica III (6)—This compendium requires that 100 tablets[1] be weighed collectively (to within 1 mg. if the tablet is lighter than 80 mg. and to within 10 mg. if the tablet is heavier than 80 mg.) and the average weight calculated (to within 0.1 mg. if the tablet is lighter than 80 mg. and to within 1 mg. if the tablet is heavier than 80 mg.). Thirty tablets are selected at random from this sample and weighed individually (to within 0.2 mg. if the tablet is lighter than 80 mg. and to within 1 mg. if the tablet is heavier than 80 mg.). Requirements are met if weight variations determined are in accord with specifications shown in Table IV.

Similarities and Differences—Although the tests described are simple, easily carried out, and serve the same purpose—namely, the establishment of the weight uniformity of uncoated, compressed tablets from a given lot—they differ markedly in both methodology and requirements for compliance.

Methodology—The USP and NF tests are based on the use of a representative sample of 20 tablets weighed collectively and individually. Results based on similar examination of only 10 tablets are accepted by the B.P. The French pharmacopeia also specifies that 10 tablets be taken for the test, while the Russian pharmacopeia requires that 10 tablets be weighed collectively to assess the average weight and another 10 be weighed individually to appraise variations from the average weight. The Nordic pharmacopeia generally calls for the weighing of 100 tablets to compute their average weight and the examination of 30 of these tablets to determine individual variations from the average weight.

Compliance—Tolerances are generally a function of average tablet weight. The greater the average tablet weight, the smaller are the weight variations permitted. Yet, the trend lacks uniformity. While the NF recognized four ranges (one range deleted, see *Footnote b*, Table I) of average tablet weights and specified corresponding tolerances, it,

[1] If it is not possible to use 100 tablets, weight determination may be made with a smaller number, but not less than 20,

as well as the B.P. and USP, now cover three such classifications. The French and Russian pharmacopeias both designate relevant parameters for only two categories—limiting tablet weights being 150 mg. and 120 mg., respectively. For uncoated compressed tablets weighing 80 mg. or more, the Nordic pharmacopeia, unlike other compendia, avoids step-wise changes in variability with respect to permitted tablet weight by using the formula: $y = 4 + 0.05x$, where y is the tolerance allowed in mg. (90% of sample), and x is the average weight in mg. In general, therefore, different tolerances are assigned to categories which cannot be readily compared, and products meeting the requirements of one national compendium need not necessarily meet those of another.

Scope—Although many products have been tested in the laboratories of the Food and Drug Directorate following the USP, NF, and B.P. procedure, few ever failed to comply. Pharmacopeial tolerances appear generally to be too wide and unappreciative of advances made during recent years in pharmaceutical manufacturing technology. Solid dosage forms of considerably smaller weight variations than those specified as pharmacopeial standards are produced with modern tableting machines.

Consider, for example, a batch of digoxin tablets, (USP requirements: assay ±8%; assay for content uniformity ±15%) formulated to weigh 100 mg. and contain 0.25 mg. of digoxin each, which had been prepared from a perfectly homogeneous and accurately dosed granulation but, manufactured under adverse conditions of compression, just met USP specifications for weight variation. A cardiac patient, maintained at a 0.25-mg. daily dose of the drug and dispensed 20 such tablets, could conceivably receive only four-fifths of the potent medication one day, and 1.5 times as much the following day (0.2 mg. and 0.3 mg., respectively).

It has been argued that weight variation is not an essential criterion of product quality—what is important is drug content. Little if any significance need be attached to differences in weight between tablets from a given batch or even from batch to batch as long as there is present in each the required amount of active ingredient.[2] Admittedly, the drug content of a tablet cannot be deduced from the weight variation test. It can only be derived from quantitative analyses of individual dosage forms. Such assays have already found recognition as pharmacopeial standards, and as their usefulness through application in pharmaceutical quality control is becoming more apparent, the need for retaining official weight variation tolerances much longer has been questioned.

As a pharmacopeial standard the test has, however, many virtues. Weight variation is easily determined. Requiring only a balance, the test provides a reliable means of gauging tablet uniformity in terms of tablet weight within a given batch as well as from batch to batch. Applied readily to all tablets, large and small, with practically the same degree of accuracy and precision, it is a dependable indicator of good pharmaceutical manufacturing practices and production technology. Uniform specifications of methodology and compliance and more realistic tolerances reflecting the precision with which tablet weight can be controlled by means of modern tableting equipment would greatly enhance its universal value in pharmaceutical quality control.

[2] It has so far not yet been established whether the physiological availability of a medication from a tablet is totally independent of tablet weight for *any* type of formulation. Lozinski, for example, has shown that dicoumarol tablets of identical formulation and drug content, but larger size, displayed markedly reduced therapeutic efficacy. [*Can. Med. Assoc. J.*, **83**, 177(1960).]

TABLE IV—WEIGHT VARIATION TOLERANCES[a] (PHARMACOPOEA NORDICA III)

Av. Tablet Wt., mg.	Tolerances Based on 30 Determinations
<80	27 tablets (90% of sample) may differ from av. wt. by ±10% and 3 tablets (10% of sample) may differ from av. wt. by ±20%[b]
>80	27 tablets (90% of sample) may differ from av. wt. by ± (4 mg. +5% of av. wt.) and 3 tablets (10% of sample) may differ from av. wt. by ± (8 mg. +10% of av. wt.)

[a] Applicable to compressed, uncoated tablets. [b] Tolerance also applicable to coated and uncoated tablets not prepared by compression, regardless of weight.

Drug Content

As a rule, pharmacopeial assays for active ingredients are based on analyses of aliquots obtained from a given number of tablets reduced to a fine powder.

USP XVII and NF XII—*Methods*—(*a*) *Composite Assays*—Ten or, in most instances, 20 tablets are required for physicochemical assays of drug content. They are finely powdered and aliquots of the triturate examined in accordance with the method of analysis specified in the corresponding monograph.

(*b*) *Single Dosage Assays (Content Uniformity)*—A representative sample consisting of 30 tablets is obtained from a given lot, and 10 of these are analyzed individually by the method of assay specified in the relevant monograph. At the analyst's discretion the degree of dilution of solutions and/or the volume of aliquots used may be adjusted so that the concentration of the drug in the final solution will be comparable to that obtained for the assay described in the corresponding monograph.

Compliance—(*a*) *Composite Assays*—Experimental results, indicative of the drug content of an aliquot from a number of tablets, are expressed in terms of the percent of labeled amount of drug claimed to be present in a single tablet. Tolerances are specified in individual monographs and vary depending on the nature of the product examined and the analytical method applied. (See under *Assays of Bulk Drugs and Compressed Tablets.*)

(*b*) *Single Dosage Assays*—Requirements which must be met are shown in Table V.

B.P. 1963—*Method*—It is essentially that adopted for composite assays by the United States Pharmacopeia, with tolerances "framed to allow for all permissible variations including that of the active ingredient itself and that due to the process of manufacturing."

TABLE V—SINGLE DOSAGE ASSAYS FOR CONTENT UNIFORMITY OF TABLETS (USP XVII, NF XII)

No. of Tablets Analyzed (Out of 30)	Requirements I	Requirements II
10	All results must be within 85–115% of av. of tolerances specified in official monograph	If one result exceeds limits specified under I, each of remaining 20 tablets must be within limits specified under I[a]

[a] A rare "flyer" will thus not cause rejection of an entire batch.

Compliance—Experimental results are expressed as previously defined. In circumstances where the required number of tablets cannot be obtained, a smaller number, but not less than five, may be assayed by the official method. To allow for sampling errors in such instances tolerances are widened progressively, as shown in Table VI.

The corrections are to be applied to tablets for which tolerances ranging from 90–110% have been specified. For limits exceeding these values, proportionately larger allowances are to be made. Reasons for extending consistently upper limits more than the corresponding lower ones are not stated.

Pharmacopée Française VIII—Monographs for tablets have not been included in this edition and generally applicable specifications for drug content and content uniformity are not described.

State Pharmacopoeia U.S.S.R. IX—Specimens are prepared by grinding one or more tablets to a fine powder. The amount of sample required for analysis, the assay procedure to be followed, and tolerances permitted are specified in official monographs. Tablets for which such monographs are not given must meet the requirements shown in Table VII.

Pharmacopoea Nordica—The examination of a specified aliquot obtained as a rule from the trituration of at least 10 tablets is required. In general, drug content may vary by not more than ±10% from label claims. The tolerances are considered to take into account variations arising from manufacture and storage as well as analytical methodology.

Canadian Food and Drugs Act and Regulations (7)—*Method*—Schedule B of the Canadian Food and Drugs Act and Regulations lists seven pharmacopeial compendia officially recognized by the Food and Drug Directorate. They include, at present, the Pharmacopoea Internationalis, the British Pharmacopoeia, the United States Pharmacopeia, the Codex Français, the Canadian Formulary, the British Pharmaceutical Codex, and the National Formulary. Methods specified in these reference texts are endorsed by the Food and Drug Directorate as valid standards of pharmaceutical quality control, unless an "official method," *i.e.*, a method of analysis or examination designated as such by the Director-General for use in the administration of the Act, is the method to be applied.

Compliance—Tolerances set forth in any of the pharmaceutical compendia cited above are accepted for products thus identified. For nonofficial drugs "put up in tablet or any other individual dosage or dispensing form other than in ampoules or vials, variations within the limits stated in the following table as determined by an acceptable method" are permitted (Table VIII).

TABLE VII—DRUG CONTENT OF TABLETS (STATE PHARMACOPOEIA U.S.S.R. IX)

Active Ingredient Per Tablet, mg.	Tolerance, %
>100	±5
<100	±10

TABLE VIII—LIMITS OF VARIABILITY FOR NONOFFICIAL SOLID ORAL DOSAGE FORMS (CANADIAN FOOD AND DRUGS ACT AND REGULATIONS)

Amt. of Drug Per Tablet gr.	Amt. of Drug Per Tablet mg.[a]	Limits, %
>5	>324	94–106
0.5 –5	32.4–324	93–107
0.02–0.5	3.24–32.4	92–108
0.01–0.02	0.65–3.24	91–109
<0.01	<0.65	90–110

[a] Equivalents not given in original table.

Two exceptions are made: (*a*) "glyceryl trinitrate shall contain not less than 85% and not more than 115% of the labelled amount," and (*b*) "if the drug consists of several ingredients, the amount of each ingredient so dispensed shall be not less than 90% and not more than 110% of the amount calculated from the label description."

Similarities and Differences—Tablet drug content and content uniformity depend on a number of processes associated with tablet manufacture, *e.g.*, compounding, mixing, drying, slugging, dispersion, compression, *etc.* Pharmacopeial standards have been established to control these processes, permit

TABLE VI—ASSAY TOLERANCES FOR TABLETS INCLUDED IN B.P. 1963 BASED ON ANALYSIS OF LESS THAN 20 SPECIMENS

Wt. of Drug in Tablet, mg.	Tablets Used for Analysis, No. 15 — Extend Limits Specified in Monographs by Following Percentages: Lower	15: Upper	10: Lower	10: Upper	5: Lower	5: Upper
<120	0.2	0.3	0.7	0.8	1.6	1.8
120–300	0.2	0.3	0.5	0.6	1.2	1.5
>300	0.1	0.2	0.2	0.4	0.8	1.0

determination of the amount of active ingredient present in a given product, and gauge the uniformity with which the drug is incorporated into individual dosage units.

Methodology—The USP and NF require the examination of a specified aliquot obtained as a rule from the trituration of 20 tablets. The B.P. accepts assay values derived from the analysis of aliquots from a smaller number of tablets as well, and endorses results obtained with as few as 5 tablets if only that many are available. The French pharmacopeia does not include monographs for solid dosage forms, and guidelines concerning general techniques and methodologies are, likewise, not described.

Assays given in the Russian pharmacopeia are not based on the examination of an aliquot from a definite number of tablets, but on direct analysis of a specified amount of sample material representing a fraction of one or several tablets. The Pharmacopoea Nordica, in general, requires the use of at least 10 tablets. The Canadian Food and Drugs Act and Regulations endorse any acceptable method, *i.e.*, any method of analysis or examination sanctioned by the Director-General for use in the administration of the Act.

It should be emphasized in this connection that different methods of analysis displaying different degrees of selectivity and sensitivity may be specified for the same preparation in different pharmacopeias. Single dosage assays have so far been adopted only by the United States Pharmacopeia[3] and the National Formulary.[4]

Compliance—Tolerances are stated in official monographs and marked variations exist between different pharmacopeial standards (see under *Assays of Bulk Drugs and Compressed Tablets*). Limits are generally a function of the weight of active ingredient claimed to be present in a single dosage unit. The greater the amount of active ingredient per tablet, the smaller the variation permitted. Unlike any other pharmacopeia, the B.P. allows for a further extension of tolerances if assays are based on less than 20 tablets. No reference is made in the USP, B.P., or NF to tolerances for products for which official monographs have not been described. The Russian pharmacopeia, on the other hand, specifies tolerances for such preparations as well. Products containing more than 100 mg. of active ingredient may vary by $\pm 5\%$ and those containing less than this amount by $\pm 10\%$ from label claims. The Canadian Food and Drugs Act and Regulations also cover nonofficial products, specifying five concentration ranges and corresponding tolerances. The classification is an unrealistic one in the light of modern technology, and efforts to revise it are now being made.

Scope—It is generally recognized that tablet weight variation does not necessarily reflect drug content variation. While tablets satisfying pharmacopeial specifications for weight variation are readily made by means of modern machines, it is most difficult to produce truly homogeneous tablet granulations and to feed solid blends continuously into the tableting machine for compaction into truly uniform dosage forms. The smaller the concentration of the active ingredient present, the more difficult it becomes to attain product uniformity. Tablets containing potent drugs, *i.e.*, tablets whose safety and efficacy demand careful control, are, therefore, particularly prone to compositional variations.

Several studies relating tablet weight and drug content have been published during recent years. They covered both practical and theoretical aspects associated with the production of solid dosage forms (8, 10), principles of mixing solids and their application to pharmacopeial standards for content uniformity in the absence of single dosage assays (11, 12), the effect of sampling and bulk mix heterogeneity on tablet variation (13), reproducibilities of assay and drug recovery from dosage forms (14), the nature and scope of sampling techniques (15), the application of automated equipment to single-tablet assays (16), and the effect of tableting technology on the relationship between tablet weight variation and percent composition (17, 18).

Relevant investigation on commercial products were carried out in the laboratories of the Canadian Food and Drug Directorate (19) and are continuing (20, 21). The following experiments may serve to illustrate some of the problems encountered during the course of these studies.

Ten tablets of hydrocortisone (5 mg.)[5] were taken at random from a bottle of 100 and analyzed in accordance with the USP procedure (tolerances allowed 90–110%). They were found to be below labeled strength (87.3%). Another analyst repeated the assay using a second lot of 10 tablets selected, likewise, at random from the same container. His results showed that the product complied (91.8%). Concerned about the discrepancy, a third analyst decided to assay 10 tablets individually. He obtained an average assay value of 100.8% on the basis of results varying from 68.4% to 151.2%. In each case, the 10 tablets used for analysis met perfectly the requirements of the weight variation test.

Because they are based on the examination of sample composites obtained from randomly selected tablets, pharmacopeial assays cannot be relied upon to provide infallible criteria for uniformity of tablet drug content. The weakness inherent in these methods is their inconsistency in relating experimental design to data utilization. They express product dosage on an individual tablet basis but are, themselves, based on sample composites of many tablets. Such analyses may not only average out minor compositional variations between tablets, as originally believed, but also mask major deviations reflecting substandard "pharmaceutical workmanship." The greater the number of tablets used for such analyses, the greater the possibility of masking variation in active ingredient due to imperfections in mixing all components during formulation, which process is considered a most critical one (9, 11, 12). On statistical grounds, the variation in drug content of an individual tablet taken from a number of tablets may

[3] Applicable to tablets of chlorpromazine hydrochloride, digoxin, ergonovine maleate, hydrocortisone, methylergonovine maleate, metyrapone, phenobarbital, prednisolone, prednisone, and prochlorperazine maleate.

[4] Applicable to tablets of amphetamine phosphate, amphetamine sulfate, betamethasone, cortisone acetate, dexamethasone, dextroamphetamine phosphate, methylprednisolone, methyltestosterone, and syrosingopine.

[5] Average weight of tablets 104.4 mg.; maximum deviation from mean 5.4 mg.

be as large as the square root of this number multiplied by the limit set for the composite assay. That is, an individual tablet taken at random from a group of 20 tablets for which drug content limits of 90–110%, *i.e.*, ±10% have been set, may deviate from the standard by as much as $\sqrt{20} \times 10 = 44.7\%$. Conversely, if all tablets should be within the range of 90–110%, *i.e.*, ±10% of label claim, the limit of variability for the composite assay based on 20 tablets should be no more than $10 \div \sqrt{20} = 2.25\%$.

Atropine sulfate tablets B.P., for example, may contain as little as 0.25 mg. of the potent anticholinergic and no less than 80 such tablets are required for the official assay. Yet, theoretically, a sample composite complying with the official B.P. standard of drug content (90–110%) may consist of individual tablets, some of which could contain as little as 10% or as much as 190% of the required amount. More pertinent information concerning the extent of tablet variation can be obtained by carrying out several composite assays and calculating standard deviations of individual tablets from the standard deviations of the composites. However, direct criteria of drug content uniformity are provided only by single-tablet assays, as described in the United States Pharmacopeia and the National Formulary, respectively (see Table V). Admittedly, such a scheme of quality control increases the time and cost of drug analysis, but it permits a more reliable appraisal of true product uniformity and its application to tablets containing potent chemotherapeutic agents should be of major concern to governmental and industrial laboratories alike.

The principle of pharmacopeial standards for monitoring intertablet dosage variation has been favorably received and accepted by the pharmaceutical industry in Canada and the United States.[6] At present, analytical methods for determining content uniformity involve spectrophotometric techniques only, and provided tablet formulations are amenable to such determinations, accurate measurements are readily made. Other equally sensitive methods are being developed in order to obtain single-tablet assays for as many products as possible. It should be in the pharmaceutical manufacturer's interest to produce only simple dosage forms which can readily be subjected to quantitative analysis.

Tablet Disintegration

Tests for gauging the disintegration of tablets under controlled conditions are described in most official compendia. Although not necessarily indicators of therapeutic efficacy, they are widely applied in pharmaceutical quality control.

Apparatus can be obtained commercially, and methodology is simple. Most pharmacopeias require that the tablet be placed in a tube (transparent plastic or glass) of precise dimensions fitted at its lower end with a wire gauze of specified mesh. The tube, suspended in a fluid kept at constant temperature, is raised and lowered at a uniform rate throughout a specified distance for a given period of time.

The tablet is considered disintegrated when, except for fragments of insoluble coating, only a soft mass having no palpable firm core remains above the gauze. The time required to reach this stage is called the disintegration time. Depending on the type of product and the pharmacopeial standard selected, a plastic disk of definite weight, shape, and size may be placed above the tablet in the tube either for the duration or throughout certain phases of the test.

Commercial units meeting official requirements are available and permit testing of as many as 6 tablets at a time.

USP XVII and NF XII—*Apparatus*—Vessel for basket rack assembly: a suitable vessel, preferably a 1-L. beaker. Temperature of medium: 37 ± 2°. Tube dimensions: length, 7.75 ± 0.25 cm.; inside diameter, 21.5 mm.; wall thickness, 2 mm. Wire mesh: nominal width of aperture 0.075 in. (1.90 mm.). Disk: material, transparent plastic, sp. gr. 1.18–1.20; thickness, 9.5 ± 0.15 mm.; diameter, 20.7 ± 0.15 mm.; perforations, five, each 2-mm. wide; notches, four having V-shaped planes. Movement: rate, 30 ± 2 c.p.m.; distance, 5–6 cm. Wire mesh position: high point, not less than 2.5 cm. below surface of fluid; low point, not less than 2.5 cm. from bottom of vessel.

Methodology and Compliance—These are summarized in Table IX.

B.P. 1963—*Apparatus*—Vessel: depth not less than 15 cm. Temperature of medium: 37 ± 2°. Tube dimensions: length, 8–10 cm.; inside diameter, 28 mm.; wall thickness, 2–3 mm.; volume, 200–250 ml. Wire mesh: nominal width of aperture 0.0661 in. (1.68 mm.). Disk: material, plastic; thickness, 2 mm.; diameter, 26 mm.; weight, 1.9–2.1 Gm. Guide ring: 27 mm. o.d. Movement: rate, 30 c.p.m. (by hand or mechanically); distance, 7.5 cm.; high point, wire gauze just breaks surface of medium; low point, upper rim of tube remains clear of medium.

Method—Five tablets are placed into the tube suspended in the required medium. The tube is raised and lowered repeatedly in a uniform manner, by hand or mechanically, through the specified distance and disintegration of the tablets observed continuously or at critical time intervals.

Compliance—(*a*) Tablets which are not enteric coated should disintegrate in water within 15 min. unless otherwise stated in the monograph.

(*b*) Tablets which are sugar coated should disintegrate in water within 1 hr.

If the tablets referred to under (*a*) or (*b*) fail to comply, the test is to be repeated on a further five tablets using the guided disk positioned directly above the tablets—and under these conditions they must meet requirements.

(*c*) Tablets which are enteric coated are tested in acid pepsin solution[7] for a period of 3 hr. (there should be no evidence of disintegration) washed rapidly by immersion in water, and thereafter placed in alkaline pancreatin solution[8] in which

[6] The authors are indebted to Dr. A. E. Slesser, Smith Kline & French Laboratories, Philadelphia, Pa., and the PMA Committee on Inter-Tablet Dosage Variation, Quality Control Section, for access to relevant reports on collaborative studies conducted in a number of industrial laboratories throughout the U. S. during the last 5 years.

[7] Composition: pepsin, 3 Gm.; hydrochloric acid, 6 ml.; water, 1,000 ml.

[8] Composition: pancreatin, 3 Gm.; sodium bicarbonate 15 Gm.; sodium tauroglycocholate, 5 Gm.; water, 1,000 ml

TABLE IX—TABLET DISINTEGRATION (USP XVII, NF XII) METHODOLOGY AND COMPLIANCE

Pretreatment	Disks	Immersion Fluid and Test Conditions	Compliance[a]
		Uncoated (6 Tablets in Test)	
None	+	Water, unless otherwise specified in official monograph	At end of time limit specified in monograph all tablets should have disintegrated. If one or two have not disintegrated, test is to be repeated on 12 additional tablets. Not less than 16 of total of 18 tablets must disintegrate completely
		For example, if disintegration time specified in monograph is 15 min., the time limit is 15 min. in water.	
		Plain Coated[b] (6 Tablets in Test)	
If desired, immerse in water at room temperature for 5 min. to wash off soluble external coating	+	Simulated gastric fluid T.S.[c] for 30 min. If disintegration incomplete at that time, simulated intestinal fluid T.S.[d] for a total period of time, including exposure to water equal to the time specified in monograph plus 30 min.	If at end of test one or two tablets have not disintegrated, repeat on 12 additional samples. Not less than 16 of total of 18 tablets must disintegrate completely
		For example, if disintegration time specified in monograph is 15 min., the time limit is either (*i*) 30 min. in simulated gastric fluid plus 15 min. in simulated intestinal fluid, or (*ii*) 5 min. in water plus 30 min. in simulated gastric fluid plus 10 min. in simulated intestinal fluid.	
		Enteric-Coated (6 Tablets in Test)	
If desired, immerse in water at room temperature for 5 min. to wash off soluble, external coating	−	Simulated gastric fluid T.S. for 1 hr., followed by	No distinct evidence of dissolution or disintegration after gastric fluid treatment
	+	Simulated intestinal fluid T.S. for 2 hr. *plus* time limit specified in individual monograph, or where only an enteric-coated tablet is recognized for only the time limit specified in monograph	If at end of test one or two tablets fail to disintegrate, repeat on 12 additional samples. Not less than 16 of total of 18 tablets should disintegrate completely
		For example, if (*i*) 60 min. is the time specified in the monograph, the time limit is 60 min. in simulated gastric fluid plus 180 min. in simulated intestinal fluid; (*ii*) an enteric-coated tablet only is recognized, and a time of 120 min. is specified, the time limit is 60 min. in simulated gastric fluid plus 120 min. in simulated intestinal fluid	
		Buccal (6 Tablets in Test)	
None	−	Water, unless stated otherwise in monograph	All tablets should have disintegrated after 4 hr.
		Sublingual (6 Tablets in Test)	
None	−	Water, unless stated otherwise in monograph	All tablets must disintegrate within time limit specified in individual monograph[e]

[a] Tablets exempted from these requirements: those exceeding 15 mm. in diameter; those used as troches; those which are to be chewed; those designed to liberate drug content gradually over a period of time (prolonged action); those designed to release the drug over two or more separate periods with a distinct time interval between such release periods (repeat action). [b] Plain coated is any tablet having a nonenteric coating. [c] Composition: sodium chloride 2 Gm., pepsin 3.2 Gm., hydrochloric acid 7.0 ml., water *ad* 1,000 ml. The pH of this solution is approximately 1.2. [d] Composition: potassium phosphate (monobasic) 6.8 Gm. in 250 ml. water, sodium hydroxide (0.2 *N*) 190 ml., water 400 ml., pancreatin 10 Gm., sodium hydroxide (0.2 *N*) to adjust pH (7.5 ± 0.1), water *ad* 1,000 ml. [e] If one or two tablets fail to disintegrate completely, repeat the test on 12 additional tablets: not less than 16 of the total of 18 tablets tested disintegrate completely (First Supplement to USP XVII).

medium disintegration should be complete within 1 hr.

If the tablets fail to disintegrate in the alkaline pancreatin solution as required, the entire test must be repeated with a further five tablets using the guided disk during operation in the alkaline pancreatin solution. The tablets must then comply.

Canadian Food and Drugs Act and Regulations—Although apparatus, methods, and requirements for compliance are similar and in some respects even identical to those specified in the USP, there are some essential differences.

Apparatus—Its size differs considerably. The F.D.D. test is carried out in a vessel of approximately 3-L. capacity containing 2.5 L. of fluid. The USP test is carried out in a 1-L. vessel but does not specify the exact volume of fluid. A specific component of the F.D.D. apparatus is its plunger—a unit of precise dimensions consisting of a stainless steel rod separating two plastic disks. It is placed above the tablet or the slotted perforated disk riding atop the tablet in the tube.

Methodology and Compliance—These are summarized in Table X.

TABLE X—TABLET DISINTEGRATION
(CANADIAN FOOD AND DRUGS ACT AND REGULATIONS) METHODOLOGY AND COMPLIANCE (22)

Disk	Plunger	Immersion Fluid and Test Conditions		Compliance[a]
Uncoated and Plain Coated (6 Tablets in Test)				
+	+	Simulated gastric juice[b] for 30 min. and, after gentle rinse with water, simulated intestinal juice[b] until disintegration is complete	Average disintegration time of tablets should be not more than 60 min. (30-min. testing in simulated gastric juice and remainder of time in simulated intestinal juice)	If 1 of 6 tablets disintegrates in more than 75 min. (30-min. exposure to gastric juice plus more than 45-min. exposure to intestinal juice) the test must be repeated with additional 12 tablets. Average disintegration time of 18 tablets must not be more than 60 min. and not more than one tablet shall disintegrate in more than 75 min. (total time)
Enteric-Coated (6 Tablets in Test)				
−	+	Simulated gastric juice for 60 min.; there should be no distinct evidence of disintegration	Tablets should not disintegrate while tested for 60 min. in gastric juice but their average disintegration time should be not more than 60 min. during subsequent testing in simulated intestinal juice	If 1 of 6 tablets disintegrates in more than 75 min. the test must be repeated with additional 12 tablets. Average disintegration time of 18 tablets must not be more than 60 min. and not more than 1 tablet shall disintegrate in more than 75 min.
+	+	Simulated intestinal juice thereafter until disintegration is complete		
Enteric-Coated Vitamins (6 Tablets in Test)				
Same as for enteric-coated tablets			Tablets should not disintegrate while tested for 60 min. in simulated gastric juice, but average disintegration time should be not more than 30 min. in simulated intestinal juice	If 1 of 6 tablets disintegrates in more than 40 min. the test must be repeated with additional 12 tablets. Average disintegration time of 18 tablets must not be more than 30 min. and not more than 1 tablet shall disintegrate in more than 40 min.

[a] All tablets intended to be swallowed whole are subject to these requirements except those which release their medicaments at time intervals (repeat action) or in sustaining quantities over a specified period of time (prolonged action). [b] Composition identical to that specified in USP XVII (1).

Pharmacopée Française VIII (Codex Médicamentarius Gallicus)—*Apparatus*—Vessel: glass jar (vol. ~400 ml.); i.d. 7.5 cm. Temperature of medium: 37 ± 2°. Petri dish: height, 3 cm.; i.d., 5 cm. Cylindrical screen: height, 9.5 cm.; i.d., 6.5 cm.; wire mesh, nominal width of aperture 0.0787 in. (2 mm.). Movement: rate, 30 c.p.m. for 30 sec. every 5 min.; distance, 5 cm.

Method—The cylindrical screen is placed upon the Petri dish in the vessel containing 350 ml. of water kept at 37 ± 2°. Five tablets are transferred onto the wire mesh of the cylindrical sieve which, after the elapse of 5 min., is moved up and down for 30 sec. completing one cycle each 2 sec. This mode of operation is maintained throughout the duration of the test.

Compliance—(*a*) Uncoated tablets must disintegrate in water within 45 min. (*b*) Coated tablets must disintegrate in water within 2 hr. (*c*) Enteric-coated tablets should not show any evidence of disintegration in 0.6% (v/w) aqueous hydrochloric acid for 1 hr., but disintegrate within 2 hr.

Tablets exempt from these requirements include: (*a*) those intended to dissolve or disintegrate in the mouth; (*b*) those which are designed for implantation; (*c*) those not intended to dissolve in the stomach; (*d*) those designed for prolonged action; and (*e*) those designed to obtain a specific therapeutic action from the active ingredient.

State Pharmacopoeia U.S.S.R. IX—*Apparatus*—Special apparatus is not required.

Method—A tablet is placed into a 100-ml. flask, 50 ml. of water heated to 37° is added, and the flask is gently moved back and forth once or twice per second.

The tablet is considered disintegrated when it has dissolved or been reduced to a powder, small fragments, or loose mass. At least three such tests must be carried out.

Compliance—(*a*) Uncoated tablets must disinte-

grate within 10 min. (*b*) Coated tablets must disintegrate within 30 min. All tablets should be tested annually.

Pharmacopoea Nordica III—*Apparatus*—No special apparatus is required.

Method and Compliance—Three tablets are placed into a conical flask containing 30 ml. of distilled water warmed to 36–40°. The flask is shaken gently while the tablets are being observed for evidence of softening, dissolution, or disintegration. All three tablets must dissolve, become a soft, palpable mass, or disintegrate within 10 min. Coated tablets are subject to the same procedure, but their disintegration time may take 1 hr.

Enteric-coated tablets are tested in 30 ml. of a phosphate buffer solution (pH 7.4) instead of in 30 ml. of distilled water. They must disintegrate in less than 1 hr.

Glyceryl trinitrate tablets must disintegrate in less than 1 min.

Similarities and Differences—Comparison of apparatus, methodology, and tolerances embodied in pharmacopeial standards for the disintegration of tablets reveals that there exist far more differences than similarities. Experimental data obtained in accordance with specifications of one pharmacopeia do not, therefore, indicate compliance with specifications of some other pharmacopeia. The most common requirement is that tests be performed at 37 ± 2°.

A few obvious differences in experimental design and data interpretation may be cited to illustrate the extent of interpharmacopeial discordance. Such a critical parameter of disintegration as the width of the aperture of the wire mesh is specified to be 1.9 mm. in the USP, NF, and the Canadian Food and Drugs Act and Regulations, 2 mm. in the French pharmacopeia, and 1.68 mm. in the B.P. No screen is used in the apparatus specified by the Russian and Nordic pharmacopeias, respectively.

The tubes and tablets are raised and lowered at a rate of about 30 c.p.m. through a distance of 5–6 cm. in accordance with specifications of the USP NF, and the Canadian Food and Drugs Act and Regulations, throughout a distance of 7.5 cm. in accordance with specifications of the B.P. (either by hand or mechanically), and throughout a distance of 5 cm. in accordance with specifications of the French pharmacopeia. No such specifications are given in the Russian or Nordic pharmacopeias. Most compendia require that movement of the tubes be a continuous one—yet the French pharmacopeia specifies that it be a discontinuous operation.

The USP, NF, and the Canadian Food and Drugs Act and Regulations specify that six tablets be tested simultaneously, each in a separate tube, whereas the B.P. requires that five tablets be tested collectively in a single tube. The French pharmacopeia specifies that five tablets be tested together in a moving cylindrical screen, and the Russian pharmacopeia requires that three tablets be examined individually. The Pharmacopoea Nordica specifies that three tablets be tested collectively.

The test medium is, moreover, of variable composition. The British Pharmacopoeia uses water as the immersion fluid for tablets which are not enteric coated, and an acid pepsin plus alkaline pancreatin solution for tablets which are enteric coated. The French pharmacopeia uses water as the immersion fluid for uncoated and plain coated tablets, but dilute hydrochloric acid as the immersion fluid for enteric-coated tablets. The Russian pharmacopeia uses water as the test medium for all types of tablets. Simulated gastric and/or intestinal fluid, different in composition from that specified in the B.P., is required for tests carried out in accordance with methodologies described in the USP, NF, and the Canadian Food and Drugs Act and Regulations. The volumes of the test media and the exposure times of different tablets to these media vary also appreciably.

Differences in apparatus and methodology are reflected in marked differences of compliance as well. The number of tablets required for examination varies considerably (from 3 to 18). The USP, NF, and the Canadian Food and Drugs Act and Regulations allow for distinct deviations of 1 or 2 tablets out of 18 from an average value, whereas the British, French, Nordic, and Russian pharmacopeias require that all tablets tested comply with specifications. Tolerances for buccal and sublingual tablets are given in the USP and NF; the Pharmacopoea Nordica indicates tolerances specifically for only glyceryl trinitrate tablets in this category. Limits, based on data of physiological availability, for the disintegration time of tablets containing vitamins are specified in the Canadian Food and Drugs Act and Regulations.

Scope—The test was developed to assess batch-to-batch disintegration reproducibility of tablet formulations made by definite processes from specific ingredients and subjected to appropriate in-process manufacturing controls. It was also considered to provide information concerning the relative ease with which tablet formulations break up under controlled experimental conditions simulating *in vivo* environment. For over a quarter of a century it has been recognized as a pharmacopeial standard (23).

Far less appreciated than its value in pharmaceutical quality control, however, remained its value in the assessment of drug response. Originally, a tablet disintegrating rapidly was thought to be clinically more effective than one disintegrating over a long period of time and the process of disintegration regarded not only as a tool for ensuring product compliance but also as a means of gauging the physiological availability of medicinal preparations. It is not intended to trace the historical development of the test or present a detailed account of its applications, for several excellent reviews have been written on this subject (24–31). The importance of the disintegration test cannot be denied. Specifying simple sets of conditions under which different types of tablets are examined, it represents a physical method of pharmaceutical quality control which allows a drug manufacturer or distributor to check his products for uniformity of performance from batch to batch without recourse to complex and expensive apparatus or personnel requiring advanced academic training. In this respect the test fulfills and will, no doubt, continue to fulfill a useful function.

As a pharmacopeial standard it postulates minimum and maximum allowable tolerances for tablet formulations most frequently used, but for a fuller appreciation of the significance of the data

it provides, other closely related and important criteria must, likewise, be taken into account. It has been pointed out that it would not be difficult to formulate a compressed tablet meeting pharmacopeial requirements for disintegration time from granules of cement passing through the gastrointestinal tract without change (25). Experiments conducted in these laboratories as well as elsewhere have shown that tablets claimed to contain potent chemotherapeutic agents do in fact so behave because of improper or faulty formulation (32). Such observations emphasize that tablet disintegration is indeed an important criterion of product quality, for no therapeutic effect can be expected from a tablet that fails to disintegrate.

The role of the disintegration test in the assessment of drug response cannot, however, be summarized that categorically. Original studies concerning this aspect of tablet disintegration were first carried out in the research laboratories of the Canadian Food and Drug Directorate under the direction of J. A. Campbell. They showed that tablet disintegration *in vitro* had to occur within a given period of time to ensure physiological availability of drugs administered as compressed or coated solid dosage forms. Data obtained from *in vitro* disintegration tests were correlated with results from *in vivo* measurements based on urinary excretion and/or blood level determinations and meaningful tolerances were thus established. Official specifications embodied in the Canadian Food and Drugs Act and Regulations—made mandatory in 1957—are largely based on this work (33–46). They motivated Canadian manufacturers to modify many of their tablet formulations for the purpose of producing pharmaceutical dosage forms displaying improved physiological availability and therapeutic efficacy.

Related studies published since are in accord with the findings that were made and confirm that results of *in vitro* disintegration tests can be considered as criteria of physiological availability only to the extent they correlate with quantitative *in vivo* data obtained on humans. *In vitro* results alone cannot be relied upon as indices of drug availability. Only through correlation with data reflecting *in vivo* response can they be utilized as parameters of biopharmaceutical quality control and monitors for product reproducibility. This shortcoming of the test is, unfortunately, not referred to in pharmacopeial texts.

What is to be more generally realized is that contrary to concepts originally conceived and accepted without question or scientific inquiry, tablets disintegrating quickly need not necessarily display enhanced clinical effectiveness and tablets disintegrating slowly need not necessarily display reduced therapeutic activity. Lack of knowledge of mechanisms underlying drug absorption and inability to duplicate precisely physiological conditions *in vitro* stand in the way of translating reliably data obtained *via* physical tests to drug response. It has been demonstrated, for instance, that agitation of a tablet during the USP disintegration test is far more intense (possibly more than three times as great) than during its residence time in the human stomach or during intestinal transit (29, 31). In this regard alone, most disintegration tests must be considered physiologically unrealistic. Only through independent and objective appraisal of physiological availability can the therapeutic efficacy of tablet formulations be ascertained. This task should be a most important consideration of the pharmaceutical manufacturer in the development of new drug products.

Although some pharmacopeial commissions have made considerable revisions for tablet disintegration times and specified stricter limits for many dosage forms in succeeding editions of compendia (see Tables XI–XIII, summarizing data extracted from the United States Pharmacopeia and the National Formulary) these standards still provide liberal tolerances for tablet disintegration time, and at the present state of the art the production of solid oral dosage forms meeting official specifications is not likely to impose any hardships on the pharmaceutical industry.

The need to establish—in Canada—tolerances providing for disintegration times longer than those stated in the Food and Drugs Act and Regulations (7) has so far not been demonstrated. Nevertheless, the Food and Drug Directorate allows for the production and sale of compressed as well as enteric-coated tablets which fail to meet official specifications for disintegration time provided experimental evidence demonstrates that all therapeutically active ingredients are physiologically available as claimed. It should be in the manufacturer's interest to keep tablet composition and processing as simple as possible in order to avoid unpredictable effects not only in disintegration time but on the therapeutic efficacy of the product as well (47–52).

Difficulties in establishing accurate methods of analysis should always be regarded as early warning signals for a reassessment of biological response. Concerned about potential health hazards resulting from formulation changes, the Canadian Food and Drug Directorate requires that all manufacturers duly inform the Director-General of any modification in composition and/or processing for any medication accepted on the basis of a preclinical or new drug submission (7, 53, 54). In this connection, the World Health Organization recently drew to the attention of member states pertinent observations concerning the composition of a chloramphenicol palmitate formulation which had failed to produce satisfactory clinical response (55). Dissemination of such information under the auspices of WHO should be encouraged.

During the last few years the inherent weaknesses of the disintegration test have come to light and into sharper focus through the development of and correlation with a companion test appraising drug dissolution. Although a prerequisite to drug response, tablet disintegration is but one of a number of phenomena preceding drug absorption. The rate at which a drug diffuses from a tablet matrix into the surrounding fluids has been shown to represent an even more important process. Studies correlating disintegration time, dissolution rate, and physiological availability have supported this concept (29–31).

Recent investigations in the authors' laboratories have shown that wide variations in rate of drug dissolution may occur not only between products of different manufacturers (different brands containing the same active ingredient), but also between different lots of a given product supplied by the

same manufacturer (56, 57). Related studies have illustrated the effects of dosage form variation on the physiological availability of drugs (58, 59).

So far, pharmacopeial standards for tablet dissolution have not been formulated. The need for such standards will grow since tablet dissolution is of more fundamental importance than tablet disintegration for determining drug availability. The disintegration test merely measures the time required for a tablet to break up into granules smaller than a given size, but it tells nothing about how rapidly the drug is released from these granules into the substrate. Dissolution, on the other hand, has been shown to control the rate of build-up of many drugs in the blood stream and has been correlated more accurately than disintegration time with therapeutic efficacy.

Undoubtedly, dual tests comprising coordinated *in vivo* and *in vitro* evaluation of drug products are becoming the most critical parameters of

TABLE XIII—COMPARISON OF DISINTEGRATION TIME DATA GIVEN IN USP XVII AND NF XII

	USP XVII	NF XII
Total number of tablets covered in monographs	117	139[a]
Tablets for which disintegration time was reduced	11 (9.4%)	36 (33.1%)
Tablets for which disintegration time was reduced by 50%	9 (7.7%)	29 (20.9%)
Tablets for which disintegration time was reduced by more than 50%	1 (0.8%)	9 (6.5%)
Tablets for which disintegration time was reduced by less than 50%	1 (0.8%)	8 (5.8%)
Tablets for which disintegration time was increased	1[b]	...
Tablets required to disintegrate in 30 min.	97 (82.9%)	91 (65.5%)
Tablets required to disintegrate in less than 30 min.	7 (6.0%)	30 (21.6%)
Tablets (nonenteric coated) permitted to disintegrate in more than 30 min.	9 (7.7%)	9 (6.5%)
Enteric-coated tablets for which disintegration times are specified	2[c]	...
Tablets for which disintegration times are not given in monographs	1	7 (5.0%)[d]

[a] Includes 26 preparations deleted from USP XVI. Disintegration times for 24 of these were left unchanged. [b] Probenecid. [c] Ammonium chloride and sodium sulfoxone. [d] Tablets of calcium cyclamate and calcium saccharin, phenoxymethyl penicillin, polymyxin B sulfate, potassium phenethicillin, sodium cyclamate and sodium saccharin, sodium saccharin, and tetracycline hydrochloride. Disintegration times were specified, however, for tablets of polymyxin B sulfate and sodium saccharin in USP XVI and for tablets of tetracycline hydrochloride in NF XI.

pharmaceutical quality control. Physiological availability data obtained through properly designed objective studies on humans together with *in vitro* disintegration and dissolution parameters reflecting the clinical performance of a dosage form are clearly emerging as prerequisites in the manufacture of drug products justifiably claimed to be safe and therapeutically effective. Any change in product formulation made subsequent to such standardization requires that both sets of data be reassembled so that adequately calibrated *in vitro* data alone may be utilized with confidence as monitors of quality control, gauging not only physicochemical variability within and between lots, but allowing also for interpretation of product safety and efficacy.

For certain dosage forms physiological availability data are already legal requirements. It is mandatory, for example, that in accordance with regulations of the Canadian Food and Drugs Act and Regulations "the manufacturer of a drug in oral dosage form represented as releasing the drug at timed intervals or in sustaining quantities over a period of time shall (a) conduct such investigations, using an acceptable method, as may be necessary to demonstrate that the drug is released

TABLE XIV—SPECIFICATIONS FOR BULK DRUGS OF THE UNITED STATES PHARMACOPEIA XVII

and is available as represented, and (b) on request submit the record of such investigations to the Director" (*Reference* 7, Section C.01.012).

More and more companies, realizing the need for such studies to ensure the safety and clinical effectiveness of a pharmaceutical formulation, are submitting to the Director-General on their own accord experimental evidence documenting the physiological availability of new drugs as defined in Section C.08.001 of the Food and Drugs Act and Regulations (7). It is merely a question of time until such data will become official requirements.

Great strides are being made in the field of biopharmaceutics and it is essential that they be evaluated periodically in order to determine whether pharmacopeial tests and specifications for drug efficacy can be established that are more meaningful and informative than those upon which we must rely at the present time.

ASSAYS OF BULK DRUGS AND COMPRESSED TABLETS

Bulk Drugs—Assay limits for bulk drugs[9] specified in the United States Pharmacopeia, the National Formulary, and the British Pharmacopoeia are summarized in Tables XIV–XVI. As a rule, limits are given in the form of a statement defining that the drug contains not less than a certain percentage and not more than a certain percentage of the chemical compound specified in the monograph. For many products only lower limits are given. In each such instance, the upper limit is considered be 100.5%.

The distribution of ranges most frequently specified in USP XVII, NF XII, and B.P. 1963 is shown in Table XVII. For all three pharmacopeias, the most popular range extends from 98–100.5%. The second most popular range specified in the USP XVII and NF XII is 98–102% (9.3 and 14.6% of the compounds listed, respectively), while that of the B.P. 1963 extends from 99–100.5% (17.5% of compounds listed).

The Pharmacopoeia of the U.S.S.R. (English edition) designates lower limits for all drugs, but specifies upper limits for only a few.[10] For compliance, 97 drugs out of 150 (64.7%) must assay 99–101%, 34 must assay 98–102%, 7 must assay 97–103%, and 3 must assay 95–105%. These requirements are more stringent than those of the USP, NF, or B.P.

Assay limits specified for bulk drugs included in both the USP and B.P., or B.P. and NF, are shown in Table XVIII. Differences in either upper or lower limits of at least 1% were considered prerequisites for entry of compounds into this table. The data recorded illustrate the magnitude of interpharmacopeial drug content variations.

Thus, phenylephrine hydrochloride B.P. assays 98.5–100.5%, whereas phenylephrine hydrochloride USP may assay 97.5–102.5%. Methylprednisolone NF XII assays from 97–103%, but methylpredni-

98–101	7.7	6.7	6.0

[9] Antibiotics, inorganics, and multicomponent drugs, *e.g.*, aminophylline (theophylline + ethylenediamine) are not included in this survey.

[10] The authors are indebted to Dr. A. N. Klimov, Division of Biology and Pharmacology, World Health Organization, Geneva, Switzerland, for advising that in the absence of specifications for complete tolerance ranges, upper limits of 100.5% apply.

TABLE XVIII—ASSAY LIMITS FOR BULK DRUGS INCLUDED IN THE UNITED STATES PHARMACOPEIA, NATIONAL FORMULARY, AND BRITISH PHARMACOPOEIA

Compd.	USP XVII	NF XII	B.P. 1963
Acetazolamide	98–102		99.0–100.5
Amodiaquine hydrochloride		97–102	98.0–101.5
Amphetamine sulfate		98–100.5	99.0–100.5
Benzocaine		98–101	99.0–100.5
Calcium lactate		98–101	97.0–103.0
Chloral hydrate	99.5–102.5		99.0–100.5
Chloroquine phosphate	98–102		98.0–100.5
Chlorothiazide		97–100.5	98.0–100.5
Chlorpromazine hydrochloride	98–101.5		99.0–101.0
Chlorpropamide	97–103		99.0–101.0
Codeine phosphate	98–101.5		98.0–100.5
Cortisone acetate		97–103	96.0–104.0
Desoxycorticosterone acetate	97–103		96.0–104.0
Dextroamphetamine sulfate	98–100.5		99.0–100.5
Dextromethorphan hydrobromide		98–100.5	99.0–100.5
Dichlorphenamide	97–100.5		98.0–100.5
Dienestrol		98–100.5	98.5–101.5
Diethylstilbestrol	97–100.5		98.5–101.5
Diiodohydroxyquin	96–100.5		97.0–100.5
Epinephrine	97–100.5		99.0–100.5
Epinephrine bitartrate	97–102		99.0–100.5
Ergonovine maleate	98–101		95.0–100.5
Folic acid	98–102		95.0–100.5
Glutethimide		98–100.5	99.0–100.5
Guanethidine sulfate	95–105		99.0–101.0
Hydralazine hydrochloride		98–100.5	98.0–102.0
Hydrochlorothiazide	97–101.5		98.0–100.5
Hydrocortisone	97–103		96.0–104.0
Hydrocortisone acetate	97–103		96.0–104.0
Hydrocortisone sodium succinate	97–103		96.0–104.0
Hydroxychloroquine sulfate	98–102		98.0–100.5
Imipramine hydrochloride		98–102	98.0–100.5
Iopanoic acid	97–101		98.0–101.0
Levarterenol bitartrate	97–102		99.0–101.0
Meclizine hydrochloride	97–100.5		98.0–100.5
Meperidine hydrochloride		98–101	99.0–100.5
Mercaptopurine	97–102		98.0–100.5
Methylene blue	98.5–100.5		96.0–101.0
Methylergonovine maleate	97–103		95.0–105.0
Methylprednisolone		97–103	96.0–104.0
Methylthiouracil		97–100.5	98.0–100.5
Neostigmine bromide	98–102		98.5–100.5
Neostigmine methylsulfate	98–102		98.5–100.5
Phenindamine tartrate		98–101.5	98.5–100.5
Phenolsulfonphthalein	95–105		94.0–100.5
Phentolamine hydrochloride		98–100.5	99.0–100.5
Phentolamine mesylate	98–102		99.0–100.5
Phenylbutazone		98–100.5	99.0–100.5
Phenylephrine hydrochloride	97.5–102.5		98.5–100.5
Prednisolone	97–103		96.0–104.0
Prednisolone acetate	97–103		96.0–104.0
Prednisone	97–103		96.0–104.0
Primaquine phosphate	98–102		97.5–100.5
Primidone	98–102		99.0–100.5
Promethazine hydrochloride	97.0–101.5		98.5–102.0
Quinidine sulfate	98–100.5		99.0–101.5
Reserpine	96–101		97.0–101.5
Riboflavin	98–102		97.0–102.0
Sodium aminosalicylate	98–101		99.0–101.0
Sodium indigotindisulfonate	96–100.5		90–100.5
Stibophen	98.5–102		98.5–101.0
Thiamine hydrochloride	98–102		98.5–100.5
Thimerosal		97–101	98.0–100.5
Tolbutamide	98–101		99.0–101.0
Undecylenic acid		95–100.5	96.0–100.5

solone B.P. may assay 96–104%. Ergonovine maleate USP must contain 98–101% of the alkaloid, but ergometrine maleate B.P. (ergonovine maleate) may assay 95–100.5%. Chlorpropamide assaying 97–103% meets USP specifications, but fails to meet B.P. requirements (99–101%).

Tolerance ranges for some drugs may differ by as much as 8%, *e.g.*, guanethidine sulfate B.P. assays 99–101%; guanethidine sulfate USP assays 95–105%. The following ranges apply to promethazine hydrochloride: USP 97.0–101.5%, B.P. 98.5–102.0%, State Pharmacopoeia of the U.S.S.R. (diprazine) 99.5–101.0%.

Diethylstilbestrol assaying not less than 97% meets USP specifications, samples assaying not less than 98.5% comply with B.P. requirements, and products assaying not less than 99.0% will meet specifications of the State Pharmacopoeia of the U.S.S.R. Sodium suramin (B.P. and USP) must contain not less than 97.5% (volumetric analysis) of the antitrypanosomal drug, but may assay 92.5% (gravimetric analysis) or 93.5% (volumetric analysis) to meet specifications of the State Pharmacopoeia of the U.S.S.R. (naganin).

It should be pointed out that bulk drugs are also covered in pharmacopeial monographs lacking methods of assay, *e.g.*, progesterone NF XII,[11] oestradiol B.P. 1963, cortisone acetate State Pharmacopoeia of the U.S.S.R.,[12] colchicine USP. Yet quantitative methods of analysis and tolerances may be specified for pharmaceutical dosage forms containing such drugs as active ingredients, *e.g.*, progesterone tablets NF XII (90–110%), oestradiol benzoate injection B.P. 1963 (90–110%), cortisone acetate tablets, State Pharmacopoeia of the U.S.S.R. (90–110%), colchicine tablets USP (90–110%). It is essential that reliable assays for bulk drugs used in the manufacture of such products be developed and tested collaboratively in pharmaceutical quality control laboratories.

Variations between assay limits for bulk drugs common to different pharmacopeias are, in part at least, due to differences in methodology. Thus ergonovine maleate USP is determined titrimetrically, but ergometrine maleate B.P. (ergonovine maleate) is assayed colorimetrically. Imipramine B.P. is determined by Kjeldahl analysis, imipramine NF by nonaqueous titration. Acetazolamide USP is assayed by infrared, acetazolamide B.P. by ultraviolet spectrophotometry. Phenylephrine hydrochloride USP is assayed iodometrically, phenylephrine hydrochloride B.P. is determined by nonaqueous titration. Chlorpropamide USP is estimated by ultraviolet spectrophotometry, chlorpropamide B.P. by Kjeldahl analysis. Guanethidine sulfate B.P. is assayed by column chromatography, guanethidine sulfate USP by colorimetry. Promethazine hydrochloride, State Pharmacopoeia of the U.S.S.R. (diprazine), is estimated by aqueous titrimetry, and promethazine hydrochloride USP by nonaqueous titrimetry, and promethazine hydrochloride B.P. by ultraviolet spectrophotometry. Diethylstilbestrol USP is assayed colorimetrically, stilboestrol B.P. (diethylstilbestrol) and diethylstilbestrol State Pharmacopoeia of the U.S.S.R. are determined titrimetrically following acetylation in pyridine.

Compressed Tablets—The drug content of compressed tablets covered in pharmacopeial monographs is usually given in the form of a statement indicating upper and lower limits. The tolerances allow for sampling variations, errors inherent in analytical methodology, variations due to compounding, differences in bulk drug uniformity, and losses in active strength during storage. The general nature and scope of the assays has been described under *Drug Content*.

Relationships between drug content and permitted variation in compressed tablets for which symmetrical tolerances are specified in the USP, NF, B.P., and the State Pharmacopoeia of the U.S.S.R. are depicted schematically in Fig. 1. It can be seen that the USP endorses six and the NF seven different ranges. Only three of these are frequently applied (95–105%, 93–107%, and 90–110%). The B.P. recognizes but three limits of variability (95–105%, 92.5–107.5%, and 90–110%), and the State Pharmacopoeia of the U.S.S.R. allows for just two such ranges (95–105% and 90–110%).

The length of the bars shown in the illustration is proportional to the number of tablets to which the specified relationship between drug content (dosage) and permitted variation applies. For example, only one product is listed in the B.P. containing 500 mg. of active ingredient for which a tolerance of ±7.5% is permitted. Three products to which this tolerance applies contain 300 mg. of active ingredient. Five, nine, and 17 products meeting this specification contain 250 mg., 200 mg., and 100 mg. of active ingredient, respectively. Similarly, only one product is found to contain 100 mg. of active ingredient to which a tolerance of ±10% applies.

For 17 products containing this concentration of active ingredient, tolerances of ±7.5% are permitted and for 11 such products, variations of only ±5% are allowed. Thus, Fig. 1 readily demonstrates the overlap in dosage levels between tablets subject to identical dosage variations as well as the overlap in dosage variation between products of identical drug content. In general, dosage variations are maximal for products containing only small concentrations of active ingredients.

Totals shown in Fig. 1 represent both different drug products as well as different dosage levels of the same drug product. Thus, for phenobarbital tablets USP, dosage levels of 15 mg., 30 mg., 60 mg., and 100 mg. are included in the data, while for phenobarbitone tablets B.P., dosage levels of 15 mg., 30 mg., 60 mg., 100 mg., and 125 mg. have been recorded.

Ranges of 93–107% and 95–105% are most frequently specified in the USP (49 and 48 products, respectively, or about 30%). Variations ranging from 90–110% are most often applied in the NF (52 products or 29.9%). The B.P. recognizes limits of 92.5–107.5% for most medications (115 products or 42.4%), allowing for an extension of these limits if assays are based on less than 20 tablets. While the USP and NF specify, furthermore, unsymmetrical ranges for a few dosage forms containing overages of drugs prone to deterioration on prolonged storage, the B.P. does not follow this practice. The most often used limits of drug content specified in the State Pharmacopoeia of the U.S.S.R. extend from 95–105% (52 products or 70.3%). Thus, as for bulk drugs, limits for solid oral dosage forms are generally also narrower and more exacting in this pharmacopeia than in the USP, NF, or B.P. Formulations composed of antibiotics, inorganics, and mixtures of drugs are not included in these data.

[11] A gravimetric assay for the steroid is given in the State Pharmacopoeia of the U.S.S.R. (98.5–100.5%) and an ultraviolet method described in the B.P. (97.0–103.0%).

[12] A colorimetric assay is given in both the B.P. (96–104%) and NF (97–103%).

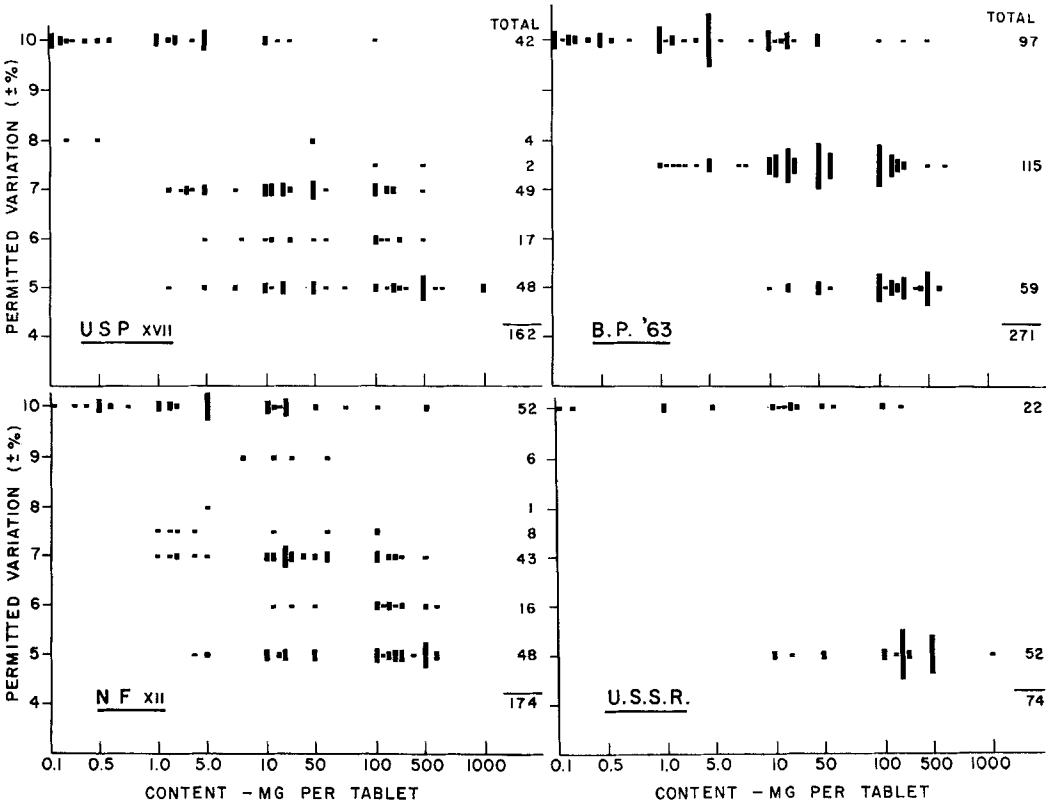

Fig. 1—Drug content tolerances for tablets included in pharmacopeial compendia.

Tablets for which different limits with regard to drug content are specified in different pharmacopeias are listed in Table XIX. Products for which symmetrical limits have been specified are given in part *A* and those for which unsymmetrical limits have been specified in at least one pharmacopeia are shown in part *B* of this table. Deviations of at least 1% in either lower or upper assay limits were considered prerequisites for compilation. Of all products thus screened—112—no less than 61 (54.5%) satisfied this requirement. Comparison of the data reproduced illustrates the extent of variation which exists between pharmacopeial specifications for products subject to identical label claims for drug content.

It is difficult to assess some of these discrepancies. They cannot always and solely be ascribed to different analytical methods. For example, guanethidine tablets USP as well as B.P. are assayed colorimetrically, yet their assay limits range from 95–105% and 90–110%, respectively. Phentolamine hydrochloride tablets B.P. and NF are both assayed gravimetrically, yet pharmacopeial limits vary from 90–110% and 93–107%, respectively. Similarly, diethylcarbamazine citrate tablets USP and B.P. are determined titrimetrically, yet assay tolerances extend from 95–105% to 92.5–107.5%, respectively. On the other hand, products may be examined by different methods yet comply with identical specifications for drug content. Thus, primidone tablets USP, B.P., and State Pharmacopoeia of the U.S.S.R. (hexamidine) (95–105%) are analyzed by either ultraviolet spectrophotometry or gravimetry. Acetylsalicylic acid tablets USP, B.P., and State Pharmacopoeia of the U.S.S.R. (95–105%) are determined by either ultraviolet spectrophotometry or by titrimetry. Similarly cyclizine hydrochloride tablets USP (93–107%) are subjected to spectral analysis, whereas cyclizine hydrochloride tablets B.P. (92.5–107.5%) are assayed by nonaqueous titrimetry.

Examples illustrating different specifications for drug content based on different methods of analysis may also be cited. Tolbutamide tablets USP (95–105%) are assayed by ultraviolet spectrophotometry, but tolbutamide tablets B.P. (92.5–107.5%) are assayed by Kjeldahl analysis. Nitrofurantoin tablets USP (95–105%) are examined by polarography. Nitrofurantoin tablets B.P. (90–110%) are examined spectrophotometrically. Sodium aminosalicylate tablets B.P. (90–110%) are analyzed by titration with nitrous acid, but sodium aminosalicylate tablets, State Pharmacopoeia of the U.S.S.R. (95–105%), are analyzed by iodimetry. Thus, limits may range from 10–20% for pharmacopeial products subject to identical label claims for drug content.

Finally, examples illustrating identical specifications based on identical methods of analysis can also be given. Diethylstilbestrol tablets USP, B.P., and Pharmacopoeia of the U.S.S.R. are all assayed colorimetrically (drug content limit 90–110%). Cortisone acetate tablets NF, B.P., and State Pharmacopoeia of the U.S.S.R. are all analyzed spectrophotometrically (assay limit 90–110%). Similarly, sulfadiazine tablets USP and B.P. are

TABLE XIX—SPECIFICATIONS FOR TABLETS INCLUDED IN TWO OR MORE PHARMACOPEIAS

Tablet	Assay Limits, %			
	USP XVII	NF XII	B.P. 1963	State Pharmacopoeia U.S.S.R. IX
A—Symmetrical				
Acetazolamide	95–105		92.5–107.5	
Amobarbital	94–106		92.5–107.5	
Amodiaquine hydrochloride		93–107	95.0–105.0	
Amphetamine sulfate		90–110	90.0–110.0	95–105
Busulfan	93–107		90.0–110.0

Chlorpromazine hydrochloride	95–105		92.5–107.5	
Chlorpropamide	95–105		92.5–107.5	
Dapsone	92.5–107.5		95.0–105.0	
Dehydrocholic acid		94–106	...	95–105
Dextroamphetamine sulfate	93–107		90.0–110.0	
Dextromethorphan hydrobromide		90–110	92.5–107.5	
Diethylcarbamazine citrate	95–105		92.5–107.5	
Digoxin	92–108		90.0–110.0	
Diiodohydroxyquin	95–105		92.5–107.5	
Ephedrine hydrochloride		93–107	92.5–107.5	95–105
Ferrous gluconate		93–107	90.0–110.0	
Guanethidine	95–105		90.0–110.0	
Hydralazine hydrochloride		95–105	92.5–107.5	
Isoniazid	93–107		95.0–105.0	
Lucanthone hydrochloride	93–107		95.0–105.0	
Mepacrine hydrochloride			95.0–105.0	90–110
Meperidine hydrochloride		95–105	92.5–107.5	
Methamphetamine hydrochloride	93–107		90.0–110.0	
Methylprednisolone		92.5–107.5	90.0–110.0	
Methyprylon		95–105	92.5–107.5	
Nitrofurantoin	95–105		90.0–110.0	
Phenacetin	94–106		...	95–105
Phenobarbital	94–106		92.5–107.5	95–105
Phenolphthalein		92.5–107.5	92.5–107.5	95–105
Phentolamine hydrochloride		93–107	90.0–110.0	
Phenylbutazone		93–107	95.0–105.0	
Phthalylsulfathiazole	94–106		95.0–105.0	95–105
Probenecid	92.5–107.5		95.0–105.0	
Prochlorperazine maleate	95–105		90.0–110.0	
Proguanil hydrochloride			95.0–105.0	90–110
Propantheline bromide	95–105		92.5–107.5	
Pyridostigmine bromide	95–105		92.5–107.5	
Quinidine sulfate	94–106		95.0–105.0	
Quinine sulfate		94–106	95.0–105.0	95–105
Sodium aminosalicylate	95–105		90.0–110.0	95–105
Sodium warfarin	95–105		90.0–110.0	
Tolbutamide	95–105		92.5–107.5	95–105
Trihexyphenidyl hydrochloride	93–107		90.0–110.0	
Tripelennamine hydrochloride	93–107		90.0–110.0	
Sodium barbital			95.0–105.0	95–105
B—Unsymmetrical				
Ascorbic acid	95–115		92.5–107.5	95–105
Ethinyl estradiol	90–115		90.0–110.0	
Folic acid	95–115		90.0–110.0	
Meclizine	95–110		92.5–107.5	
Mepacrine hydrochloride			95.0–105.0	95–110
Mercaptopurine	93–110		90.0–110.0	
Niacin		95–115	92.5–107.5	
Nitroglycerin	80–112		85.0–115.0	86–116
Promazine hydrochloride		95–110	90.0–110.0	
Promethazine hydrochloride	95–110		92.5–107.5	90–110
Sodium amobarbital			92.5–107.5	93–105
Sodium barbital			95.0–105.0	93–105
Sodium pentobarbital		90–105	92.5–107.5	90–105

both examined titrimetrically and, to comply with specifications for drug content, must assay 95–105%.

Further comparisons of pharmacopeial specifications for drug content of compressed tablets are made in Table XX. The compilation illustrates that 45 products for which specifications are found in the B.P. are covered in other compendia as well. Only 11 such products are included in the Russian pharmacopeia. It is also seen that of the four pharmacopeias surveyed, the USP contains the

TABLE XX—PHARMACOPEIAL SPECIFICATIONS FOR DRUG CONTENT OF COMPRESSED TABLETS

	USP XVII	NF XII	B.P. 1963	U.S.S.R. IX
No. of tablets listed in one or more pharmacopeial texts	29	17	45	11
No. of tablets with potency limits narrower than specified in other pharmacopeial texts	20	6	12	6
No. of tablets with potency limits equal to those specified in other pharmacopeial texts	1	0	2	4

highest proportion of products (covered in other compendia as well) with narrowest limits. On the other hand, the State Pharmacopoeia of the U.S.S.R. commands the highest ratio of products (for which monographs are given in other compendia as well) with limits narrower than or equal to those of the USP, NF, and B.P. (10 products out of 11).

Of the four reference compendia, the State Pharmacopoeia of the U.S.S.R. appears to be the most rigorously standardized. It allows for only two ranges and very few dosage levels of the same product. It specifies, moreover, all substances which may be incorporated as excipients into solid oral dosage forms and states their concentrations as normally used. Thus, tablet manufacture and pharmaceutical quality assurance are more strictly controlled.

SUMMARY

Considerable differences exist between pharmacopeial specifications applied in the quality control of bulk drugs and solid oral dosage forms. Often experimental results obtained by different national laboratories in accordance with national standards cannot be readily compared. Methodology and compliance vary significantly for even a test as simple as weight variation. Only a few common features characterize the disintegration test. Products meeting one pharmacopeia's standard may therefore fail to meet specifications, and be rejected, if tested by another pharmacopeia's standard.

Progress in drug evaluation, advances in drug therapy, and improvement of international drug trade would be facilitated immeasurably if a code of pharmaceutical specifications could be sanctioned internationally and adopted universally.

These objectives can and must be reached. They are embodied in the resolution adopted by the World Health Assembly at its recent plenary session and endorsed by the World Health Organization (60, 61). This resolution "requests the Director-General (a) to continue his assistance to Member States for the improvement of the quality control of pharmaceutical preparations, and for the establishment of quality control laboratories for national or regional purposes where such laboratory facilities are insufficient; (b) to implement the proposals made in his report; particularly in regard to the establishment of general principles for the quality of pharmaceutical preparations and the quality control of the products entering into international commerce; and (c) to report on the results to the Executive Board and the Twentieth World Health Assembly."[13]

It should be the solemn duty of all privileged to participate in these programs to do their utmost so that collectively they may be brought to fruition. There are indeed no higher stakes—the health and happiness of mankind.

Determination of Antimony in Talc

By HARVEY D. SPITZ and ALEXANDER J. GOUDIE

A method has been developed to determine trace amounts of antimony present in talc. The spectrophotometric method is based upon the reaction of antimony (V) with rhodamine B in isopropyl ether after extraction of the antimony from 1.5 *M* hydrochloric acid.

RECENTLY, the Food and Drug Administration set limits for antimony in certain foodstuffs and dyes at 2 p.p.m. Because of the possible extension of this regulation to talc, a method has been developed for the semiquantitative determination of antimony in talc in the concentration range of 2 p.p.m.

Several methods have been developed to determine micro amounts of antimony. Iodide ion in acid solution (1, 2) or with iodide and pyridine (3) have been used, but not with the sensitivity of some other chromophoric reagents. Busev (4, 5) and his co-workers have developed a sensitive method using antipyrine dyes. However, the unavailability of these noncommercial dyes negated any work with them. Matulis and Guyon (6) have recently developed a sensitive system of analysis based on the enhancement by antimony of a blue hue due to the reduction of the molybdate aggregate near pH 1.4.

The most common technique has employed rhodamine B (7–14). A relatively simple and moderately accurate method for the determination of antimony in talc has been developed with rhodamine B as the chromophoric reagent.

Received January 6, 1967, from the Johnson & Johnson Research Center, New Brunswick, NJ 08903
Accepted for publication August 18, 1967.
The authors express their appreciation to Mrs. A. Bollman for her technical assistance.

EXPERIMENTAL

Apparatus and Reagents—A Zeiss PMQ II spectrophotometer employing 1-cm. silica cells was used.

Hydrochloric Acid, 6 M—Dilute 500 ml. of concentrated hydrochloric acid with sufficient purified water to make 1000 ml. of solution.

Hydrochloric Acid, 1 M—Dilute 20.8 ml. of concentrated hydrochloric acid with sufficient purified water to make 250 ml. of solution.

Sulfuric Acid, 0.5 M—Dilute 2.8 ml. of concentrated sulfuric acid with sufficient purified water to make 100 ml. of solution.

Ceric Sulfate—Dissolve 3.3 Gm. of anhydrous ceric sulfate in 100 ml. of 0.5 *M* sulfuric acid.

Hydroxylamine Hydrochloride—Dissolve 1 Gm. of hydroxylamine hydrochloride in 100 ml. of purified water.

Hydroxylamine Hydrochloride, Acidic—Dissolve 1 Gm. of hydroxylamine hydrochloride in 100 ml. of 1 *M* hydrochloric acid.

Isopropyl Ether (Peroxide Free)—Saturate the isopropyl ether with 1 *M* hydrochloric acid.

Rhodamine B Reagent—Dissolve 0.02 Gm. of rhodamine B in 100 ml. of 1 *M* hydrochloric acid.

Sodium Sulfite—Dissolve 1 Gm. of reagent grade sodium sulfite in 100 ml. of purified water.

Antimony Postassium Tartrate, Reagent Grade—$[K(SbO)C_4H_4O_6 \cdot {}^1/_2H_2O]$.

Preparation of Standard—Weigh to the nearest tenth of a milligram a 274-mg. sample of antimony potassium tartrate into a 100-ml. volumetric flask. Dissolve the sample in and make up to the mark with 6 *M* hydrochloric acid. Pipet 10.00 ml. of this solution into a 100-ml. volumetric flask and dilute

Ceric Sulfate—Dissolve 3.3 Gm. of anhydrous ceric sulfate in 100 ml. of 0.5 *M* sulfuric acid.

Hydroxylamine Hydrochloride—Dissolve 1 Gm. of hydroxylamine hydrochloride in 100 ml. of purified water.

Hydroxylamine Hydrochloride, Acidic—Dissolve 1 Gm. of hydroxylamine hydrochloride in 100 ml. of 1 *M* hydrochloric acid.

Isopropyl Ether (Peroxide Free)—Saturate the isopropyl ether with 1 *M* hydrochloric acid.

Rhodamine B Reagent—Dissolve 0.02 Gm. of rhodamine B in 100 ml. of 1 *M* hydrochloric acid.

Sodium Sulfite—Dissolve 1 Gm. of reagent grade sodium sulfite in 100 ml. of purified water.

Antimony Postassium Tartrate, Reagent Grade—$[K(SbO)C_4H_4O_6 \cdot {}^1/_2H_2O]$.

Preparation of Standard—Weigh to the nearest tenth of a milligram a 274-mg. sample of antimony potassium tartrate into a 100-ml. volumetric flask. Dissolve the sample in and make up to the mark with 6 *M* hydrochloric acid. Pipet 10.00 ml. of this solution into a 100-ml. volumetric flask and dilute

to the mark with 6 *M* hydrochloric acid (solution *A*). Pipet 10.00 ml. of solution *A* into a 500-ml. volumetric flask and dilute to the mark with 6 *M* hydrochloric acid (solution *B*). One milliliter of solution *B* is equivalent to 2 mcg. of antimony.

Add to two 125-ml. separators 27.0 and 30.0 ml. of 6 *M* hydrochloric acid, respectively. Buret or pipet into the first separator 3.00 ml. of solution *B*. The second separator serves as the blank. Add 1 ml. of the sodium sulfite solution to each separator, swirl, add 15 ml. of purified water, and shake each separator gently to mix the contents.

Cool the solution in each separator to 25° or less and add 3 ml. of ceric sulfate solution. Mix thoroughly and allow the funnel contents to stand for 5 min. Add 1 ml. of aqueous hydroxylamine hydrochloride to each separator and mix the contents by gently shaking the funnels. Allow the funnel contents to stand for 1 min. Add 71 ml. of purified water to each separator and cool the contents to 25° or less. Add 5.00 ml. of isopropyl ether to each separator and shake the funnel with moderate vigor for 1 min. Allow the solution to stand for approximately 5 min. and drain off all but 0.5 ml. of the aqueous phase. Add 2 ml. of the acidic hydroxylamine hydrochloride solution to each separator and shake the funnels for approximately 5 sec. Allow the phases to separate and drain off all but 0.5 ml. of the aqueous phase. Add 2 ml. of 1 *M* hydrochloric acid to each separator and shake for approximately 3 sec. Allow the phases to separate and drain off the aqueous phase. Add 2 ml. of the rhodamine B solution to the separators and shake vigorously for 15 sec. Allow the phases to separate, drain off the lower layer, and pour the ether extract (from the top of the separator) into a cell. If so desired, one may pipet the isopropyl ether solution into the cell with the aid of a 3-ml. pipet.

Measure the absorbance of the solution at 550 mμ with the blank in the reference cell.

Procedure—Weigh to the nearest milligram a 3-Gm. sample of talc into a 100-ml. beaker. Add 25 ml. of 6 *M* hydrochloric acid to the beaker and disperse the sample thoroughly with the aid of a stirring rod. Cover the beaker with a watchglass.

Place the beaker on a steam bath for 0.5 hr. with occasional gentle stirring (approximately every 10 min.).

Add 1 ml. of the sodium sulfite solution to the beaker and stir; filter the contents through white ribbon filter paper and collect the filtrate in a 125-ml. separator. Rinse the beaker and residue in the funnel with 5 ml. of 6 *M* hydrochloric acid, followed by three 5-ml. washings with hot water.

Continue the procedure as indicated under *Preparation of the Standard*, starting with the paragraph, "Cool the solution . . . ."

The absorbance reading of the sample should not exceed that of the standard which represents 2 p.p.m.

RESULTS

Recovery studies were performed in duplicate by two operators at 4 different levels of antimony (1.0, 1.5, 2.0, and 2.5 p.p.m.). Antimony standards (ranging from 3.0 to 7.6 mcg.) were first added to the talc and the recovery was calculated (from a standard curve) after subtracting the antimony found in the talc samples. The accuracy was found to be 91.1%. The results of this study are given in Table I.

TABLE I—RECOVERY OF ANTIMONY FROM SPIKED TALC

Antimony Added, mcg.	Antimony Found,[a] mcg.
3.0	2.7
4.6	4.2
6.0	5.5
7.6	6.9

[a] Average of 8 determinations at each level of antimony.

Analyses for the determination of antimony in two types of talc were performed by two operators in duplicate. The range of antimony found in the talcs was 0.04 to 0.15 p.p.m.

DISCUSSION

Originally, antimony trichloride was used to prepare a standard curve for the recovery study. However, antimony potassium tartrate was substituted for antimony trichloride since the latter compound required a titration for standardization, while the former could be used as a standard by simply weighing the salt. Similar results were obtained with both compounds, indicating either salt could be used as an antimony standard with equal reliability.

Ward (13) indicates that the addition of acidic hydroxylamine hydrochloride to the isopropyl ether solution decreases the concentration of iron (III) by reducing it to iron (II) which isopropyl ether does not extract. He also mentions that 1 and 2 *M* hydrochloric acid fails to extract quantitatively some other elements, including iron (III), which also reacts with rhodamine B. It has been found that a very small percentage of iron (III) is extracted from a 1.5 *M* hydrochloric acid solution (8). Hence, with this system, antimony can be detected satisfactorily in the presence of 30,000 mcg. of iron (III). Since talc contains a significant amount of iron, it was felt that 1.5 *M* hydrochloric acid would be a desirable system to reduce any possible error contributed by the iron or any other interfering elements present in the talc. This choice of acid concentration was further reinforced as higher concentrations of acid were found to be unsuitable because of the apparent loss of isopropyl ether during the extraction process. It was found that shaking 8.0, 6.0, 5.0, 3.0, and 1.5 *M* hydrochloric acid solutions with 5.00 ml. of isopropyl ether gave significantly lower recovery volumes at the 8.0, 6.0, and 5.0 *M* hydrochloric acid concentration. This decrease in volume occurred even though the ether was previously saturated with its respective acid concentration.

Van Aman and co-workers (14) have shown that dilution of concentrated hydrochloric acid before the antimony is extracted into the ether phase results in low absorbance values. The ratio of ether to acid phase (e/a = 2.1) and concentration of antimony employed by Van Aman is considerably higher as compared to that used by the authors (e/a = 0.1). However, it was not feasible to employ their system for our samples. Although lower absorbance values would be obtained with this system, it still represents a highly sensitive one.

In order to substantiate the method of preparing the standard curve for the recovery study, the standards were determined according to the exact procedure employed for the talc samples (heating, filtering). There was no significant change in the least square line as compared to a standard curve prepared without the heating and filtering steps. This indicated that any loss of antimony in the spiked samples probably involves the presence of talc.

An experiment, similar in design to the foregoing procedure, was performed with a final concentration of 3 *M* hydrochloric acid instead of the 1.5 *M* hydrochloric acid as in the preceding method. In this procedure, the concentration of acid was kept constant throughout the method. The major advantage of the modified method is the elimination of adding 71 ml. of water before extraction with the isopropyl ether. This particular step is not desirable because of the possible increase in rate of hydrolysis of antimony (V) to a nonreactive form, antimony (IV). In the original procedure, the volume of aqueous phase was 121 ml. up to the ether extraction step as compared to 65 ml. in the modified method. Thus, the latter procedure should create a more favorable environment for a higher partition coefficient.

A recovery study was performed at the 4 levels of antimony previously mentioned. The recoveries were similar to those obtained in the original method. These results seem to indicate that the partition coefficient is the same for both methods even though the ratio of organic to aqueous phase is different.

Several authors have indicated with their systems that the rhodamine B–antimony complex is fairly stable. However, the stability of the complex in isopropyl ether has been found to vary between authors. Ward and Lakin (13) state that the color is stable up to 6.5 hr., while Van Aman (14) indicates the color fades 1.2% in 1.5 hr. or 30% in 18 hr. However, Maren (8) mentions that the color is not stable, and the absorbance readings must be made within 30 min. of the extraction. We have found that there was a decrease in the absorbance readings of the color complex with time when water was used in the reference cell. A study of absorbance *versus* time for three levels of antimony and a blank was performed at 5-min. intervals for 35 min. The results obtained show that the initial absorbance readings decreased continuously for 20 min. The difference between the initial reading and those taken at 20 min. ranged from 0.017–0.027 absorbance units with 1–4 mcg. of antimony, respectively, and in most cases much less for the blank. However, from 25–35 min. the absorbance readings for the antimony complex remained almost constant (0.004 maximum difference). Subtraction of the blank absorbance reading from the antimony complex absorbance reading at the same respective time yielded a nearly constant absorbance for 35 min. In effect, absorbance readings can be made any time during the first 35 min. after the extraction step for the samples as long as the blank is prepared and read at the same time as the sample.

In conclusion, the methods show that the antimony content found in the talcs tested is considerably lower than the 2 p.p.m. level which may be required by the Food and Drug Administration.

Determination of Meprobamate in Tablets by NMR

By JOHN W. TURCZAN and THEODORE C. KRAM

A rapid NMR procedure was developed for the analysis of meprobamate tablets with malonic acid as internal standard. An average error of 0.9 percent was obtained on seven synthetic mixtures. The NMR spectrum, in addition, provided a very specific means of identification for meprobamate.

THE CURRENT development of more complex drugs and drug mixtures, and the necessity for the analysis of many more samples has led to the need for rapid and simple methods of analysis. We have successfully analyzed many high-dosage-form pharmaceuticals by extracting them with a suitable solvent and obtaining their NMR spectra with the aid of an internal standard. The recorded spectrum from the NMR spectrometer provides an identification of the active ingredient, which contributes to the specificity of the procedure. Meprobamate has been determined by this technique, using acetone as solvent and

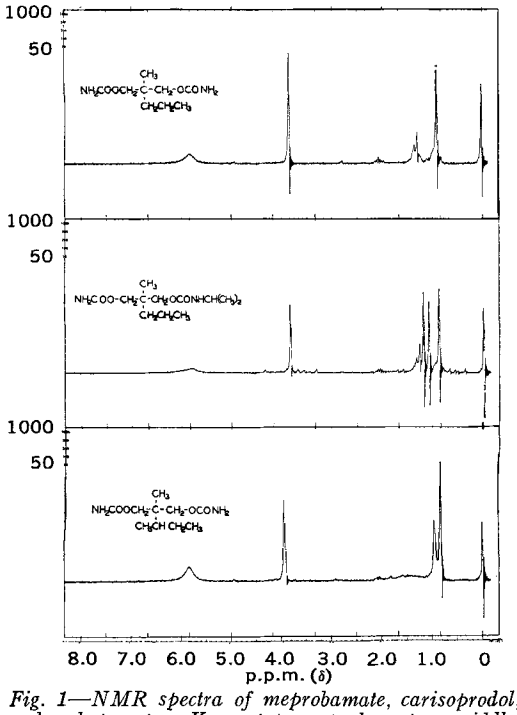

Fig. 1—NMR spectra of meprobamate, carisoprodol, and mebutamate. Key: top, meprobamate; middle, carisoprodol; bottom, mebutamate.

malonic acid as internal standard (Fig. 1). Two drugs closely related in structure and use, carisoprodol[1] and mebutamate, show distinct differences in their spectra from that of meprobamate and also can be analyzed by the same procedure.

Meprobamate is usually determined by the NF XII method (1) which involves an acidic solvolysis followed by a titration with sodium hydroxide in the presence of formaldehyde. This method is more time consuming and less specific than the proposed NMR method. Other published procedures are based on alkaline hydrolysis of the carbamate group followed by steam distillation (2), color reactions (3, 4), and infrared spectroscopy (5, 6). A near infrared method recently developed in this laboratory appears to be promising (7). The chief advantages of the NMR method over these other methods is rapidity and specificity.

PROCEDURE

Weigh and finely powder not less than 20 tablets. Then weigh accurately a portion of the powder, equivalent to about 400 mg. of meprobamate, in a glass-stoppered centrifuge tube and add about 400 mg. of malonic acid. Shake with 5 ml. of acetone for 2 min. and centrifuge. Transfer approximately 0.4 ml. of the clear supernatant to an analytical NMR tube, place in an NMR spectrometer (60 MHz), and obtain the spectrum, adjusting the spin rate so that no spinning sidebands occur between 3.1 and 4.0 p.p.m. The peaks of interest are integrated several times in each direction.

[1] Soma. Wallace Laboratories, Cranbury, N. J.

RESULTS AND DISCUSSION

The 60-MHz spectrum of meprobamate (Fig. 1) shows a peak at 3.8 p.p.m., representing 2 equivalent methylene groups. It was chosen for quantitative analysis and compared with the peak produced by the two methylene protons of malonic acid at 3.3 p.p.m. The clusters appearing at 0.8–1.4 p.p.m. confirm the meprobamate identity. Since acetone's carbon-13 satellite at 3.1 p.p.m. does not interfere with the upfield portion of the meprobamate spectrum, it is unnecessary to use the deuterated solvent for routine work.

The amount of meprobamate per tablet may be calculated as follows:

$$\frac{\text{mg. meprobamate}}{\text{tablet}} = \frac{A_{\text{mep.}}}{A_{\text{mal.}}} \times \frac{EW_{\text{mep.}}}{EW_{\text{mal.}}} \times \text{mg. mal.} \times \frac{\text{wt. 1 tablet}}{\text{wt. sample}}$$

$A_{\text{mep.}}$ = integral value of the singlet at 3.8 p.p.m.
$A_{\text{mal.}}$ = integral value of the singlet at 3.3 p.p.m.
$EW_{\text{mep.}}$ = formula weight of meprobamate/4 = 54.56.
$EW_{\text{mal.}}$ = formula weight of malonic acid/2 = 52.03.

The average deviation obtained for 7 standard preparations was 0.9% (Table I). The proportion of malonic acid to meprobamate appears to have no significant bearing on the accuracy of the determination for the range of proportions shown in the table.

Table I—Determination of Meprobamate in Synthetic Samples by NMR

Synthetic Sample	Malonic Acid Internal Std., mg. Added/ml.	Meprobamate, mg./ml. Added	Found	Deviation, %
1	87.3	99.7	98.0	1.7
2	87.5	98.1	99.9	1.8
3	85.1	100.1	99.0	1.1
4	87.6	100.3	99.7	0.6
5	67.5	73.5	73.3	0.3
6	129.8	74.6	74.4	0.3
7	70.7	91.5	91.7	0.2

Table II—Determination of Meprobamate in Commercial Samples by NMR

Commercial Tablet	Malonic Acid Internal Std., mg. Added/ml.	Declared mg./ Tablet	Found, mg./Tablet NMR	NF XII
1	76.1	400	393	391
2	78.8	400	398	396
3	75.1	400	413	397
4	72.9	400	399	402

Since this method was developed, approximately 30 commercial preparations of meprobamate have been analyzed by NMR. Four of these samples have also been analyzed by the NF XII method as well (1). Results obtained by both methods are shown in Table II.

Tablets have been marketed in which meprobamate was combined with other active ingredients. The following substances have been examined and found to produce no interference in the determination of meprobamate: amphetamine sulfate, hydrochlorothiazide, dexamethasone, pentaerythritol tetranitrate, benactyzine hydrochloride, and aspirin.

Carisoprodol and mebutamate were analyzed by the same procedure. Their NMR spectra are also shown in Fig. 1. Unlike meprobamate, two peaks are produced at 3.8 p.p.m. Further differences may be noted in the area of 0.8 to 1.4 p.p.m. Preliminary work shows the accuracy to be of the same order as for meprobamate.

The speed, accuracy, and specificity of the NMR method make it useful as a rapid procedure that can provide both a quick and conclusive identification and an assay having an accuracy of about 1–2%.

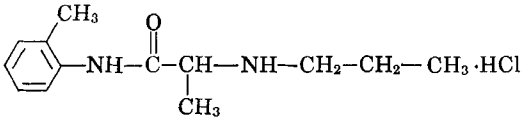
Qualitative and Quantitative Tests for Prilocaine Hydrochloride

By EDWARD F. SALIM* and BERTIL ÖRTENBLAD†

Provisional, unofficial monographs are developed by the Drug Standards Laboratory, in cooperation with the manufacturers of the drug concerned, for publication in the *Journal of Pharmaceutical Sciences*. The ready availability of this information affords discriminating medical and pharmaceutical practitioners with an added basis for confidence in the quality of new drug products generally, and of those covered by the monographs particularly. Such monographs will appear on drugs representing new chemical entities for which suitable identity tests and assay procedures are not available in the published literature. The purity and assay limits reported for the drugs and their dosage forms are based on observations made on samples representative of commercial production and are considered to be reasonable within expected analytical and manufacturing variation.

2-(PROPYLAMINO) - *o* - PROPIONOTOLUIDIDE HYDROCHLORIDE; $C_{13}H_{20}N_2O \cdot HCl$; mol. wt. 256.78. The structural formula of prilocaine hydrochloride may be represented as:



Physical Properties—Prilocaine hydrochloride occurs as a white, odorless crystalline powder with a bitter taste, m.p. 166–169° (USP class I). It is freely soluble in water and in alcohol, slightly soluble in chloroform, very slightly soluble in acetone, and practically insoluble in ether.

Identity Tests—The infrared spectrum of a 0.5% dispersion of prilocaine hydrochloride in potassium bromide, in a disk of about 0.82 mm. thickness, is shown in Fig. 1.

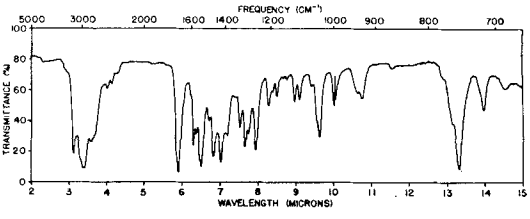


Fig. 1—Infrared spectrum of prilocaine hydrochloride in potassium bromide disk (0.5%); Perkin-Elmer model 21 spectrophotometer, sodium chloride prism.

Dissolve about 100 mg. of prilocaine hydrochloride in about 3 ml. of water, add ammonia T.S. until basic, and filter. Acidify the filtrate with diluted nitric acid, and add 1 ml. of silver nitrate T.S.: a white precipitate forms, which is insoluble in diluted nitric acid, but soluble in ammonia T.S. (presence of chloride).

Transfer about 300 mg. of prilocaine hydrochloride to a separator and dissolve in 5 ml. of water. Add 4 ml. of ammonia T.S. and extract with four 15-ml. portions of chloroform, filtering the extracts through paper. Evaporate the combined

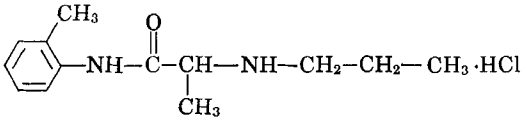
Such monographs will appear on drugs representing new chemical entities for which suitable identity tests and assay procedures are not available in the published literature. The purity and assay limits reported for the drugs and their dosage forms are based on observations made on samples representative of commercial production and are considered to be reasonable within expected analytical and manufacturing variation.

2-(PROPYLAMINO) - *o* - PROPIONOTOLUIDIDE HYDROCHLORIDE; $C_{13}H_{20}N_2O \cdot HCl$; mol. wt. 256.78. The structural formula of prilocaine hydrochloride may be represented as:



Physical Properties—Prilocaine hydrochloride occurs as a white, odorless crystalline powder with a bitter taste, m.p. 166–169° (USP class I). It is freely soluble in water and in alcohol, slightly soluble in chloroform, very slightly soluble in acetone, and practically insoluble in ether.

Identity Tests—The infrared spectrum of a 0.5% dispersion of prilocaine hydrochloride in potassium bromide, in a disk of about 0.82 mm. thickness, is shown in Fig. 1.

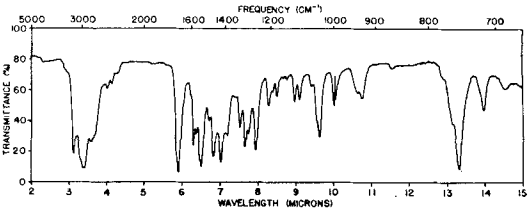


Fig. 1—Infrared spectrum of prilocaine hydrochloride in potassium bromide disk (0.5%); Perkin-Elmer model 21 spectrophotometer, sodium chloride prism.

Dissolve about 100 mg. of prilocaine hydrochloride in about 3 ml. of water, add ammonia T.S. until basic, and filter. Acidify the filtrate with diluted nitric acid, and add 1 ml. of silver nitrate T.S.: a white precipitate forms, which is insoluble in diluted nitric acid, but soluble in ammonia T.S. (presence of chloride).

Transfer about 300 mg. of prilocaine hydrochloride to a separator and dissolve in 5 ml. of water. Add 4 ml. of ammonia T.S. and extract with four 15-ml. portions of chloroform, filtering the extracts through paper. Evaporate the combined

extracts on a steam bath with the aid of a current of air: the oily residue responds to the following tests.

Dissolve about 100 mg. of the free base in 1 ml. of alcohol, add 10 drops of cobaltous chloride T.S., and shake for 2 min.: a bright green color develops, and a fine precipitate is formed.

Dissolve about 100 mg. in a mixture of 5 ml. of water and 1 ml. of diluted nitric acid, warming if necessary to effect solution. Add 3 ml. of mercuric nitrate T. S., and heat nearly to boiling: the solution turns yellow or yellow-green.

Purity Tests—Dry about 1 Gm. of prilocaine hydrochloride, accurately weighed, at 105° for 4 hr.: it loses not more than 0.3% of its weight.

Char about 1 Gm. of prilocaine hydrochloride, accurately weighed, cool the residue, add 1 ml. of sulfuric acid, heat cautiously until evolution of sulfur trioxide ceases, ignite, cool, and weigh: the residue does not exceed 0.1%.

Dissolve about 200 mg. of prilocaine hydrochloride in 10 ml. of water, add 2 ml. of diluted hydrochloric acid, and 1 ml. of barium chloride T.S.: no turbidity is produced (absence of sulfate).

Dissolve about 200 mg. of prilocaine hydrochloride in 20 ml. of water, add 2 ml. of diluted hydrochloric acid and saturate the solution with hydrogen sulfide: no color or precipitate results (absence of heavy metals).

Assay—*Chloride*—Transfer about 200 mg. of prilocaine hydrochloride accurately weighed, to a 125-ml. conical flask, and dissolve in 10 ml. of water. Add 10 drops of potassium chromate T.S. and titrate with 0.1 *N* silver nitrate to a red-brown end point. Each milliliter of 0.1 *N* silver nitrate is equivalent to 3.546 mg. of chloride (Cl). The chloride content is not less than 13.4% and not more than 14.2%.

Prilocaine Hydrochloride—Transfer about 500 mg. of prilocaine hydrochloride, accurately weighed, to a tall-form 200-ml. beaker, and dissolve in 50 ml. of glacial acetic acid. Add 10 ml. of mercuric acetate T.S. and 2 drops of crystal violet T.S., and titrate with 0.1 *N* acetous perchloric acid to a blue-green end point. Perform a blank determination, and make any necessary correction. Each milliliter of 0.1 *N* perchloric acid is equivalent to 25.68 mg. of $C_{13}H_{20}N_2O \cdot HCl$. The amount of prilocaine hydrochloride found is not less than 99.0% and not more than 101.0%.

DOSAGE FORMS OF PRILOCAINE HYDROCHLORIDE

Prilocaine Hydrochloride Injection

Physical Properties—Prilocaine hydrochloride injection is a sterile aqueous solution with methylparaben present as a preservative. The pH of the solution is adjusted between 6.0 and 7.0 with sodium hydroxide.

Identity Tests—Transfer to a separator a volume of injection equivalent to about 300 mg. of prilocaine hydrochloride, and proceed as directed under the bulk drug beginning with "Add 4 ml. of ammonia T.S . . . ."

Assay—Transfer to a separator an accurately measured volume of prilocaine hydrochloride injection equivalent to about 200 mg. of prilocaine hydrochloride. Add 2 ml. of sodium hydroxide T.S. and extract with four 25-ml. portions of chloroform, filtering each portion through chloroform moistened paper into a titrating beaker. Concentrate the filtrate to about 10 ml. on a steam bath with the aid of a current of air, add 40 ml. of glacial acetic acid, 2 drops of crystal violet T.S., and titrate with 0.1 *N* acetous perchloric acid to a blue-green end point. Perform a blank determination, and make any necessary correction. Each milliliter of 0.1 *N* perchloric acid is equivalent to 25.68 mg. of $C_{13}H_{20}N_2O \cdot HCl$. The amount of prilocaine hydrochloride found is not less than 95.0% and not more than 105.0% of the labeled amount.

DISCUSSION

USP and NF terminology for solubility, melting range, reagents, *etc.*, has been used wherever feasible.

Prilocaine hydrochloride,[1] synthesized by Lofgren and Tegner (1), is a local anesthetic agent whose potency is comparable to lidocaine but whose toxicity is significantly reduced (2, 3). It is intended for use in infiltration and regional anesthesia, therapeutic nerve blocks such as intercostal and paravertebral blocks, and blockades of major nerve trunks *via* the peridural and caudal routes. Prilocaine hydrochloride is administered by injection and is available in 1, 2, 3, and 4% solutions. Prilocaine hydrochloride was formerly known by the generic name propitocaine hydrochloride.

Identity Tests—The reaction of prilocaine and mercuric nitrate to produce a yellow or yellow-green color differentiates the compound from anesthetics derived from *p*-aminobenzoic acid which turn red or orange. The free base isolated by chloroform extraction from alkaline solution can be reacted with methanesulfonic acid in anhydrous ether for identification. The methanesulfonate (mesylate) salt so obtained recrystallized from dehydrated alcohol–isopropyl ether (1,3) melts between 168–171°.

Quantitative Tests—Determination of chloride content by the Mohr method gave an average value of 13.8 ± 0.1%.[2] The theoretical value for the chloride content is 13.81%. The halide salt can be determined by many conventional methods of analysis for ionizable chloride.

Nonaqueous titration of prilocaine hydrochloride with perchloric acid gave an average value of 100.2 ± 0.3%.[2] The isolation of prilocaine base from the 1% injection and subsequent titration gave an average value of 100.4 ± 0.5%[2] of the labeled amount of prilocaine hydrochloride. Analyses of the 2, 3, and 4% injections yielded recoveries corresponding to 99–100% of label declaration.

Titration Assembly and Experimental Procedure for Accurate pH Stat Measurements of Substrate Hydrolysis Rates in Blood Plasma

By CLIFFORD W. CHONG, LEWIS W. DITTERT*, HARRY B. KOSTENBAUDER†, and JOSEPH V. SWINTOSKY‡

A study was undertaken to establish an experimental procedure whereby accurate rates of enzyme-catalyzed substrate hydrolysis could be measured with a pH stat when solutions of blood plasma are used as the enzyme source. pH stat procedures which neglect the effects of plasma deterioration and loss of CO_2 from plasma solutions yield apparent hydrolysis rates which are faster and slower, respectively, than the true rates. To overcome the problems of anomalous substrate hydrolysis rates and apparent nonstoichiometric titrations, the plasma solutions were prepared aseptically and the titration assembly from a Radiometer pH stat was modified to effect a virtually closed system. Hydrolysis rate data are presented for acetylcholine, benzoylcholine, and phenyl butyrate in 0.5 percent solutions of human blood plasma to demonstrate the utility of the proposed experimental procedure and the modified pH stat titration assembly.

SOLUTIONS of whole human blood plasma are useful and convenient media for studying the *in vitro* enzymic cleavage of a number of drugs (1–7). However, they are seldom used in kinetic studies which utilize the pH stat for the determination of hydrolysis rates. This is apparently due to the labile nature of blood plasma (8). When exposed to air, solutions of blood plasma are prone to deterioration and loss of CO_2. Plasma deterioration results in a spontaneous increase in acidity, whereas loss of CO_2 decreases acidity. Thus, either effect may cause sizable errors in studies where hydrolytic processes occurring in blood plasma solutions are followed potentiometrically. This report describes a pH stat titration assembly and an experimental procedure useful for circumventing these errors.

Most studies which utilize blood plasma solutions as the enzyme media employ spectrophotometric (3, 4, 6, 7, 9, 10) or manometric (11–13) means of following the kinetics of substrate hydrolysis. Although capable of considerable precision, both methods have limitations. The spectrophotometric method is applicable only (*a*) to substrates with convenient absorption spectra which are distinguishable from those of their respective products; (*b*) to reaction mixtures devoid of extraneous substances which interfere with the assay of the substrates or products; and (*c*) to relatively low concentrations of substrate and enzyme. The manometric method, in addition to being laborious and time consuming, requires precise control of the CO_2 content of the reaction mixture. Both methods require the use of added buffers and, because of this, the enzymic reactions occur in an environment which differs from the physiological state of blood plasma.

Continuous potentiometric titration at constant pH without the use of additional buffers provides a convenient method for following enzymic hydrolysis reactions, especially of substrates with indistinguishable ultraviolet or visible absorption spectra. With the recent development of commercial automatic pH stats, this method has become increasingly useful (14–16, 18). Several factors which may influence pH stat results have been mentioned, but these are of little significance when the more recently developed techniques and apparatus are employed (17–21). The main objection to the method has concerned dilution of the reaction mixture by the titrant, but this effect can be overcome by keeping the volume of titrant small with respect to the volume of the reaction mixture or by correcting the kinetic data mathematically (22). When solutions containing blood plasma are used as the enzyme media, two additional effects must be considered. These are (*a*) the spontaneous production of an acid due to deterioration of the plasma, and (*b*) the loss of CO_2 from the plasma solution. Both effects, to our knowledge, are often either overlooked or inadequately considered in studies

which utilize the pH stat to follow hydrolytic processes occurring in blood plasma solutions.

It has been observed in these laboratories that nonsterile solutions of blood plasma slowly decrease in pH on standing in a closed vessel where the CO_2 content of the solutions is kept constant. This effect is presumably due to bacterial deterioration of some ingredient of plasma, the result of which is a spontaneous production of an acid. Although the identification of the acid as well as its source have not been an objective of this study, the possible effect of the acid on pH stat results is of paramount importance. The pH stat plots the course of a hydrolysis reaction as a function of time by automatically titrating with a standard base solution the hydrogen ions produced as the reaction proceeds at a constant pH. Therefore, the acid produced as a result of plasma deterioration will obviously contribute to the rate as well as to the extent of the hydrolysis reaction. It was found that the acid may be produced in such large amounts that it could completely mask the hydrolytic process of substrates which hydrolyze at relatively slow rates. It is apparent, therefore, that, in order to obtain reliable data with the pH stat, adequate steps should be taken to minimize bacterial contamination during all phases of handling of the blood plasma.

The presence of large amounts of CO_2 in solutions of blood plasma presents another problem in pH stat determinations of hydrolysis rates. If the reaction is carried out in an open vessel, CO_2 will rapidly diffuse from the plasma solution to the atmosphere. The loss of CO_2 results in an increase in the basicity of the system which subsequently contributes to the titration of the hydrogen ions produced by the hydrolysis reaction. The conventional use of a nitrogen flush, while useful in systems completely free of CO_2 and bicarbonates (19), accelerates the loss of CO_2 by expelling it out of solution at a faster rate. Thus, to maintain constant CO_2 content of blood plasma solutions, the hydrolysis reactions should be carried out in a closed system.

In preliminary work with the pH stat using a 0.5% solution of blood plasma as the reaction medium, several attempts were made to completely purge the solution of CO_2. This was done by bubbling nitrogen gas through the plasma solution. In every instance, the pH of the solution first rose quite rapidly to about 9.5 where it remained constant. Since there was no further rise in pH, it was assumed that no more CO_2 could be removed from the solution. However, upon returning the pH of the solution to 7.4 and then continuing with the nitrogen flush, the pH once more rose to about 9.5, this time at a slower rate than previously. The same procedure was repeated several times with similar results, except that it took longer for the pH to reach 9.5 with each succeeding trial. While it may have been possible to remove all of the CO_2 from the solution, the procedure would be considerably difficult and time consuming. In addition, the rise in pH and change in plasma composition resulting from such treatment could affect the activity of the enzymes in blood plasma.

On the basis of the foregoing discussions, it seems obvious that adequate control over plasma deterioration and loss of CO_2 must be exercised to obtain accurate hydrolysis rate data with the pH stat. The manner in which this is achieved, that is, the use of an aseptic procedure for preparing the blood plasma solutions and the design of a virtually closed titration assembly, is described in this report.

EXPERIMENTAL

Materials—One-half percent solutions of whole human blood plasma[1] were prepared by an aseptic procedure using sterile, pyrogen-free, isotonic saline solution (0.15 *M* NaCl)[2] as the dilution medium. Alcoholic stock solutions of acetylcholine iodide,[3] benzoylcholine chloride,[3] and phenyl butyrate[3] in a concentration of 0.04 *M* were used as substrates. The standard base titrant was 0.02 *M* NaOH which was prepared free of CO_2 in the usual manner.

Apparatus—A Radiometer pH stat[4] was used. It consisted of a type TTT1 automatic titrator, SBR2c recorder, SBU1 syringe buret, and TTA3 titration assembly which was modified to effect a virtually closed system. The modified titration assembly is shown in Fig. 1.

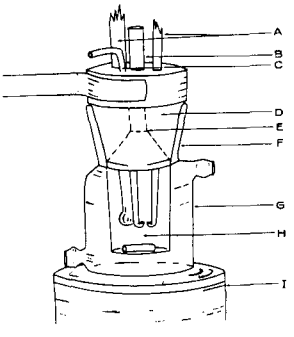

Fig. 1—Diagram of modified pH stat titration assembly described in the text.

The reaction vessel (H) is equipped with a water jacket (G) and a ground-glass joint (F) which pro-

[4] Radiometer, Copenhagen, Denmark.

vides an air-tight fit on the tapered Teflon plug (D). The Teflon plug holds the electrodes (A), the titrant delivery tube (C), and an inlet tube (B) 6 mm. in diameter and concentrically located on the plug. The bottom of the plug is tapered inward to form an inverted cone which peaks at the bottom of the inlet tube. The vessel is so made that when 20 ml. of plasma solution is used and the vessel is placed in position on the plug, the level of the solution just covers the bottom end of the inlet tube. A drop of light liquid petrolatum is then placed in the inlet tube to form a thin layer of oil on the surface of the plasma solution (E). By confining the oil layer only to the small opening of the inlet tube, the tendency is minimized for any oil-soluble component of the reaction mixture to partition into the oil. The inlet tube also serves as a means of introducing the enzyme, substrate, and other additives into the system by the use of a hypodermic syringe and needle. Stirring of the reaction mixture is done by means of magnetic stirrer (I) located beneath the vessel.

Preparation of the Blood Plasma Solutions—Blood plasma is usually supplied frozen in 120- to 150-ml. quantities. When defrosted and exposed to air, it deteriorates quite readily. Since plasma deterioration is apparently due to bacterial contamination, it is expected that antibacterial agents such as a streptomycin and sulfathiazole might be used to alleviate this condition (23). However, it was felt that the addition of such agents might further complicate the system, for example, by reducing the enzyme activity or by interfering with the potentiometric titration, and that the use of an aseptic procedure for preparing the plasma solutions might be more practical.

The procedure is as follows. The plasma is first defrosted, mixed well, and then transferred in a sterile room to serum flint vials in 1–2-ml. portions. The vials are sealed with rubber closures and placed in a freezer at −18°. Dividing the plasma into small portions eliminates the need to defrost and refreeze the bulk plasma every time a sample is removed and, thus, reduces the chances for the plasma to deteriorate. At the time of use, a vial of plasma is removed from the freezer and allowed to thaw at 37°. One milliliter of the plasma is transferred under sterile conditions to a 100-ml. volumetric flask and brought up to volume with sterile, pyrogen-free, isotonic saline solution to make a 0.5% solution of blood plasma. This solution is stable up to 24 hr. with respect to its enzyme activity and relative freedom from deterioration by bacteria.

Cleaning of the Titration Assembly—Immediately prior to the start of a run, the reaction vessel, as well as all parts of the titration assembly which normally come in contact with the plasma solution, are cleaned first by washing with a 70% solution of ethanol, and then thoroughly rinsing with the sterile saline solution. They are then wiped dry with a sterile cotton gauze.

Procedure for a Typical Kinetic Run—Twenty milliliters of the 0.5% blood plasma solution is transferred to the reaction vessel by means of a sterile pipet and the vessel is placed in position on the pH stat. A drop of light liquid petrolatum is placed on the surface of the solution through the inlet tube. The speed of the magnetic stirrer is adjusted so that stirring is just sufficient to cause rapid flow of the solution past the electrodes without creating cavitation and foaming. Constant-temperature water (37 ± 0.2°) is circulated through the jacket of the reaction vessel.

The plasma solution is first adjusted to pH 7.4 with the pH stat. The pH stat is set so that, as the pH of the solution approaches 7.4, the titrant is added at a rate essentially the same as that required by the reaction. This procedure quickly titrates the free acids present, prevents the possibility of the automatic titration falling behind the reaction, and eliminates large "step-effects" due to the addition of excess titrant. The pH stat is left to run until no titrant is consumed for at least 15 min. with the pH remaining constant at 7.4. When this occurs, the system is said to have achieved pH equilibrium. The recording pen is returned to zero and the syringe buret is refilled with titrant.

The kinetic run commences when 0.1 ml. of stock substrate solution is added to the plasma solution. The pH stat is adjusted once more to compensate for any change in reaction rate, and the reaction is allowed to proceed either to completion or until sufficient data are obtained.

Several investigations were made using 0.5% solutions of blood plasma with and without substrates to determine the effects of (*a*) plasma deterioration, (*b*) the loss of CO_2 from the reaction mixture, and (*c*) a virtually sterile and closed reaction system in which the effects of both plasma deterioration and loss of CO_2 are minimized.

The magnitude of the effect of plasma deterioration was determined by the use of two solutions of blood plasma: one which was freshly prepared and the other which was left exposed to air at room temperature for 2 hr. No precautions were taken to maintain the sterility of these solutions. To eliminate the effects due to the loss of CO_2 from the reaction mixture, the reactions were carried out in the modified titration assembly.

The effect due to the loss of CO_2 from the reaction mixture was determined by the use of a sterile solution of blood plasma in the titration assembly supplied with the instrument. This assembly, not being a closed system, allows CO_2 to escape freely from the reaction vessel. A 0.02 *N* HCl titrant was used to follow the rate of base production. After a specified time, a nitrogen flush similar to the one described by Applewhite (20) was introduced to show the in-

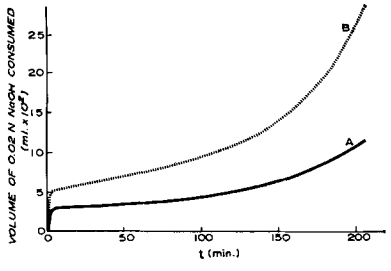

Fig. 2—Plots showing the effect of blood plasma deterioration. The increased rate of base consumed reflects the rate at which acid is spontaneously produced when plasma degrades. Curve A *was obtained using a freshly prepared plasma solution. For curve* B, *a plasma solution which had been aged for 2 hr. at room temperature was used. (Plasma concentration, 0.5%.)*

creased rate of base production due to a faster loss of CO_2.

Finally, the utility of the proposed experimental procedure and the modified pH stat titration assembly was demonstrated. Solutions of 0.5% blood plasma, prepared in the manner described, were used as the enzyme media with acetylcholine, benzoylcholine, and phenyl butyrate as substrates. To check the accuracy of the results obtained with the pH stat, parallel runs were made with the latter two substrates on a Cary model 15 spectrophotometer according to the method of Kalow *et al.* (9).

All experiments were conducted at pH 7.4 and 37°. For purposes of comparison, the hydrolysis rates for benzoylcholine and phenyl butyrate were determined from apparent zero-order rate plots of the initial stages of the hydrolytic processes.

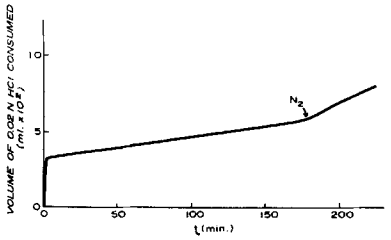

Fig. 3—Plot showing the effect of CO_2 loss. The rate of base production appears linear in the time range studied. At the point N_2 a nitrogen flush was introduced into the system. The increased rate of base production is due to the faster rate at which CO_2 is expelled from solution. (Plasma concentration, 0.5%.)

RESULTS AND DISCUSSION

The effect of the acid produced as the result of plasma deterioration is shown by curves A and B in Fig. 2.

Curve A was obtained from the freshly prepared, but nonsterile solution of blood plasma. During the early stages of the run, the rate of acid production appears linear and the amount of acid produced is relatively insignificant. However, as the run progresses, the acid is produced at an increasing rate. The system behaves as if the acid exerts a catalytic effect which accelerates the production of more acid.

Curve B was obtained using a similar solution of blood plasma except that it was left to stand in an open vessel at room temperature for 2 hr. The higher initial uptake of the base titrant indicates that more free acids were present in this solution at the beginning of the run than in the fresh solution of plasma. The plasma had obviously undergone some deterioration during the 2-hr. period to produce the additional acid. Apparently, due to autocatalytic effects, the rate of acid production is noticeably faster at corresponding time periods than in the previous run with the fresh plasma solution.

During the initial stages, the rate of uptake of the base titrant is 2.0 μm./L./min. and 6.5 μm./L./min. for curves A and B, respectively. After 2 hr., the rates increase markedly to 9.6 μm./L./min. for curve A and 18.8 μm./L./min. for curve B. Thus, it is highly probable that the effect due to plasma deterioration might largely influence or even mask hydrolytic processes especially of substrates which hydrolyze slowly.

Figure 3 shows the effect due to the loss of CO_2 from the reaction mixture. The rate of CO_2 loss is 2.8 μm./L./min. and it is linear in the range studied. It is slightly greater than the initial rate of plasma deterioration for the freshly prepared plasma solution, but less than that for the plasma solution which was aged for 2 hr. At the point N_2 on the curve, a nitrogen flush was introduced into the system. This resulted in a more rapid loss of CO_2 as indicated by the higher rate of uptake of the acid titrant.

The consequences of plasma deterioration and loss of CO_2 are opposite in effect. Usually, the rate of CO_2 loss exceeds the rate of plasma deterioration during the early stages of a run. However, as the run progresses, the rate of plasma deterioration accelerates markedly, presumably by autocatalysis,

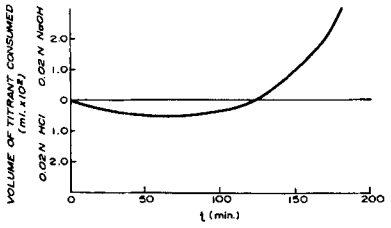

Fig. 4—Data showing the simultaneous effects of plasma deterioration and CO_2 loss with time. Up to about 2 hr., the effect of CO_2 loss predominates, after which time the effect of plasma deterioration becomes more pronounced. (Plasma concentration, 0.5%.)

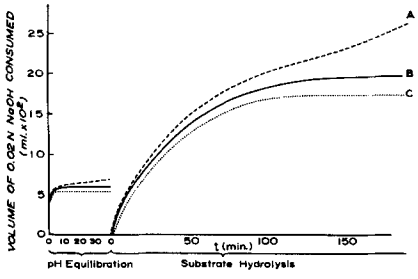

Fig. 5—Plots showing the effects of plasma deterioration and CO_2 loss on the enzymic hydrolysis rate of acetylcholine. Curve A shows the effect of plasma deterioration, curve C the effect of CO_2 loss, and curve B the true hydrolysis rate of the substrate. Curve B was obtained by use of the experimental procedure described in the text. (Plasma concentration, 0.5%.)

and becomes far greater than the rate of CO_2 loss. To demonstrate these effects, which are shown in Fig. 4, two separate pH stat units were used with a common titration assembly. One unit contained a 0.02 *N* NaOH titrant which followed the rate of plasma deterioration while the other unit, with a 0.02 *N* HCl titrant, followed the rate of CO_2 loss.

The data represent the difference between the amounts of base and acid titrants consumed during the run. It can be seen that up to about 2 hr., the rate of CO_2 loss predominates. Beyond this time, the rate of plasma deterioration becomes increasingly faster and gradually exceeds the rate of CO_2 loss. Thus, the effect on the over-all hydrolysis rate of a substrate which cleaves slowly would probably be

TABLE I—INITIAL HYDROLYSIS RATES OF ACETYLCHOLINE, BENZOYLCHOLINE, AND PHENYL BUTYRATE IN 0.5% HUMAN BLOOD PLASMA DETERMINED AT DIFFERENT EXPERIMENTAL CONDITIONS

first a slowing down of the rate up to the 2-hr. period, followed by an acceleration of the rate. The hydrolysis reaction then appears to proceed beyond the stoichiometric level because the acid from plasma deterioration continues to be titrated.

Jensen-Holm (16), who was perhaps the first to note that a nonspecific acid production takes place in most tissue homogenates and blood solutions, reported that: "By keeping the system anaerobic (bubbling nitrogen through it for 20 minutes and then maintaining an atmosphere of nitrogen in a half-closed system) the spontaneous, unspecific acid liberation can be not only greatly reduced, but also often converted into a fairly constant base production." It seems apparent that by bubbling nitrogen through the system, he was driving off CO_2 (resulting in an increased basicity of the system) at a rate which was nearly the same or which exceeded the rate of acid production.

Figure 5 shows the effects of plasma deterioration and CO_2 loss on the hydrolysis rate of acetylcholine in a 0.5% solution of blood plasma. The figure also shows data which attest to the utility of the proposed experimental procedure and the modified pH stat titration assembly for minimizing these effects.

The effect due to plasma deterioration is shown by curve A. It can be seen that a pH equilibration could not be attained due to the slow but continuous titration of the acid produced. Upon the addition of acetylcholine, the hydrolysis reaction proceeds at a rate faster than normal because the acid resulting from the deterioration of plasma is titrated in addition to the acid produced by the hydrolytic process. Curve A also shows that the consumption of base titrant continues far beyond the stoichiometric amount equivalent to complete hydrolysis of the substrate. The excessive uptake of titrant is obviously due to the acid produced as the result of plasma deterioration.

Curve C shows the effect due to the loss of CO_2 from the reaction mixture. Although a pH equilibration seemed to have been attained prior to the addition of acetylcholine, the pH of the plasma solution was actually above 7.4 due to the loss of some CO_2 from the plasma solution. Since the pH stat does not begin to record the amount of titrant delivered until the pH of the solution is returned to 7.4, there is a slight lag between the time the substrate is added and the start of the titration. The hydrolysis reaction then proceeds at a rate slower than normal, and reaches a level below that for complete hydrolysis of the substrate. Obviously, the base formed as the result of CO_2 loss also serves to titrate the acid produced by the hydrolysis reaction. Thus, less of the base titrant is needed for the over-all reaction.

The data obtained using the proposed experimental procedure and the modified pH stat titration assembly are shown by curve B. The pH equilibration of the plasma solution is attained readily and remains stable until the substrate is added. The pH stat, which is now unaffected by errors due to plasma deterioration and loss of CO_2, plots the true course of the hydrolytic process and reaches an equilibrium when the amount of base titrant consumed is nearly the same as that theoretically required by the hydrolysis reaction.

The enzymic hydrolysis rates for benzoylcholine and phenyl butyrate, determined both by the potentiometric titration method (pH stat) and the spectrophotometric method (Cary model 15), are shown in Table I. The pH stat data for acetylcholine are also presented for the purpose of comparison. The "initial" rates were determined from the slopes of the essentially linear portions of the titrator plots in the initial 10-min. periods.

The results obtained by the use of the closed pH stat titration vessel and sterile plasma solutions correlate well with the spectrophotometric results. The results, which were influenced by the effects of plasma deterioration and the loss of CO_2, were higher and lower, respectively, than the results obtained spectrophotometrically. It will be noted that the percent deviation from normal becomes smaller the faster the hydrolysis reaction. For example, in the case of benzoylcholine which hydrolyzes 1.14 and 2.22 times faster than phenyl butyrate and acetylcholine, respectively, the deviation due to plasma deterioration is 2.5% and that due to the loss of CO_2 is 8.5%. On the other hand, in the case of acetylcholine, the slowest hydrolyzing substrate of the three, the deviation is 7.5% for plasma deterioration and 11.3% for CO_2 loss. Thus, while the effects of plasma deterioration and CO_2 loss may not be highly significant in studies of rapidly hydrolyzing substrates, they may have considerable influences on the hydrolysis of substrates which cleave at relatively slow rates.

SUMMARY

The effects of plasma deterioration and CO_2 loss may be significant in studies which utilize the pH stat for the determination of enzymic hydrolysis rates occurring in solutions of blood plasma. To minimize these effects, the plasma must be kept virtually free of bacterial contamination and the

reactions should be carried out in a closed system. A method for the aseptic preparation of blood plasma solutions and the utility of a closed pH stat titration assembly are described. Data are presented to show the utility of the experimental procedure for following the hydrolysis of substrates such as acetylcholine, benzoylcholine, and phenyl butyrate in solutions of blood plasma.

Radiation and the Detoxication of Chemicals

By THOMAS J. HALEY* and L. KOSTE

The detoxication of benzoate and resorcinol has been investigated in irradiated animals. In both instances detoxication was inhibited from the third to the seventh post-irradiation days. The common denominator for this action of X-irradiation appears to be co-enzyme A and/or its substrates.

EXPOSURE to X-irradiation is known to increase protein catabolism (1) and increase the free and dynamic glycine pools in the animal (2–4) but Schreier *et al.* (5) found no change in hippurate excretion during the first 3 days post-irradiation. However, Gerber and Remy-Defraigne (6) found that the irradiated liver synthesized more hippurate when exogenous glycine was excluded from the perfusion fluid than when it was present. Chiriboga (7) reported that whole body irradiation caused a decreased glucuronide excretion and suggested that further investigation was necessary to elucidate its role in the radiation syndrome. Inasmuch as both hippurate and glucuronide synthesis involve co-enzyme A and through it the detoxication of benzoate and phenolic compounds, we have investigated the detoxication of benzoate and resorcinol in irradiated rats.

METHODS AND MATERIALS

Hippurate excretion was determined in 18 Charles River CD strain female rats weighing 250 to 300 Gm. and glucuronide excretion was obtained with 6 similar rats. Total 24-hr. urine volumes based upon 137 collections was 22.1 ± 10.5 ml. with a range of 6.5 to 55.8 ml. Urinary output depended upon water consumption which also had the same degree of variation. Normal excretion values for both hippurate and glucuronide were obtained in nine separate experiments and control values after administration of either 100 mg./Kg. of sodium benzoate or 50 mg./Kg. of resorcinol intraperitoneally in three separate experiments after which the animals received 600 rads acute whole body X-irradiation. In all cases urine was collected over a 7-day period by the method of Haley *et al.* (8). Urinary hippurate was determined with an Aminco-Bowman spectrophotofluorometer using the method of Ellman *et al.* (9) and glucuronide was determined by the method of Mead *et al.* (10). Quadruplicated samples of each urine specimen were analyzed. The results were analyzed statistically by the Student *t* test for significance. The radiation characteristics of the industrial unit were: 250 KVP; 15 ma.; FOD 55 cm.; filters 0.21 mm. Cu inherent; 0.5 mm. Cu parabolic and 1 mm. Al; HVL 1.95 mm. Cu; dose rate measured in air, 24.97 rads/min. The machine was calibrated prior to and after each experiment with a Victoreen thimble *r*-meter and during exposure with a Radacon unit.

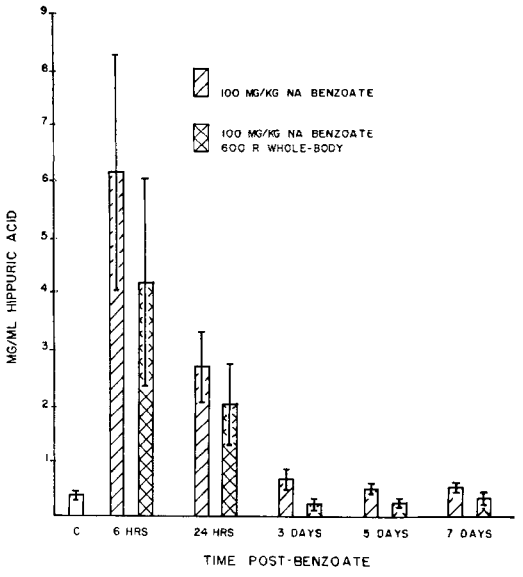

Fig. 1—Hippurate excretion in nonirradiated and irradiated rats. Note nonsignificant decrease in hippurate excretion during the first 24 hr. and significant decrease (P = 0.001) at the third through the seventh days post-irradiation.

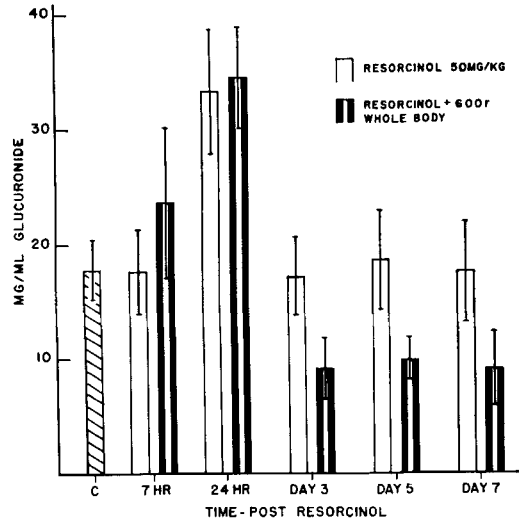

Fig. 2—Effect of 600 rads whole body X-irradiation on glucuronide excretion following 50 mg./Kg. of resorcinol. Compared to the normal excretion all irradiated values from the third to seventh days are significant at P = 0.001. The increased excretion at 24 hr. is significant at P = 0.01.

RESULTS AND DISCUSSION

The results obtained are illustrated in Figs. 1 and 2. In confirmation of Schreier *et al.* (5), it was found that hippuric acid was a normally occurring metabolite in rat urine, but contrary to their report it was observed that X-irradiation did affect hippurate excretion on the third day post-irradiation. Furthermore, there was no significant difference in hippurate excretion between nonirradiated rats until that time. From the third to the seventh post-irradiation days inclusive, the irradiated group's hippurate excretion was significantly depressed ($P = 0.001$), although both groups were again approaching the normal hippurate excretion level by the seventh day.

In confirmation of Chiriboga (7), it was observed that urinary glucuronide excretion was significantly depressed ($P = 0.001$) from the third through the seventh post-irradiation days and had not as yet begun to approach the normal level. Of interest is the observation that both hippurate and glucuronide excretion were unaffected until the third post-irradiation day, indicating that the detoxication pathways for both benzoate and resorcinol seem to be functional in the early post-irradiation period. Perhaps the failure occurring on the third day is related to the intestinal malabsorption of glucose and B-complex vitamins previously reported (11–14) or to exhaustion of the enzyme system(s) involved in the detoxication processes, or both. A clue to one aspect of the problem was the report of Hanel and Wilian-Ulrich (15) that acetylation of sulfanilamide was also depressed on the third day. In every instance the common mechanism of detoxication involved co-enzyme A. Moreover, decreased fatty acid synthesis on the third day also involves this co-enzyme (15). Perhaps other metabolic pathways are activated by irradiation, thus gradually decreasing the co-enzyme's activity or the availability of the substrate required for active detoxication. On the other hand, it is possible that ionizing radiation or the products it produces in cell cytoplasm through free radical formation may have a direct effect on co-enzyme A and/or its substrate. Both are distinct possibilities because ionizing radiation affects sulfhydryl groups and one of the function entities in co-enzyme A is a sulfhydryl group. All of these points remain to be elucidated, if we are to understand why radiation depresses detoxication mechanisms.

Metabolism of 2-Methyl-2-(4-acetaminophenoxy)propane

By A. KLUTCH* and M. BORDUN†

The metabolism of the *tert*-butyl analog of acetophenetidin (phenacetin USP XVII) has been investigated. A metabolite which is hydroxylated in the alkyl side chain was isolated.

THE MAJOR metabolic pathway of acetophenetidin (phenacetin USP XVII) involves *O*-dealkylation to *N*-acetyl-*p*-aminophenol (acetaminophen, NF XII) (1). Studies in these laboratories indicated that the *tert*-butyl homolog of acetophenetidin undergoes very little *O*-dealkylation to *N*-acetyl-*p*-aminophenol but that it possesses analgesic and antipyretic activity (2, 3). Although toxicity studies have ruled out the use of this compound as a substitute for acetophenetidin, the authors have investigated its metabolism because these studies could provide interesting data as to structure–metabolism relationships. The identification of a metabolite which is hydroxylated in the side chain is reported.

EXPERIMENTAL

Chemicals—2 - Methyl - 2 - (4 - acetaminophenoxy)propane [*p-tert*-butoxy acetanilid] (I) and 2-methyl-2-(4-acetaminophenoxy) propanol (II) were synthesized in these laboratories.[1] *N*-Acetyl-*p*-aminophenol was supplied by Eastman's Distillation Products, Inc., Rochester, N. Y.

Animal Experiments—2-Methyl-2-(4-acetaminophenoxy)propane was administered orally to three adult dogs (50 mg./Kg./day) for 2 days, a total of 3.29 Gm. The urine collected (1270 ml.) during the 2 days was combined. Urine was also collected for the day prior to drug administration.

Chemomatographic Analysis of the Urine—Urine was hydrolyzed and extracted according to the method described earlier in connection with urine obtained from animals treated with acetophenetidin (4). For the preliminary studies, the residue obtained after evaporation of the organic solvent was chromatographed on paper with system *1* previously employed for the separation of acetophenetidin metabolites (4). More recent studies were carried out with thin-layer chromatography as previously described (4). The solvent systems used for thin-layer chromatography are shown in Table I. Visualization of compounds was achieved with ultraviolet light.

Isolation of the Metabolite—A mixture of 800 ml. of urine, 800 ml. of pH 5, 0.2 *N* acetate buffer (5), and 800 ml. of β-glucuronidase[2] was incubated for 18 hr. at 37.5°. The urine was then mixed with 60 ml. of 4 *N* NaOH and 800 ml. of 1.0 *M* phosphate buffer (pH 7.4),[3] and extracted 3 times with 3 L. of $CHCl_3$. The organic extracts were combined and evaporated at room temperature under vacuum. The residue (1.3 Gm.) was dissolved in 5 ml. $CHCl_3$ and chromatographed on an aluminum oxide (10 Gm.) column (acid alumina, DG 4 grade, 100–200 mesh as supplied by Bio Rad Co., Los Angeles, Calif.). The column was washed with 1 ml. of chloroform, 15 ml. of benzene, 150 ml. of benzene–chloroform (35:65 v/v), and 400 ml. of chloroform–ethyl acetate (85:15 v/v). Each fraction was examined chromatographically for the presence of metabolite. The solvent was evaporated from the chloroform–ethyl acetate fraction and the residue (200 mg.) was treated 6 times with 100 ml. of boiling cyclohexane. An insoluble black residue was discarded and the cyclohexane extracts were combined. The cyclohexane was evaporated and the residue was recrystallized 6 times from benzene. More metabolite was obtained from the mother liquors, and a total of 90 mg. of pure product was obtained.

TABLE I—ANALYSIS OF TEST COMPOUNDS BY THIN-LAYER CHROMATOGRAPHY

Compd.	System *1*[a]	System *2*[b]	System *3*[c]
2-Methyl-2-(4-acetaminophenoxy)propane	0.87	0.78	0.94
2-Methyl-2-(4-acetaminophenoxy) propanol	0.23	0.29	0.52
N-Acetyl-*p*-aminophenol	0.08	0.10	0.35

[a] System *1*, previously described (4). [b] The upper phase of a toluene–benzene–water–acetic acid (2:2:1:2) mixture for thin-layer chromatography. [c] The lower phase of a chloroform–methanol–water–acetic acid (20:10:20:1) mixture for thin-layer chromatography.

Acidic Cleavage of Compounds—The acidic cleavage of compounds I and II was done by treating 200 mcg. of each substance with 1 ml. of 2 *N* HCl at room temperature. After a time lapse of 10 min. to 24 hr., portions of the solution were extracted with 10 ml. of a methylene chloride–isopropanol–water (75:25:2) mixture. The solvent was evaporated and the resulting residues were chromatographed on thin-layer plates.

Gas Chromatography—For gas chromatographic analysis of 2-methyl-2-(4-acetylaminophenoxy)propane and the hydroxylated metabolite, urine was enzyme hydrolyzed and extracted as described above. For the analyses of *N*-acetyl-*p*-aminophenol, hydrolyzed urine was extracted with the methylene chloride–isopropanol mixture described above. The analyses were carried out on a Barber-Coleman model 10 gas chromatograph equipped with a Sr-90 detector. The column packing [SE-30, 6% coated on Gas Chrom S, 80–100 mesh supplied by Applied Science Labs., Inc., College Point, Pa., or a mixture of SE-30 (1%)–Carbowax 20 M (1%) coated on Anakrom AS, 80–90 mesh, supplied by Analabs, Inc. Hamden, Conn.] was packed in a U-shaped, glass column, 120 cm. in length and 3.5 mm. i.d.

The transformations of 2-methyl-2-(4-acetaminophenoxy) propane and 2-methyl-2-(4-acetaminophenoxy) propanol

Scheme I

TABLE II—ANALYSIS OF URINE BY GAS CHROMATOGRAPHY

Compd.	Retention Time, min.	Urinary Concn., mcg./ml.	Dose % Recovery in Dogs
2-Methyl-2-(4-acetaminophenoxy)propane	2.1	23	0.9
2-Methyl-2-(4-acetaminophenoxy)propanol[a]	6.1	295	11.4
N-Acetyl-*p*-aminophenol[b]	12.5[c]	101	3.9

[a] The SE-30 column. [b] The SE-30 Carbowax 20 M column. [c] *N*-Acetyl-*p*-aminophenol (retention time = 3 min.) has too broad a peak for accurate quantitation using column a.

The inlet pressure was 25 psig and the outlet pressure was atmospheric. The instrument was operated isothermally at 150° for the SE-30 column and at 200° for the SE-30–Carbowax column. The samples, dissolved in 2–5 μl. of ethyl acetate varied from 0.5–1.5 mcg. The concentration of compound was determined from the proportion of peak area of unknown to peak area of standard (appropriate reference compound added to control urine). Peak areas were calculated from the product of peak height and width at one-half the peak height.

RESULTS AND DISCUSSION

Initial chromatographic studies on extracts of urine obtained from dogs which had received oral doses of 2-methyl-2-(4-acetaminophenoxy)propane, indicated the presence of a metabolite. The chromatographic mobility of the substance was different from that of drug or *N*-acetyl-*p*-aminophenol. Since the compound was freed by treatment with β-glucuronidase it appeared likely that it was hydroxylated.

In order to identify the metabolite, it was isolated as described under *Experimental*. The crystals obtained melted at 120.5–121.5°. The elemental analysis for carbon-hydrogen was in agreement with a hydroxylated derivative of the *tert*-butoxy compound administered.

Anal.—Calcd. for $C_{12}H_{17}NO_3$: C, 64.55; H, 7.68. Found: C, 64.90; H, 7.70.

The location of the hydroxyl group was now considered. Since the metabolite did not react with the Pauly reagent (6), it appeared that the compound was hydroxylated in the side chain.

The metabolite and the drug administered were subjected to mild acid hydrolysis and the products were examined chromatographically. The drug was hydrolyzed completely to *N*-acetyl-*p*-aminophenol in about 15 min. and the metabolite gave about an 80% yield of the same phenol after 24 hr. Since the same product was formed from both, it was established that the hydroxylation was associated with the alkyl moiety.

Authentic 2-methyl-2-(4-acetaminophenoxy) propanol (II) was now synthesized[1] and the metabolite and the authentic synthetic sample were shown to be identical in the following way. A mixed melting point determination carried out on the metabolite and the synthetic compound showed no depression of the melting point. The infrared spectra of the metabolite and of II were identical.

The chromatographic mobilities of the three compounds are shown in Table I.

The structures of 2-methyl-2-(4-acetaminophenoxy)propane (I), the metabolite (II), and *N*-acetyl-*p*-aminophenol (III) are shown in Scheme I.

During the studies on the metabolism of 2-methyl-2-(4-acetaminophenoxy) propane, small amounts of a substance with the chromatographic mobility of *N*-acetyl-*p*-aminophenol were observed. Gas chromatography was utilized to measure the amounts of unchanged drug, the hydroxylated metabolite, and *N*-acetyl-*p*-aminophenol excreted in the urine. The results are shown in Table II.

The results for the small amount of *N*-acetyl-*p*-aminophenol in the urine of animals treated with the *tert*-butoxy compound contrasts with larger amounts of the dealkylated compound excreted by animals treated with acetophenetidin (1). These results, however, were not investigated further.

The substitution of a *tert*-butyl group in the acetophenetidin molecule inhibited the *O*-dealkylation of this compound. These observations can be applied in the synthesis of potential substitutes for drugs when the slowing down of the metabolic process would help in providing a longer duration of therapeutic action. This approach to the development of new drugs has already been discussed in connection with another group of compounds (7).

Isolation and Identification of Eburicoic Acid from *Fomes pinicola*

By KIRTI SHETH*, PHILIP CATALFOMO, and LEO A. SCIUCHETTI†

The petroleum ether extract of *Fomes pinicola*, upon chromatography on an alumina column, yielded ergosterol and a crystalline compound which was identified as eburicoic acid by means of IR and NMR spectroscopy. Ultraviolet spectrum analysis indicated that eburicoic acid was contaminated with trace impurities of dehydroeburicoic acid.

BASIDIOMYCETES belonging to family *Polyporaceae* have been found to be rich sources of triterpene acids. The genera *Polyporus* and *Fomes* are noteworthy members among this group. Kariyone and Kurono (1), in 1940, isolated eburicoic acid, a triterpenic acid, from *Fomes officinalis*. Since then it has been isolated from a number of other species such as *P. sulphureus, P. anthracophilus, P. eucalyptorum, etc.*, when these species were grown on a synthetic medium (2). Besides eburicoic acid, its hydroxylated derivatives such as sulphurenic acid and tumulosic acid have also been encountered (3, 4). When grown on a synthetic medium, the mycelia of *P. sulphureus* produced eburicoic acid in huge yields (as much as 50% or more of the dried mycelial weight). This ready availability of eburicoic acid has led to extensive investigation of its biogenesis on the one hand (5) and degradation to steroids of various structures for potential medicinal usage on the other (6).

Polyporus pinicola is now recognized as the same species as *Fomes pinicola* (7). From this species, Halsall and co-workers (8–11) have isolated, among other steroidal derivatives, five closely related triterpenes. They are 21-hydroxylanosta-7,9(11)-24-triene-3-one (I*a*), lanosta-7,9(11)-24-triene-3β,21-diol (I*b*), 3α-oxylanosta-8,24-diene-21-oic acid (II*a*), pinicolic acid A (II*b*), and polyporenic acid C (III). Eburicoic acid (IV*a*), which can be viewed as a reduced form of polyporenic acid C (III), has not been reported to occur in *F. pinicola*. This fact, coupled with the widespread occurrence of eburicoic acid in species of *Fomes* and *Polyporus*, led to the investigation of this species. This paper reports that eburicoic acid indeed occurs in *F. pinicola*.

III

RESULTS AND DISCUSSION

The petroleum ether extract of *F. pinicola*, upon thin-layer chromatography, revealed a complex mixture of sterols–triterpenes. Hence the mixture was chromatographed over a column of alumina. Elution with chloroform removed a sterol which after several crystallizations from diluted ethanol gave a homogeneous compound melting at 159–161°. It was identified as ergosterol from its characteristic UV spectrum with $\lambda_{max.}^{CHCl_3}$ at 264, 273, 283, and 294 mμ. Undepressed mixed melting point with an authentic specimen of ergosterol and their superimposable IR spectra further verified the identity of the isolate as ergosterol.

Continued elution of the column with methanol yielded a highly polar compound which after repeated crystallizations from dilute ethanol gave fine needles of a compound, m.p. 280–283°. It gave a positive Liebermann-Burchard color reaction and it was identified as eburicoic acid (IV*a*) from the following evidence.

The IR spectrum (KBr pellet) of the isolate (IV*a*) showed strong absorption bands at 3430 (—OH), a group of small bands at 2700, a strong absorption band at 1700 (—COOH), and bands at 1640 and 887 cm.$^{-1}$ (>=CH$_2$). In the IR spectrum of the acetyl derivative (IV*b*), the absorption band in the 3500 cm.$^{-1}$ region was eliminated while the bands due to free carboxyl and terminal methylene groups were maintained. An additional band in the carbonyl region at 1725 cm.$^{-1}$ indicated the esterification of the hydroxyl group in IV*b*. On the other hand, the IR spectrum of the methyl ester (IV*c*) showed the absorption bands due to free hydroxyl (3420 cm.$^{-1}$) and terminal methylene (1640 and 885 cm.$^{-1}$) groups but it lacked absorptions due to a free carboxyl group. Instead, a single strong absorption band at 1730 cm.$^{-1}$ indicated the esterification of the free

IV*a*, eburicoic acid; R = R_1 = H
IV*b*, acetyl eburicoic acid; R = CH_3CO, R_1 = H
IV*c*, methyl eburicoate; R = H, R_1 = CH_3

carboxyl group of IV*a*. The NMR spectra of methyl eburicoate (IV*c*) and acetyl eburicoic acid (IV*b*) were in complete agreement with those recorded by Fried *et al.* (3).

Finally, the IR spectra of the isolate (IV*a*) and its methyl ester (IV*c*) were superimposable over those of eburicoic acid and its methyl ester,[1] thus confirming the identity of the isolate as eburicoic acid.

The UV spectrum of the isolate (IV*a*) showed a trio of absorption bands of low intensity but characteristic $\lambda_{max.}^{MeOH}$ at 234, 243, and 251 mμ. These absorption bands are ascribed to the presence of multicyclic terpenes with a $\Delta^{7,9(11)}$ conjugated diene system. These dienes, often called dehydro compounds, occur frequently as adjuncts to the more common terpenes with a $\Delta^{8,9}$ double bond. Holker *et al.* (12) have commented upon the co-occurrence of dehydroeburicoic acid (V) along with eburicoic acid (IV*a*) and also on the very great difficulty of separating these compounds from each other. Hence, the characteristic but low intensity UV absorption bands in the sample of the isolate must be ascribed to the traces of dehydroeburicoic acid in it.

The melting points of eburicoic acid isolated from different sources and its derivatives prepared by different workers vary considerably (*cf.* under *Experimental*). These variations can be ascribed possibly to the differing amounts of dehydroeburicoic acid which may be present in the samples of eburicoic acid.

EXPERIMENTAL

Melting points were determined using a Kofler micromelting point apparatus. Ultraviolet spectra were recorded on a Beckman spectrophotometer, model DB. Infrared spectra were recorded on a Beckman IR-8 spectrophotometer. NMR spectra were determined in $CDCl_3$ on a Varian Associates A-60 instrument through the courtesy of Dr. F. T. Bond, Oregon State University.

[1] Eburicoic acid and methyl eburicoate were obtained through the courtesy of the Squibb Institute for Medical Research, New Brunswick, N. J., and Professor Josef Fried, Ben May Laboratory for Cancer Research, University of Chicago, Chicago, Ill., respectively.

Material—Naturally occurring carpophores of *Fomes pinicola*, growing on larch trees (*Larix occidentalis*) in Linn County, Oreg., were collected during the summer of 1966. The collection was identified by Dr. Lewis F. Roth, Oregon State University.

Extraction—Approximately 250 Gm. of fungus was cut up in small bits and pulverized in an Abbé mill. The powdered material was exhaustively extracted with petroleum ether in a Soxhlet extractor for 48 hr. The extract was concentrated under reduced pressure at 40° to a small volume of syrupy residue.

Isolation of Ergosterol—About one-half the quantity of the concentrated petroleum ether extract was dissolved in 75 ml. of benzene and the solution was chromatographed on an alumina[2] column (500 Gm., 35 × 5 cm.). Careful elution with chloroform yielded a fraction which deposited crystals upon evaporation. The crystals were collected and crystallized once from ethyl acetate and then thrice from dilute ethanol. Colorless plates were obtained m.p. 159–161°, $[\alpha]_D$ = −128° ($CHCl_3$). [Reported m.p. 163°, $[\alpha]_D$ = −133° ($CHCl_3$) (13).]

Isolation of Eburicoic acid—After ergosterol was eluted, the column was developed with solvents of increasing polarity. Methanol eluted a chalky component which was found to contain inorganic impurities. These were removed by treating the compound with boiling water for 10 min. and then collecting it on a Büchner funnel. The compound thus collected was crystallized four times from dilute ethanol. Colorless needles of eburicoic acid (IV*a*) were obtained, m.p. 280–283°, $[\alpha]_D$ = +31° (pyridine). [Reported m.p. 283° (1); m.p. 280° (14); m.p. 292–293°, $[\alpha]_D$ = +34° (pyridine) (15).] Mixed melting point with an authentic sample of eburicoic acid (m.p. 275–277°) did not show any depression.

Preparation of Acetyl Eburicoic Acid—Eburicoic acid (48 mg.) was dissolved in 1.0 ml. of pyridine, and 1.0 ml. of acetic anhydride was added to the solution. After refluxing the mixture for 30 min., it was poured onto crushed ice. The precipitate was collected, washed thoroughly with water, and crystallized thrice from ethanol. Acetyl eburicoic acid was obtained, m.p. 248–253°, $[\alpha]_D$ = +40° ($CHCl_3$). [Reported m.p. 240° (1); m.p. 259° $[\alpha]_D$ = +42° ($CHCl_3$) (15).]

Preparation of Methyl Eburicoate—A chilled solution of diazomethane (prepared from 5 Gm. of *N*-nitrosomethylurea) in ether was added to a chilled solution of eburicoic acid (150 mg.) in methanol (100 ml.). The mixture was allowed to evaporate spontaneously and the residue was crystallized repeatedly from *n*-hexane. Fine needles of methyl eburicoate were obtained, m.p. 138–141°, $[\alpha]_D$ = +42° ($CHCl_3$). [Reported m.p. 141° (1); m.p. 146–147°, $[\alpha]_D$ = +45° ($CHCl_3$) (15).] An admixture with an authentic sample of methyl eburicoate (m.p. 132–137°) did not show depression in melting point.

Opium Alkaloids V. Structure of Porphyroxine

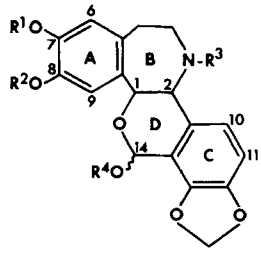
By EINAR BROCHMANN-HANSSEN and KENTARO HIRAI

Porphyroxine is a monophenolic alkaloid isolated from opium. It contains a methyl acetal group and has three asymmetric centers. The position of the phenolic hydroxyl group has been determined by NMR spectroscopy. Evidence has been presented for the configuration at position-14.

In 1837, MERCK (1) discovered a minor opium alkaloid which he named porphyroxine because it produced a red color when heated with dilute mineral acids. He suggested that this reaction might be used as a test for opium in forensic cases (2). The concentration of the alkaloid varies with the source of opium, and the color reaction is useful for determining the geographic origin of opium seized in illicit traffic (3, 4). Although there has been a great deal of interest in porphyroxine for more than 100 years and many investigators claim to have isolated it, it is only recently that it has been obtained in a form sufficiently pure for structure studies (5–7). In 1962 the empirical formula was determined by Pfeifer and Teige (6) as $C_{20}H_{21}NO_6$. In a series of investigations of the alkaloids of the genus *Papaver*, Pfeifer *et al.* (8, 9) described a total of six alkaloids which gave the characteristic red color with mineral acids. They coined the name "papaverrubines" for these compounds. All papaverrubines are secondary amines. The *N*-methyl derivatives, several of which have been found in the *Papaveraceae* family, do not give the red color reaction with acids. The gross structures of some of these alkaloids are illustrated in I–V.

Papaverrubine A (I), glaudine (III), isorhoeadine (IV), and glaucamine (V) have a *trans*-configuration at the junction of ring B and ring D, whereas papaverrubine E (I), oreodine (III), and rhoeadine (IV) have the *cis*-configuration (10–12).

Porphyroxine (II) has been established as a member of the B/D *trans*-series by methylation to glaudine (13). The only structural features of porphyroxine which have not yet been reported are the exact position of the hydroxyl group in ring A and the stereochemistry at position-14. During studies



I, $R^1 + R^2 = CH_2$, $R^3 = H$, $R^4 = CH_3$; papaverrubine A and E
II, $R^1 = H$ or CH_3, $R^2 = CH_3$ or H, $R^3 = H$, $R^4 = CH_3$; papaverrubine D (porphyroxine)
III, $R^1 = R^2 = R^3 = R^4 = CH_3$; glaudine and oreodine
IV, $R^1 + R^2 = CH_2$, $R^3 = R^4 = CH_3$; isorhoeadine, rhoeadine
V, $R^1 = R^2 = R^3 = CH_3$, $R^4 = H$; glaucamine

of the minor alkaloids of opium, this alkaloid was isolated. The isolation and subsequent studies of the structure of porphyroxine are described.

EXPERIMENTAL

Isolation—Four pounds of powdered opium of Indian origin were extracted, and a preliminary separation of alkaloid groups was carried out as described in a previous communication (14). The phenolic alkaloid fraction was subjected to preparative thin-layer chromatography on silica gel with chloroform–methanol (9:1). Bands were obtained of reticuline, isoboldine, and scoulerine. One band with a high R_f value was a mixture of several alkaloids which were separated on an alumina column (Merck, neutral, activity IV) with chloroform. The first fractions contained an alkaloid which, when crystallized from methanol, melted at 190° (micro m.p. K.). [Lit. m.p. 192° (6).] It gave a single peak by gas chromatography on silicone rubber SE-30 (3.8%, 4 ft., 200°) and single spots by thin-layer chromatography on silica gel in two different solvent systems (15). The spots produced a red color when

sprayed with dilute hydrochloric acid and heated. The IR and UV spectra were identical with those reported for porphyroxine (6). The NMR spectrum[1] in $CDCl_3$ (internal TMS standard) was consistent with the structure assigned to porphyroxine (II).

RESULTS AND DISCUSSION

The chemical shifts and coupling constants are listed in Table I. The C-1 and C-2 protons resonated as an AX quartet, $J_{1,2}$ 9 c.p.s., indicative of a B/D *trans*-configuration and in good agreement with the values reported for glaudine (10) (*cf.* Table I), glaucamine (11), and isorhoeadine (12). A smaller coupling constant ($J_{1,2}$ 2–2.5 c.p.s.) is observed for the B/D *cis*-series (10, 12).

Recently, the position of phenolic hydroxyl groups of alkaloids has been determined by deuteration of the *ortho* and/or *para* aromatic protons, followed by NMR spectroscopy (16–19). Attempts to apply this technique to porphyroxine were unsuccessful because of the instability of the alkaloid. Instead, a comparison of the chemical shifts of the aromatic protons in the phenolate ion and the undissociated phenol was used (20–22). In hexadeutero DMSO, the signals of the C-6 and C-9 protons appeared at 3.27 and 2.83 τ, respectively. Small amounts of sodium deuteroxide were added successively until no further changes took place in the chemical shifts. The results are listed in Table II. Porphyroxine

TABLE II—CHANGES IN CHEMICAL SHIFTS OF C-6 AND C-9 PROTONS OF PORPHYROXINE ON ADDITION OF NaOD IN $(CD_3)_2SO$

τ	1	2	3	4	$\Delta\tau$
C-6 proton	3.27	3.33	3.43	3.57	0.30
C-9 proton	2.83	2.99	3.03	3.25	0.42
	phenol ——→ phenolate				

could be recovered from the solution, proving that no structural changes occurred in the alkaloid as a result of the alkali treatment. The C-6 proton was shifted upfield 0.30 p.p.m. by conversion to the phenolate, and the C-9 proton was shifted 0.42 p.p.m. in the same direction. The following ranges have been reported (20) for anion shifts in alkyl and alkoxyl substituted phenols: *ortho*, 0.42–0.59 p.p.m.; *meta*, 0.19–0.39 p.p.m.; and *para*, 0.71–0.79 p.p.m. Therefore, it may be concluded that the C-6 proton in porphyroxine is *meta* to the phenolic hydroxyl group, and C-9 proton is *ortho*. Thus, the hydroxyl group in ring A was assigned to position-8.

Most of the naturally occurring papaverrubine alkaloids and their *N*-methyl analogs have a thermodynamically unstable configuration at position-14 and are readily epimerized by heating with methanol containing catalytic amounts of acid (23, 24). Porphyroxine has the same configuration at position-14 as glaudine, which can be epimerized to epiglaudine (13, 23).

The C-1 proton resonance of porphyroxine appears at a much higher τ-value than that of glaudine (Table I) due to the *N*-methyl group. *N*-Methylporphyroxine, prepared by reacting porphyroxine with formaldehyde and sodium borohydride (18, 25), gave essentially the same NMR spectrum as glaudine, except for the *Ar*-OMe group in position-8 (Table I).

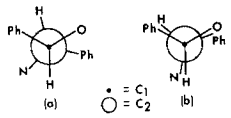

Fig. 1—Possible conformations and configurations of ring D.

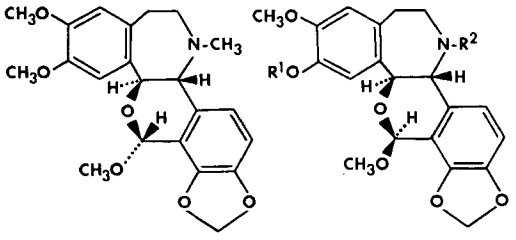
Epiglaudine was prepared from glaudine[2] as described by Pfeifer *et al.* (23) and its NMR spectrum determined in $CDCl_3$ (Table I). There was no change in the coupling constants for the C-1 and C-2 proton signals, indicating that the epimerization did not involve a change in the conformation of ring D, the two possible conformations of which are shown in Fig. 1. Conformation (a) is close to the staggered form and is the more stable, while conformation (b) approaches the eclipsed form. The large coupling constants (9 c.p.s.) of the C-1 and C-2 protons (Table I) tend to indicate an approximately diaxial orientation corresponding to Fig. 1 (a) (26) and illustrated in structures VI and VII. The conversion of glau-

[1] Varian A-60A NMR spectrometer.

[2] The authors are indebted to Professor S. Pfeifer for a sample of glaudine.

dine to epiglaudine caused the 14-OMe signal to be shifted upfield 0.13 p.p.m. while a strong downfield shift of 0.38 p.p.m. was observed for the C-1 proton. This downfield shift may be explained on the basis of a 1,3-diaxial orientation of the C-1 proton with respect to the O—CH_3 group. Thus, it may be attributed to anisotropy effects of the C—OMe single bond, to effects due to C—OMe electric dipoles (27) or, perhaps equally well, to van der Waals interactions deshielding the C-1 proton (28). Therefore, one may conclude that the C-1 proton and the OMe group of epiglaudine are on the same side of the acetal oxygen bridge, with the OMe group in the axial position, as illustrated in VI. It follows that



VI VII

glaudine and porphyroxine may be represented by structure VII or its mirror image (glaudine: $R^1 = R^2 = CH_3$; porphyroxine: $R^1 = R^2 = H$).

There was no significant difference in the ORD and CD spectra[3] of glaudine, epiglaudine, and *N*-methylporphyroxine {glaudine ORD: $[\phi]_{299}23325$ (pk), $[\phi]_{282}0$ (tr.); CD: $[\theta]_{309}0$, $[\theta]_{293}15640$, $[\theta]_{269}0$, $[\theta]_{251}-5536$, $[\theta]_{244}0$}. These compounds have three asymmetric centers adjacent to benzene chromophores, and the weak effect of the configurational change at C-14 appears to be covered by strong active absorption due to the C-1 and C-2 centers. Only porphyroxine showed a slightly different spectrum in the short wavelength region {ORD: $[\phi]_{333}6010$, $[\phi]_{298}15025$ (pk), $[\phi]_{281}2394$ (tr.), $[\phi]_{242}19240$ (pk), $[\phi]_{237}18028$ (tr.), $[\phi]_{249}60092$; CD: $[\theta]_{313}0$, $[\theta]_{292}10314$, $[\theta]_{267}0$, $[\theta]_{255}0$, $[\theta]_{238}8727$}.

SUMMARY AND CONCLUSIONS

Porphyroxine has been isolated from the phenolic alkaloid fraction of opium. It belongs to the "papaverrubine" group of alkaloids which contain a 7-membered heterocyclic nitrogen ring (ring B) fused to a cyclic lactol ether (ring D). The nitrogen is a secondary amine, and the B/D ring junction of porphyroxine (II) has a *trans*-configuration. Based on NMR spectroscopy at different pH values, the phenolic hydroxyl group has been assigned to position-8. The steric configuration at position-14 of porphyroxine is the same as that of glaudine (III) and is thermodynamically unstable. Epimerization of glaudine results in a strong downfield shift of the C-1 proton signal, while the coupling constants for the C-1 and C-2 protons are unchanged. This indicates that the conversion of glaudine to epiglaudine has not changed the conformation of ring D, but only the stereochemistry at the asymmetric center at position-14. From model considerations and the large coupling constants for the C-1 and C-2 protons, it may be concluded that these protons have an approximately diaxial orientation as illustrated in Fig. 1 (a) and in structures VI and VII. The downfield shift of the C-1 proton signal on epimerization may be explained by anisotropy effects of the C—OMe single bond or by a deshielding caused by van der Waals forces, thereby indicating a 1,3-diaxial orientation of the C-1 proton and the O—Me group in epiglaudine (VI). Consequently, glaudine and porphyroxine must have the configuration at position-14 illustrated in structure VII.

The ORD and CD spectra were not useful for elucidating the configuration of ring D because the effect of the configuration change at position-14 was masked by the stronger absorption due to the asymmetric centers at C-1 and C-2.

Ability of Certain Additives to Influence the Absorption of Salicylic Acid from Solutions in an *In Vivo* Study: Preliminary Report

By CLYDE W. WHITWORTH* and LOUDON D. YANTIS

The influence of polysorbates, sucrose, polyethylene glycols (PEG), propylene glycol, and dimethylsulfoxide (DMSO) on the absorption of salicylic acid has been studied. An immersion technique utilizing the frog was used. Results were analyzed by the Student *t* test. Certain concentrations of additives were seen to enhance absorption.

In recent years interest has been growing in the area of pharmaceutical research involving factors that influence drug absorption. Certain theories or concepts have been advanced concerning drug absorption. Shore *et al.* (1) reported certain drugs cross the intestinal epithelium chiefly in the unionized form and these workers advanced the pH-partition theory to explain the passive absorption of drugs. Various investigators (2–5) have found that oil-soluble drugs penetrate the skin more readily than water-soluble substances.

It was found that the frog, *Rana pipiens*, absorbed salicylic acid from solutions (6). The object of this study was to determine the effect of certain additives on the absorption of salicylic acid utilizing this immersion technique.

EXPERIMENTAL

Ten frogs were used in each determination. Each frog was placed in 500 ml. of the drug-additive solution and at 20-min. intervals the solutions were assayed for salicylic acid content using a Beckman DU spectrophotometer at a wavelength of 297 mμ. Samples were quickly returned to the solutions in order to maintain volume. It was determined that none of the additives interfered with the assay procedure. The solutions were 2.5×10^{-4} *M* with respect to salicylic acid.

It has been pointed out (6) that the absorption of salicylic acid by the frog in the manner described appears to conform to the pH-partition theory of passive absorption of drug in that the molecular form of drug is favored over the ionic. Proper maintenance of pH during such a study is therefore recognized to be of importance. It was found that most of the solutions except those containing the polysorbates exhibited a slight increase in pH (averaging about 0.15 pH units) during the second hour of the measurements. Part of this increase can be accounted for by the reduction in salicylic acid concentration as the drug is absorbed. Several buffer systems were tried. All were rejected because they either were deleterious to the frogs, or they greatly changed the rate of absorption possibly indicating an effect on the permeability of the skin of the frog. It appeared that the slight increase in pH observed did not appreciably influence the results of the study.

The aqueous solubility of salicylic acid in the presence of the additives was determined in an effort to correlate this property to the rates of absorption.

RESULTS AND DISCUSSION

Additives studied included polysorbate 80 USP, dimethylsulfoxide, sucrose, propylene glycol USP, polyethylene glycol 300 NF, and polyethylene glycol 4000 USP. The concentration of each additive was varied to observe this influence.

Figure 1 shows the effect of various concentrations of polysorbate 80 on the absorption of salicylic acid from solutions. This surfactant is seen to alter the rate of absorption of salicylic acid. The 0.1% concentration of additive has the greater effect in increasing absorption whereas the 1.0% polysorbate 80 is seen to have little effect for the first hour and then to inhibit absorption thereafter. Statistical analyses of the results by the Student *t* test at the 2-hr. mark show significant differences between control and the solutions containing 0.1% polysorbate 80 but not with the 0.5% additive solution. Levy *et al.* (7) found low concentrations of polysorbate 80 increased the absorption rate of certain barbiturates by goldfish, but higher concentrations of the surfactant inhibited absorption. Table I shows the aqueous solubility of salicylic acid to be greater in the presence of polysorbate 80. Each increase in surfactant concentration produced an increase in solubility. The surface tension lowering properties of polysorbate 80 prob-

ably permit better wetting action by the solution, thereby enhancing absorption of the salicylic acid.

Dimethylsulfoxide has received wide acclaim recently for its alleged ability to penetrate the skin. The use of this solvent as a vehicle for enhancing absorption of drugs remains a possibility. DMSO was found in this study to be more effective than any other additive observed in increasing the rate of absorption of salicylic acid by the live frog. All concentrations of DMSO significantly increased the amount of salicylic acid absorbed at the end of 2 hr. (Fig. 2). There appears to be an optimum concentration of DMSO, however, which will increase absorption just as was true with the polysorbate 80. Morain and his co-workers (8) observed DMSO to increase the permeability of frog skin to mannitol, urea, and other substances. The solubility of salicylic acid is seen to be increased by DMSO only by the 5.0% concentration.

The presence of sucrose (Fig. 3) increases the rate of absorption of salicylic acid by the frog but does not influence the solubility. All differences between control and solutions containing additives were significant at the 2-hr. limit. Again there appears to be an optimum concentration of additive for increasing absorption with 1% sucrose having the greatest effect.

As seen in Fig. 4 propylene glycol significantly increases the absorption of salicylic acid. As the concentration of additive is increased, however, the effect is less pronounced. No change in solubility was noted.

Figure 5 shows the 1.0% concentration of polyethylene glycol 300 to be more effective in increasing absorption than the 0.5% (not significant) or the

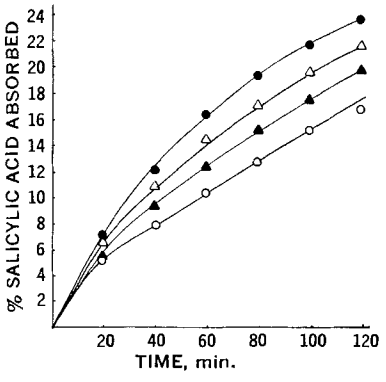

Fig. 6—Percent of salicylic acid absorbed over 2-hr. period when ten frogs each were placed in 500 ml. of aqueous drug solution. Key: ○, salicylic acid, 2.5 × 10^{-4} M and salicylic acid, 2.5 × 10^{-4} M in presence of: △, 0.5% polyethylene glycol 4000; ●, 1.0% polyethylene glycol 4000; ▲, 5.0% polyethylene glycol 4000.

5.0%. Only the 5.0% concentration of the additive influenced solubility which was slightly increased.

Polyethylene glycol 4000 significantly increased the absorption of salicylic acid (Fig. 6) with the 1.0% concentration again being the most effective. The solubility was increased only by the 5.0% additive solution.

Efforts at linearizing all the curves in the same manner were not successful. It was previously shown (6) that the absorption rate for salicylic acid from solutions using this technique appeared to be first order. This did not prove to be true, however, for most of the solutions containing the additives especially in the instances in which the absorption rate was greatly increased. Throughout the experiments the concentration of drug in the immersion media greatly exceeded the concentration of drug in the frogs. Considering this and the fact that a large volume of drug solution was used indicates that a fairly constant concentration gradient of drug was maintained after the initial 20-min. period of absorption. This explains the apparent zero-order absorption process seen for some of the solutions after the first 20 min. Several of the plots, namely for propylene glycol and polyethylene glycol 4000 additives, show similar slopes for all concentrations of additive indicating similar absorption rates after the initial absorption period.

The failure of certain of the data to show zero-order or first-order characteristics might be due to excretion of the drug by the frog toward the end of the experiments. This explanation is perhaps plausible for those additives that showed the greatest ability to enhance absorption after which the drug may have been partially excreted.

Current studies are being conducted to determine what part complexation, pH, concentration of drug, and other parameters are playing in the absorption of salicylic acid by the frog.

SUMMARY AND CONCLUSIONS

1. The effect of six additives at various concentrations on the absorption of salicylic acid from solutions has been studied using the frog as the test animal. The solubility of salicylic acid in each solvent was determined.

2. The additives were seen to enhance absorption of salicylic acid significantly in most cases, however, there appeared to be an optimum concentration for most of the additives.

3. The influence of various adjuvants on the absorption of the active ingredient of a pharmaceutical formulation should be carefully considered.

4. The frog may be useful for studying drug absorption.

Biotransformation Studies on 1-Chloro-2,3-propanediol Dinitrate

By ALBERT J. DIETZ, JR.*

Metabolic studies on the coronary vasodilator, 1-chloro-2,3-propanediol dinitrate (CPD), show that two metabolites can be isolated from the urine of dogs receiving the compound orally. The data suggest that the biotransformation of CPD commences with the splitting of the nitrate ester forming a free hydroxyl group which is then conjugated with glucuronic acid. The probable metabolites are 1-chloropropyl-3-glucuronide-2-nitrate and 1-chloropropyl-2-glucuronide-3-nitrate. Upon treatment with β-glucuronidase, these metabolites correspond to the products from the partial hydrolysis of CPD, which could only be the mono nitrate esters.

IN THE TREATMENT of coronary insufficiency, glyceryl trinitrate is the standard coronary vasodilator with which others have been compared. Krantz *et al.* (1) have shown that the number of nitrate groups in the molecule is not the major factor in determining vasodilating potency. Activity was found to be due to the intact molecule and not to the hydrolysis products of the ester. Likewise, the oil/water coefficient was found to be a factor in determining potency.

In recent years the search has been directed to related compounds that show a greater specificity for the coronary arteries and provide a longer duration of action with less side effects. Toward this end, 1-chloro-2,3-propanediol dinitrate[1] (CPD) was investigated. Burgison *et al.* (2) have shown that CPD and glyceryl trinitrate are equipotent in increasing coronary flow in the Langendorff rabbit heart preparation, and the latter appears to evoke a lesser degree of depressor response in the dog. Further, they have shown that the chlorinated ester manifests more persistent activity, and clinical trials (3) have confirmed these findings.

Previous metabolic studies on coronary vasodilators in this laboratory have shown that no CPD could be found in the urine of dogs which had received the compound orally. The logical step in metabolism would be the hydrolysis of the nitrate ester to the free hydroxyl group and conjugation with glucuronic acid. It was also of interest to see if the chlorine atom was cleaved during biotransformation.

METHODS

Three female mongrel dogs were fasted for 24 hr., and the urine was then collected for an additional 24 hr. as a control. On the next day, the dogs were again fasted for 24 hr., then 6 mg. of CPD was administered orally, and the urine was collected for 24 hr. after administration of the compound. The test urines were evaporated to dryness at 40° *in vacuo*. The residues were dissolved in buffer (pH 4.5) consisting of 5.79 Gm. $CH_3COONa \cdot 3H_2O$ and 3.25 ml. of glacial acetic acid in 1 L. of distilled water. Each test urine was then divided into two parts. To one part β-D-glucuronide glucuronohydrolase (β-glucuronidase) from *Helix pomatia*[2] was added, after which each part was incubated at 37° for 2 hr. Each part was then evaporated to dryness at 40° *in vacuo* and the residues were extracted three times with 5-ml. portions of anhydrous ethyl ether and the ether extracts were combined. The volume was reduced to 5 ml. by spontaneous air evaporation. The control urines were treated similarly but without the enzyme β-glucuronidase. A 10-μl. portion of the control, of the enzyme-treated sample, and of the untreated urines of each dog were spotted on thin-layer chromatography plates coated with silica gel + fluorescein (0.25 mm.) which had been activated at 100° for 30 min. The plates were developed by ascending techniques with two solvent systems, one a 2-propanol–ammonium hydroxide (4:1) mixture, the second a benzene–ethyl acetate (4:1) mixture. One plate from each solvent system was sprayed with a 1,3-dihydroxynaphthalene (naphthoresorcinol)–trichloroacetic acid mixture[3]

[3] One part by volume of an alcoholic naphthoresorcinol solution (0.2 Gm. naphthoresorcinol dissolved in 100 ml. ethanol) is mixed with 1 part by volume of an aqueous 20% solution of trichloroacetic acid (4).

and incubated in a humidified oven at 75° for 15 min. An additional plate from each solvent system was sprayed with a silver nitrate–ammonium hydroxide mixture[4] and exposed to an intense source of ultraviolet light for 5 min. A third plate was sprayed with a 1% solution of diphenylamine in methanol and exposed to ultraviolet light (4).

To help identify the metabolites, 1 mmole of CPD and 1.25 mmoles of NaOH were placed in 100 ml. of water and shaken for 2 hr. at 37°. The aqueous solution was concentrated to 25 ml. and extracted three times with anhydrous ethyl ether. The ether extracts were combined and evaporated to dryness. The residue was dissolved in 5 ml. of ether and 10-μl. portions spotted on each plate.

RESULTS

Table I gives the R_f values of the urine samples and reference compounds in a benzene–ethyl acetate solvent system and a 2-propanol–ammonium hydroxide solvent system sprayed with various identifying reagents. Two spots appeared on each plate from each solvent system sprayed with the naphthoresorcinol reagent which visualizes glucuronides. Both spots appeared in the test urines not treated with β-glucuronidase. No spots appeared in either the control urines or the enzyme-treated test urines, suggesting that the metabolites of CPD are glucuronide conjugates. On plates sprayed with silver nitrate–ammonium hydroxide mixture which visualizes organic chlorides, spots appeared in both the untreated and treated test urines, indicating that organically bound chlorine is present.

However, the spots in the untreated urine did not correspond to those in the enzyme-treated urines. Finally, one plate from each solvent system was sprayed with diphenylamine which colors organic nitrate esters. Spots appeared in both the treated and untreated test urines but they did not correspond to each other.

The partial alkaline hydrolysis of CPD was used to produce a mixture of the two mono nitrate esters and the completely hydrolyzed 1-chloro-2,3-propanediol. The conclusive identification of which spot corresponds to which mono nitrate ester could not be made without very sophisticated instrumentation, and the introduction by synthesis of only one nitrate group into the molecule without two or a mixture of the mono nitrates is nearly impossible. The spots from the partially hydrolyzed CPD, which could only be a mixture of the mono nitrates, do indeed correspond to the spots from the urine hydrolyzed by β-glucuronidase.

[4] One part by volume of a 1% solution of silver nitrate in ammonium hydroxide is mixed with 1 part by volume of ethanol (4).

Smooth Muscle and Cardiovascular Pharmacology of α-Elaterin-2-D-glucopyranoside Glycoside of *Citrullus colocynthis*

By S. P. BANERJEE and P. C. DANDIYA

The active principle present in the pulp of *Citrullus colocynthis* which exhibits cathartic abortifacient activity is not yet well established. The cardiovascular and smooth musculature activity of a recently identified glycoside, α-elaterin-2-D-glucopyranoside (coloside A) was therefore carried out to discover if it was the purgative or the ecbolic principle. Coloside A failed to stimulate the uterus, but elicited purgative properties. It demonstrated antihistaminic and antiacetylcholine-like activity on the intestinal musculature and exhibited negative chronotropic and negative inotropic activity in isolated mammalian and amphibian heart.

IN THE Ayurvedic system of medicine, the pulp of *Citrullus colocynthis* is recommended as a purgative (1) and is known to cause miscarriage when administered to pregnant women. The abortive activity of *C. colocynthis* is considered to be an indirect action, a manifestation of the cathartic activity of the drug produced by the congestion in the pelvic region (2). However, the possibility of some direct action on the uterus cannot be completely ruled out, since Stimpson (3) had shown that alcohol-free tincture of *C. colocynthis* produced increased tone and amplitude of contraction of isolated rabbit uterus. It is therefore likely that besides causing congestion in the pelvic region *C. colocynthis* possesses some principle which directly stimulates the uterus.

There is a controversy regarding the constituent responsible for its purgative action. From the water extract of the pulp, Walz (4) isolated a glycoside, colocynthin, which was believed to be the purgative principle. Subsequent workers, however, failed to isolate the glycoside from the water-soluble fraction. Power and Moore (5) after detailed chemical and pharmacological studies concluded that *C. colocynthis* does not contain any glycoside, and the purgative principle resided in the chloroform and ether-soluble resins and amorphous alkaloid (6–8). Lavie *et al.* (9) isolated a glycoside from the chloroform extract of the pulp of *C. colocynthis* which was identified by Khadem and Rahman (10, 11) to be α-elaterin-2-D-glucopyranoside. Since no systemic

Accepted for publication August 14, 1967.

and incubated in a humidified oven at 75° for 15 min. An additional plate from each solvent system was sprayed with a silver nitrate–ammonium hydroxide mixture[4] and exposed to an intense source of ultraviolet light for 5 min. A third plate was sprayed with a 1% solution of diphenylamine in methanol and exposed to ultraviolet light (4).

To help identify the metabolites, 1 mmole of CPD and 1.25 mmoles of NaOH were placed in 100 ml. of water and shaken for 2 hr. at 37°. The aqueous solution was concentrated to 25 ml. and extracted three times with anhydrous ethyl ether. The ether extracts were combined and evaporated to dryness. The residue was dissolved in 5 ml. of ether and 10-μl. portions spotted on each plate.

RESULTS

Table I gives the R_f values of the urine samples and reference compounds in a benzene–ethyl acetate solvent system and a 2-propanol–ammonium hydroxide solvent system sprayed with various identifying reagents. Two spots appeared on each plate from each solvent system sprayed with the naphthoresorcinol reagent which visualizes glucuronides. Both spots appeared in the test urines not treated with β-glucuronidase. No spots appeared in either the control urines or the enzyme-treated test urines, suggesting that the metabolites of CPD are glucuronide conjugates. On plates sprayed with silver nitrate–ammonium hydroxide mixture which visualizes organic chlorides, spots appeared in both the untreated and treated test urines, indicating that organically bound chlorine is present.

However, the spots in the untreated urine did not correspond to those in the enzyme-treated urines. Finally, one plate from each solvent system was sprayed with diphenylamine which colors organic nitrate esters. Spots appeared in both the treated and untreated test urines but they did not correspond to each other.

The partial alkaline hydrolysis of CPD was used to produce a mixture of the two mono nitrate esters and the completely hydrolyzed 1-chloro-2,3-propanediol. The conclusive identification of which spot corresponds to which mono nitrate ester could not be made without very sophisticated instrumentation, and the introduction by synthesis of only one nitrate group into the molecule without two or a mixture of the mono nitrates is nearly impossible. The spots from the partially hydrolyzed CPD, which could only be a mixture of the mono nitrates, do indeed correspond to the spots from the urine hydrolyzed by β-glucuronidase.

[4] One part by volume of a 1% solution of silver nitrate in ammonium hydroxide is mixed with 1 part by volume of ethanol (4).

pharmacological studies have yet been made with this compound, the smooth musculature and cardiovascular pharmacology of α-elaterin-2-D-glucopyranoside was undertaken. The glycoside α-elaterin-2-D-glucopyranoside will be referred to as coloside A in the text.

EXPERIMENTAL

Coloside A (m.p. 156°) was isolated from the Indian variety of the pulp of *C. colocynthis* by the method described by Khadem and Rahman (11). The solution of the drug was made by dissolving a weighed quantity of the compound in a known minimal quantity of warm ethanol, and the volume was made up with warm water so that solution did not contain more than 10% of ethanol. Experiments were run simultaneously with the solution of coloside A and the solvent containing 10% ethanol. Since the control experiments with the solvents, *i.e.*, 10% ethanol, did not exhibit any pharmacological action, only the activity of coloside A is described here.

Smooth Muscle—The isolated uterus of rat, the intestine of rabbit, and the ileum of guinea pig were set up by the methods described by Smith (12) and Turner (13).

The interaction between coloside A and uterine stimulants, such as oxytocin 0.002 units/ml. and ergometrine 0.01 mg./ml., were studied on the isolated rat uterus suspended in oxygenated de Jalons solution as described by Burn (14).

Antiacetylcholine, antihistaminic, and antibarium chloride activity of the glycoside was determined both on rabbit intestine and guinea pig ileum. The doses employed and preparations used are shown in Table I.

TABLE I—DOSES AND PREPARATIONS

Drug	Rabbit Intestine, mcg./ml.	Guinea Pig Ileum, mcg./ml.
Acetylcholine	0.5	5
Histamine	5	0.1
Barium chloride	0.2	0.2

Cardiovascular System—The experiment of frog heart perfusion was carried out by Bulbring's method as described by Burn (15). For the Straub heart preparation the excised frog heart was prepared according to the Straub procedure as quoted by Gaddum (16). Perfusion of the isolated rabbit heart was performed by the modified method of Langendorff as described by Burn (17).

To study the effect of coloside A on the blood pressure and heart *in situ*, mongrel dogs of either sex, between 7–12 Kg. weight, were employed and anesthetized with morphine, 5 mg./Kg., followed 15 min. later by urethan, 1.4 Gm./Kg., both given intramuscularly. The left common carotid artery was cannulated and blood pressure was recorded on a slowly moving kymograph. The drug was administered through the cannulated right femoral vein. The chest was then opened under artificial respiration. A bent entomological pin passed near the tip of the ventricle and was attached to a Starling lever after passing through a pulley. Similar arrangements were made to record auricular beats.

RESULTS

Results described below are the average of three experiments.

Smooth Muscle—*Isolated Rat Uterus*—Coloside A did not produce any contractions of the rat uterus in concentration up to 0.1 mg./ml. On the other hand, it exhibited a uterine depressant property. Though the drug did not elicit any relaxation of the uterus in concentrations up to 0.1 mg./ml., it decreased the rate and amplitude of contraction. Coloside A also failed to alter the response produced by uterine stimulants such as oxytocin and ergometrine.

Isolated Rabbit Intestine and Guinea Pig Ileum—Coloside A did not produce any spasmogenic activity on the isolated intestine. Neither did it affect the rhythmic movements of rabbit intestine, nor did it produce any contraction of the guinea pig ileum suspended in Tyrode's solution up to 0.1 mg./ml. However, it exhibited antihistaminic and antiacetylcholine-like action which is described in Table II. Coloside A did not counteract the action of barium chloride on intestine.

TABLE II—ANTIACETYLCHOLINE AND ANTIHISTAMINIC ACTIVITY OF COLOSIDE A[a]

Dose, mg./ml.	Prepn.	Stimulant	Dose, mcg./ml.	% Inhibition
0.1	Rabbit intestine	Acetylcholine	0.5	43
0.1	Rabbit intestine	Histamine	5.0	92
0.05	Guinea pig ileum	Acetylcholine	5.0	27
0.1	Guinea pig ileum	Acetylcholine	5.0	49
0.05	Guinea pig ileum	Histamine	0.1	67
0.1	Guinea pig ileum	Histamine	0.1	90

[a] Three experiments were performed in each case.

Cardiovascular System—*Frog Heart Perfusion*—Coloside A diminished the force of contraction of the ventricle and reduced the heart rate. A dose of 1 mg. decreased the amplitude of contraction and heart rate by 35 and 15%, respectively. Results are shown in Table III.

TABLE III—EFFECT OF COLOSIDE A ON THE FROG HEART PERFUSION[a]

Dose, mg.	% Decrease in Amplitude	% Decrease in Heart Rate	Recovery, Time, min.
0.25	0	0	0
0.50	12	7	12
1.00	36	16	22

[a] Three experiments were performed in each case.

Straub Heart Preparation—When a dose of 1:10,000 of the drug was administered to a Straub heart preparation, the amplitude of contraction was decreased by 70%, and the heart rate was reduced by 25%. At 1:10,000 concentration, it produced a mid-diastolic arrest (Table IV).

TABLE IV—EFFECT OF COLOSIDE A ON THE STRAUB HEART PREPARATION[a]

Dose	% Decrease in Amplitude	% Decrease in Heart Rate
1:100,000	11	0
1:10,000	70	23
1:1000	Mid-diastolic arrest	Mid-diastolic arrest

[a] Three experiments were performed in each case.

Isolated Rabbit Heart—The glycoside exhibited a negative chronotropic and a negative inotropic effect and reduced the coronary flow. At a 3-mg. dose it produced a mid-diastolic arrest (Table V).

TABLE V—EFFECTS OF COLOSIDE A ON THE ISOLATED RABBIT HEART[a]

Dose, mg.	% Decrease in Amplitude	% Decrease in Coronary Flow	% Decrease in Heart Rate
0.05	37	14	23
0.3	Mid-diastolic arrest	Mid-diastolic arrest	Mid-diastolic arrest

[a] Three experiments were performed in each case.

Dog Heart In Situ—Coloside A had no effect on this preparation up to 5 mg./Kg. dose level.

Dog Blood Pressure—A dose of 5 mg./Kg. of the drug failed to produce any significant hypotensive action.

DISCUSSION

The pulp of *C. colocynthis* is well-known for its cathartic and abortifacient activity. But the chemical constituents responsible for the purgative and ecbolic activity have not yet been definitely identified. A controversy exists regarding the nature of the cathartic principle. No compound has so far been isolated which exhibits uterine stimulant properties. An attempt was therefore made to distinguish and to isolate in pure form the cathartic and oxytocic principles of the drug.

Coloside A has been found to possess purgative properties.[1] However, it did not produce any contraction of the rat isolated uterus. Thus, coloside A is the cathartic principle without any oxytocic activity. It exhibited a uterine depressant property and decreased the rate and amplitude of contraction, and demonstrated antihistaminic and antiacetylcholine activity to confirm the finding of Hollander (18), who reported that a solution of colocynth blocked the parasympathetic nerve endings. It does not possess a direct depressant activity on the intestine, as it failed to counteract the response of barium chloride.

The drug produced a negative chronotropic and a negative inotropic effect on isolated mammalian and amphibian hearts. Similar activity was reported on the rabbit heart by Stimpson (3) in the alcoholic extract of the pulp of *C. colocynthis*. Since coloside A is a steroidal glycoside and shows cardiac depressant properties, this drug may be a cardiotonic. Further work on this aspect would be fruitful.

Coloside A did not have cathartic activity when administered intraperitoneally, although orally it produced drastic purgation. Since the drug is believed to bring about purgation by irritation of the intestine, one possibility is that when it is given by a route other than oral, the concentration of the glycoside in the lumen of the intestine is not sufficiently high to exhibit any activity. However, Gaddum (19) has suggested that bile is necessary for the activity of the pulp of *C. colocynthis*. It is plausible to assume that the active principle of *C. colocynthis* forms some complex with the bile to manifest its activity. Erspamer and Paolini (20) have shown that antihistaminics slow down the purgative response of *C. colocynthis*. Surprisingly enough coloside A has been found to be an antihistaminic. It is probable that coloside A is an antagonist at the histaminic receptors with affinity and no intrinsic activity, while the complex is an agonist and possesses both affinity as well as intrinsic activity on the same receptors.

[1] Unpublished observations.

New Derivatives of Quinuclidine as Potential Antihypertensive Agents

By LANCE L. COLLINS, CHARLES A. PAPACOSTAS*, and SAMUEL ELKIN

Five new 3-aminoalkoxy derivatives of quinuclidine have been synthesized. All compounds reduced blood pressure in dogs to varying degrees, the most effective being 3-(3-dimethylaminopropoxy) quinuclidine. The evidence points to ganglionic blockade as the principal mechanism of action with the possibility that it may also be due to some direct depressant action on the cardiovascular system

QUINUCLIDINE, 1-azabicyclo[2.2.2]octane, is an integral part of the quinine molecule. Because of the many and varied responses produced by quinine and the other cinchona alkaloids, there has been a great interest in the quinuclidine nucleus as a possible therapeutic agent. Quinuclidine itself, as the hydrochloride salt, has been found to be a potent hypotensive and smooth muscle relaxant (1).

Therapeutically active quinuclidine derivatives have been synthesized and pharmacological activity has been found in both mono- and disubstituted products. The range in activity is quite varied.

The greatest volume of synthetic work involved the preparation of 3-substituted quinuclidines. Series of esters of bicyclic aminoalcohols, including 3-quinuclidinol have been prepared by Martell and Soine (2), by Sternbach and Kaiser (3), and by Mikhlina and Rubtsov (4). These derivatives have marked spasmolytic activity, one of the most active being 3-diphenylacetoxyquinuclidine.

Several 3-substituted derivatives of quinuclidine have been reported by Grob (5) to stimulate the central nervous system.

A series of 2-aminomethyl quinuclidines have been prepared and tested by Nikitskaya *et al.* (6). Some members of the series were found to have strong ganglionic blocking activity. Diethylaminoethyl-quinuclidine-2-carboxylate was found to be a good hypotensive. Ganglionic blocking was also noticed with 2,3-disubstituted products (7), the greatest activity being shown by 2-*N*-phenylaminomethyl-3-(2-*N*-phenylaminoethyl) quinuclidine. Perrine (8) synthesized a series of 4-phenyl substituted compounds for investigation as possible analgesics.

This investigation is involved with the synthesis of a series of 3-aminoalkoxy derivatives of quinuclidine and the pharmacological testing of their dimethiodide salts. All of the compounds showed antihypertensive activity, the most effective being 3-(3-dimethylaminopropoxy) quinuclidine.

DISCUSSION

Five new compounds were synthesized and are represented by the general formula shown. All products were prepared as the dimethiodide salts.

All compounds were prepared by the Williamson synthesis. A mixture of sodium and 3-quinuclidinol was refluxed in dry benzene to give sodium 3-quinuclidinoxide. This was reacted with the various aminoalkyl chlorides to give the corresponding ethers. These compounds were high boiling, colorless liquids which darkened upon standing.

	R	*n*
I, 3-(2-diethylaminoethoxy) quinuclidine	$-N(C_2H_5)_2$	2
II, 3-(2-dimethylaminoethoxy) quinuclidine	$-N(CH_3)_2$	2
III, 3-(3-dimethylaminopropoxy) quinuclidine	$-N(CH_3)_2$	3
IV, 3-[2-(1-piperidinyl)ethoxy] quinuclidine		2
V, 3-[2-(1-morpholino)ethoxy] quinuclidine		2

An attempt was made to isolate the ethers as their hydrochloride salts. This was done by bubbling dry HCl into a cold benzene solution of the ethers. The oily residues which formed were extremely hygroscopic and could not be crystallized.

The products were ultimately isolated as their dimethiodide salts which were stable in air and very soluble in water.

The infrared spectra showed characteristic alkyl ether bands between 8.9–9.4 mμ. Elemental analysis further confirmed the preparation of the desired products (Table I).

EXPERIMENTAL

All melting points are uncorrected. Analyses were performed by the Schwarzkopf Microanalytical Laboratory, Woodside, N. Y.

Sodium 3-Quinuclidinoxide—Into a 300-ml. 3-necked flask equipped with stirrer, dropping funnel, and condenser (drying tube) were placed 10.0 Gm. (0.08 mole) of 3-quinuclidinol[1] and 100 ml. of dry benzene. This mixture was heated until the 3-quinuclidinol was completely dissolved. Then 1.0 Gm. (0.08 mole) of sodium, cut into small strips, was added over a period of 1 hr. while heating and stirring. The mixture was refluxed until all the sodium had reacted (about 48 hr.) whereupon a light yellow slurry resulted.

Aminoalkyl Chlorides—These were prepared by the neutralization of the hydrochloride salts with sodium hydroxide according to the method of

Shirley (9). *N*-(β-Chloroethyl) piperidine could not be isolated in pure form as heating produced a viscous nondistillable substance. An ether solution of the crude material was used in the reaction.

Preparation of Ethers—The aminoalkyl chloride (0.08 mole) was added dropwise, over a period of 1 hr., to a refluxing suspension of sodium 3-quinuclidinoxide (0.08 mole) in dry benzene. The mixture was refluxed for 48 hr., cooled, filtered, and the residue washed with 10–20 ml. of dry benzene. After removing the benzene the residue was distilled under reduced pressure to give the ether and unreacted 3-quinuclidinol. The distillate, cooled in a dry ice–acetone bath, was treated with 10–20 ml. of anhydrous ether, and the precipitated 3-quinuclidinol was removed by filtration. The filtrate, after removal of the ether, was distilled under reduced pressure.

Preparation of Dimethiodides—Excess methyl iodide was added dropwise, with stirring, to a cold benzene solution of the ether whereupon a white precipitate formed. The mixture was filtered and the residue recrystallized from hot absolute ethanol.

PHARMACOLOGY

Preliminary pharmacological evaluation showed that all of the compounds evoked some degree of antihypertensive activity, the most effective being the dimethiodide of 3-3-dimethylaminopropoxy quinuclidine. The pharmacological study of the latter is described.

Method—Mongrel dogs weighing 8 to 13 Kg. were anesthetized with sodium pentobarbital, 30 mg./Kg., given intravenously. Mean arterial blood pressure was monitored from an exposed cannulated femoral artery, using a Statham pressure transducer attached to a multichannel recorder (Electronics for Medicine); heart rate was measured with a lead 2 to electrocardiogram and cardiac output using a standard indocyanine green[2] dye dilution technique. Injections of drugs were made into a cannulated femoral vein.

TABLE II—CARDIOVASCULAR DYNAMICS OF 3-(3-DIMETHYLAMINOPROPOXY) QUINUCLIDINE

	Normal	After Drug Adm. 5 min.	25 min.
B.P.[a]	131	99	90
H.R.[b]	184	144	128
C.O.[c]	2.715	1.564	1.546
S.V.[d]	14.7	10.7	12.0
T.P.R.[e]	3.13	3.97	3.72
No. animals	5	4	5

[a] Mean blood pressure in mm. Hg. [b] Mean heart rate in beats per minute. [c] Mean cardiac output in liters per minute. [d] Mean stroke volume in ml. [e] Mean calculated total peripheral resistance in arbitrary units.

Following control measurements of the various parameters described, the compound was injected intravenously at a dose of 3.0 mg./Kg. in one animal and at 5.0 mg./Kg. in 9 other animals since the latter dose produced greater and more prolonged effects.

Results—Blood pressure usually fell precipitously reaching a nadir within 30 to 40 sec. following injection, then rose slightly but generally stabilized within 3 to 4 min. at a level significantly lower than the control. Along with the hypotension there occurred a significantly reduced heart rate and cardiac output and some depression in stroke volume. The calculated total peripheral resistance showed a slight increase (Table II). Pressure gradually rose over a period of 2 hr. but was still significantly reduced at the end of this time interval.

[2] Cardio-green.

In an attempt to delineate the mechanism of action of this compound a number of pharmacologic techniques were employed. Atropine sulfate, 0.5 mg./Kg., did not alter the action of the compound. It was subsequently determined that the compound could effectively block the following procedures: electrical stimulation of the peripheral end of the right vagus, the carotid occlusion pressor reflex, and the pressor effect of nicotine salicylate. In addition, potentiation of the pressor response to epinephrine was noted as well as elimination of the reflex vagal effect that usually develops at the height of the epinephrine response. These findings were observed in 3 animals 20 to 30 min. following administration of the compound.

CONCLUSIONS

The evidence points to ganglionic blockade as the principal mechanism of action of this agent, however, the possibility that it may also exert some direct depressant action on the cardiovascular system has not been eliminated.

SUMMARY

Five new derivatives of quinuclidine have been prepared by reacting 3-quinuclidinol with various aminoalkyl halides *via* the Williamson synthesis. The resulting ethers, as the dimethiodide salts, were tested for antihypertensive activity. All showed varying degrees of activity, the most effective being 3-(3-dimethylaminopropoxy) quinuclidine.

Determination of Moisture in Crude Drugs by Gas–Liquid Chromatography

By NOURI Y. MARY

The use of gas–liquid chromatography was investigated as a means of determining the moisture content of crude drugs. Sixteen crude drugs representing a variety of plant parts and products were analyzed using this technique. Water was extracted from the crude drugs by disintegration with anhydrous methanol in a Waring blender and analyzed with a column of Teflon-6 coated with 10 percent polyethylene glycol 1500, using *n*-propanol as an internal standard. Peak height ratios were used to calculate the moisture content. The results obtained with the gas–liquid chromatographic procedure were quantitatively in accord with the results obtained by oven drying at 105° and toluene distillation methods. In addition, the new chromatographic procedure is simpler, more rapid, and has a very good precision (the maximum standard deviation was 0.36).

THE USE of gas–liquid chromatography for the direct analysis of moisture in a number of materials has been reported by many investigators. This technique was found to be reliable and convenient. Most of these studies utilized the method for the analysis of aqueous solutions of organic compounds (1–8). In only a few instances has this method been applied to the determination of water in natural products. The National Bureau of Standards (9) has adopted gas–liquid chromatography for moisture determination of grains. Schwecke and Nelson (10) used gas–liquid chromatography in determining the moisture content of cereal pellets, dried raisins, flour, and other food, and Brekke and Conrad (11) measured the water content of fruits and fruit products employing the same technique.

The simplicity, rapidity, and accuracy of the gas chromatographic process should also make the method well suited to the estimation of moisture in crude drugs. The methods currently recognized in the USP and NF for moisture content measurement of crude drugs include oven drying and toluene distillation. Both of these methods are time-consuming, and in the case of toluene distillation, the use of a comparatively large sample of the crude drug is a further disadvantage. The present investigation was, therefore, undertaken in order to develop an alternate procedure for the rapid measurement of moisture content in crude drugs utilizing a direct gas–liquid chromatographic technique.

EXPERIMENTAL

The crude drugs used in this work were obtained from S. B. Penick and Co., New York, N.Y. All drugs, except digitalis and peppermint leaves, were in powdered form. The leaf samples of digitalis and peppermint were powdered, before analysis, according to the NF XII (12) specification.

Moisture Determination by Oven Drying—The moisture content of all of the crude drugs, except

cinnamon, clove, ginger, and peppermint was determined by the NF XII method (12) for drugs containing no constituents volatile at 105°. The moisture content of cinnamon, clove, ginger, and peppermint was determined by the NF XII method (12) for drugs containing ether-soluble constituents volatile at 105°.

Moisture Method by Toluene Distillation—The azeotropic procedure described in the USP XVII (13) was followed in determining the moisture content of all of the crude drugs.

Moisture Determination by Gas–Liquid Chromatography—*Apparatus*—The chromatograph used in this study was a Perkin-Elmer model 154 vapor fractometer equipped with a dual chamber thermistor thermal conductivity cell.

Column Packing—The column used was a stainless steel tubing, 2 m. long and 0.625 cm. in o.d. packed with Teflon-6, 35-mesh, coated with 10% polyethylene glycol (PEG) 1500.[1] The packed column was purchased from Perkin-Elmer, Norwalk, Conn., and was conditioned at 100° for 24 hr. before use.

Chromatography Conditions—The operating temperature was 100°, the detector voltage was 8 v., and the helium carrier gas flow rate was 65 ml./min. The sample size injected was 4 μl.

Standard Curve—The internal standard used in this work was *n*-propanol, which is eluted before the water. Elvidge and Proctor (2) used *n*-propanol and obtained good separation from water in their analysis of aqueous pharmaceutical preparations.

A standard curve was prepared by chromatographing samples containing various amounts of water in mixtures of 3 ml. *n*-propanol and 100 ml. anhydrous methanol. The ratio of peak height of water to *n*-propanol was calculated from the chromatogram and plotted against the corresponding weight[2] ratio of the two compounds; a linear relation was obtained (Fig. 1). Although the standard curve appeared to be very reproducible (the standard deviation of peak height ratios for the standard curve noted at four different runs was 0.047), new standard solutions were prepared every day that unknown samples were chromatographed.

Calculations—Samples of unknowns were chromatographed under the same conditions as the standards. The amount of moisture in the unknown was determined by computing the water–*n*-propanol peak height ratio from the chromatogram, obtaining the corresponding weight ratio from the standard curve, and multiplying by the weight of *n*-propanol. The value so obtained was then converted to percent moisture in the original drug sample.

Extraction Procedure—The procedure used to remove water from the crude drugs was a simple disintegration of the drug with anhydrous methanol in a Waring blender. This procedure has been utilized, with good quantitative results, in the extraction of water from a variety of food products (10, 11).

A 15-Gm. sample of the crude drug to be analyzed was transferred to a stainless steel Waring blender fitted with air-tight screw cap and threaded sampling plug. One hundred milliliters of anhydrous methanol and 3.00 ml. of *n*-propanol were added and

[2] Water and *n*-propanol were measured by volume and converted to weight using specific gravity calculations.

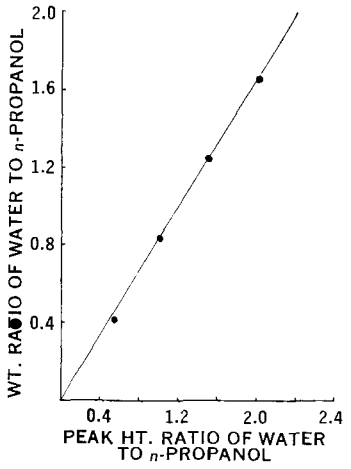

Fig. 1—Weight/peak height ratios relation of water to n-propanol.

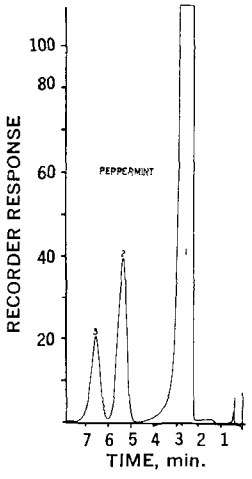

Fig. 2—Typical gas chromatogram of the methanol extract from crude drug (peppermint.) Key: 1, methanol; 2, n-propanol; 3, water.

the sample was disintegrated for 5 min. After blending, the mixture was allowed to settle for 1 min., a sample of the supernatant was transferred with a pipet into a 10-ml. vial, and 4 μl. was injected with a Hamilton microliter syringe into the gas chromatograph.

RESULTS AND DISCUSSION

Water exhibits tailing during elution, particularly on nonpolar liquid phases or on those of intermediate polarity, and on solid supports with appreciable adsorptive properties (14). The separation and quantitative analysis of water has been markedly improved by the use of highly polar liquid phases and inert supports of fluorinated hydrocarbon polymers. Recent work on the analysis of various aqueous systems (5, 8, 10, 11) has shown that the use of columns of Teflon powder coated with 5–20% PEG produced water peaks with greatly reduced tailing and low retention time. The chromatographic column used in this work was Teflon-6 powder coated with 10% PEG 1500. It afforded good resolution and symmetrical peaks. In addition, the retention time of water was low; this allowed its rapid analysis in the extracts. Peak heights were used in the calculation, since standard operating conditions could be well reproduced,

TABLE I—PERCENT MOISTURE IN CRUDE DRUGS AS DETERMINED BY OVEN DRYING (OD), TOLUENE DISTILLATION (TD), AND GAS–LIQUID CHROMATOGRAPHY (GLC) METHODS

Crude Drug	OD[a]	TD[a]	GLC[b]
Agar	15.13	14.00	14.72
Aloe (Cape)	5.00	4.00	5.47
Belladonna root	6.66	6.32	6.43
Cascara sagrada	7.09	6.32	7.11
Colchicum corm	6.22	6.63	5.74
Powdered digitalis (*D. purpurea*)	4.21	4.00	3.89
D. purpurea leaf	5.80	5.49	5.92
D. lanata leaf	7.01	6.00	7.07
Ergot	5.64	5.03	5.55
Gentian	6.07	5.99	6.08
Glycyrrhiza	7.49	6.32	6.87
Starch (corn)	8.69	8.66	9.00
Cinnamon	6.56	6.65	7.38
Clove	5.42	5.44	4.60
Ginger	6.84	6.50	5.95
Peppermint	7.12	6.74	6.91

[a] The values are the average of two determinations each. [b] The results are the means of five chromatographic injections, representing two or more extractions of each crude drug sample.

TABLE II—REPRODUCIBILITY OF GLC PROCEDURE[a]

	% Moisture	
	3-min. Blending	5-min. Blending
Cascara sagrada	6.91, 6.99	6.99, 7.23
D. purpurea leaf	5.78, 5.95	5.78, 6.08
Ergot	5.47, 5.79	5.47, 5.63
Gentian	5.95, 6.11	6.08, 6.08
Starch (corn)	9.08, 9.32	8.92, 9.08

[a] Each value recorded represents the mean of five chromatographic injections from an extract of the crude drug.

the peaks were sharp and symmetrical, and the half-peak widths of water and the standard were essentially equal. A typical chromatogram of the methanol extract from peppermint appears in Fig. 2.

The moisture content of the crude drugs analyzed by gas–liquid chromatography are given in Table I. The results are compared with those obtained by oven drying at 105° and toluene distillation methods. The values obtained with the gas–liquid chromatographic procedure in each case are quantitatively in accord with the values given by the other two methods. The reproducibility of the chromatographic analysis is satisfactory. The maximum standard deviation found was 0.36. The reproducibility of the method for five crude drugs can be readily seen from an examination of the figures shown in Table II.

In preparing the extracts for chromatographic analysis, the crude drugs were disintegrated with anhydrous methanol in a Waring blender for 5 min. Although it seemed that 3 min. of blending were adequate (Table II), the drugs were disintegrated for 5 min. to insure the complete extraction of their water content. The results show that the increased blending time did not increase the values for moisture content. While the gas–liquid chromatographic method furnishes a reliable value for water extractable by methanol, there is a good reason to believe that this water consists of all but that which is chemically combined with the sample of the crude drug (9). This chemically combined water represents a negligible amount of the total moisture present in the drug.

It was possible in this work to evaluate some of the technical problems encountered with each of the three methods. Where it is certain that the loss on drying of a drug is actually water, moisture determination by oven drying is a fairly quantitative procedure. Since a large number of vegetable drugs contain variable amounts of volatile substances other than water, oven drying is not generally applicable except for rough estimations, and the toluene method is to be preferred. However, some disadvantages are also inherent in the toluene distillation method. Moisture determination by this method requires considerable care and attention during operation, particularly when frothing or similar difficulties occur; previous cleaning of the condenser and collecting tubes with dichromate–sulfuric acid solutions does not always prevent the collection of droplets of water on the internal surface, particularly if the material contains traces of volatile fatty acids. Moreover, large amounts of a drug, in some cases more than 50 Gm., must be used, and the direct use of a solvent like toluene without dispersion of the material may fail to obtain the release of all the moisture from the crude drug, a fact which was especially noticeable in this work in the case of aloe. Gas–liquid chromatography, on the other hand, is simple, requires a relatively small sample size, has very good precision, and is more selective than oven drying or toluene distillation methods. When the speed of the three methods is compared, it is found that the chromatographic method is much more rapid. Once the standard curve has been prepared, a determination by gas–liquid chromatography can be completed in a maximum of 15–20 min. Oven drying requires more than 5 hr. for drugs containing no volatile constituents and more than 48 hr. for drugs containing ether-soluble constituents which volatilize at the oven temperature used, while a determination by toluene distillation takes from 3–4 hr.

When all these factors are considered, it can be readily seen that the new chromatographic method is distinctly superior. It surpasses oven drying and toluene distillation in many ways and should be easily adaptable to moisture estimation in a variety of crude drugs and similar natural products.

Percutaneous Toxicity of Pyridinethiones in a Dimethylsulfoxide Vehicle

By WELLON D. COLLOM and CHARLES L. WINEK

The percutaneous toxicity of three salts of pyridinethione in water and dimethylsulfoxide is described. Sodium and zinc pyridinethione penetrated the skin of rabbits when applied in a dimethylsulfoxide vehicle and caused hind quarter paralysis. Cadmium pyridinethione did not penetrate the skin in amounts comparable to the other two salts regardless of the vehicle.

THE SALTS of 1-hydroxypyridine-2-thiol have been shown to be effective antifungal and antibacterial agents. The zinc salt (ZnPT) is in current use as an antidandruff agent. Snyder *et al.* (1) have reported on the toxicity of ZnPT in a shampoo base and found no percutaneous effects in rabbits. The sodium salt (NaPT) was shown to penetrate the skin of rabbits causing hind quarter paralysis. Winek and Buehler (2) reported on the intravenous toxicity of the pyridinethiones. Following the recent usage of dimethylsulfoxide (DMSO) by Jacob *et al.* (3, 4) and others as a topical drug for arthritic conditions, considerable work on the enhancement of percutaneous absorption of various compounds by DMSO has been reported. Kligman (5) studied the percutaneous absorption of a large number of different types of compounds in different concentrations of DMSO and other solvents. With most, he found absorption greatly enhanced over other solvents.

The present study concerns the effects of the sodium, zinc, and cadmium salts of pyridinethione in a DMSO vehicle after application to the skin of rabbits.

MATERIALS AND METHODS

Albino rabbits of both sexes with a weight range of 2 to 3 Kg. were used in the study.

Nuded areas on the backs of rabbits, each approximately 100 sq. cm. in size, were dosed for 14 consecutive days. The material was applied using a dermal applicator. Some concentration occurred at the hairline edging the nuded area. The rabbits were fitted with the Newmann (6) restraining harnesses. A commercial depilatory was used to denude the skin. The dose levels were 300 mg./Kg. with sodium-1-hydroxypyridine-2-thiol (NaPT) as a 10% solution in either water or DMSO, 400 mg./Kg. of cadmium-1-hydroxypyridine-2-thiol (CdPT) as a 20% suspension in a 2% solution of methylcellulose[1] in either water or DMSO, and 400 mg./Kg. of zinc-1-hydroxypyridine-2-thiol (ZnPT) as a 10% suspension in a 2% solution of methylcellulose in either water or DMSO. The difference in dose is based on preliminary data concerning toxicity. The number of animals treated is indicated in the tables. A water control without PT salt and two DMSO control animals without PT salt were used for each group.

The pyridinethione salts used were technical, new drug grade obtained from the R. T. Vanderbilt Co. The dimethylsulfoxide was a technical grade obtained from Fisher Scientific. The animals were individually housed with food and water *ad libitum*. Both abraded and nonabraded skin were studied. The head of a small animal clipper was used to abrade the skin.

Animals were observed during the dosing period and for 1 week after treatment. Incoordination, paralysis, and death were the major points of observation. Minor points of observation were diarrhea, weight, and effects on the eyes of the animals.

RESULTS

Results are summarized in Table I; observations on individual animals are presented in Tables II–V. All animals treated with NaPT in DMSO showed signs of incoordination[2] by day 3, while those treated with aqueous NaPT showed these signs on day 5. The NaPT–DMSO treated animals were unable to rise[2] by the sixth day while the two NaPT–water treated animals were unable to rise on the sixth and eighth days, respectively. Seventy percent of the animals dosed with NaPT–DMSO showed sluggish pupillary response by the fourth day and 80% developed diarrhea by the third day. One animal treated with NaPT–water developed a sluggish pupillary response on day 11 and had cloudy drainage of the eye on day 12; it also developed diarrhea.

The animals treated with NaPT–DMSO all died by day 7 with a mean value of 4.3 days, while the two animals treated with NaPT–water died on day 8 and day 13, respectively.

One animal treated with CdPT–water and two treated with CdPT–DMSO showed changes. The remainder of the animals were grossly comparable with the water control. One treated with CdPT–water was unable to rise and showed weight loss. One treated with CdPT–DMSO developed incoordination and weight loss, while the other on the same treatment showed only weight loss.

The animals which were treated with Zn PT–DMSO all developed incoordination from day 2 to day 7, and were unable to rise from times beginning between day 8 and day 13. Twelve animals developed eye drainage, three developed sluggish pupillary responses, and two developed corneal opacities. Thirteen animals died between days 9 and 17. This represents 72% of the animals on this treatment. The other three were sacrificed after 21 days, when they appeared to be recovering. Of the animals dosed with ZnPT–water two died, one on day 2 and one on day 9. These two also developed eye diffi-

culties; both had drainage and one developed corneal opacity. Weight change data varied, ranging from the loss of 1035 Gm. to a gain of 360 Gm. The two deaths represent 29% of the animals treated. Figure 1 shows the hind limb paralysis produced by treatment and Fig. 2 shows a control animal.

Lung necrosis was present in seven of the 12 animals which died after dosing with NaPT, and in 14 of the 17 which died after ZnPT treatment.

The control animals which were dosed with DMSO–methylcellulose did not develop any of the outward signs of intoxication, and gained from 30 Gm. to 445 Gm. during the course of the dosing. None of the animals developed corneal opacities or irritations of the eye.

Fig. 1—Hind limb paralysis produced by treatment with ZnPT in DMSO. Animal is in a Newmann harness.

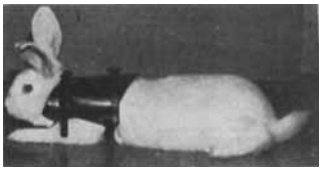

Fig. 2—Control animal in Newmann harness.

All of the animals treated with a pyridinethione salt, either in DMSO or water, showed skin irritation at the site of application which cleared when the treatment was terminated.

DISCUSSION

Dimethylsulfoxide apparently aided in the penetration of both NaPT and ZnPT in comparison with water. The sodium salt readily penetrated the skin when applied in an aqueous solution, but when applied in DMSO, the onset of toxic signs was earlier and paralysis and death resulted earlier in the treatment regimen. The animals all lost weight which is attributed to their inability to eat because of the hind quarter paralysis.

In the ZnPT treated group, DMSO apparently facilitated percutaneous absorption with the production of toxic signs and, in most cases, death. ZnPT in water did not produce paralysis or death except in two cases where the animals were observed to lick applied material from the sides of their cages. A precaution that must be taken in percutaneous studies is to avoid the transfer of applied material from the backs of animals to the sides of the cages. If this occurs, the study becomes an oral ingestion study and not a percutaneous study. In all other cases the material remained on the backs of the animals and was not observed on the sides of the cages. Adequate-size cages can prevent the transfer in most cases.

DMSO apparently did not aid the penetration of CdPT. The present study indicates an apparent lack of penetration regardless of the vehicle. As indicated in Table III, two animals developed toxic signs and lost weight, but recovered completely when treatment ended. All animals were comparable with the water control grossly, except for the animal treated with CdPT in an aqueous vehicle. This animal had lost considerable weight, but returned to normal weight within 1 week after treatment ended. Whether or not the skin was abraded apparently had no effect on penetration. Further study of CdPT in DMSO and aqueous vehicles is planned to gain evidence for the lack of penetration of this salt.

The concurrent use by the public of DMSO and other drugs, cosmetics, and soap products can be a potential hazard, as this study and others indicate. Substances that do not penetrate the skin and have been shown to be safe may become hazardous if applied concurrently with DMSO. This may be the strongest indication for restrictions on the use of DMSO regardless of the safety of DMSO itself.

As a continuation of this study and in an attempt to explain the difference in penetration between the two insoluble salts, ZnPT and CdPT, when applied in DMSO, an analytical method for the analysis of pyridinethione in tissues is in progress. A possible explanation for the difference in penetration is that Cd^{2+} is known to have a higher affinity for sulfur in the lower oxidation states, *i.e.*, S^{2-}, while Zn^{2+} does not show so great an affinity. This might cause a stronger complex with hydroxypyridinethione (PT) as compared with DMSO for Cd^{2+}, and the reverse of this for Zn^{2+}, thereby freeing the pyridinethione for penetration.

Biosynthesis of Ergot Alkaloids. Origin of the Oxygens of Chanoclavine-I and Elymoclavine

By H. G. FLOSS, H. GUENTHER*, D. GROEGER†, and D. ERGE†

The oxygen of the hydroxyl groups of chanoclavine-I and elymoclavine has been shown not to be derived from water. This indicates that these hydroxyl groups do not originate from the reaction of an allylic carbonium ion with water, but may be introduced by direct hydroxylation.

ERGOT ALKALOIDS are formed from tryptophan and mevalonic acid (1, 2). A hypothetical biogenetic scheme which accounts for the experimental results so far available has been proposed recently (Scheme I) (3). The formation of the tetracyclic ergoline skeleton, as well as many of the known alkaloid interconversions, involves a number of oxidative cyclizations and hydroxylations. As pointed out by Agurell *et al.* (4), most of these reactions can be accounted for by oxidations at positions allylic to the exocyclic double bond. Very little experimental evidence about the mechanism of these oxidations is, however, available. Ramstad, Taylor, and their co-workers (5) have shown that the conversion of agroclavine to setoclavines and of elymoclavine to penniclavines can be brought about by horseradish peroxidase in the presence of hydrogen peroxide. This oxidation was

Hypothetical Scheme of Ergot Alkaloid Formation

Scheme I

shown to involve an initial attack at position 10 and rearrangement of the product to give the 8-hydroxylated compound (5). It is also known that these conversions cannot only be carried out by the ergot fungus but also by a whole variety of other organisms (6–10). However, agroclavine was not converted to elymoclavine by either the peroxidase system or by the organisms that do not produce ergot alkaloids. These findings suggest that the mechanism of 8-hydroxylation differs from that of the other oxidations involved in ergot alkaloid formation.

It seems to be a reasonable assumption that the oxidative cyclizations involve formation of allylic carbonium ions as the reactive species. Evidence for this, for instance, is the fact that the hydroxymethyl group of chanoclavine-I reacts with the amino nitrogen to form ring D (11, 3). Several mechanisms can, however, be discussed for the formation of these carbonium ions. The above-mentioned conversion of chanoclavine-I to agroclavine would suggest that initially a hydroxyl group is introduced at an allylic position, followed by phosphorylation and phosphate elimination. In this case the oxygen of the hydroxyl groups would originate from molecular oxygen. It has, however, not been assessed with certainty that chanoclavine-I is a natural intermediate in ergot alkaloid formation. It may only be in equilibrium with an intermediate, the corresponding allylic carbonium ion. In this case, the latter could be formed by hydride abstraction from the allylic position. Reaction of the carbonium ion with the nitrogen would lead to agroclavine, whereas its reaction with water would lead to chanoclavine-I. The oxygen of the hydroxyl group would then originate from the oxygen of the water. The same considerations hold for the formation of elymoclavine from agroclavine, except that cyclization is not possible here.

In order to distinguish between these possibilities the authors have conducted experiments in ^{18}O enriched water and determined the incorporation of ^{18}O into chanoclavine-I and elymoclavine.

METHODS

Claviceps strain SD-58 was grown for 3 days in the medium given previously (12). The mycelium from three 100-ml. shake cultures was then transferred under sterile conditions into a flask containing 110 ml. of the same medium made up with water containing about 1.3% excess ^{18}O. After 14 days of fermentation the culture was harvested and found to contain 40 mg. of alkaloid. The culture filtrate was lyophilized to recover the ^{18}O water for analysis. The residue was dissolved in normal water, and elymoclavine was isolated and purified from this solution (12).

Two fermentations were carried out to produce chanoclavine-I using *Claviceps paspalum* strain Li 342/SE 156. The fungus was grown for 8 days in medium NL 563 (13). In the first experiment the mycelium was then transferred to a 500-ml. flask containing 100 ml. of the following medium (NL 619), made up with water containing about 0.6% excess ^{18}O: ammonium succinate, 3 Gm.; sorbitol, 5 Gm.; propylene glycol, 2 ml.; KH_2PO_4, 0.1 Gm.; $MgSO_4$, 0.03 Gm.; water to 100 ml.; pH adjusted to 5.4 with HCl. After 5 days of fermentation in this medium the alkaloid yield was 44.6 mg. In the second experiment the my-

TABLE I—INCORPORATION OF ^{18}O FROM $H_2{}^{18}O$ INTO ELYMOCLAVINE AND CHANOCLAVINE-I BY *Claviceps*

Claviceps Strain Used	Alkaloid Isolated	Atom % ^{18}O Excess in Water of Medium	Atom % ^{18}O Excess in Isolated Alkaloid	Atoms of Oxygen Incorporated
SD 58	Elymoclavine	1.111	0.006	0.005
Li 342/SE 156	Chanoclavine-I	0.496	0	0
Li 342/SE 156	Chanoclavine-I	3.397	0.021	0.006

celium was transferred to two 500-ml. flasks each containing 50 ml. of NL 500 (13) made up with water containing about 3.5% ^{18}O excess. After 7 days of fermentation the alkaloid yield was 65 mg. In both experiments an aliquot of the culture filtrate was distilled to recover water for ^{18}O analysis. From the remainder, chanoclavine-I was isolated as described previously (13).

^{18}O analyses were carried out by pyrolysis of the organic compounds at 650° in a sealed glass tube with break tip (14). For the analysis of water, naphthalene was added as a carbon source. The tubes were opened in a vacuum system connected to the inlet of an Atlas M 86 mass spectrometer. CO_2 was condensed with liquid nitrogen and the noncondensible gases were pumped off. The CO_2 was then introduced into the mass spectrometer and analyzed for its ^{18}O content. As a reference for the natural ^{18}O content, the same chemical compounds containing no ^{18}O excess were analyzed.

RESULTS AND DISCUSSION

The results given in Table I show that the incorporation of oxygen from water into the hydroxyl groups of both chanoclavine-I and elymoclavine is negligible. Since the ^{18}O enrichment of the water was determined after the fermentation, the possibility can be excluded that extensive dilution of the ^{18}O by oxygen of other components of the medium is responsible for this result. The oxygen of the hydroxyl groups of these two alkaloids must therefore originate from molecular oxygen. Attempts to confirm this directly in the case of elymoclavine have been made using *Claviceps* strain SD-58. However, on incubation under an artificial atmosphere containing ^{18}O enriched oxygen gas, the metabolism of the fungus changed drastically, resulting in a consistently low alkaloid production. Nevertheless, the conclusion seems to be valid that the introduction of the hydroxyl groups into these alkaloids does not involve reaction of OH^- with a carbonium ion generated by hydride abstraction from an allyl position. The results suggest that the oxidation reactions involved in ergot alkaloid formation occur by an initial hydroxylation, possibly by a mixed function oxygenase. In the case of the oxidative cyclizations, these hydroxylations may be followed by phosphorylation and phosphate elimination to generate the reactive carbonium ion.

New Alkaloid from *Lobelia portoricensis* Urban

By ESTEBAN NÚÑEZ MELÉNDEZ*, LUIS CARRERAS, and JOSÉ RUÍZ GIJÓN

A major alkaloid has been isolated from the leaves of *Lobelia portoricensis* Urban. Alkaloids are extracted with ether in alkaline ammoniacal solution, an average of 1.25 percent in the dried leaves. The crystalline alkaloid has a melting point of 115–116°, the hydrochloride, m.p. 187–188°, perchlorate, m.p. 156–158°, and the picrate, m.p. 175–176°. The new alkaloid showed the same sensitivity to reagents as lobeline. Paper chromatography, ascending process, was employed. Stationary phase consisted of formamide, ammonium formate, and formic acid; the mobile phase, equal parts of benzene and chloroform; R_f 75. Infrared absorption spectra showed a R—CO—aromatic organization and the presence of a —NH group; no CH_3 or OH group as in lobeline. The empirical formula is $C_{21}H_{23}NO_{23}$. The formula is shown in structure I. The new alkaloid was found to stimulate the respiratory center.

AMONG THE various members of the *Lobeliaceae* in Puerto Rico, there grows in the wet mountain forests a medium size handsome endemic plant, commonly named tupa and tibey tupa, the *Lobelia portoricensis* Urban, *Tupa portoricensis* Vatke or *Tupa assurgens* A.DC. (1).

The plant is described by Britton (2) and also in *Linnaea* (3) and by Stahl (4). A complete study of the anatomy and histology of the plant is being conducted by the author for publication.

Leaves were collected while the plants were blooming and dried in an air-drier at 45° and powdered in a ball grinder. The material was sifted through a No. 40 sieve.

The powdered material was extracted in a Soxhlet extractor using 200-Gm. samples each time. The material was macerated with a mixture of 4 vol. of strong ammonia T.S., 5 vol. of ethanol, 10 vol. of ether, and mixed well. It was extracted with ether

The formula is shown in structure I. The new alkaloid was found to stimulate the respiratory center.

AMONG THE various members of the *Lobeliaceae* in Puerto Rico, there grows in the wet mountain forests a medium size handsome endemic plant, commonly named tupa and tibey tupa, the *Lobelia portoricensis* Urban, *Tupa portoricensis* Vatke or *Tupa assurgens* A.DC. (1).

The plant is described by Britton (2) and also in *Linnaea* (3) and by Stahl (4). A complete study of the anatomy and histology of the plant is being conducted by the author for publication.

Leaves were collected while the plants were blooming and dried in an air-drier at 45° and powdered in a ball grinder. The material was sifted through a No. 40 sieve.

The powdered material was extracted in a Soxhlet extractor using 200-Gm. samples each time. The material was macerated with a mixture of 4 vol. of strong ammonia T.S., 5 vol. of ethanol, 10 vol. of ether, and mixed well. It was extracted with ether

* College of Pharmacy, University of Puerto Rico, Rio Piedras, PR 00931
The author expresses his appreciation to Dr. César González Gómez and to the research personnel and assistants for their valuable help, to Drs. Jesús Morcillo, Manuel Rico, and Apolo Gómez Morrillas, Instituto de Química-Física Rocasolano, to Dr. Antonio Hidalgo, Instituto de Optica Daza de Valdés, for their valuable work done in the infrared and nuclear magnetic resonance spectroscopic studies of the alkaloid discovered, and to S. B. Penick and Co., and Sandoz, S. A. for the powdered lobelia and the different alkaloids used in the present investigation.

until the ether in the Soxhlet became almost colorless and the last extractions gave a negative reaction with the usual alkaloidal reagents.

The liquid extract was evaporated on a water bath and the residue shaken with 50 ml. of ether and 150 ml. of 0.5 *N* sulfuric acid and evaporated again to remove the ether. The acid solution was filtered through a dry filter and the filtrate transferred to a separator. The residue was dissolved again in ether and 0.5 *N* sulfuric acid, shaken, and filtered. This procedure was repeated until a small portion of the last filtrate gave a negative test for alkaloids. Silicotungstic acid reagent was used.

The combined filtered portions in the separator were made slightly alkaline with ammonia T.S. and extracted with 40-ml. portions of ether.

The alkaloids present in the combined ether extracts were purified by the addition of 20-ml. portions of 0.5 *N* sulfuric acid, the separation of the aqueous layer, and extraction with ether in slightly alkaline solution.

The combined ether extracts were evaporated *in vacuo* at a temperature of 40° until the volume was markedly reduced. The temperature was changed to about 20° and the evaporation continued. Abundant crystallization was observed. The last liquid residue, about one-tenth the original volume, was also collected. The crystals in the flask were carefully washed with a small portion of ether and the washings added to the liquid residue collected. The crystals were dried *in vacuo* over phosphoric acid. The melting point of the dried crystalline alkaloidal base was 115–116°. The determination was repeated after the material was recrystallized.

Preparation of Various Alkaloidal Salts—Crystalline hydrochloride, picrate, and perchlorate were prepared and carefully purified, m.p. 187–188°, 175–176°, and 156–158°, respectively.

Quantitative Alkaloidal Determination—The quantitative determination of the alkaloids was performed using the principles of Lynch and Evers (5), who recommended a procedure involving their careful isolation and titration with 0.02 *N* sulfuric acid. The official method of the "Pharmacopoeia of Japan" (6) for lobelia using a Soxhlet extractor was followed. It was found that the leaves contain an average of 1.25% alkaloids.

Sensitivity of the New Alkaloid to Several Common Alkaloid Precipitating Reagents—Martello and Farnsworth (7) published a detailed study on the sensitivity of several common alkaloid precipitating reagents. Their observations included alkaloids of broad spectrum of the various groups.

Seven different alkaloidal reagents for the pyridine–piperidine group of alkaloids were selected for testing the new alkaloid. Five drops of the alkaloidal reagent was added to 1 ml. of a 1 mg. in 100 ml. aqueous solution of the alkaloid dissolved in tartaric acid solution. The amount and nature of the precipitate was observed. Mercuric chloride 1% solution gave a negative result. The rest of the reagents gave a positive reaction in the following order: phosphomolybdic acid reagent, only slightly positive reaction; picric acid, silicotungstic acid, Dragendorff, Mayer, and Wagner reagent.

The same reagents were respectively added to a 1-ml. solution of lobeline sulfate of the same concentration. The same results were obtained.

Chromatography—Several studies in chromatography with the lobelias and their alkaloids are reported in the literature. Steinegger and Ochsner determined the alkaloids in *Lobelia salicifolia* (8) and in *L. inflata* (9) using chromatographic procedures. They also described a method for the determination of lobeline in small quantities in alkaloidal extracts followed by spectrometric work (10). Schmidt and Steinegger (11) reported the separation of the alkaloids of *L. syphilitica* with the aid of paper and column chromatography. In 1959 Steinegger and Ochsner (12) reported new alkaloids in *L. salicifolia* also by means of paper chromatography.

Paper chromatography, ascending process, was employed for the separation of the alkaloids in the extract of *L. portoricensis*. Scheibler and Schull paper No. 204-B was used.

The stationary phase consisted of a solution of 9 vol. formamide saturated with ammonium formate, the excess salt precipitated with 20 vol. of acetone, and the mixture filtered and 1 vol. of formic acid added to the filtrate. The mobile phase best adapted for the resolution of the alkaloids consisted of a mixture of equal parts of benzene and chloroform.

Microburets with ether–formamide solution of the total alkaloidal extract of the leaves of *L. portoricensis*, crystals of the main alkaloid, and residue of the extract after the main alkaloid was separated were used.

A run of about 6 hr. in the solution at a room temperature of 24° sufficed. Then it was placed in the drying oven at a temperature of about 85° for about 1 hr.; it was then examined with ultraviolet light. Alkaloidal spots were clearly seen. Dragendorff reagent with Muniere's modification (13) was used for the development of the chromatogram. Orange-colored precipitates were obtained.

In the first column where the total alkaloidal extract was placed, good resolution of the alkaloids was obtained. A distinct spot of the main alkaloid was observed in the upper part away from the rest of the alkaloids. Six other small size spots were observed.

In the second column where the main alkaloid was placed, a large spot was observed just at the same level as the main spot in the upper part of the first column. Both spots consisted of the same alkaloid. Repeated procedures revealed an R_f of 75.

In the third column, where the rest of the alkaloidal extracts were placed, successive spots were observed at the same level as those of the total alkaloidal extract. No spot was observed in the upper part of the paper in this case, a confirmation that the main alkaloid was already separated and observed in the second column.

Chromatographic studies were conducted under the same conditions with the total alkaloidal extract of *L. inflata*, lobeline alkaloid, lobelanine, lobelanidine, lobelidine, and the total alkaloids of *L. portoricensis*.

Upon examination of the chromatogram of these alkaloidal materials, it was observed that none of the alkaloidal spots were located in a position near or at the same level as the main alkaloid of *L. portoricensis*. Their R_f's were less than 50.

Preliminary Chemical Tests—Chemical tests were

performed with the new alkaloid and with lobeline to test for the formation of acetophenone in alkaline solution. Nitroprussate 5% solution and glacial acetic acid were employed. A positive reaction was obtained; it suggested a lobeline type of alkaloid.

The presence of a carbonyl nucleus was confirmed by the formation of an oxime, which was prepared with various mg. amounts of the crystalline alkaloid. The crystalline compound obtained has a melting point of 237°.

Spectrometric Studies—Infrared absorption spectra analysis was conducted with the pure alkaloid using also pure lobeline for comparison (Fig. 1.). A Perkin-Elmer infrared instrument, model 125, was employed as well as a Perkin-Elmer nuclear magnetic resonance, 60 Mc. apparatus.

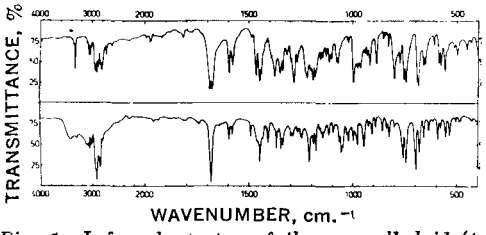

Fig. 1—Infrared spectra of the new alkaloid (top) and lobeline (bottom).

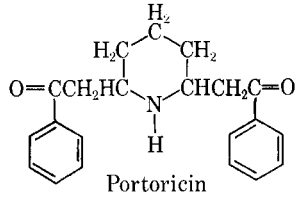
The spectra showed the presence of benzene rings at 1601, 1587, 1495, and 1452 cm.$^{-1}$ confirmed by the presence of small bands at 3085 and 3005 cm.$^{-1}$.

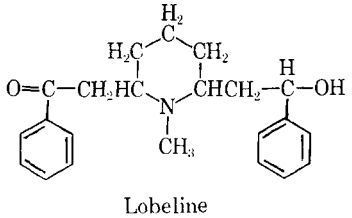
The band at 1690 cm.$^{-1}$ showed valence vibration of —CO groups, in R—CO—Ar organization. The band at 3260 cm.$^{-1}$ is due to the presence of a —NH group. No CH_3 group as in lobeline was indicated nor any —OH group. The suggested empirical formula for the new alkaloid of *L. portoricensis* is $C_{21}H_{23}NO_2$.

The formula suggested is shown in structure I and for lobeline in II.



Portoricin

I



Lobeline

II

Pharmacologic Studies—Though lobelia was introduced into medicine as an emetic by the Rev. Mannasse Gutler in 1775, the first important pharmacologic work was done by Von Ott in 1875. The separation of the alkaloids was done by Heinrich Wieland and Mayer in 1922 (13). Alpha lobeline, lobelidine, and the base B were found. It was determined that α-lobeline has a marked effect on the respiration and at the same time is free from the emetic action which characterizes the administration of the crude lobelia preparations.

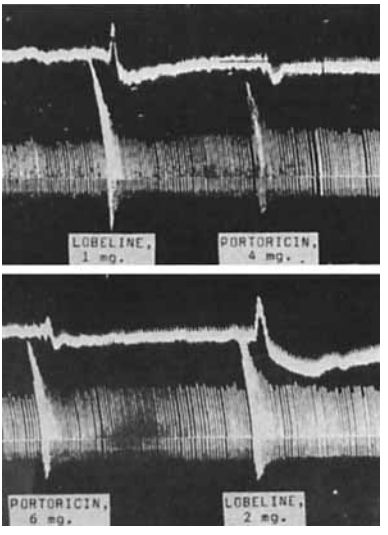


Fig. 2—Action of the new alkaloid on the respiration and blood pressure in dogs.

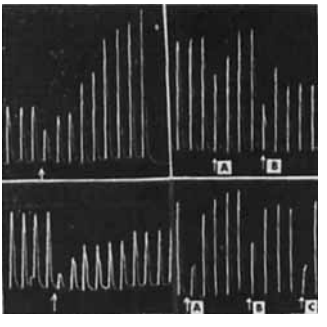

Fig. 3—Action on parasympathetic nervous system of the guinea pig intestine. Contractions with acetylcholine, 0.4 ml. solution, 2:1,000 each, 4 min. Top left: 0.8 mg. portoricin. Top r ght: A, *0.4 mg. lobeline;* B, *0.2 mg. portoricin. Bottom left: 0.8 mg. lobeline. Bottom right:* A, *0.002 mg. atropine sulfate;* B, *0.200 mg. portoricin:* C, *0.001 mg. atropine sulfate.*

Action of the New Alkaloid on the Respiration and Blood Pressure in the Dog—Dogs were anesthetized with pentobarbital using 50 mg./Kg. intravenously and the animal positioned for respiration and blood pressure records. Twenty milligrams of the alkaloid was dissolved in 20 ml. of distilled water with the aid of an equivalent quantity of tartaric acid. Different doses were injected intravenously. A solution of lobeline of the same concentration was prepared and injected periodically to compare the action in the anesthetized dog.

It was clearly shown that the alkaloid stimulates the respiratory center, though the effect is not so marked as with the same concentration of lobeline.

However, the effect in lowering the blood pressure was very slightly demonstrated. (Fig. 2.)

Action in the Cat—Cats were anesthetized with chloralose, 150 mg./Kg. Respiration and arterial pressure were recorded when the alkaloidal solution was injected through the femoral vein. Intravenous injection of the alkaloid stimulates the respiration, though not so marked as when administered to dogs. The action is stronger in the case of lobeline.

Action on the Isolated Intestine of the Guinea Pig—It was demonstrated that the alkaloid blocks the action of acetylcholine in a way similar to atropine, though in a lesser degree, approximately 1/200. Lobeline exerts less activity than the alkaloid (Fig. 3).

Action on the Isolated Intestine of the Rabbit—Trendelenburg technique was employed. When 30 mcg. of the alkaloid was used, inhibition of intestinal motility was observed. With an increased dosage of 100 mcg., the effects were stronger and persisted even after several washings.

Action on the Bronchi of the Isolated Lungs of the Guinea Pig—Konsett technique on the isolated lungs of the guinea pig was used, except that for the registration of the bronchial tonus a water manometer was employed instead of the Piston-Rekorder. Part of the experiments were done on the opened thorax and the rest on the intact organ. Results did not vary, especially when the animal received adequate anesthesia. The experiment was repeated many times.

Results showed that neither the alkaloid nor lobeline inhibited the bronchiospasms produced by the intravenous injection of 12.5 and 25 mcg. of histamine. These effects were neutralized by some synthetic antihistaminics in low concentration.

LD_{50} Determination—White mice in sets of six were used, each of uniform size and weighing 20 to 25 Gm. The determination was carefully performed. The LD_{50} was found to be 95 mg.

SUMMARY

A major alkaloid has been isolated from the leaves of *Lobelia portoricensis* Urban, an endemic woody plant of the wet mountain forests of Puerto Rico.

The alkaloids are extracted with ether in an alkaline ammoniacal medium, an average of 1.25% in the dried leaves. The main alkaloid is separated in monoclinic prisms upon the partial vacuum evaporation of the ether extract at low temperature. The crystalline alkaloid has a melting point of 115–116°. The crystalline hydrochloride has a m.p. of 187–188°; the crystalline alkaloidal perchlorate, m.p. of 156–158°, and the crystalline alkaloidal picrate, m.p. of 175–176°.

The new alkaloid exhibits the same sensitivity as lobeline to the alkaloidal reagents applied to the alkaloids with a pyridine or piperidine structure. This alkaloid was used to compare results and showed the same degree of sensitivity as the new alkaloid in the following order: Wagner, Mayer, Dragendorff, silicotungstic acid, picric acid, and phosphomolybdic acid reagents.

The new alkaloid is separated with paper chromatography, ascending process, using a liquid phase which consisted of formamide, ammonium formate, and formic acid. The mobile phase consisted of a mixture of equal parts of benzene and chloroform. The alkaloid separates in the uppermost portion with an R_f of 75 and quite far from the next six visible much smaller spots.

Infrared absorption spectra showed the presence of benzene rings, a carbonyl structure in a R—CO— aromatic organization, and the presence of a —NH group. No CH_3 or OH group as in lobeline is indicated.

The name portoricin is suggested for the new alkaloid. The suggested empirical formula is $C_{21}H_{23}NO_2$ and the developed formula is shown in structure I.

It stimulates the respiratory center in various animals, particularly in the dog, though the effect is not so marked as with lobeline in the same concentration. However, it has only a very slight effect in lowering the blood pressure.

It inhibits the action of acetylcholine on the isolated intestine of the guinea pig and the rabbit.

Neither the new alkaloid nor lobeline inhibited the bronchiospasms produced by the intravenous injections of small amounts of histamine.

The LD_{50} was determined with white mice and was found to be 95 mg.

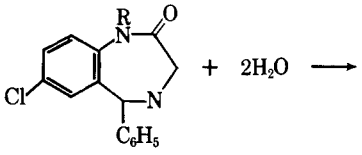
Stability Assay for Prazepam and Related Drugs

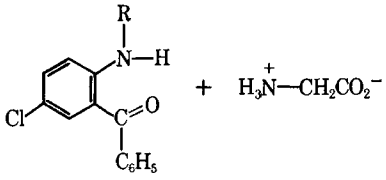
By LESTER CHAFETZ and CHARLES A. GAGLIA, JR.*

The observation that a pronounced difference in spectra of prazepam and its hydrolysis products can be produced by protonation was exploited in the development of an ultraviolet spectrometric stability assay for the drug in tablet and capsule dosage forms. The modified spectrophotometric assay provides sensitivity equivalent to that of a polarographic assay, and its precision and convenience are superior. The procedure applies equally to diazepam dosage forms.

PRAZEPAM (1) is a new psychotropic drug structurally related to diazepam. The compounds differ chemically in the alkyl substituent at the 1-position of the diazepin ring, and their analytical chemistry is closely similar. The only route of degradation observed with these benzodiazepine drugs has been hydrolysis to a benzophenone derivative and glycine. The reaction is illustrated below, where I is prazepam when R is cyclopropylmethyl; diazepam when R is methyl. A suitable assay for use in stability studies should thus discriminate between I and the 2-alkylamino-5-chlorobenzophenone (II).



I



II

Oelschläger, Volke, and Kurek (2) reported that diazepam and its hydrolysis products exhibit closely similar ultraviolet spectra in methanol solution, with absorption maxima at 230 mμ and 236 mμ, respectively, and similar absorptivities. On the basis of this limitation, they developed an oscillographic polarographic determination for the drug in the presence of its degradation products. Polarographic methods have also been reported for diazepam by Senkowski *et al.* (3) and Cimbura and Gupta (4).

Examination of the spectra of prazepam and its benzophenone hydrolysis product showed that one could measure the latter selectively in methanol solution at 408 mμ in the violet; however, it was deemed preferable to combine the stability determination with a content assay by measuring the intact drug instead of the decomposition product. Use of the 365 mμ absorbance maximum in acid–methanol was found to provide a direct measure of unhydrolyzed prazepam in dosage forms. The method was compared with conventional polarography and found to be superior in precision and convenience.

Received June 29, 1967, from the Pharmaceutical Research and Development Laboratories, Warner-Lambert Research Institute, Morris Plains, NJ 07950

Accepted for publication August 10, 1967.

The authors are grateful to F. H. McMillan for preparation of 2-cyclopropylmethylamino-5-chlorobenzophenone and to Allen I. Kay for providing the data used in Table II.

* Present address: Picatinny Arsenal, Dover, NJ 07801

EXPERIMENTAL

Equipment and Supplies—A Beckman DU spectrophotometer and a Beckman DK-2 recording instrument were employed with 1-cm. silica cells. A Sargent model XXI polarograph equipped with a dropping mercury electrode (DME) and a saturated calomel reference electrode (SCE) was used with the variable instrumental parameters set as follows: span, −1.0 v.; percent EMF applied, 0–50; initial, −0.6 v.; DME (−); d.c. EMF, 1.5 v. span; initial EMF, additive; sensitivity, 0.010 μamp./mm.; drop rate, 1/3–4 sec. damping, off. $E_{1/2}$-values and diffusion currents were determined by the method described by Meites (5).

A 4.08% potassium biphthalate solution was used as buffer, polysorbate 80[1] as maximum suppressor, and 2 *M* potassium chloride as the supporting electrolyte in the polarographic work. Methanol and a mixture of 3 vol. of absolute methanol diluted to 100 vol. with concentrated sulfuric acid (acid–methanol reagent) were the spectrophotometric solvents.

Spectrometric Procedure—Accurately weigh a sample corresponding to about 5 mg. of prazepam into a 100-ml. volumetric flask. Add about 50 ml. of acid–methanol reagent, mix, and dilute to the mark with acid–methanol. Filter the mixture, and determine the absorbance at the maximum, about 365 mμ. Concomitantly determine the absorbance of a dilution of reference prazepam containing about 5 mg./100 ml., accurately known, in the same solvent and at the same wavelength. Designating the absorbance of the sample A_u, the absorbance of the standard, A_s, and the concentration of the standard in mg./100.0 ml. as *C:*

$$\text{prazepam, mg./cap. (tab.)} = A_u/A_s \times C \times \frac{\text{mg. av. cap. (tab.) wt.}}{\text{mg. sample wt.}}$$

Polarographic Method—Accurately weigh an amount of sample equivalent to about 5 mg. of prazepam in a 100-ml. volumetric flask. Add exactly 20.0 ml. of absolute methanol and shake the flask mechanically for 30 min. Add exactly 25.0 ml. of biphthalate, 1 drop of polysorbate 80, and 5.0 ml. of 2 *M* potassium chloride, and dilute the solution to the mark with distilled water. Filter the mixture through paper, discarding the first 10–15 ml. of filtrate. Rinse the polarographic cell with portions of filtrate three times, then fill the cell and deaerate with nitrogen. Insert the DME, passing nitrogen over the surface of the solution, and

[1] Marketed as Tween 80 by Atlas Chemical Industries, Wilmington, Del.

allow the cell to equilibrate 3 min. Record the polarogram. Prazepam exhibits an $E^1/_2$ of −0.83 to −0.84 v.; the $E^1/_2$ of the decomposition product is about −0.94 v.

Accurately weigh about 100 mg. of reference standard prazepam into a 100-ml. volumetric flask, add 50–60 ml. of absolute methanol, shake the mixture to dissolve the drug, and dilute to the mark with methanol. Pipet 4.0-ml. and 6.0-ml. volumes of the standard into appropriately labeled 100-ml. volumetric flasks, add 16.0 ml. and 14.0 ml. of absolute methanol to the two flasks to bring the volume in each to 20 ml., and proceed as described above for the sample, omitting filtration. Designate the concentration of the standard solution in mg./100 ml. as C, and perform the calculation using both values of C. Designating the diffusion current value of the sample as i_u and the diffusion current of the standard, i_s:

$$\text{prazepam, mg./cap. (tab.)} = C \times i_u/i_s \times \frac{\text{mg. av. cap. (tab.) wt.}}{\text{mg. sample wt.}}$$

RESULTS AND DISCUSSION

Validity of the Spectral Method—Ultraviolet spectral data obtained in methanol and in acid–methanol for prazepam, diazepam, and 2-cyclopropylmethylamino-5-chlorobenzophenone are displayed in Table I. Measurement of the absorbance at 365 mμ in acid–methanol provides a close approximation of the concentration of intact prazepam (or diazepam), since the hydrolysis product has less than 5% its absorptivity. A concomitant of the use of this wavelength is relative freedom from interference by dosage form excipients or many other drugs. The absorbance of prazepam solutions in the acid–methanol solvent was found to be stable for at least 2 hr. This is consistent with the observation of Cimbura and Gupta (4) on the relative stability of diazepam in acid solution. No degradation of prazepam was apparent by either the spectrometric or polarographic techniques in dosage forms stored up to 35 months at room temperature. In order to assess the validity of the method with degraded samples, mixtures of prazepam and molar equivalents of its degradation product were prepared to simulate various degrees of hydrolysis, and the mixtures were assayed for intact prazepam by spectrometry in acid–methanol. The results are presented in Table II.

TABLE I—ULTRAVIOLET SPECTRAL DATA FOR PRAZEPAM, DIAZEPAM, AND 2-CYCLOPROPYLMETHYLAMINO-5-CHLOROBENZOPHENONE

Compd.	λmax., mμ	ε, L./mole cm.	a, L./Gm. cm.
In Methanol			
Prazepam	227	33,350	102.5

[a] Normalized to a concentration of 5.0 mg./100.0 ml.

SUMMARY

A simple spectrophotometric assay for the stability assessment of prazepam dosage forms has been described which uses the absorption maximum at 365 mμ of the protonated form of the drug. Recovery and precision data indicate the validity of the method in routine stability testing of prazepam formulations, and the superiority of the procedure to polarographic assay has been demonstrated. The method would be expected to be equally applicable to diazepam dosage forms because of the close structural relationship of the drugs.

New Compounds: *N*-Arylglyoxylohydroxamyl Derivatives of Nitrogen Mustard

By JOSEPH P. LAROCCA and COY AVERY GIBSON

The synthesis and physical properties of some *N,N*-bis(2-chloroethyl)arylglyoxylohydroxamamides are described.

COMPOUNDS having antineoplastic activity have been classified in the following types (1, 2): alkylating agents, antimetabolites, hormones and steroids, antibiotics, and miscellaneous. Of these types, the alkylating agents and the antimetabolites are represented by the greatest number of clinically useful antineoplastic drugs. The common alkylating agents are derivatives of bis(2-chloroethyl)-amine (nitrogen mustard), ethylenimines, methane sulfonates, and epoxides. These compounds react spontaneously with electron-rich centers of biologically important material. The first alkylating agent to be used was methyl bis(2-chloroethyl)amine which was also the first drug to be used systemically against cancer (2). Its high toxicity led to the development of other nitrogen mustards (1) of the general type, $R—N(CH_2CH_2Cl)_2$, in an effort to reduce the toxicity. In many cases the nitrogen mustard has been attached to a "carrier moiety" in an effort to permit the nitrogen mustard to be more specific or localized in its effect (3). Recently, the work of Popp (4, 5), Wiley and Irick (6), and Sen and Shirley (7) has shown that less toxic and more effective compounds can be developed through this concept. This "carrier moiety" theory led to the synthesis and testing of benzimidazole, quinacrine, chloroquine, and amino acid mustards (3).

The synthesis and reduction of various arylglyoxylohydroxamides and chlorides have been studied (8). The unreduced chlorides have slight antineoplastic activity (9) probably due to the chemical reactivity of the chlorine (10) resulting in a monoalkylating-like action.

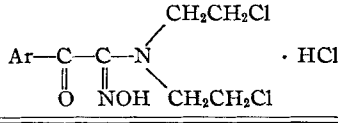
EXPERIMENTAL

Preparation of Intermediates—*Arylglyoxylohydroxyamyl Chlorides*—These compounds were prepared by previously described procedures (8, 10).

Bis(2-chloroethyl)amine—Bis(2-chloroethyl)amine hydrochloride was prepared according to the method of Ward (11). The free amine was obtained by the method employed by Friedmann and Seligman (12).

Synthesis of Arylglyoxylohydroxamamides—A solution of 0.04 mole of arylglyoxylohydroxamyl chloride in 50 ml. of anhydrous ether was treated dropwise with 0.071 mole of bis(2-chloroethyl)amine in a benzene–chloroform mixture (4:1). The solution became warm and bis(2-chloroethyl)-amine hydrochloride precipitated as the addition was continued. After the addition of the amine was completed, the flask was stoppered tightly and allowed to stand overnight in the refrigerator.

TABLE I—*N,N*-BIS(2-CHLOROETHYL)ARYLGLYOXYLOHYDROXAMAMIDE HYDROCHLORIDES



No.	Ar	M.p.,[a] °C.	% Yield	Anal.—Cl Calcd.	Cl Found[c]	N Calcd.	N Found[c]
1		101–103.5	47.3	32.40	31.30 32.00	8.64	7.86 7.64
2		124–126	50.5	39.38	38.24 39.00	7.79	7.30 7.55
3		125–127	43.4[b]	29.78	27.87 26.99	7.85	7.10 7.14
4		145–147	24.0	26.44	25.84 25.79	6.99	6.55 6.55

[a] All melting points were uncorrected and taken with a Thomas-Hoover capillary melting point apparatus. [b] Allowed to stand under refrigeration for 6 days before crystallization occurred. [c] Analyses performed in this laboratory. Chlorine determined by the Parr peroxide bomb method and nitrogen by the Henegar method of Kjeldahl's analysis.

Received May 29, 1967, from the School of Pharmacy, University of Georgia, Athens, GA 30601

Accepted for publication July 28, 1967.

Presented to the Walter H. Hartung Memorial Symposium.

Abstracted in part from a thesis presented by Coy Avery Gibson to the Graduate School, University of Georgia, Athens, Ga., in partial fulfillment of the Master of Science degree requirements.

The amine hydrochloride was removed by filtration and the clear supernatant liquid treated for 10 min. with dry hydrogen chloride gas by bubbling the gas continuously through the solution. A viscous oily semisolid separated which crystallized after standing under refrigeration for 48 hr. The crystals were collected by filtration, washed with anhydrous ether, and dried in a vacuum desiccator. All compounds were found to be hygroscopic. The results are summarized in Table I.

New Compounds: Preparation and Hydrogenation of Azomethines Derived from 2,4-Dihydroxyphenyl Benzyl Ketones

By O. LEROY SALERNI, A. POST, F. BAIOCCHI, B. E. SMART, and C. C. CHENG

Reaction of 2,4-dihydroxyphenyl benzyl ketones with primary amines and subsequent catalytic hydrogenation with platinum catalyst has afforded a series of polyphenolic amines derived from resorcinol.

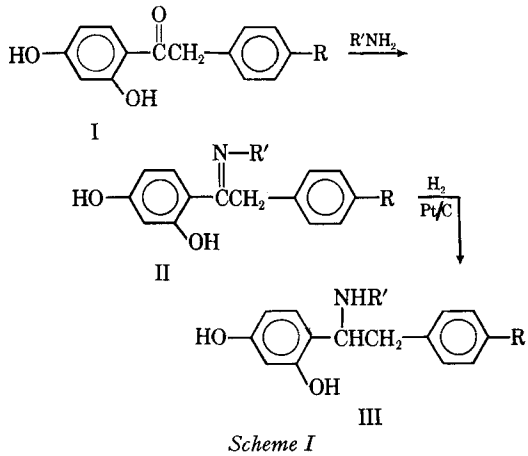
IT HAS BEEN alleged that quinine and mepacrine may exert their antimalarial activity by inhibition of the phosphorylation of glucose (1, 2). Because a number of polyphenolic compounds have been demonstrated to be inhibitors of oxidative phosphorylation (3–6), a number of polyphenolic amines derived from resorcinol have been synthesized in this laboratory as potential antimalarial agents.

The synthetic method is shown in Scheme I. Data on the compounds with structures II and III are presented in Tables I and II, respectively. All the compounds of structure III were isolated and characterized as the hydrochlorides.

Hydrogenation of the azomethines (Table I), where R′ = 2,4-dichlorobenzyl and 3,4-dichlorobenzyl, and subsequent treatment with hydrogen chloride gave a mixture of hydrochloride salts. 2,4-Dichlorobenzylamine hydrochloride was isolated from the former and 3,4-dichlorobenzylamine hydrochloride from the latter. Elemental analyses of the desired secondary amine salts indicated incomplete removal of the primary amine hydrochlorides (based on the calculation of the desired secondary amine salts).

EXPERIMENTAL[1]

The ketones (I), where R = H and R = Cl, were prepared by the method of Chapman and Stephen (7). The ketones (I), where R = OCH_3, was prepared as described by Klarmann (8).



Scheme I

N - (2,4 - Dihydroxyphenyl - p - methoxybenzylmethylene)benzylamine—A solution of 10.3 Gm. (0.04 mole) of 2,4-dihydroxyphenyl-*p*-methoxybenzyl ketone and 4.3 Gm. (0.04 mole) of benzylamine in 350 ml. of dry toluene was refluxed for 24 hr. until the theoretical amount of water was collected in a Dean-Stark apparatus. The solution was concentrated *in vacuo* and the residue on recrystallization from toluene gave 14.0 Gm. (quantitative yield) of yellow crystalline product, m.p. 177–179°. An analytical sample was obtained after an additional recrystallization from toluene, m.p. 180–181°. (See Table I.)

N - (2,4 - Dihydroxyphenyl - p - chlorobenzylmethyl)veratrylamine Hydrochloride—A solution of *N*-(2,4-dihydroxyphenyl-*p*-chlorobenzylmethylene)veratrylamine (4.1 Gm., 0.01 mole) in 150 ml. of acetone was hydrogenated at a pressure of 30 p.s.i. and room temperature, using 1.0 Gm. of 5% platinum-on-charcoal as the catalyst. After 90 min. the theoretical uptake of hydrogen was observed and the catalyst and solvent removed. The waxy residue was dissolved in 50 ml. of anhydrous

Some Biological Properties of 2-(4-Isobutylphenyl)-propionic Acid

Sir:

We have previously described some of the biological properties of ibufenac (4-isobutylphenylacetic acid) (1), an anti-inflammatory, analgesic antipyretic compound, which subsequently has proved to be effective in the treatment of rheumatoid arthritis and other rheumatic diseases.

Since then we have prepared and investigated the biological properties of a large number of other substituted phenylalkanoic and alkenoic acids and derivatives. The highest pharmacological activity is found in substituted 2-phenylpropionic acids, and 2-(4-isobutylphenyl)-propionic acid, ibuprofen (British Pharmacopoeia Commission approved name), has been selected for further studies. Some of the properties of this compound are given below.

Ibuprofen, a colorless crystalline stable solid, m.p. 75–77°, is relatively insoluble in water, but readily soluble in most organic solvents.

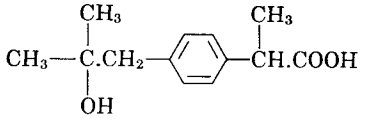
The anti-inflammatory, analgesic, and antipyretic potencies of this compound compared with ibufenac and acetylsalicylic acid are shown in Table I. Three of the experimental methods used have been described previously (1), the other is a modification of a mouse-writhing technique in which intraperitoneal acetylcholine was used as the writhing agent. In all tests the compounds were administered orally in 10% mucilage of acacia in graded doses. From the results in Table I it will be noted that ibuprofen is approximately 4 to 8 times more active than ibufenac.

TABLE I—ANTI-INFLAMMATORY, ANALGESIC, AND ANTIPYRETIC ACTIVITIES OF IBUPROFEN AND IBUFENAC AFTER ORAL ADMINISTRATION (ACETYLSALICYLIC ACID = 1)

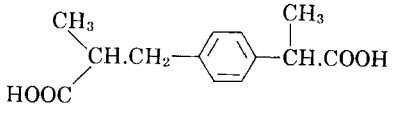
	Anti-Inflammatory Activity UV Erythema	Analgesic Activity—Mouse Writhing	Analgesic Activity—Inflamed Rat's Paw	Anti-pyretic Activity Yeast-Fevered Rat
Ibufenac	2–4	2	2–4	4
Ibuprofen	16–32	16–32	8–16	20

The resolution of ibuprofen has been effected with (−)-1-phenylethylamine, and no difference has been detected in the anti-inflammatory potency of the two enantiomorphs in the guinea pig ultraviolet erythema test. Shen and his colleagues (2), have however found in related compounds, *e.g.*, 2-(3-chloro-4-cyclohexylphenyl) propionic acid, that a large part of the anti-inflammatory activity resides in the *dextro* isomer.

The principal urinary metabolites of ibuprofen in man have been isolated and characterized by infrared and nuclear magnetic resonance spectra as I and II. It may be significant that both of these metabolites were found to be *dextro*-rotatory.



I



II

No appreciable species differences have been found in the blood level/time curves after single oral doses of ibuprofen. In the dog, rat, and guinea pig, peak levels of the drug occurred at or before 1.5 hr. When six healthy men took a dose of 200 mg. after overnight fasting, the mean plasma concentrations at 0.75, 1.5, 3, and 6 hr. were 15.0, 14.0, 7.4, and 2.3 mcg./ml., respectively. The amount of drug in the serum or plasma of animals was measured by the method previously described (3). The same method was used for human plasma, except that the amount of drug was assayed by thin-layer chromatography. Experiments in which the ^{14}C-labeled drug was administered orally to dogs indicated that ibuprofen is well absorbed. Clinical studies are in progress and will be reported later.

Kinetics of Pharmacologic Activity of Succinylcholine in Man

Sir:

Studies of the kinetics of pharmacologic effects of drugs in man are only in their beginning. The limited knowledge of this aspect of pharmacokinetics restricts considerably the utility of mathematical analyses of the kinetics of drug absorption, distribution, and elimination. This author has recently developed a number of mathematical expressions which relate the time course of pharmacologic activity of a drug to its apparent first-order rate constant for elimination, to the nature of its dose-response relationship, and to the dose given (1–5). While they have been found to describe satisfactorily the time course of pharmacologic activity of a number of drugs (5), a relatively rigorous evaluation of these mathematical expressions has been difficult due to the paucity of quantitative clinical data. A very extensive quantitative clinical study of the effects of the skeletal muscle relaxant succinylcholine in man by Walts and Dillon (6) has now provided an opportunity for a thorough evaluation of the pharmacokinetic formulations developed in previous reports from this laboratory (1–5).

Walts and Dillon (6) administered succinylcholine chloride in doses of 0.5, 1.0, 2.0, and 4.0 mg./Kg. body weight to a total of 120 patients under general anesthesia and determined the effect of this drug on the contraction of a skeletal muscle (thumb adduction) in response to stimulation of its motor nerve (ulnar nerve at the wrist). The results of their study form the basis of the pharmacokinetic analyses which follow.

It has been proposed that the duration (t) of a pharmacologic effect elicited by a drug given intravenously may be related to its dose (A_0) by the expression:

$$t = \frac{2.3}{k} \log A_0 - \frac{2.3}{k} \log A_{\min.} \qquad \text{(Eq. 1)}$$

where k is the apparent first-order rate constant for elimination, and $A_{\min.}$ is the minimum effective dose. The derivation of the equation and the assumptions upon which it is based have been outlined previously, and the linear relationship between duration of effect and logarithm of dose predicted by the equation has been shown to occur with several drugs (5). It has been pointed out that the equation should hold for any arbitrary end point (for example, 20, 80, or 100% of a normal value for grip strength) (5). A rigorous test of the applicability of Eq. 1 would be to demonstrate that the slope of the line obtained by plotting t *versus* log A_0 is the same regardless of the end point used. Such a test is now possible with the data of Walts and Dillon (6). Figure 1 shows that (*a*) there is a linear relationship between the duration of a given degree of muscular paralysis and the logarithm of the dose of succinylcholine, and (*b*) the slopes of the respective lines for 3 different end points are essentially the same. The apparent first-order elimination rate constant for succinylcholine determined from these slopes is 0.20 reciprocal minutes. $A_{\min.}$ values for 10, 50, and 90% muscle paralysis were calculated by use of Eq. 1; a plot of the logarithm of these values against the intensity of the pharmacologic effect yields a straight line (inset of Fig. 1).

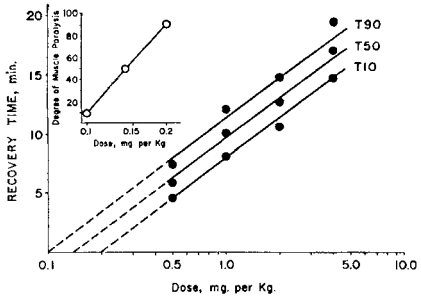

Fig. 1—Relationship between intravenous dose of succinylcholine chloride and duration of various degrees of neuromuscular inhibition in human subjects. T10, T50, *and* T90 *are the times required to recover 10, 50, and 90% of normal muscle contraction force. The data are from* Reference 6 *and represent average values from 13–16 subjects for each dose. Inset: intensity of effect* vs. *log dose, based on dose values obtained by extrapolation of duration of effect* vs. *log dose plots.*

The rate of decline of a pharmacologic effect with time should be constant (rather than exponential) if (*a*) the drug is eliminated by apparent first-order kinetics, (*b*) there is a linear relationship between the logarithm of the dose and the intensity of the elicited pharmacologic effect, and (*c*) certain other requirements are met (5). Specifically,

$$E = E_0 - \frac{km}{2.3} t \qquad \text{(Eq. 2)}$$

where E is the intensity of the pharmacologic effect at time, t, k is the apparent first-order rate constant for drug elimination, m is the slope of the linear portion of a plot of E *versus* log dose, and E_0 is the intercept at zero time of the extrapolated linear portion of a plot of E against t (5). Since the requirements listed above are met by succinylcholine, the intensity of its effect should

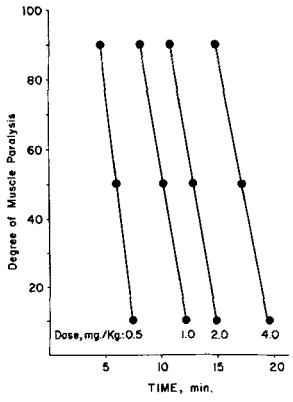

Fig. 2—Degree of muscle paralysis as a function of time after intravenous administration of 0.5 to 4.0 mg./Kg. succinylcholine chloride to groups of 13–15 human subjects. Data from Reference 6.

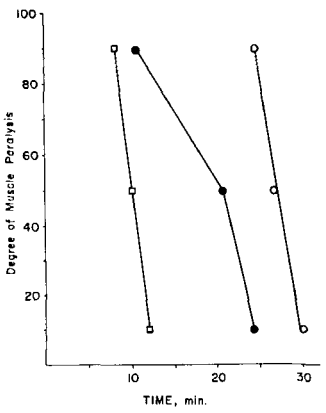

Fig. 3—Degree of muscle paralysis as a function of time after intravenous and intramuscular administration of succinylcholine chloride to human subjects. Key: □, 1 mg./Kg. i.v., 15 subjects; ●, 1 mg./Kg. i.m., 7 subjects; ○, 2 mg./Kg. i.m., 9 subjects. Data from Reference 6.

decline linearly with time, the rate of decline being independent of dose. This is indeed the case with doses ranging from 0.5 to 4 mg./Kg. (Fig. 2). The apparent first-order rate constant for elimination of succinylcholine, as determined from the slopes in Fig. 2 (which yield values of *km*) and the response-log dose plot shown as the inset in Fig. 1 (which yields the value of *m*) is 0.18 reciprocal minutes. This value, obtained from *terminal* pharmacologic activity data (*i.e.*, from the last 0.2 mg./Kg. of each dose), is in very good agreement with the 0.20 $min.^{-1}$ value obtained from *total* pharmacologic activity data (*i.e.*, duration of effect from doses up to 4 mg./Kg.).[1] These results demonstrate therefore the successful application of both equations to the data and provide further support for the contention that the kinetics of many pharmacologic effects of drugs in man can be described adequately by means of appropriate mathematical expressions.

An interesting example of the use of pharmacologic activity data for biopharmaceutic analyses is provided by the data shown in Fig. 3. It is evident that the intensity of pharmacologic activity after intramuscular administration of 1 mg./Kg. succinylcholine declines more slowly than after the same dose given intravenously. This shows that the drug is still being absorbed from its intramuscular injection site. The activity decline slope following the 1 mg./Kg. intramuscular (i.m.) dose approaches that obtained with the i.v. dose when 10–15% of the i.m. dose remains in the body (as evident by reference to the log dose-response plot in Fig. 1). In the case of the 2 mg./Kg. i.m. dose, the activity decline 25 min. after injection is similar to that following an i.v. dose, showing that absorption is essentially complete when about 10% of the i.m. dose remains in the body. This consistency in the data from the 1 mg./Kg. and 2 mg./Kg. doses suggests, as a first approximation, that absorption was by first-order kinetics. Additional information for doses between 1 mg./Kg. and 2 mg./Kg. would permit more definitive conclusions. Thus, a kinetic analysis of pharmacologic activity data is useful not only in clinical pharmacology where it can be employed to establish the most effective dosage regimen for a drug, but also in biopharmaceutics where it can be applied for the evaluation of dosage form effects (5).

[1] This rate constant reflects the rate of decline of drug concentration at the neuromuscular junction; the rate-limiting step in this process is probably diffusion of succinylcholine from that site to the blood rather than enzymic hydrolysis in the blood (7).

Absolute Configurations of the Enantiomeric Pheniramines, Methylphenidates, and Pipradrols

Sir:

The configurations of biologically active compounds are of interest in studies on the modes of drug action and on the interactions of drugs with receptors (1, 2). Antipodes of the title compounds exhibit significant differences in biological activity (2–6) and speculation regarding the absolute configuration of chlorpheniramine (I*a*) and its receptor exists in the literature (*cf. References 7* and *8*). Since the title compounds are congenerically related, it was possible to develop and exploit a single sequence of reactions leading to the determination of the absolute configurations of all 16 optical isomers of the seven compounds (I*a*, *b*, *c*, threo-VII, XVIII, XIX, XX) of biological interest. Accordingly, the pheniramines (I) were converted to the methylphenidate series (*cf.* VII) in which the relative configuration of the two asymmetric centers is known (6, 9). The endocyclic center of asymmetry introduced in the process was maintained intact while the original exocyclic center was destroyed in the sequence leading to XIII and the pipradrols (XVIII, XIX, XX) the absolute configuration of which was determined by an aufbau sequence[1] involving pipradrol (XVIII) prepared from XIV, (+)-(R)-piperidine-2-carboxylic acid.

Palladium–hydrogen dehalogenation of both (+) - 3 - (*p* - chlorophenyl) - 3 - (2′ - pyridyl)-1-dimethylaminopropane (I*a*) hydrogen maleate, m.p. 113–114°, $[\alpha]_D^{22}$ + 19°, (c 1.15, water) and the corresponding bromine analog (I*b*), m.p. 106–108°, $[\alpha]_D^{25}$ +34° (c 10.40, dimethylformamide) afforded (+)-3-phenyl-3-(2′-pyridyl)-1-dimethylaminopropane (I*c*) identified as the monohydrobromide salt, m.p. 176–177°. Hydrogenation of I*a*, I*b*, and I*c* with platinum oxide yielded, in each case, an uncrystallizable, dextrorotatory (ethanol) mixture of diastereoisomeric amines. The mixtures were subjected to Schotten-Baumann conditions to convert them to the dextrorotatory *N*-benzoyl derivatives which gave (+)-erythro-3-phenyl-3-(2′-[1′-benzoyl]-piperidyl)-1-dimethylaminopropane (II), m.p. 134–136°, $[\alpha]_D^{30}$ +50.5° (c 6.95, ethanol), by fractional crystallization. Subjection of II to the conditions of the Hofmann elimination yielded (+) - erythro - 3 - phenyl - 3 - (2′ - [1′ - benzoyl]-piperidyl)-1-propene (III), m.p. 125–126°, $[\alpha]_D^{26}$ +121° (c 4.66, carbon tetrachloride). Ozonolysis of III provided (−)-erythro-2-phenyl-2-(2′-[1′-benzoyl]piperidyl)acetic acid (IV), m.p. 221–222°, $[\alpha]_D^{27}$ −51.4° (c 4.71, ethanol), from which (−) - erythro - 2 - phenyl - 2 - (2′ - piperidyl)-acetic acid hydrochloride (V), m.p. 233–235°, $[\alpha]_D^{26}$ −84° (c 1.00, water), was obtained by acid hydrolysis.

An authentic sample of V was prepared from racemic erythro-2-phenyl-2-(2′-piperidyl)acetamide (*cf.* VI), m.p. 174–175°. The (−)-erythro-

[1] We recently learned that Portoghese and Pazdernik also completed the aufbau sequence and reported this at the Fourth Annual Medicinal Chemistry Meeting in Miniature, University of Kansas, Lawrence, Kan., April 4, 1966; (*cf. Reference 2*).

isomer (VI), m.p. 168–169°, $[\alpha]_D^{26}$ −64° (c 1.00, 6:4-ethanol-water), obtained by resolution with (−)-tartaric acid (6) afforded V, m.p. 233–235°, $[\alpha]_D^{26}$ − 81°, (c 1.00, water) upon acid hydrolysis. The mixed melting point of both samples of V was not depressed. Esterification of V yielded the crude levorotatory (water) erythro-ester hydrochloride (VII) which was converted to VIII, (−)-erythro-2-phenyl-2-(2′-[1′-benzenesulfonyl]piperidyl)acetic acid methyl ester, m.p. 154–155°, $[\alpha]_D^{26}$ −49°, (c 1.13, methanol) with benzenesulfonyl chloride in pyridine. Lithium aluminum hydride reduction of VIII yielded (−)-erythro-2-phenyl-2-(2′-[1′-benzenesulfonyl]piperidyl)ethanol (IX), m.p. 105–105.5°, $[\alpha]_D^{20}$ −4.5° (c 4.88, methanol). This was treated with *p*-toluenesulfonyl chloride in pyridine to obtain (+)-erythro-2-phenyl-2-(2′-[1′-benzenesulfonyl]piperidyl)ethyl chloride (X), m.p. 157–158°, $[\alpha]_D^{26}$ +25° (c 2.00, benzene) which was converted to 1-phenyl-1-(2′-[1′-benzenesulfonyl]piperidyl)ethylene (XI), m.p. 87–88°, $[\alpha]_D^{23}$ −66.8°, (c 1.80, benzene), with potassium amide in liquid ammonia. Ozonolysis of XI afforded (−)-1-benzenesulfonyl-2-benzoylpiperidine (XII), m.p. 103–104°, $[\alpha]_D^{26}$ −20° (c 7.00, tetrahydrofuran). Treatment of this ketone with phenyl magnesium bromide yielded XIII, (−)-α-(2′-[1′-benzenesulfonyl]piperidyl)-benzhydrol, m.p. 167–169°, $[\alpha]_D^{20}$ −67°, (c 1.19, tetrahydrofuran), which was also obtained, m.p. and mixed m.p. 167–169°, $[\alpha]_D^{20}$ −64° (c 1.21, tetrahydrofuran), from (R)-(+)-piperidine-2-carboxylic acid (XIV), m.p. 276–277°, $[\alpha]_D^{21}$ +25.5° (c 3.00, water). Following platinum oxide reduction of picolinic acid in the presence of, and resolution with (+)-tartaric acid, XIV was obtained and was treated with benzenesulfonyl chloride in base to give a crude dextrorotatory (benzene) product (XV), 1-benzenesulfonylpiperidine-2-carboxylic acid. Esterification afforded (+)-1-benzenesulfonylpiperidene-2-carboxylic acid methyl ester (XVI), m.p. 61–63°, $[\alpha]_D^{24}$ +54° (c 3.03, benzene). Treatment with phenyl magnesium bromide converted XVI to XIII. Esterification of XIV provided crude, dextrorotatory (ethyl ether) piperidine-2-carboxylic acid methyl ester (XVII) which was converted with phenyl magnesium bromide to (+)-α-(2-piperidyl)-benzhydrol (XVIII), m.p. 98–99°, $[\alpha]_D^{26}$ +58° (c 4.00, methanol), and thence, with benzenesulfonyl chloride in pyridine, to XIII, identical in all respects to that obtained by the other methods described. Birch reduction of XVIII afforded (+)-2-benzhydrylpiperidine (XIX) isolated as the levorotatory hydrochloride salt. The rotatory dispersion curves of the levorotatory hydrochlorides of XVIII, XIX, and XX justify assignment of the same configuration to these compounds.

Accordingly, the absolute configuration of the the more active (2, 5) levorotatory pipradrol hydrochlorides and their dextrorotatory free bases is (R). The absolute configuration of V, VI, and VII is (2S:2′R) while the base-catalyzed epimerization (6) of VI to the (+)-threo-amide and conversion of the latter to the corresponding (+)-threo-acid (*cf.* V) and (+)-threo-ester hydrochloride (*cf.* VII) establishes the latter, the more active analeptic antipode (6) as (2R:2′R). The antihistaminically more active, dextrorotatory pheniramine maleates have the (S) configuration.

The significance of these findings will be discussed in definitive reports to follow (*cf. References 2, 8*).

This investigation was supported in part by grant NB-3593 from the National Institute of Neurological Diseases and Blindness, U. S. Public Health Service, Bethesda, Md.

The authors gratefully acknowledge partial financial support from Schering and Ciba Laboratories and gifts of generous samples of (+)-chlorpheniramine supplied by Drs. H. Wolkoff, B. Jatul, and H. Leitzow, Schering Laboratories, of (+)-brompheniramine supplied by Dr. W. Schlesinger, White Laboratories, of racemic erythro-2-phenyl-2-(2′-piperidyl)acetamide supplied by Drs. L. Lachman and J. Cooper, Ciba Laboratories, and of (+)- and (−)-α-(3-[1,4-thiamorpholinyl])benzhydrol hydrochlorides made available by Dr. B. Belleau, University of Ottawa, and Dr. H. Dickison, Bristol Laboratories.

The authors thank Dr. P. Portoghese, University of Minnesota, for running the ORD curves. Satisfactory elemental analyses were obtained for all compounds for which melting points are reported.

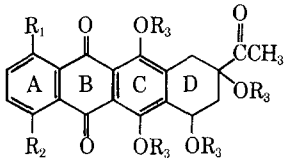
* To whom inquiries should be addressed.

Identity of Rubidomycin and Daunomycin

Sir:

Rubidomycin (1), an antibiotic isolated from the culture of *Streptomyces coeruleorubidus*, has been reported (2) to be chemically identical to daunomycin, an antibiotic isolated from the mycelium of *Streptomyces peucetius*. This identity was based on comparisons of ultraviolet and infrared data, chromatographic behavior, and certain color reactions. Similar biological activities have also been reported (3) for these two antibiotics. The structures of daunomycinone and daunosamine, the aglycone and the sugar moiety, respectively, of daunomycin, were elucidated by Arcamone and co-workers (4). In view of the current interest in rubidomycin and daunomycin as antitumor agents, it was deemed essential to place this identity on a more rigorous chemical basis.

Commercial samples[1] of the two antibiotics showed diffuse and indistinct X-ray diffraction patterns; the recrystallized[2] samples yielded dim, but definitely nonequivalent, patterns. The commercial samples showed similar, but definitely not identical, spectra (infrared, ultraviolet, and NMR), although samples which were exhaustively exchanged with D_2O yielded identical NMR spectra. By thin-layer chromatography, commercial daunomycin was shown to be homogeneous and commercial rubidomycin was shown to be heterogeneous, consisting of one major component (chromatographically identical with daunomycin) contaminated by a minor component possessing the same color and R_f value as the aglycone.[3] Because these antibiotics are hygroscopic and labile, they are difficult to characterize *per se;* therefore a common crystalline derivative for these samples was sought. Since the objective of this investigation was to show the identity of these two antibiotics, and since their elemental data indicated different amounts of water, it was necessary to purify these samples by a common procedure. To remove the aglycone from the rubidomycin sample and to start with materials of the same degree of hydration in the characterization studies, samples of both antibiotics were partitioned between chloroform and water. The aqueous solutions were lyophilized to yield solids that were chromatographically homogeneous. Benzoylation of these materials was conducted under identical conditions with identical stoichiometry. The use of excess benzoyl chloride in pyridine at room temperature for 20 hr. gave mixtures of benzoates consisting primarily of a pentabenzoate. This major component was isolated by preparative thin-layer chromatography and then was recrystallized from ethanol. The NMR of the crystalline solid showed that it was a pentabenzoate, and the infrared spectrum identified it as the tetra-*O*-mono-*N*-benzoate (I),[4] m.p. 236–238°. The equivalence of the two pentabenzoates from the two antibiotics was demonstrated by experimentally identical infrared, ultraviolet, NMR, chromatographic, melting point, and elemental data, as well as by X-ray diffraction patterns, which were identical in spacings and intensities.[5] The crude benzoylation products from the respective antibiotics showed very similar chromatographic patterns. When the major components were isolated from preparative plates, the mixture from rubidomycin yielded 58% pentabenzoate, 11% tetrabenzoates,[6] and 15% of an unknown benzoate(s), and the mixture from daunomycin yielded 56% pentabenzoate, 13% tetrabenzoates,[6] and 16% of the same unknown benzoate(s) isolated from the rubidomycin mixture. The essential identity of the benzoylation yield data and the identity of the pentabenzoates from the two antibiotics provide proof of the identity of these two materials.



I

R_1R_2 = H, OCH_3
R_3 = three of the R_3 are Bz and the fourth is daunosamine, *N,O*-dibenzoate

[1] Samples of daunomycin, a product of Farmitalia, Milan, Italy, and rubidomycin, a product of Rhone-Poulenc Co., Vitry sur Seine, France, were generously furnished by Cancer Chemotherapy National Service Center.

[2] The authors thank Dr. W. Yanko, Monsanto Chemical Co., for the recrystallization procedure.

[3] Mild acid hydrolysis of the antibiotics afforded the same aglycone, daunomycinone, in good yields. The equivalence of these aglycones was established by X-ray diffraction patterns, which were identical in spacings and intensities.

[4] The locations of the methoxyl in ring A and the glycosidic linkage in the molecule have not been established. The latter problem is presently under investigation in this laboratory.

[5] The samples which yielded these X-ray patterns were recrystallized from a chloroform–ethanol mixture.

[6] More than one tetrabenzoate is theoretically possible. Chromatography of the isolated tetrabenzoate fraction showed one main component and 2 trace contaminants.
