6-Mercapto-9H-purine-9-ylpropylamine Hydrochloride (LIII)—A mixture of 2.51 Gm. (7.3 mmoles of LIV, 60 ml. of 2-methoxyethanol, and 1.38 ml. of 85% hydrazine hydrate was refluxed with magnetic stirring for 20 min., then diluted with 160 ml. of ethyl acetate and stored at 5° for 2 hr. The intermediate phthalamide was collected on a filter and washed with ethyl acetate. The solid was stirred with 80 ml. of 1 *N* aqueous hydrochloric acid at about 80° for 20 min. The phthalhydrazide containing considerable LIV was removed by filtration and washed with water. The phthalhydrazide containing LIV (1.47 Gm.) was retreated with hydrazine and aqueous hydrochloric acid as above. The two hydrochloric acid solutions were combined and spin evaporated *in vacuo*. Recrystallization from aqueous acetone gave 1.78 Gm. (86%) of nearly white crystals, m.p. 274–276°. A second recrystallization of a portion from aqueous acetone gave the analytical sample, m.p. 274–276°; $\lambda_{max.}$ (H_2O): 327 mμ; $\nu_{max.}$ 3100–2400 (NH, NH+); 1600, 1540 (C=C, C=N); no C=O near 1700 cm.$^{-1}$.

Anal.—Calcd. for $C_8H_{11}N_5S \cdot HCl \cdot H_2O$: C, 36.4; H, 5.35; N, 26.5. Found: C, 36.5; H, 5.22; N, 26.5.

9-(3′-Dichloroacetamidopropyl)-6-mercaptopurine (IX)—A solution of 442 mg. (1.8 mmoles) of LIII in 3.5 ml. of 1 *N* aqueous sodium hydroxide was spin evaporated *in vacuo*. The dry residue was suspended in 3.4 ml. of *N,N*-dimethylformamide, then cooled in an ice bath. To the magnetically stirred mixture was added 519 mg. of anhydrous K_2CO_3 followed by 0.70 ml. of dichloroacetyl chloride. After being stirred in the ice bath for 1 hr., the mixture was diluted with 50 ml. of water. The product was collected on a filter and washed with water; yield, 120 mg. (21%), m.p. 180–190°, which gave a single spot on TLC in *n*-butanol–acetic acid–H_2O (10:5:1). Recrystallization from aqueous acetone gave nearly white crystals, m.p. 203–205°; $\nu_{max.}$ 3400 (NH); 2600–2500 (acidic H); 1690 (amide C=O); 1590, 1575 cm.$^{-1}$ (C=C, C=N); $\lambda_{max.}$ (pH 1): 326 mμ; (pH 13): 312 mμ.

Anal.—Calcd. for $C_{10}H_{11}Cl_2N_5OS$: C, 37.5; H, 3.47; N, 21.8. Found: C, 37.2; H, 3.60; N, 21.8.

Irreversible Enzyme Inhibitors 99

Inhibitors of Thymidine Phosphorylase 7. Further Studies on Hydrophobic Bonding with Hydrocarbon Substituents on Acidic Uracils

By B. R. BAKER, MITSUTAKA KAWAZU, and J. D. MCCLURE

Replacement of the 6-methyl group of 6-methyluracil (II) by 6-trifluoromethyl gives a sevenfold increment in binding to thymidine phosphorylase presumably due to the increased acidity of the uracil. Similarly, replacement of the 6-methyl group by 6-methylsulfonyl gave a fifteenfold increment in binding. The binding of 6-methyluracil (II) was increased only 2.5-fold by introduction of a 5-phenylazo group. 6-(Trifluoromethyl)uracil (IV) was further substituted at the 5-position by six different alkyl, aryl, and aralkyl groups; the best inhibitor of this series was 5-phenylbutyl-6-(trifluoromethyl)uracil (XI) which was complexed tenfold better than IV and 67-fold better than 6-methyluracil. Comparison of 5-(phenylazo)uracils substituted with methyl, phenyl, benzyl, or *n*-amyl at the 6-position showed that the *n*-amyl derivative (XVI) gave the best binding; XVI was complexed 23-fold better than 6-methyl-5-(phenylazo)uracil (XII) and 58-fold better than 6-methyluracil.

THYMIDINE PHOSPHORYLASE is an enzyme that catalyzes phosphorolysis of thymidine and related 2′-deoxynucleosides to thymine (1) or the reverse conversion of thymine to thymidine (2), depending upon the stress of genetic or dietary deficiencies upon the cell line (3). The enzyme can also convert the anticancer agent, 5-fluorouracil, to its 2′-deoxyriboside (FUDR) or *vice versa* (3, 4). The chemotherapeutic utility for a tissue-specific inhibitor of thymidine phosphorylase has been previously discussed (5), and initial studies from this laboratory on the mode of binding of inhibitors to this enzyme have been reported (5–10).

It was previously noted that hydrophobic bonding to the enzyme could take place with alkyl or aralkyl groups on uracil at the 1-position (6) or the 5- and 6-positions (7, 8), for example, 6-benzyluracil (XV) was eighteenfold more effective than uracil (7) (Table I). Furthermore, binding of uracils could be made more effective when substituted with electron-withdrawing groups at the 5- or 6-position which increased the acidity of the uracil (9); for example, 5-bromouracil (III) was ninefold more effective than uracil (I). Finally, the best inhibitors were obtained by combining both phenomena, that is, hydrophobic bonding and increased acidity (10); for example, 5-bromo-6-benzyluracil (XVIII) was complexed to the enzyme fortyfold more effectively than the substrate, FUDR, and 150-fold more effectively than uracil (I) (Table I). Therefore, further studies on combinations of hydrophobic groups and electron-withdrawing groups attached to the 5- and 6-positions of uracil were initiated and are the subject of this paper.

DISCUSSION

It was previously reported (9) that the electron-withdrawing trifluoromethyl group at the 6-position (IV) of uracil gave a sevenfold increment in enzyme

binding over 6-methyluracil (II); similarly, it has now been observed that the electron-withdrawing methylsulfonyl group at the 6-position (V) gave fifteenfold better binding than the 6-methyl group (II). Therefore, a search for hydrophobic bonding by hydrocarbon groups at the 5-position of 6-(trifluoromethyl)uracil was undertaken.

The first two compounds studied were the 5-(*p*-chlorophenyl) (VII) and 5-phenylbutyl (XI) uracils since they were readily synthesized by deamination of available 2-aminopyrimidines (XIX, XXII) previously prepared in this laboratory (11). The *p*-chlorophenyl substituent of VII give a fourfold increment in binding over 6-(trifluoromethyl)uracil (IV). The 5-phenylbutyl substituent of XI gave a tenfold increment in binding over IV. The intermediate phenylalkyl derivatives (VIII–X) were then synthesized and evaluated; none were as effective as the phenylbutyl substituent (XI). The *n*-amyl substituent at the 5-position (VI) was then investigated; it showed only a twofold increment in binding due to its hydrocarbon interaction with the enzyme. From these studies emerge two problems worthy of pursuit: (*a*) a similar hydrophobic bonding study of 5-substituents on 6-(methylsulfonyl)uracil (V) and (*b*) placement of leaving groups and the benzene ring of VII–XI to convert them to potential active-site-directed irreversible inhibitors (12, 13) of thymidine phosphorylase that could be further modified for isozyme specificity (14).

Since 5-(phenylazo)uracils are readily synthesized by one of two routes and since the phenylazo group should increase acidity of the uracil by its electron-withdrawing power, a series of 5-(phenylazo)uracils with hydrocarbon substituents were investigated. Note that the 5-phenylazo group (XII) on 6-methyluracil (II) gives a threefold increment in binding, which is not as effective an increment as observed with the 5-bromo (III), 6-methylsulfonyl (V), or 6-trifluoromethyl (IV) groups. Replacement of the 6-methyl group of XII by 6-phenyl (XIII) resulted in a loss of binding—a not unexpected result based on the binding ability of 6-phenyluracil previously observed (8). Better hydrophobic interaction was observed with the 6-benzyl (XIV) and 6-(*n*-amyl) (XVI) groups.

The 6-benzyl group (XIV) on 5-(phenylazo)-uracil gave a fivefold increment in binding due to a hydrophobic interaction; this increment is considerably less than the 37-fold increment between 6-benzyl (XV) and 6-methyluracil (II). Thus it would appear that the large phenylazo group hinders the ability of the benzyl group to assume the proper conformation for optimum binding, as previously observed with 1,5,6-trisubstituted uracils (7). The more flexible *n*-amyl group (XVI) on 5-(phenylazo)uracil gave a 23-fold increment in binding over the 6-methyl group of XII; compared another way, the 5-phenylazo group of XVI gave an eightfold increment in binding compared to the 6-(*n*-amyl)uracil (XVII).

Further studies on placement of a leaving group on the 5-phenyl substituent of XIV and XVI, to convert them to potential active-site-directed irreversible inhibitors (12, 13), would be worthy of pursuit.

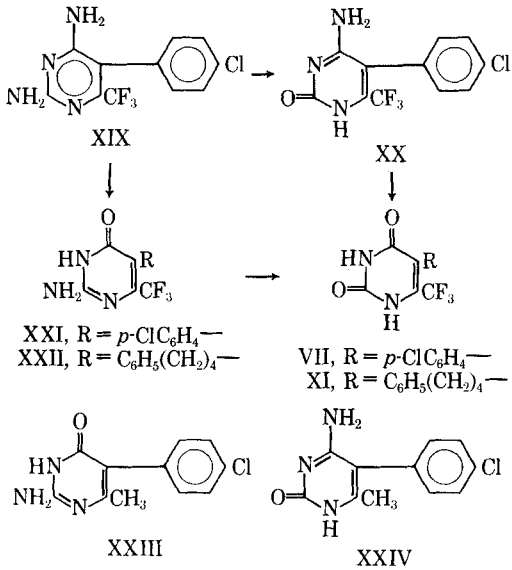
[a] Thymidine phosphorylase was a 45–90% saturated ammonium sulfate fraction from *E. coli* B that was prepared and assayed with 0.4 m*M* 5-fluoro-2′-deoxyuridine (FUDR) in arsenate–succinate buffer (pH 5.9) diluted with 10% dimethylsulfoxide as previously described (5). [b] Ratio of concentration of inhibitor to 0.4 m*M* FUDR giving 50% inhibition. [c] Data from *Reference 8*. [d] Data from *Reference 9*. [e] The authors thank Professor William Prusoff for a sample of this compound. [f] Estimated from 18% inhibition at 0.5 m*M*, the maximum concentration allowing full light transmission. [g] Data from *Reference 10*.

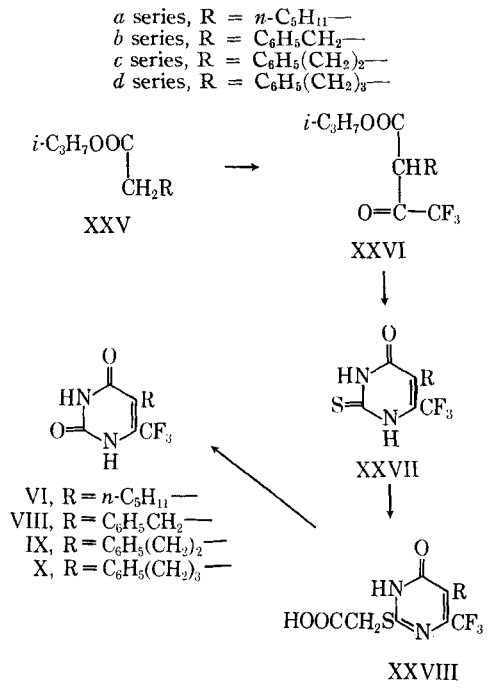
nitrite in glacial acetic acid at room temperature gave a 76% yield of the 5-phenylbutyluracil (XI). Similar treatment of the 5-(*p*-chlorophenyl)-2,4-diaminopyrimidine (XIX) (11) at room temperature did not give the desired uracil derivative (VII), but gave instead an aminopyrimidinol which would have structure XX or XXI. According to Trattner *et al.* (15) treatment of the 6-ethyl analog of XIX with nitrous acid deaminated the 2-amino group; this result was based on comparative ultraviolet data where the 2-amino-4-hydroxypyrimidine showed no shifts between acid and base solution. Later work in this laboratory (16) did not agree with these ultraviolet values—XXIII, synthesized in an unequivocal manner, had an ultraviolet maximum at 15 mμ longer wavelength in alkali than in acid solution, but the 2-hydroxy-4-aminopyrimidine XXIV, also synthesized by an unequivocal method, showed no difference in absorption maximum in acid or base solution. Since the product of deamination of XIX showed a shift of 35 mμ to longer wavelengths in alkali, the 2-amino-4-hydroxypyrimidine structure (XXI) was assigned to this product. These results conflict with those of Trattner *et al.* (15); repetition of their experiments indicated that the product of both hydrochloric acid hydrolysis or nitrous acid deamination was the 2-amino-4-pyrimidinol resulting from attack at the 4-position (17), in agreement with the results of deamination of XIX to XXI. (Scheme I.)



Scheme I

When the reaction of the diaminopyrimidine (XIX) with sodium nitrite was performed at 50° in aqueous acetic–hydrochloric acid, deamination of both amino groups took place to give the desired phenyluracil (VII).

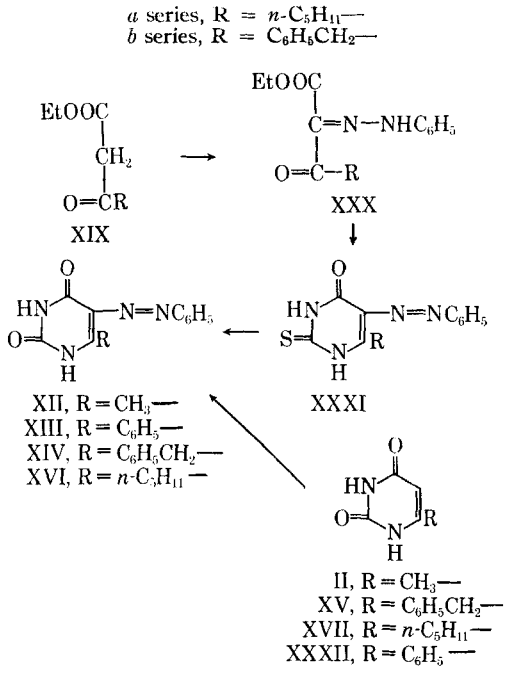
The remaining 5-substituted-6-(trifluoromethyl)-uracils (VI, VIII–X) (Scheme II) were synthesized by a variant of the earlier synthesis (11). The appropriate isopropyl esters (XXV) were condensed with ethyl trifluoroacetate in the presence of sodium hydride; the resultant β-keto esters (XXVI) were then condensed with thiourea to give the 2-mercapto-4-pyrimidinols (XXVII), rather than condensed with guanidine (11). Treatment of XXVII with boiling 5% aqueous chloroacetic acid converted the mercapto group to the carboxymethylthio group (XXVIII), but the thio group did not hydrolyze in the reaction mixture to give the desired uracils (VI, VIII–X), as previously observed with other 5- or 6-substituted-2-thiouracils (8). However, the thioglycolate residue was readily hydrolyzed with aqueous hydrochloric acid. Apparently, the 6-trifluoromethyl group of XXVIII deactivated attack by acid. If it is logically assumed that the pyrimidine ring of XXVIII must be protonated before attack by water occurs, then an acid stronger than 5% aqueous chloroacetic acid would have to be used for protonation since the 6-trifluoromethyl group decreases the basicity of the pyrimidine by about 5 pKa units compared to 6-methyl (11).



Scheme II

6-Methyl-5-(phenylazo)uracil (XII) has been previously synthesized (18) by coupling 6-methyluracil (II) with phenyldiazonium chloride; this reaction was successfully repeated to give a 48% yield of pure material. The 6-phenyl analog (XIII) was also synthesized in this manner in 31% yield of pure material; XIII has been prepared previously by an alternate method (19). The 6-benzyl analog (XIV) was prepared similarly from 6-benzyluracil (XV) in 63% yield. (Scheme III.)

The identical 5-phenylazo-6-benzyluracil (XIV) was also synthesized by an alternate route previously used (19) for the 6-phenyl derivative (XIII) which gave a structurally unequivocal product. Ethyl γ-phenylacetoacetate (XIX*b*) was coupled with phenyldiazonium chloride in aqueous alcohol buffered with sodium acetate; the resultant phenyl-



Scheme III

azo keto ester (XXX*b*) was condensed with thiourea to give the 2-*thio*uracil derivative (XXXI*b*) in good over-all yield. Since hydrolysis of the 2-mercapto group of XXXI*b* with aqueous chloroacetic acid to XIV was unsuccessful, the group was removed by oxidative cleavage with hydrogen peroxide (19) to give XIV in 58% yield that was identical with XIV prepared *via* XV. The remaining 6-(*n*-amyl)-5-phenylazouracil (XVI) was synthesized *via* XXXI*a* since the route starting with 6-(*n*-amyl)uracil (XVII) gave a mixture which was difficult to purify.

EXPERIMENTAL

Melting points were taken in capillary tubes on a Mel-Temp block and those below 230° are corrected. Infrared spectra were determined in KBr pellet with a Perkin-Elmer 137B or 337 spectrophotometer. Ultraviolet spectra were determined in 10% alcohol with a Perkin-Elmer 202 spectrophotometer. Thin-layer chromatograms (TLC) were run on Brinkmann Silica Gel GF, and spots were detected by visual examination under ultraviolet light.

2 - Amino - 5 - (p - chlorophenyl) - 6 - (trifluoromethyl) - 4 - pyrimidinol (XXI)—*Method C*—To a stirred solution of 58 mg. (2 mmoles) of XIX (11) in 20 ml. of glacial acetic acid cooled in an ice bath was added a solution of 560 mg. (8 mmoles) of $NaNO_2$ in 20 ml. of water at such a rate that the temperature was 2–5°. The solution was then allowed to stand at ambient temperature for about 18 hr. during which time the product separated. The product was collected on a filter and recrystallized from 50% aqueous acetic acid; yield, 300 mg. (52%) of slightly yellow plates, m.p. 326–328°; $\nu_{max.}$ 3470, 3300, 3180 (NH); 1650–1600, 1550 (NH, C=O, C=C, C=N); 1020 (CF_3); 840 cm.$^{-1}$ (p-C_6H_4). See Table II for additional data.

5 - (p - Chlorophenyl) - 6 - (trifluoromethyl)-uracil (VII)—To a stirred solution of 350 mg. (1.2 mmoles) of XIX (11) in 10 ml. of glacial acetic acid and 5 ml. of 10% aqueous hydrochloric acid maintained at 50° was added dropwise a solution of 480 mg. (7 mmoles) of $NaNO_2$ in 10 ml. of water. After standing 3 days at ambient temperature, the mixture was filtered and the product was recrystallized from aqueous ethanol; yield, 120 mg. (34%) of white plates, m.p. 250–251°; $\nu_{max.}$ 3180, 3130, 3030 (NH); 1710, 1680 (uracil C=O); 1600 (C=C); 1000 (CF_3); 830 cm.$^{-1}$ (p-C_6H_4). See Table II for additional data.

5 - Substituted - 6 - (trifluoromethyl) - 2 - thiouracils (XXVII)—*Method A*—The appropriate α-substituted isopropyl γ,γ,γ-trifluoroacetoacetate (XXVI) was prepared by condensation of XXV with ethyl trifluoroacetate as previously described for XXVI, R = $C_6H_5(CH_2)_4$ (11). A mixture of 30 mmoles of XXVI, 50 ml. of *tert*-butyl alcohol, 30 mmoles of thiourea, and 30 mmoles of solid sodium methoxide was refluxed with magnetic stirring for about 18 hr., then spin evaporated *in vacuo*. The residue was dissolved in water, the solution was clarified by filtration, then acidified with acetic acid. The product was collected on a filter, washed with water, then recrystallized from aqueous ethanol. See Table II for additional data.

5 - Substituted - 6 - (trifluoromethyl)uracils—*Method B*—A mixture of 3 mmoles of XXVII and 20 ml. of 5% aqueous chloroacetic acid was refluxed for 5 hr.; the intermediate (XXVIII) which could be isolated at this point, was further hydrolyzed by addition of 10 ml. of 10% aqueous hydrochloric acid and by reflux for another 5 hr. The mixture was cooled, the product was collected on a filter, washed with water, then crystallized from aqueous ethanol. See Table II for additional data.

6 - Substituted - 5 - (phenylazo)uracils—*Method D*—A solution of 0.93 Gm. (10 mmoles) of aniline in 5.0 ml. of 12 *N* aqueous HCl was diazotized at −5 to 0° in the usual fashion with a solution of 0.69 Gm. (10 mmoles) of $NaNO_2$ in 5 ml. of water. This diazonium solution was added to a stirred and recooled solution of 10 mmoles of XXXII or XVII in 150 ml. of 2 *N* aqueous NaOH at such a rate that the temperature was 0–5° (in some cases, such as with XXXII, it was necessary to add about 50 ml. more of water to dissolve the uracil prior to addition). After being stirred for an additional 3 hr. in the ice bath, the solution was acidified with acetic acid. The product was collected on a filter and washed thoroughly with water, then recrystallized from aqueous dioxane. See Table III for additional data.

Ethyl α - Phenylazo - γ - phenylacetoacetate (XXXb)—To a stirred solution of 4.12 Gm. (20 mmoles) of XXIX*b* (20) in 72 ml. of ethanol cooled in an ice bath was added a solution of 10.7 Gm. (0.13 mole) of anhydrous sodium acetate in 25 ml. of water; water was then added dropwise until the separated sodium acetate dissolved. Then the diazonium solution from 1.86 Gm. (20 mmoles) of aniline (see under *Method D*) was added dropwise with vigorous stirring, maintaining the temperature at 0–5°. After the addition of 25 ml. more of water, the mixture was stirred in the ice bath for another hour. The product was collected on a filter and washed with cold 50% alcohol; yield, 5.4 Gm.

Irreversible Enzyme Inhibitors 100

Inhibitors of Thymidine Phosphorylase 8. 6-(*p*-Bromoacetamidobenzyl)uracil, an Active-Site-Directed Irreversible Inhibitor

By B. R. BAKER and MITSUTAKA KAWAZU

Four candidate active-site-directed irreversible inhibitors for thymidine phosphorylase have been synthesized from 6-benzyluracil (I). Of these four, only 6-(*p*-bromoacetamidobenzyl)uracil (III) inactivated the enzyme; since neither iodoacetamide nor the *m*-isomer (VI) of III inactivated the enzyme under the conditions used for III, the inactivation by III most probably proceeds by a neighboring group reaction within the enzyme–inhibitor complex—the so-called active-site-directed mechanism.

PREVIOUS PAPERS in this series have described the mode of uracil binding (1, 2) to thymidine phosphorylase. Hydrophobic bonding to this enzyme by uracil derivatives has also been detected (2–6) and the mode of binding has been summarized (7). An effective inhibitor of this enzyme was 6-benzyluracil (I) (5), which was complexed 4.5-times better than the substrate, 5-fluoro-2′deoxyuridine; increasing the acidity of the uracil system by introduction of a 5-bromo group (II) gave a further ninefold increment in binding (6), II being complexed fortyfold better than the substrate. Therefore, 6-benzyluracil (I) and its 5-bromo derivative (II) were considered logical structures to be further modified for con-

version to potential active-site-directed irreversible inhibitors (8, 9) of thymidine phosphorylase. The *p*-bromoacetamido derivatives (III and IV) of I and II were selected for initial study; also selected were the 3′-nitro-4′-fluoro (V) and the *m*-bromoacetamido (VI) derivatives of 6-benzyluracil (I). The enzyme results with these compounds and their intermediates are the subject of this paper.

DISCUSSION

Since a number of new intermediates were available from this study, they were investigated for reversible inhibition in order to shed further light on the anomalous binding of 5-bromo-6-(*p*-nitrobenzyl) uracil (VIII) (6). It was previously noted that the 4.5-fold enhancement in binding by 5-bromo group of II and the sevenfold enhancement of the *p*-nitro group of VII were not additive (Table I); in fact, VIII was considerably less effective than II or VII (6).

It was previously proposed (6) that either the nitro group of VII had an electronic effect on the binding of the benzyl moiety or that the nitro group was itself complexed directly to the enzyme. Since the 3-nitro group of IX has even a more beneficial effect on binding than the 4-nitro group of VII, it is clear that the nitro group of VII cannot be binding directly to the enzyme—else it would be position sensitive. Therefore, an electronic effect is much more likely. The evidence previously cited against an electronic effect by the nitro group of VII was the fact that a *p*-sulfonamide group was detrimental to binding (6). This difference can now be attributed to a difference in the hydrophilic character of

[a] Thymidine phosphorylase was a 45–90% ammonium sulfate fraction prepared from *E. coli* B and assayed with 400 μM FUDR in arsenate–succinate buffer (pH 5.9) in the presence of 10% dimethylsulfoxide as previously described (15). [b] The ratio of the concentration of inhibitor to 400 μM FUDR giving 50% inhibition. [c] Data previously reported (5). [d] Data previously reported (6). [e] Estimated from 30% inhibition at 400 μM, the maximum concentration still allowing light transmission. [f] Estimated from 31% inhibition at 500 μM, the maximum concentration still allowing light transmission.

the nitro group and sulfonamide groups with Hansch π-constants of +0.24 (to −0.28) and −1.82, respectively (10). That a polar group on the benzene is detrimental to binding is indicated by the seven- to eightfold loss in binding when the polar 4-acetamido group is placed on I or IX to give X or XI, respectively. Conversely, if a polar group on the benzyl group is detrimental to binding, then a hydrocarbon group could enhance binding; the latter observation has now been made (11).

That nitration of the benzyl group could enhance binding by 16–60-fold was noted in four out of five cases; compare I and VII, I and IX, XVI and XII, and X and XI where enhancement was good, but in contrast 6-(4-fluorobenzyl)uracil (XIII) showed little change in binding on nitration to V.

The introduction of a 5-bromo group had one of three effects in the seven pairs of compounds that were studied, a loss in binding, a gain in binding, or little change. A 9–14 gain in binding with II and XVII was observed only with the parent benzyluracil (I) or when the phenyl ring was substituted by an electron-donating amino group (XVI). The opposite effect—a loss in binding—was noted when the benzene ring was substituted by electron withdrawing groups; compare the pairs VII and VIII, XI and XIV, and III and IV. Little change in binding was noted with the electronically neutral acetamido group and with a benzene ring containing

both the electron withdrawing 3-nitro and electron-donating 4-amino substituents; compare the pairs X and XV, and XII and XVIII.

Since 5-bromo-(6-*p*-bromoacetamidobenzyl)uracil (IV) was such a poor reversible inhibitor (Table I), it was not investigated as an irreversible inhibitor. Of the other three candidate irreversible inhibitors, III, V, and VI, only 6-(*p*-bromoacetamidobenzyl)-uracil (III) showed inactivation of the enzyme (Table II). At a concentration of 100 μM, III showed 24% inactivation of the enzyme in 1 hr. and 36% inactivation in 2 hr. In contrast, an equal concentration of iodoacetamide run simultaneously showed no inactivation of the enzyme in 2 hr.; this latter result clearly demonstrates that III does not inactivate the enzyme by a random bimolecular process with no specificity, but supports the suggestion that III inactivates the enzyme within a reversible enzyme–inhibitor complex by the active-site-directed mechanism (12, 13). That the active-site-directed mechanism was operable for irreversible inhibition of thymidine phosphorylase by III was further supported by the observation that the *m*-bromoacetamido isomer (VI) showed no inactivation of the enzyme.

Further studies on inhibition of thymidine phosphorylase by 6-substituted uracils are continuing (11) to determine if additional hydrophobic bonding can be obtained by substitution of hydrocarbon groups on the 6-benzyl group of I or related compounds and to determine if faster active-site-directed irreversible inhibitors can be found before tissue specificity (9) studies are started.

CHEMISTRY

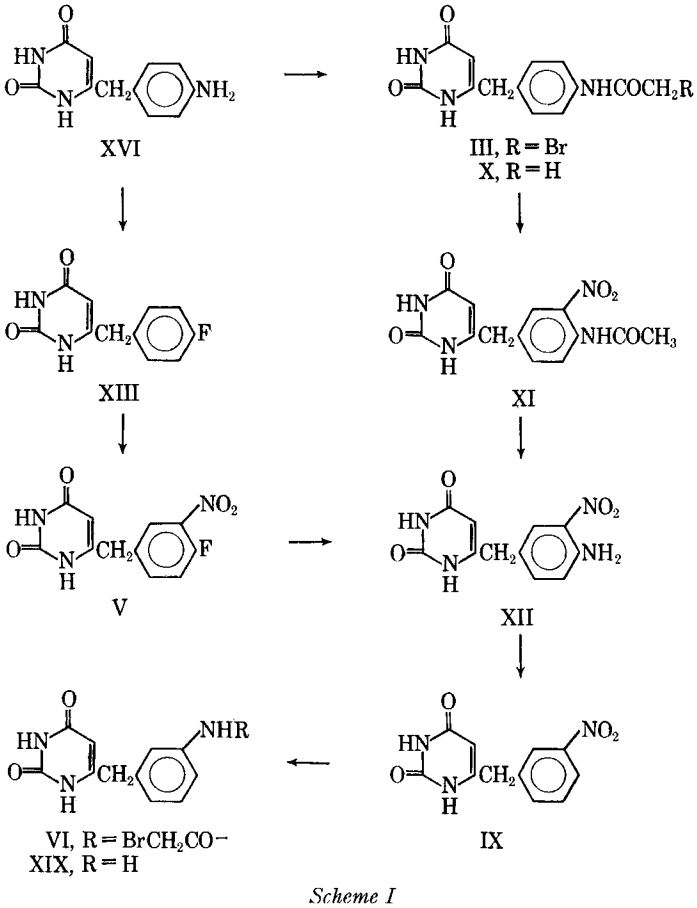
Conversion of 6-benzyluracil (I) to its *p*-amino derivative (XVI) by nitration and hydrogenation has been previously described (5). Reaction of XVI in *N*,*N*-dimethylformamide with bromoacetic anhydride at 0° proceeded smoothly to the bromoacetamide (III) which was uniform on TLC and showed the proper color reactions (14). Similarly, bromoacetylation of 6-(*p*-aminobenzyl)-5-bromouracil (XVII) (6) afforded the 5-bromo bromoacetamide (IV) (Table I).

Attempts to prepare 6-(*m*-aminobenzyl)uracil (XIX) by a primary synthesis starting with *m*-nitro- or *m*-acetamidophenylacetyl chloride were unsuccessful; the condensation of the acid chlorides with ethyl sodioacetoacetate gave black, resinous mixtures. Therefore, attention was turned to the conversion of 6-(*p*-aminobenzyl)uracil (XVI) to XIX by classical benzene chemistry. (Scheme I.)

Acetylation of XVI with acetic anhydride in *N*,*N*-dimethylformamide at 20° gave the *p*-acetamido derivative (X). Nitration of X with a mixture of 70% nitric acid and 96% sulfuric acid at 10–25° proceeded smoothly to the mononitro derivative (XI). That the nitro group had not entered the 5-position of the uracil was shown by nearly identical ultraviolet absorption of X and XI. The *N*-acetyl group of XI was removed with boiling 3 *N* aqueous hydrochloric acid to give a good yield of the nitroaniline derivative (XII). Diazotization of the aryl amino group of XII proceeded with difficulty due to a combination of poor reactivity and poor solubility; diazotization was eventually achieved, although poorly, by using 75% aqueous *N*,*N*-dimethylformamide. The resultant diazonium salt was then reduced *in situ* with hypophosphorus acid. The resultant 6-(*m*-nitrobenzyl)uracil (IX) was contaminated with two other minor products, but could be isolated in 21% yield by preparative TLC. Hydrogenation of IX to the *m*-aminobenzyl uracil (XIX) with a platinum oxide catalyst, followed by reaction with bromoacetic anhydride in *N*,*N*-dimethylformamide afforded the desired 6-(*m*-bromoacetamidobenzyl)uracil (VI).

Attempts to synthesize the 3-nitro-4-fluorobenzyl derivative (V) by diazotization of XII in 50% fluoboric acid with or without *N*,*N*-dimethylformamide as a solvent were unsuccessful due to the difficulty of diazotization. The desired V was then synthesized by an alternate method. Diazotization of 6-(*p*-aminobenzyl)uracil (XVI) in dilute aqueous fluoboric acid gave an insoluble diazonium fluoborate that was converted to XIII in 23% yield by heating at 150°. Nitration of XIII at 40° in a mixture of nitric and sulfuric acids gave V; that the nitro group had entered *ortho* to the fluorine atom was shown by conversion of V to XII with ammonia in *N*,*N*-dimethylformamide at 100°.

The 5-bromouracil derivatives, XIV and XV (Table I), were prepared by bromination of the corresponding uracil derivatives, XI and X, respectively. Hydrolysis of XIV with hot 3 *N* aqueous



Scheme I

hydrochloric acid afforded 6-(4′-amino-3′-nitrobenzyl)-5-bromouracil (XVIII).

EXPERIMENTAL

Melting points were determined in capillary tubes on a Mel-Temp block and those below 230° are corrected. Ultraviolet spectra were determined in 10% ethanol (unless otherwise indicated) with a Perkin-Elmer 202 spectrophotometer. Infrared spectra were determined in KBr pellet with a Perkin-Elmer 137B or 337 spectrophotometer. All analytical samples gave a single spot on thin-layer chromatography (TLC) on Brinkmann Silica Gel GF when spots were detected by visual examination under ultraviolet light.

6-(p-Bromoacetamidobenzyl)uracil (III)—*Method A*—To a stirred solution of 540 mg. (2.64 mmoles) of XVI (5) in 5 ml. of *N,N*-dimethylformamide cooled in an ice bath was added 650 mg. (2.7 mmoles) of bromoacetic anhydride. The mixture was stirred at ambient temperature for 4 hr., then diluted with 5 ml. of water. The product was collected on a filter and recrystallized from aqueous *N,N*-dimethylformamide; yield, 420 mg. (50%) of white needles, m.p. 251–252° dec.; $\nu_{max.}$ 3400, 3140, 3000 (NH); 1700, 1680, 1600, 1530 (C=O, NH, C=C); 840 cm.$^{-1}$ (*p*-C_6H_4). See Table III for analytical data. The compound gave a positive 4-(*p*-nitrobenzyl)pyridine test for active halogen and a negative Bratton-Marshall test for aromatic amine (14).

6-(p-Fluorobenzyl)uracil (XIII)—A solution of 1.08 Gm. (5.26 mmoles) of XVI (5) in 100 ml. of water and 3 ml. of 50% fluoboric acid was cooled in an ice bath with magnetic stirring, then treated dropwise with a solution of 0.40 Gm. (5.8 mmoles) of $NaNO_2$ in 10 ml. of water at such a rate that the temperature was 3–5°. After an additional hour in the ice bath, the mixture was filtered and the diazonium fluoborate was washed with ice water, then dried *in vacuo;* 1.2 Gm. of white solid showing an N≡N band at 2280 cm.$^{-1}$ was obtained.

The diazonium salt was heated in a bath at 150° until gas evolution was essentially complete. The residue was recrystallized from ethanol; yield, 0.25 Gm. (23%) of white crystals, m.p. 274–276° dec.; $\nu_{max.}$ 3350, 3150, 3050 (NH); 1710, 1650, 1610 (NH, C=O, C=C); 1210 (C—F); 830 cm.$^{-1}$ (*p*-C_6H_4). See Table III for additional data.

6-(p-Chlorobenzyl)uracil (XX)—A solution of 1.27 Gm. (6.2 mmoles) of XVI (5) in 150 ml. water and 5 ml. of 12 *N* hydrochloric acid was cooled in an ice bath with stirring, then treated dropwise with a solution of 0.38 Gm. (5.5 mmoles) of $NaNO_2$ in 10 ml. of water at such a rate that the temperature was 3–5°. After being stirred an additional 10 min., the solution was treated with 0.5 Gm. of Cu_2Cl_2. The mixture was stirred an additional 2 hr. in the ice bath, then the product was collected on a filter and washed with water. Recrystallization from ethanol gave 0.38 Gm. (34%), of white plates, m.p. 257–259° dec.; $\nu_{max.}$ 3400, 3100, 3000 (NH);

[a] All compounds were uniform on TLC and had infrared spectra compatible with their assigned structures. [b] Yield of analytically pure material. [c] The compound gave a positive 4-(*p*-nitrobenzyl)pyridine test for active halogen and a negative Bratton-Marshall test for aromatic amine (14). [d] Recrystallized from aqueous *N,N*-dimethylformamide. [e] Reaction performed at 40°. [f] See *Experimental* also. [g] Monohydrate. [h] Corrected for 2% ash from silica gel. [i] 30% excess of acetic anhydride employed at 20°. [j] Recrystallized from dimethylsulfoxide–ethanol. [k] Recrystallized from *N,N*-dimethylformamide–ethanol. [l] Recrystallized from ethanol. [m] Reaction performed at 80° in suspension. Solution occurred in 20 min. and the product was isolated by cooling.

1720, 1650 (uracil); 845 cm.$^{-1}$ (*p*-C_6H_4). See Table III for additional data.

6-(4′-Acetamido-3′-nitrobenzyl)uracil (XI)—*Method B*—To a stirred mixture of 10 ml. of 70% nitric acid and 10 ml. of 96% sulfuric acid cooled in an ice bath was added portionwise 3.0 Gm. (14.5 mmoles) of X at such a rate that temperature was 7–10°. After being stirred at ambient temperature for 1 hr., the mixture was poured on ice. The product was collected on a filter and washed with water, then ethanol. Recrystallization from hot dimethylsulfoxide by addition of ethanol gave 2.5 Gm. (71%) of yellow prisms, m.p. 311–313° dec.; $\nu_{max.}$ 3350, 3080, 3000 (NH); 1730, 1700, 1640, 1500 (NH, C=O, C=C, NO_2); 1330 cm.$^{-1}$ (NO_2). See Table III for additional data.

6-(4′-Amino-3′-nitrobenzyl)uracil (XII)—*Method C*—A mixture of 2.50 Gm. (10 mmoles) of XI and 30 ml. of 3 *N* aqueous hydrochloric acid was refluxed for about 18 hr., then spin evaporated *in vacuo*. The residue was recrystallized by solution in hot *N,N*-dimethylformamide, then addition of ethanol; yield, 1.5 Gm. (79%) of yellow crystals, m.p. 298–300° dec.; $\nu_{max.}$ 3450, 3300, 3150, 3000 (NH); 1700, 1650, 1570, 1500 (NH, C=C, C=O, NO_2); 1340 cm.$^{-1}$ (NO_2). See Table III for additional data.

This compound was also prepared by treatment of V with *N,N*-dimethylformamide saturated with ammonia at 100° in a Parr bomb for 9 hr. Recrystallization from water gave yellow crystals, m.p. 297–299° dec., that were identical with the preceding preparation.

6-(3′-Nitrobenzyl)uracil (IX)—A warm solution

of 1.7 Gm. (6.8 mmoles) of XII in 75 ml. of *N,N*-dimethylformamide and 1.5 ml. of 12 *N* aqueous hydrochloric acid was cooled in an ice bath with magnetic stirring, then treated with a solution of 0.55 Gm. (8 mmoles) of sodium nitrite in 20 ml. of water at such a rate that the temperature was 3–5°. After being stirred an additional 10 min. in the ice bath, the mixture was treated dropwise with 10 ml. of 10% hypophosphorus acid at such a rate that the temperature was 3–5°. After being stirred for 5 hr. in the ice bath, the mixture was stirred at ambient temperature for about 18 hr. The mixture was filtered, and the filtrate was diluted with 150 ml. of water. The product was collected on a filter and washed with water, then ethanol. The crude product was recrystallized from aqueous *N,N*-dimethylformamide; the resultant solid showed 3 spots on TLC. This product was further purified by preparative TLC on eight 20 × 20-cm. plates by the technique previously described (4). The major product, appearing in the second zone, was eluted with acetone; yield, 0.31 Gm. (21%) of yellow crystals, m.p. 288–291° dec. See Table III for additional data.

6-(3′-Bromoacetamidobenzyl)uracil (VI)—A suspension of 120 mg. (0.51 mmole) of IX in 50 ml. of glacial acetic acid was shaken with hydrogen at 2–3 Atm. in the presence of 50 mg. of platinum oxide catalyst; reduction was complete in 30 min. The filtered solution was spin evaporated *in vacuo*. The residue was dissolved in 5 ml. of 3 *N* aqueous hydrochloric acid. Spin evaporation *in vacuo* gave a residue of XIX hydrochloride that was recrystallized from 90% ethanol; yield, 70 mg. (54%) of XIX hydrochloride as white prisms, m.p. 279–281° dec.; $\nu_{max.}$ 3400 (NH); 2570, 2350, 2200 (NH^+); 1700, 1660, 1645, 1600–1500 (NH, C=O, C=C); 718 $cm.^{-1}$ (*m*-C_6H_4); $\lambda_{max.}^{H_2O}$ (pH 6): 279 mμ; (pH 13): 293 mμ.

Treatment of IX with bromoacetic anhydride by method *A* gave VI as off-white prisms, m.p. 269–271° dec., that was uniform on TLC, gave a positive 4-(*p*-nitrobenzyl)pyridine test for active halogen, and a negative Bratton-Marshall test for aromatic amine (14). See Table III for additional data.

6-(p-Acetamidobenzyl)-5-bromouracil (XV)—*Method D*—To a solution of 300 mg. (1.2 mmoles) of X in 30 ml. of glacial acetic acid at 60° was added 200 mg. (1.25 mmoles) of bromine. Orange crystals rapidly separated. The mixture was cooled, then the product was collected on a filter and washed with ethanol. Recrystallization from aqueous *N,N*-dimethylformamide gave 250 mg. (54%) of white needles, m.p. above 360°; $\nu_{max.}$ 3400, 3250, 3000 (NH); 1700, 1650, 1620, 1560 (NH, C=C, C=O); 830 $cm.^{-1}$ (*p*-C_6H_4). See Table III for additional data.

ENZYME ASSAYS

Thymidine Phosphorylase—A 45–90% ammonium sulfate fraction from *E. coli* B was prepared as previously described (15). The final volume from 40 Gm. of frozen cells was 47 ml. in 0.05 *M* Tris buffer, pH 7.4.

Reversible Inhibition—Reversible inhibition of thymidine phosphorylase was performed as previously described with 0.4 m*M* 5-fluoro-2′-deoxyuridine (FUDR) as substrate in succinate–arsenate buffer (pH 5.9) containing 10% dimethylsulfoxide.

Irreversible Inhibition—The rate o cleavage of FUDR was previously observed to be proportional to the enzyme concentration when 0.4 m*M* FUDR was employed in the usual manner (15) as long as the total reaction did not exceed 0.5 absorbance units. The enzyme in pH 7.4 Tris buffer in the presence of 10% dimethylsulfoxide was stable over the 2-hr. incubation period at 37°. The inactivation experiments were performed as follows.

Incubation—In two tubes were placed 125 μl. of enzyme solution in 0.05 *M* Tris buffer (pH 7.4) and 0.55 ml. of deionized water in a 37° bath. After 5 min., 75 μl. of dimethylsulfoxide was added to tube 1 and 75 μl. of dimethylsulfoxide containing the inhibitor was added to tube 2. The contents were mixed, the time noted, then a 0.38-ml. aliquot was withdrawn from each tube as rapidly as possible and stored in an ice bath until ready for assay. The aliquot from the enzyme control was labeled C_1; the aliquot from the inhibitor tube was labeled I_1. The remainder in the two tubes (labeled C_2 and I_2) were then kept at 37° for the specified incubation time, then cooled in an ice bath until ready for assay.

Assay—An assay mix was prepared from 1.50 ml. of 4 m*M* FUDR, 7.50 ml. of 0.2 *M* succinate–arsenate buffer (pH 5.9), and 4.50 ml. of water; a larger amount can be made up if many assays are to be done, since the solution is stable at room temperature.

Three pairs of tubes are necessary to assay each time point for each solution; the C_1 and I_1 sets can be made up for assay during the 1–2-hr. incubation period. The back tube of each set serves as a zero time tube. In each back tube were placed 0.45 ml. of assay mix and 300 μl. of 3 *M* aqueous potassium hydroxide; the contents were mixed, then 50 μl. of C_1 incubation was added and the contents mixed again. In the three front tubes were placed 0.45 ml. of assay mix and 50 μl. of C_1 incubation mixture; the contents were mixed and the time noted. After 10–20 min., the time depending upon the activity of the enzyme (15), 300 μl. of 3 *M* aqueous potassium hydroxide was added and the contents mixed. The absorbance of each pair of tubes was read using the same 1-ml. cell for a pair of tubes. The C_2, I_1, and I_2 aliquots were assayed similarly. The average absorbance change between a front and back pair of tubes, which is proportional to the enzyme concentration, was plotted on a log scale against the incubation time on a linear scale (13). This procedure is satisfactory for a routine screen for a plus or minus answer on inactivation.

When a compound showed inactivation, a larger amount of inhibitor–enzyme mixture could be set up and a number of aliquots removed at varying times in order to obtain the half-life of inactivation.

The results of the inactivation experiments are shown in Table II.

Method to Estimate Small Amounts of L-Triiodothyronine in D-Triiodothyronine

By IRVING B. EISDORFER and ALEX POST

One of the requirements for the use of D-triiodothyronine as a serum cholesterol-lowering agent is that it be essentially free of its optical isomer, L-triiodothyronine. A method for estimating small amounts of L-triiodothyronine in D-triiodothyronine is described. After removing any free triiodothyroacetic acid that may be present, the sample is reacted with stereospecific L-amino oxidase (from snake venom) to oxidize the L-triiodothyronine to triiodothyropyruvic acid. The triiodothyropyruvic acid is degraded to triiodothyroacetic acid, extracted, and chromatographed on paper to separate it from the unoxidized D-triiodothyronine. The final quantitative estimation is made by comparing the size and intensity of the colored spot, as visualized by an appropriate spray reagent, with those obtained from known mixtures of L- and D-triiodothyronine carried through the entire procedure. As little as 0.05 per cent L-triiodothyronine could be estimated in the various samples evaluated.

L-TRIIODOTHYRONINE (L-T3), the most potent of the naturally occurring thyroid hormones, is both a powerful calorigenic agent and an active serum cholesterol-lowering agent. Its use for the latter purpose is rather limited, however, since it cannot be used safely in patients suffering from angina pectoris and related diseases. In contrast, its optical antipode, D-triiodothyronine (D-T3), is potentially a very valuable agent for this purpose since it retains much of the serum cholesterol-lowering properties of the natural isomer without the liability of the latter's hypermetabolic activity.

Since L-T3 is such a potent calorigenic agent, its presence in any appreciable amount in lots of the D-T3 destined for clinical trials as a serum cholesterol-lowering agent would badly confound the results. For this reason, heroic efforts were made to limit the amount of L-T3 present in test lots of D-T3 to very small values (of the order of less than 0.2%). In this connection a procedure was required that would be capable of estimating the L-T3 content of samples of D-T3 in the 0–1% range. Since the analytical procedure was designed primarily for acceptance or rejection purposes, sensitivity was deemed more important than great accuracy, and values accurate to one or at most two significant figures were considered satisfactory.

Direct measurement of optical rotation as a means of determining the amount of L-T3 in samples of D-T3 proved to be rather too insensitive for this purpose. With a specific rotation of $-24.5°$ for D-T3, it was not found possible to reliably distinguish samples that contained 0.5% L-T3 from those that contained less than 0.1%. In any case, it was not possible by this procedure to detect 0.2% of L-T3 in samples of D-T3.

The most widely used procedure for determining small amounts of an L-amino acid in the presence of a large amount of its enantiomorph is by stereospecific enzymatic degradation with micromanometric measurement of gas taken up or released (1–5). While this procedure is reported to be capable of estimating as little as 0.1% of an L-amino acid in the presence of its D-isomer, the authors were not able to reliably detect less than 2% of L-T3 in samples of D-T3 manometrically. This may be due to the poor aqueous solubility of the triiodothyronines which prevented the use of an adequate size sample.

Although micromanometric procedures for determining L-amino acids in the presence of the D-isomers were not sensitive enough for the purposes of this work, stereospecific oxidation with an enzyme such as L-amino acid oxidase appeared to be a promising approach to the solution of this problem, provided a sensitive procedure could be

Method to Estimate Small Amounts of L-Triiodothyronine in D-Triiodothyronine

By IRVING B. EISDORFER and ALEX POST

One of the requirements for the use of D-triiodothyronine as a serum cholesterol-lowering agent is that it be essentially free of its optical isomer, L-triiodothyronine. A method for estimating small amounts of L-triiodothyronine in D-triiodothyronine is described. After removing any free triiodothyroacetic acid that may be present, the sample is reacted with stereospecific L-amino oxidase (from snake venom) to oxidize the L-triiodothyronine to triiodothyropyruvic acid. The triiodothyropyruvic acid is degraded to triiodothyroacetic acid, extracted, and chromatographed on paper to separate it from the unoxidized D-triiodothyronine. The final quantitative estimation is made by comparing the size and intensity of the colored spot, as visualized by an appropriate spray reagent, with those obtained from known mixtures of L- and D-triiodothyronine carried through the entire procedure. As little as 0.05 per cent L-triiodothyronine could be estimated in the various samples evaluated.

L-TRIIODOTHYRONINE (L-T3), the most potent of the naturally occurring thyroid hormones, is both a powerful calorigenic agent and an active serum cholesterol-lowering agent. Its use for the latter purpose is rather limited, however, since it cannot be used safely in patients suffering from angina pectoris and related diseases. In contrast, its optical antipode, D-triiodothyronine (D-T3), is potentially a very valuable agent for this purpose since it retains much of the serum cholesterol-lowering properties of the natural isomer without the liability of the latter's hypermetabolic activity.

Since L-T3 is such a potent calorigenic agent, its presence in any appreciable amount in lots of the D-T3 destined for clinical trials as a serum cholesterol-lowering agent would badly confound the results. For this reason, heroic efforts were made to limit the amount of L-T3 present in test lots of D-T3 to very small values (of the order of less than 0.2%). In this connection a procedure was required that would be capable of estimating the L-T3 content of samples of D-T3 in the 0–1% range. Since the analytical procedure was designed primarily for acceptance or rejection purposes, sensitivity was deemed more important than great accuracy, and values accurate to one or at most two significant figures were considered satisfactory.

Direct measurement of optical rotation as a means of determining the amount of L-T3 in samples of D-T3 proved to be rather too insensitive for this purpose. With a specific rotation of $-24.5°$ for D-T3, it was not found possible to reliably distinguish samples that contained 0.5% L-T3 from those that contained less than 0.1%. In any case, it was not possible by this procedure to detect 0.2% of L-T3 in samples of D-T3.

The most widely used procedure for determining small amounts of an L-amino acid in the presence of a large amount of its enantiomorph is by stereospecific enzymatic degradation with micromanometric measurement of gas taken up or released (1–5). While this procedure is reported to be capable of estimating as little as 0.1% of an L-amino acid in the presence of its D-isomer, the authors were not able to reliably detect less than 2% of L-T3 in samples of D-T3 manometrically. This may be due to the poor aqueous solubility of the triiodothyronines which prevented the use of an adequate size sample.

Although micromanometric procedures for determining L-amino acids in the presence of the D-isomers were not sensitive enough for the purposes of this work, stereospecific oxidation with an enzyme such as L-amino acid oxidase appeared to be a promising approach to the solution of this problem, provided a sensitive procedure could be

Received April 14, 1967, from Smith Kline & French Laboratories, Philadelphia, PA 19101

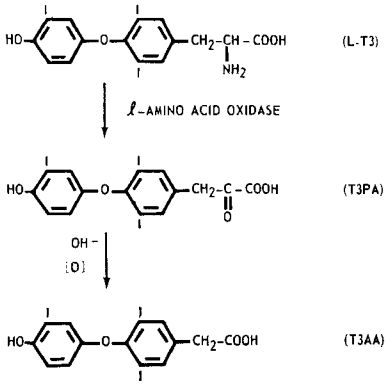
Conversion of L-T3 to T3AA



Scheme I

devised for estimating the very small amount of reactants that disappear or products that form. A number of workers (6–10) have reported that L-amino acid oxidase from snake venom oxidizes the L-iodothyronines to a mixture of the corresponding iodothyropyruvic and iodothyroacetic acids. The latter appears to be a degradation product of the former. Since procedures were at hand for separating and estimating small amounts of the various iodothyronines as well as their desamino derivatives by paper chromatography, this was explored as possible means for estimating the product of the oxidation reaction.

The method that was evolved and is reported here utilizes L-amino acid oxidase from snake venom to stereospecifically oxidize L-T3 in the sample of D-T3 to T3PA and T3AA. These are separated from D-T3 by solvent extraction and heated with alkali to convert the T3PA to T3AA (Scheme I). The L-T3 content of the sample is estimated from the amount of T3AA found after chromatographic separation of the digest extract. (The iodothyronines and derivatives are listed in Table I with their respective structures and abbreviations.)

Synthetic samples of D-T3 often contain small amounts of T3AA so it is essential that this material be removed before analysis for L-T3 lest the L-T3 content appear erroneously high. To this end a clean-up step has been incorporated in the procedure. The procedure as written also includes a chromatographic method for estimating the amount of T3AA present in the D-T3 sample. Since it is often valuable to know the D-T2 and D-T4 content of D-T3 samples and the same chromatographic solvent system is used as is used for the estimation of T3AA, a general procedure for this purpose is included also.

While the procedure described here was designed for estimating the L-T3 content of D-T3, it also worked equally well for the determination of L-T2 in D-T2, that is, for estimating the purity of the intermediate. There is good reason also to believe that it works satisfactorily for the determination of L-T4 in D-T4, as well as for the determination of L-T4 in D-T3, *etc.*

PROCEDURE

Chromatography—Prepare a 12 × 18-in. sheet of Whatman 3 MM paper for spotting by drawing light pencil lines connecting the diagonal opposite corners. Also draw a light line through the intersection point of the lines parallel with the long sides of the paper. Finally draw a circle with a $^3/_4$-in. radius around the intersection point of the lines. The junction points of the circle and the lines are the spotting points.

After spotting, thread a 4-in. cotton cord wick (about 2 mm. thick) through a close fitting hole in

the center of the sheet so that about 1/4 in. protrudes above and the rest hangs below. Place the sheet between the sections of a chromatographic chamber made from two 12 × 18 × 3 in. rectangular glass trays with ground rims fitted face-to-face. Allow the wick to rest in a 1 × 3-in. Petri dish placed at the center of the bottom tray.

Equilibrate a mixture of 50 ml. of isoamyl alcohol, 50 ml. of tertiary amyl alcohol, and 100 ml. of 6 *N* aqueous ammonia solution. Transfer all of the lower phase and about 20 ml. of the upper phase to the bottom of the chamber without wetting the paper or the inside of the Petri dish. Allow the paper to come to equilibrium with the solvent vapors for 2 hr., and then start development of the chromatogram by adding about 75 ml. of the upper phase of the solvent mixture to the Petri dish through a small hole in the side of the lower tray with the aid of a long pipet.

Allow the chromatogram to develop until the solvent front reaches the nearest wall of the chamber, then remove and dry in air.

Emerson Reagent (Modified)—*Solution A*—Dissolve 2 Gm. of 4-aminoantipyrine hydrochloride in 2% aqueous sodium carbonate solution. Clarify by shaking with 1% of activated charcoal, filter, and store in a dark bottle in a refrigerator until used. Discard when the solution becomes noticeably yellow.

Solution B—Two per cent aqueous potassium persulfate solution.

Spray the front and back of the chromatogram lightly with solution *A*. Dry in a stream of air at room temperature and then respray with solution *B*. Examine after drying in air at room temperature. Colors are stable.

Venom (L-Amino Acid Oxidase)—Dehydrated *Crotalus adamanteus* venom, obtained from Nutritional Biochemicals Corp., Cleveland, Ohio. Combine the contents of several bottles of venom, mix thoroughly, and standardize as described below. Transfer 10-mg. portions to individual vials, stopper tightly, and store in freezer until needed.

Venom Standardization—Pipet 5-ml. portions of a 0.10 mg./ml. solution of L-T_3 in 2% KOH into a series of beakers each of which contains 300 ml. of 0.1 *M* phosphate pH 7.2 buffer, 0.2 Gm. of KCl, and 7.5 ml. of 95% alcohol. Adjust the pH of each to 7.2 with dilute HCl or KOH. Add 10 mg. of snake venom to the first beaker, 20 mg. to the second, and 30 mg. to the third, *etc.*, then proceed as directed under *L-T3 Content*.

After extracting the product into 0.05 *N* NaOH, transfer to a 50-ml. volumetric flask, and dilute to volume. Determine the ultraviolet absorption spectrum of this solution in a 5-cm. cell over the range 300–360 mμ. Calculate the difference between the absorbance of the solution at 327.5 mμ and that of the point at the same wavelength on a straight line drawn between the points on the curve at 302.5 mμ and 350 mμ.

The smallest amount of venom that gives a maximum absorbance difference at the point chosen is the optimum weight to be used in the analysis.

Free T3AA Content—Dissolve 50 mg. of the D-T3 sample in 25 ml. of 2% KOH solution. Pipet 5 ml. of this solution into a 250-ml. separator containing 100 ml. of 0.2 *N* HCl. Extract three times with 30-ml. portions of dichloromethane (redistilled from anhydrous Na_2CO_3). Backwash the combined dichloromethane extract once with 30 ml. of 0.1 *N* HCl and once with distilled water. Retain the combined aqueous layers for determination of L-T3 content.

Evaporate the dichloromethane to small volume, transfer to a 50-ml. pear-shaped flask, and evaporate to dryness under vacuum. Dissolve the residue in 0.5 ml. of methanol and transfer by repeated spotting and drying under a stream of N_2 gas to a spotting point on a sheet of Whatman 3 MM paper prepared for chromatography. Rinse the flask twice with 0.25 ml. of methanol and transfer each in turn to the same spotting point.

Transfer 10, 20, and 30 mcg. of T3AA reference compound to other spotting points and chromatograph. Spray the dried chromatogram with Emerson reagent. Estimate the amount of T3AA in the sample from the relative size and intensity of the sample spot as compared to those of the corresponding standards.

L-T3 Content—*Enzymatic Oxidation*—Transfer the aqueous layer obtained under *Free T3AA Content* determination to a 600-ml. beaker. Heat the solution to about 37° and bubble air through it until the odor of the dichloromethane is no longer evident. Cool to room temperature and add 1 *N* KOH dropwise with stirring until the solution is approximately neutral to litmus paper. Add 7.5 ml. of 95% ethanol and 200 ml. of 0.1 *M* pH 7.2 phosphate buffer. Adjust to pH 7.2 ± 0.1 by dropwise addition of dilute HCl or KOH if necessary. Mix thoroughly with a mechanical stirrer for 30 min., and filter through Whatman No. 41 paper. Adjust the temperature of the filtrate to 37 ± 1°, add the required amount of L-amino acid oxidase, and bubble a very slow stream of filtered air through the gently stirred solution for 3 hr.

Transfer the solution to a separator, add 10 ml. of concentrated HCl, mix thoroughly, cool to room temperature, and extract 4 times with 40-ml. portions of redistilled dichloromethane. Collect the extracts in another separator, remove the aqueous phase, and break the slight residual emulsion by the addition of anhydrous sodium sulfate. Filter the clear dichloromethane layer into another separator and wash the residual salt mixture with two 15-ml. portions of dichloromethane. Wash the combined dichloromethane extract with 25 ml. of water and discard the aqueous phase. Finally, extract the dichloromethane solution four times with 10-ml. portions of 0.05 *N* NaOH.

Conversion of T3PA to T3AA—Heat the combined alkaline extract in a loosely stoppered vessel for 2 hr. on a steam bath. Cool to room temperature, add 1 ml. of concentrated HCl, and extract 3 times with 15-ml. portions of redistilled dichloromethane. Filter each portion of extract through a small bed of anhydrous Na_2SO_4 supported in a funnel by a small pledget of well-extracted adsorbent cotton. Evaporate the combined filtrates to dryness under vacuum in a 50-ml. pear-shaped evaporation flask.

Estimation of L-T3 Content—Dissolve the residue in 0.5 ml. of methanol and transfer, by repeated spotting and drying under a stream of N_2 gas to a spotting point on a sheet of Whatman 3 MM paper prepared for chromatography. Rinse the flask twice with 0.25-ml. portions of methanol and trans-

fer each in turn to the same spotting point. In a similar fashion transfer the residues from equivalent weight samples of pure D-T3,[1] pure D-T3 that has had 0.2%, and pure D-T3 that has had 0.4% of L-T3 added and carried through the entire procedure starting from *Free T3AA Content* to other spotting points on chromatographic sheet. Transfer to other spotting points a mixture of 10 mcg. each of L-T3 and T3AA as reference points.

Develop the chromatogram, dry thoroughly in air, and spray with Emerson reagent. Estimate the amount of L-T3 in the sample from the size and intensity of the T3AA spot as compared to that of the T3AA spot present in each of the known mixtures carried through the entire procedure.

T2 and T4 Content of D-T3 Samples—Transfer 10 μl. of a 10 mg./ml. solution of the sample dissolved in 2% ammonia in ethanol to one of the spotting points and 20 μl. to another. Transfer 2 μl. of a solution containing 1 mg./ml. each of T-2 and T-4 dissolved in 2% ammonia in ethanol to one of the other spotting points and 4 μl. to another. The sample spots should contain 100 and 200 mcg., respectively, and the standards should contain 2 and 4 mcg. each of T-2 and T-4. Develop the chromatogram. Spray the dried chromatogram with Emerson reagent, or alternatively immerse it in a 0.25% solution of ninhydrin in 1:100 acetic acid–acetone and allow to dry in air at room temperature. Estimate the amount of T-2 and T-4 present in the sample from the sizes and intensities of the spots as compared to those of the appropriate standards (Fig. 1).

RESULTS AND DISCUSSION

Paper Chromatography—Samples of D-T3 could contain D-T2, D-T4, T2AA, T3AA, and possibly T4AA, all of which are intermediates and side reaction products of the synthesis of D-T3. A chromatographic procedure was needed that would separate these compounds from each other. The chromatographic procedure used in this work does indeed accomplish this purpose. (Figs. 2–4.) Detection of all of these compounds at very low levels was accomplished by use of a modification of the Emerson reagent (10) for phenols. As originally described, potassium ferricyanide was used as the oxidant to bring out the color. This caused the colors to appear (red, orange, purple, *etc.*) on a yellow background. By substituting potassium persulfate for the potassium ferricyanide, it was possible to achieve equivalent color production on a white background with resultant increase in sensitivity (Table II).

Under certain circumstances, it was found useful to be able to distinguish the iodothyronines from the iodothyroacetic acids. Ninhydrin immersion proved to be a valuable means for making the thyronines visible without bringing out the desamino acids. Air drying at room temperature produced colors of equal sensitivity as those produced with the Emerson reagent. The latter, however, produced different shades of color with different degrees of iodine substitution while the former, of course, gave purple colors with all of the amino acids used. All of the compounds used in this work were visible even at very low levels under short wavelength U.V. light (256 mμ) which proved useful under certain circumstances. Table II lists the R_f values, colors, and limits of detection for each of the compounds used in this work.

Estimation of Free T3AA Content—Since final estimation of the amount of L-T3 present in the sample of D-T3 is dependent upon the amount of

[1] D-T3 and T3AA samples used as reference materials in this study were prepared at Smith Kline & French by standard procedures. D-T3 free of L-T3 was prepared by recrystallization of D-T3 samples until no T3AA spot was shown on the chromatogram after being carried through the above procedure. This indicated the presence of less than 0.05% of L-T3 in the D-T3 sample.

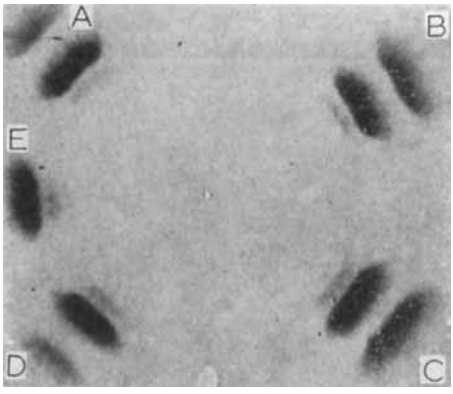

Fig. 4—Chromatogram of T3AA and T3. Key: A, *50 mcg. T-3 + 10 mcg. T-3AA;* B, *50 mcg. T-3 + 20 mcg. T-3AA;* C, *50 mcg. T-3 + 30 mcg. T-3AA;* D, *50 mcg. T-3 + 5 mcg. T-3AA;* E, *50 mcg. T-3.*

T3AA produced in the enzymatic reaction, it is essential that any T3AA present in the original sample (as intermediate or side reaction product of the synthesis) be removed prior to enzyme treatment. The solvent extraction scheme described in the method proved very efficient for this purpose. When tested on synthetic mixtures, the dichloromethane extracts gave a negative test with ninhydrin showing no significant loss of the iodothyronines into the extract, and the final dichloromethane extract gave a negative test with Emerson reagent indicating complete extraction of T3AA in the first two extractions. This was further confirmed by spectrophotometric examination of the two phases.

All of the samples of D-T3 evaluated in this study contained detectable amounts of T3AA (Table III). Although as little as 0.05% of T3AA was detected in some of the D-T3 samples (Fig. 5), this was not the lower limit of the procedure since as little as 0.01% of T3AA could be detected in synthetic mixtures.

Enzymatic Oxidation of L-T3 to T3PA—The medium used in this work for the enzymatic oxidation of L-T3 by snake venom L-amino acid oxidase, pH 7.2 phosphate buffer containing small amounts of KCl, corresponds well with media recommended for use with this enzyme for this purpose (6, 7). However, due to the low solubility of triiodothyronine in this medium, it was not found possible to get enough of the sample dissolved in the medium to achieve anywhere near the desired sensitivity. Reasoning, however, that it was only necessary to retain the L-T3 in solution and not the D-T3, a slow recrystallization step was incorporated in the procedure. This proved to be quite efficient as shown by the good sensitivity of the final procedure and the proportionate recovery of different amounts of added L-T3. The addition of a small amount of alcohol appeared to aid the enzymatic action as well as increase the solubility of the iodothyronines in the medium. The addition of too much alcohol inactivates the enzyme.

Conversion of T3PA to T3AA—Since it was reported that L-T2 was oxidized by snake venom oxidase to T2PA, and the latter partially oxidized to T2AA by peroxides formed by accompanying enzymes, it was presumed that L-T3 reacted the same way. This indeed proved to be the case, so it was not possible to accurately estimate the amount of L-T3 present in a sample until a means could be devised for converting it to one instead of two products.

Since both T3PA and T3AA are strong absorbers in the U.V. and have maxima at slightly different wavelengths, attempts at conversion of one to the other were followed by this means. An initial attempt to prevent oxidation of the T3PA to T3AA by addition of catalase appeared promising but it failed to work reliably so it was discarded. Conversion of T3PA to T3AA by heating with dilute alkali proved to be a more reliable procedure. The appropriate conditions for this conversion were determined by following the reaction spectrophotometrically using known mixtures as well as enzyme digests.

L-T3 in D-T3—When samples of D-T3 containing known added amounts of L-T3 in the range of interest were taken through the procedure, the T3AA spots found on the chromatogram were quite adequate in sensitivity; however, comparison of their size and intensity with those of known amounts of T3AA spotted on the same sheet, showed rather less than complete recovery (Fig. 6). Whether these loses were due to incomplete recovery of L-T3 in the recrystallization step, incomplete oxidation by the enzyme, or to glass surface adsorption, *etc.*, is not known. Attempts to increase recovery by increasing the enzyme ratio proved of no avail. It was found, however, that there was a remarkable proportionality between the size and intensity of the T3AA spots found on the chromatograms and the L-T3 content of D-T3 samples that contained known added amounts of L-T3. Since it was not possible to use absolute reference standards, relative standards were used. That is, D-T3 samples containing known amounts (added) of L-T3 were run through the procedure with the unknown samples using the same enzyme, reaction times, *etc.*, and also spotting the samples and knowns on the same chromatogram, *etc.* Results obtained by this relative standardization procedure proved highly satisfactory if a bit tedious (Fig. 7).

TABLE IV—L-T2 CONTENT OF D-T2 SAMPLES

Sample	% L-T2
051-67B	Trace
051-73A	0.5
051-73B	1.5
051-8A	0.6
PD-39-281	0
051-25A	2
051-25B	0.25

L-T2 in D-T2—The procedure described for estimation of L-T3 in D-T3 also proved satisfactory for the estimation of L-T2 in D-T2, the immediate precursor of D-T3 in the synthetic process (Table IV).

Table III is a list of the amounts of T2, T4, T3AA, and L-T3 found in representative lots of D-T3 prepared at Smith Kline & French and elsewhere. It can be seen that it is possible to produce and analyze D-T3 of very low L-T3 content.

SUMMARY

A procedure has been developed for estimating as little as 0.05% of L-triiodothyronine in samples of D-triiodothyronine. It is also applicable to the determination of equally small amounts of L-diiodothyronine in samples of D-diiodothyronine and very probably for the determination of small amounts of L-tetraiodothyronine (thyroxine) in D-tetraiodothyronine.

A chromatographic procedure has also been described for separating and estimating diiodo-, triiodo-, and tetraiodothyronines in the presence of each other as well as in the presence of diiodo-, triiodo-, and tetraiodothyroacetic acids.

These procedures have been used to estimate the L-triiodothyronine and the D-diiodo and tetraiodothyronine contents of a number of lots of D-triiodothyronine derived from different sources.

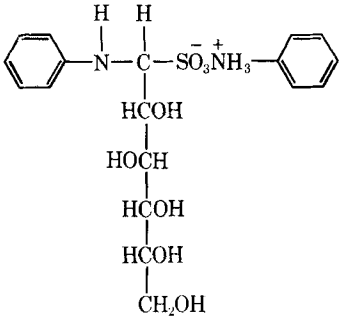
Reactions of Amine Drugs with Sugars I

Reaction of Amphetamine with Aldoses, Glycosylamines, and Bisulfite

By J. C. GRIFFIN* and G. S. BANKER

Amphetamine bisulfite was reacted with D-glucose, D-mannose, *N*-phenylisopropyl-D-mannosylamine, and *N*-phenyl-D-mannosylamine. The effect of an aryl or alkyl amine as the amino substituent at C-1 of the aldose on the formation of amino sulfonates was investigated. Alkyl substitution was found to yield bisulfite addition products, while aryl substitution yielded amino sulfonates. Mannose amphetamine sulfonate and glucose amphetamine sulfonate were synthesized.

THE REACTION of arylamine bisulfites with aldoses has been shown by Ingles (1) to produce amino sulfonates. The structure of an amino sulfonate of this type (D-glycero-D-ido-1-anilino-2,3,4,5,6-pentahydroxyhexylanilinium sulfonate) is shown in I.



I

The hydrolysis characteristics of these compounds (2) were found to be similar to those reported for glycosylamines derived from arylamines (3, 4). Decomposition of the sulfonate structure was observed when the amino sulfonate was dissolved in 10% acetic acid or 0.05 *N* sodium hydroxide solution (2).

The formation of bisulfite addition products, or hydroxysulfonates, by the reaction between inorganic bisulfites and aldehydes is well known (5, 6). The formation of aldose-bisulfite addition products is less well recognized with recent standard texts of organic chemistry (5, 6) indicating that aldoses will not form bisulfite addition products. The chemical literature does not uniformly concur in this view. As early as 1904 Kerp (7) reported the isolation of an impure glucose-sodium bisulfite addition product, while in more recent work Braverman (8) reported the preparation of a pure glucose sodium bisulfite addition product. The preparation of bisulfite addition products of D-glucose, D-galactose, D-mannose, and L-arabinose has also recently been reported by Ingles (9).

The stabilization of pharmaceuticals by the addition of inorganic bisulfites has been common practice for many years (10). The addition of bisulfite to dosage forms containing an amine drug and an aldose could provide the necessary reactants for the formation of aldose-bisulfite addition products as well as amino sulfonates. The implications of this reaction, to modification of amine drug absorption and activity as well as to the browning reaction of sugars, are manifold.

The synthesis of glucose bisulfite compounds of alkoxyamino pyridine by Friedman (11) represents a pharmaceutical application of amino sulfonate formation. The preparation of dialdehyde polysaccharide addition products from various amine bisulfites and dialdehyde starch has been claimed by Borchert (12). These products were of the hydroxy ammonium sulfonate type rather than amino sulfonates. Adams and Garber (13) prepared a number of hydroxy ammonium sulfonates but were unable to obtain products from D-glucose.

The objective of this study was to investigate the reaction of a primary aralkylamine drug with an aldose-bisulfite addition product. The amine drug selected for this phase of the study was dextroamphetamine. The aldose-bisulfite addition product selected was mannose sodium sulfonate.

A further purpose of this work was to examine the reaction of amphetamine bisulfite with the epimeric aldoses, D-glucose and D-mannose, and to examine the effect of an aryl- or alkylamine as

the *N*-substituted constituent at C-1 of the aldose on the formation of amino sulfonates.

EXPERIMENTAL AND RESULTS

Reactions of Amines with Mannose Sodium Sulfonate

Synthesis of Mannose Sodium Sulfonate—D-Mannose,[1] 18 Gm. (0.1 mole), and sodium bisulfite,[2] 12 Gm. (0.115 mole), were separately dissolved in 18 ml. of distilled water with the aid of heat. The two solutions were mixed immediately after preparation. In 20 min. crystallization began and a solid cake formed in approximately 4 hr. The crystalline mass was separated from the mother liquor by filtration, washed with methanol–water (9:1), and finally with methanol. The product was recrystallized twice from a methanol–water (7:3) solvent system.

The recrystallized material had the following characteristics: m.p. 184°; $[\alpha]_D^{25}$ + 7.2 (c 3, 10% acetic acid); sulfite content [method of Adams and Garber (13)] 27.3% found, 28.1% theory.

Reaction of Amphetamine with Mannose Sodium Sulfonate—Mannose sodium sulfonate, 2.8 Gm. (0.01 mole) was added directly to 1.95 Gm. (0.0144 mole) of amphetamine base[3] and the mixture thoroughly mixed. A paste was obtained initially which gradually solidified as a white mass.

The crude product was extracted with 100 ml. of ether for 24 hr. to remove unreacted amphetamine. The ether extract contained 158 mg. of unreacted amphetamine.

The amphetamine content of the crude product was 38.7% as determined by hydrolyzing the adduct with base and extracting the liberated amine with chloroform. Sulfite content of the product was 18.9%. Theoretical values for the condensation product, amphetamine mannose sodium sulfonate, are: amphetamine, 39.0%; sulfite, 19.9%.

The infrared absorption spectrum of the compound between 9.75 and 12.25 μ, as determined by KBr pellet, is shown in Fig. 1 (spectrum A). Also shown in Fig. 1 are the absorption spectra in this region for amphetamine sodium sulfite (B), physical mixture of amphetamine sodium sulfite and mannose sodium sulfonate (C), and mannose sodium sulfonate (D). Amphetamine sodium sulfite was prepared by the addition of amphetamine base to an equimolar amount of sodium bisulfite.

Reaction of Amine Bisulfites with Aldoses

Preparation of Mannose Amphetamine Sulfonate—Amphetamine base, 13.6 Gm. (0.1 mole), was added to 14 ml. of water, and sulfur dioxide[4] from a compressed gas cylinder was bubbled through the suspension. Considerable evolution of heat and the formation of a white solid resulted almost immediately upon introduction of the sulfur dioxide. The white solid redissolved and formed a clear, slightly yellow solution on continued addition of sulfur dioxide. A solution of D-mannose, 9 Gm. (0.05 mole), in 9 ml. of water was prepared with the aid of heat and the mannose solution added to the amphetamine bisulfite solution. Crystallization began in approximately 2 min., and a solid cake was present in the beaker within 20 min. The crude product was suspended in 250 ml. of 95% ethanol and stirred for 1 hr. The product was separated by filtration and dried.

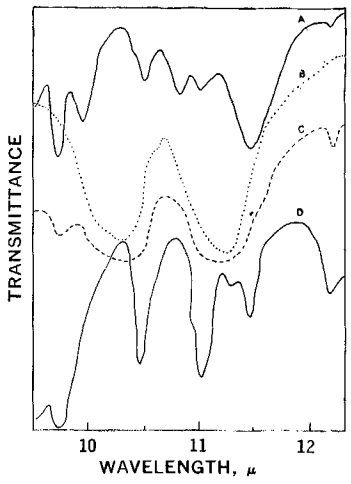

Fig. 1—Infrared absorption spectra. Key: A, *isolated compound;* B, *amphetamine sodium sulfite;* C, *physical mixture of amphetamine sodium sulfite and mannose sodium sulfonate;* D, *mannose sodium sulfonate.*

Free sulfite could not be detected in the product (14) after recrystallizing twice from methanol–water (8:2). Total combined sulfite, determined iodometrically, was 19.8%; theoretical 20.14% for mannose amphetamine sulfonate. Aqueous solutions of the compound gave a positive test for sugar with reagent tablets.[5] The melting point of the recrystallized material was 137°.

The ultraviolet absorption spectrum of the recrystallized product exhibited the characteristic absorption peaks of amphetamine. Amphetamine content, as determined by a chloroform extraction technique from alkaline solution, was 34.6%; theoretical value 34.0% for mannose amphetamine sulfonate.

The infrared absorption of the compound in KBr disk showed the following absorption peaks: 3 μ, —OH, —NH; 5.1 μ, amine salt (15); 8.7 μ, R—SO_3^-; 13.5 and 14.5 μ, monosubstituted benzene.

The infrared absorption spectrum of the compound in potassium bromide disk appeared to be consistent with structure II.

Preparation of Glucose Amphetamine Sulfonate—A solution of amphetamine bisulfite, prepared from 13.6 Gm. (0.1 mole) amphetamine base, 14 ml. of water, and sulfur dioxide gas was added to a solution of D-glucose,[6] hydrous, 9.9 Gm. (0.05 mole), in 9 ml. of water. The solution was allowed to stand in an open beaker at room temperature. Crystallization began in about 4 hr. and was allowed to continue for 18 hr. The product was separated and washed in 250 ml. of ethanol (95%).

The characteristics of the isolated reaction product

corresponded to those of mannose amphetamine sulfonate described above. Crystallization was, however, observed to be considerably slower than with the mannose reaction.

Reactions of Amine Bisulfite with Glycosylamines

Reaction of N - Phenylisopropyl - D - mannosylamine with Amphetamine Bisulfite—A solution of *N*-phenylisopropyl-D-mannosylamine was prepared by refluxing a mixture of D-mannose (5.4 Gm., 0.03 mole), amphetamine (4.0 Gm., 0.03 mole), and methanol (25 ml.) for 20 min. after solution of the sugar was effected. A solution of amphetamine bisulfite, prepared from amphetamine base (4.0 Gm., 0.03 mole), water (0.54 ml., 0.03 mole), methanol (2 ml.), and sulfur dioxide was added to the *N*-phenylisopropyl-D-mannosylamine solution. The resulting solution was placed on a rotary vacuum evaporator and concentrated to small volume. The concentrated solution was placed in an open beaker and allowed to stand at room temperature. Crystallization started within a few minutes and was allowed to continue for 24 hr. The resulting crystalline product was separated, washed with ether, and recrystallized from 95% ethanol.

Physical and chemical characteristics of the recrystallized product were identical to those of mannose amphetamine sulfonate described previously.

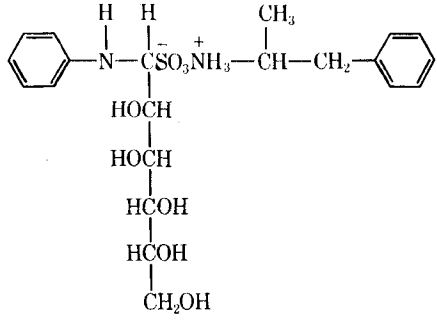
Reaction of N-Phenyl-D-mannosylamine with Amphetamine Bisulfite—A solution of *N*-phenyl-D-mannosylamine was prepared by refluxing a mixture of aniline,[7] 0.93 Gm. (0.01 mole), D-mannose, 1.8 Gm. (0.01 mole), and 10 ml. of methanol for 30 min. The mixture formed a clear solution in approximately 10 min. A white precipitate formed from the clear solution after refluxing for 25 min. Distilled water, 5 ml., was added to the reaction mixture and refluxing was continued. A clear solution resulted in 5 min. and refluxing was terminated at this point.

Sulfur dioxide was bubbled through a mixture of amphetamine, 1.36 Gm. (0.01 mole), distilled water, 0.18 ml. (0.01 mole), and methanol, 3 ml. A clear solution of amphetamine bisulfite resulted and was added to the preformed *N*-phenyl-D-mannosylamine. The solution was refluxed for 4 hr., transferred to a 50-ml. beaker, and allowed to stand at room temperature. Crystallization started within a few minutes and was allowed to continue for 24 hr.

The crystalline material was removed by filtration and washed first with methanol, then with absolute ethanol, and finally with ethyl ether. The product was recrystallized from methanol–water (8:2) and dried in a vacuum desiccator over calcium sulfate.

Sulfite content found, 16.3%; theoretical 16.9% for the amino sulfonate.

The ultraviolet absorption spectrum of the crystalline product dissolved in pH 10 buffer indicated the presence of both aniline and amphetamine chromophores and strongly suggests the structural formula III.



III

DISCUSSION

The reaction of an arylamine bisulfite with an aldose produces, as the normal reaction product, an amino sulfonate. The aralkylamine bisulfite, amphetamine bisulfite, when reacted with the aldoses, D-mannose and D-glucose, was observed to form a bisulfite addition product rather than an amino sulfonate.

A possible explanation of this difference in reaction products may be developed by an examination of the probable reaction mechanisms. Amino sulfonate formation may take place as a result of nucleophilic substitution of the amine at C-1 of the aldose, followed by addition of bisulfite. The strongly basic alkylamine bisulfites exist primarily as the protonated amine, in the system studied, and are thus no longer capable of nucleophilic substitution. The reaction products would thus appear to be limited to bisulfite addition products.

The reactions of *N*-phenyl-D-mannosylamine and *N* - phenylisopropyl - D - mannosylamine with amphetamine bisulfite provide information relative to the effect of the *N*-substituted constituent at C-1 of the aldose on the stability of amino sulfonates. The successful formation of the amino sulfonate, *N*-phenyl-D-mannose amphetamine sulfonate, and the failure to form the corresponding *N*-phenylisopropyl-D-mannose amphetamine sulfonate indicates that amino sulfonate synthesis requires, under the conditions used in this portion of the study, an arylamine as the *N*-substituted constituent at C-1 of the aldose.

Differences in the infrared spectra and absence of free amphetamine base in the product isolated from direct addition of amphetamine base to mannose sodium sulfonate would indicate that a new

[7] General Chemical Division, Allied Chemical and Dye Corp., New York, N. Y.

compound had been formed, possibly of the amino sulfonate type.

Failure to isolate an amino sulfonate from *N*-phenylisopropyl - D - mannosylamine and amphetamine bisulfite would suggest that the mannosylamine had reacted with bisulfite to form an unstable amino sulfonate. The amino sulfonate would then undergo expulsion of the amine, as in the hydrolytic reactions of glycosylamines (16), to form the more stable aldose bisulfite addition product. The reaction was undoubtedly driven in this direction as a result of the insolubility of the aldose bisulfite addition product which was observed to crystallize out of the reaction solution.

Reactions of Amine Drugs with Sugars II

Synthesis and *In Vivo* Evaluation of Mannose Amphetamine Sulfonate and *N*-Phenylisopropyl-D-mannamine

By J. C. GRIFFIN* and G. S. BANKER

Mannose amphetamine sulfonate was synthesized from the reaction of amphetamine bisulfite with D-mannose. *N*-Phenylisopropyl-D-mannamine was synthesized by catalytic hydrogenation of *N*-phenylisopropyl-D-mannosylamine. The products were evaluated *in vivo* by the Williamson activity cage method. Mannose amphetamine sulfonate was found to have a significantly longer duration of activity and produced a higher level of mean activity, from 3.5 hr. to 4.5 hr. after administration, than dextroamphetamine sulfate. *N*-Phenylisopropyl-D-mannamine was found to be orally inactive at dosage levels of 10 and 50 mg./Kg. of body weight.

ADAMS *et al.* (1, 2) have extensively investigated the reaction of various amine bisulfites with aldehydes and ketones. The products isolated, using aldehydes such as benzaldehyde, were of the α-hydroxy sulfonate type. They were, however, unsuccessful in obtaining products with D-glucose. The formation of alkylamine bisulfite addition products with aldoses has been reported by Ingles (3).

The preparation of glycamines by catalytic hydrogenation of *N*-glucosides of alkylamines has been reported by a number of workers (4, 5). Mitts and Hixon (6) have reported on the properties of a number of alkylglucamines obtained by catalytic hydrogenation of glucosylamines.

The purpose of this work was the synthesis and *in vivo* evaluation of an aldose bisulfite addition product and a glycamine derived from an alkylamine drug.

EXPERIMENTAL

Synthesis of Mannose Amphetamine Sulfonate—The synthesis of this product was carried out by reacting dextroamphetamine bisulfite with D-mannose as described in the first paper of this series (7).

Synthesis of N-Phenylisopropyl-D-mannamine—*N*-Phenylisopropyl-D-mannosylamine was prepared by reacting dextroamphetamine,[1] 6.80 Gm. (0.05 mole), with D-mannose,[2] 9.00 Gm. (0.05 mole), in methanol, 5 ml., at 60–65° for 30 min. The resulting light amber colored solution of the mannosylamine was used without further purification for the catalytic hydrogenation.

Hydrogenation of the mannosylamine was carried

Reactions of Amine Drugs with Sugars II

Synthesis and *In Vivo* Evaluation of Mannose Amphetamine Sulfonate and *N*-Phenylisopropyl-D-mannamine

By J. C. GRIFFIN* and G. S. BANKER

Mannose amphetamine sulfonate was synthesized from the reaction of amphetamine bisulfite with D-mannose. *N*-Phenylisopropyl-D-mannamine was synthesized by catalytic hydrogenation of *N*-phenylisopropyl-D-mannosylamine. The products were evaluated *in vivo* by the Williamson activity cage method. Mannose amphetamine sulfonate was found to have a significantly longer duration of activity and produced a higher level of mean activity, from 3.5 hr. to 4.5 hr. after administration, than dextroamphetamine sulfate. *N*-Phenylisopropyl-D-mannamine was found to be orally inactive at dosage levels of 10 and 50 mg./Kg. of body weight.

ADAMS *et al.* (1, 2) have extensively investigated the reaction of various amine bisulfites with aldehydes and ketones. The products isolated, using aldehydes such as benzaldehyde, were of the α-hydroxy sulfonate type. They were, however, unsuccessful in obtaining products with D-glucose. The formation of alkylamine bisulfite addition products with aldoses has been reported by Ingles (3).

The preparation of glycamines by catalytic hydrogenation of *N*-glucosides of alkylamines has been reported by a number of workers (4, 5). Mitts and Hixon (6) have reported on the properties of a number of alkylglucamines obtained by catalytic hydrogenation of glucosylamines.

The purpose of this work was the synthesis and *in vivo* evaluation of an aldose bisulfite addition product and a glycamine derived from an alkylamine drug.

EXPERIMENTAL

Synthesis of Mannose Amphetamine Sulfonate—The synthesis of this product was carried out by reacting dextroamphetamine bisulfite with D-mannose as described in the first paper of this series (7).

Synthesis of N-Phenylisopropyl-D-mannamine—*N*-Phenylisopropyl-D-mannosylamine was prepared by reacting dextroamphetamine,[1] 6.80 Gm. (0.05 mole), with D-mannose,[2] 9.00 Gm. (0.05 mole), in methanol, 5 ml., at 60–65° for 30 min. The resulting light amber colored solution of the mannosylamine was used without further purification for the catalytic hydrogenation.

Hydrogenation of the mannosylamine was carried

[2] Nutritional Biochemicals Corp., Cleveland, Ohio.

out in a Parr type bomb using activated Raney nickel as the catalyst. The mannosylamine was mixed with 250 ml. of ethanol and 10 Gm. of the catalyst, and hydrogenation was carried out below 100° at 1,000 p.s.i. hydrogen pressure. The reaction was terminated after 24 hr. and the solvent reduced to a small volume under vacuum. The resulting crystalline product was filtered off and dried in a vacuum desiccator over calcium sulfate.

Amphetamine Assay—A qualitative test for amphetamine was considered necessary because of the possibility that the unsaturated benzene ring of the amphetamine moiety had been reduced to cyclohexane during the catalytic hydrogenation of the mannosylamine. Amphetamine exhibits a characteristic ultraviolet absorption spectrum which would be destroyed by hydrogenation of the benzene ring. A qualitative test, based on the ultraviolet absorption spectrum of amphetamine was, therefore, selected. Solutions of the mannamine and of dextroamphetamine sulfate in pH 10 buffer were prepared and the ultraviolet absorption spectra of the solutions were compared and found to be identical. The amphetamine content of the mannamine as determined spectrophotometrically was 46.3%; the theoretical amphetamine content is 45.3%.

In Vitro Acid-Base Stability—A quantitative test for amphetamine content, based on the extraction of amphetamine base from alkaline solutions by an organic solvent, was used to determine the acid-base stability of the mannamine. An aqueous solution containing 10.13 mg. of the mannamine per ml. was prepared and 1 ml. of this solution was added to each of three extraction tubes. One milliliter of 1 *N* sodium hydroxide solution was added to each tube and the time recorded. Ten milliliters of chloroform was added to one tube immediately after the addition of the sodium hydroxide solution. Extraction was carried out and the amphetamine content of the chloroform determined spectrophotometrically. The second sample was extracted after 1 hr. and the third sample after 9 hr. Results indicated that less than 50 mcg. of amphetamine was being extracted at each extraction, and that the value did not change during the course of the experiment.

Since the mannamine was apparently stable in the presence of 1 *N* sodium hydroxide, the procedure for the determination of its acid stability characteristics was considerably simplified. If the mannamine were unstable in acid solution, it would liberate the free base which would immediately convert to the salt form; subsequent addition of base would convert the salt form to the free base which could be extracted by chloroform.

The mannamine was found to be stable over a 9-hr. period in artificial gastric fluid.

In an experiment designed to study the partitioning of the mannamine between a pH 8 aqueous solution and chloroform, it was found that when 1 ml. of the aqueous solution containing the equivalent of 3.24 mg. of amphetamine per milliliter was shaken with 10 ml. of chloroform for 24 hr., the concentration of amphetamine present in the chloroform was 10 mcg./ml., thus indicating partitioning strongly in favor of the buffer. The product was found to have a solubility in chloroform equivalent to 50 mcg. of amphetamine per milliliter.

In Vivo Evaluation—For the *in vivo* evaluation by the Williamson[3] activity cage method, male Holtzman rats were selected as the test animal. Their initial weight was between 150 and 175 Gm. In all test runs, the rats were fasted for 10 to 12 hr. in an isolation cage prior to dosing and were preconditioned 30 min. to acquaint the animal with the cage. In each experiment three animals were run simultaneously. Each cage was used an equal number of times for each drug system and six observations were conducted for each of the drugs evaluated. All doses were administered as a solution. The control animals received 3.75 to 5.0 ml. of distilled water by stomach tube, corresponding to the volume of solution required to dose an equivalent weight test animal. All animals were maintained on a diet of Wayne Lab Blox and water *ad libitum* and were housed in an air-conditioned animal room at 23–25°. Animal colony size was 30 rats, maintained in two cages of 15 rats each.

Dosage was calculated on the basis of 10 mg. and 50 mg. of amphetamine per kilogram of body weight. Solutions of the test drugs were prepared in a concentration representing 1 or 5 mg. of amphetamine per 2.5 ml. of solution. All tests were conducted so that the starting time of the test period was between 7:30 and 8:00 p.m.

This procedure was used to evaluate dextroamphetamine sulfate, mannose amphetamine sulfonate, and *N*-phenylisopropyl-D-mannamine at a dosage level of 10 mg./Kg. and to establish control activity levels. *N*-Phenylisopropyl-D-mannamine was also evaluated at a dosage level of 50 mg./Kg.

At the end of the test period, the average number of responses per 0.5-hr. interval was calculated. A statistical analysis of the data was accomplished by first applying an over-all *F* test to determine if a significant difference existed in any of the possible combinations. If a significant F ($\alpha = 0.05$) was found, the Student Newman-Kuels test was used to evaluate each of the possible combinations (8). Table I presents the average activity, at each 0.5-hr.

TABLE I—MEAN ACTIVITY COUNTS PER 0.5-hr. PERIOD FOR DEXTROAMPHETAMINE COMPOUNDS[a] AND FOR THE CONTROL

interval, for all test groups. Results of the statistical analysis are given in Table II. Figure 1 is a plot of the mean activity exhibited by the animals used in the study at 0.5-hr. intervals.

DISCUSSION

Mannose amphetamine sulfonate and dextroamphetamine sulfate were found to have an immediate onset of pharmacologic action. The dextroamphetamine sulfate had a duration of activity of 4.5-hr. while the mannose amphetamine sulfonate had a 5-hr. duration of activity. Furthermore, the mannose amphetamine sulfonate produced a significantly higher CNS response than dextroamphetamine sulfate, from 3.5 hr. after administration, to 4.5 hr. after administration. No significant difference in the activity of dextroamphetamine sulfate and mannose amphetamine sulfonate was demonstrated during the first 3 hr. Further investigations of this and similar compounds would seem to be necessary for an elucidation of the mechanism responsible for the observed increased duration and level of activity produced by mannose amphetamine sulfonate.

N-Phenylisopropyl-D-mannamine was found to be inactive when administered orally to rats at a dosage level equivalent to 10 and 50 mg./Kg. of dextroamphetamine. This observation would, therefore, indicate that the compound was not degraded in the gastrointestinal tract to release the amphetamine moiety. It is highly improbable that the mannamine itself was absorbed, since the *in vitro* tests indicated a very low lipid solubility and almost no partitioning from an aqueous (pH 8) phase to a chloroform phase. From the results of this study, it could be assumed that the conversion of this class of amine drugs to glycamines would probably result in the formation of orally inactive compounds.

SUMMARY

Mannose amphetamine sulfonate was synthesized and evaluated *in vivo*. The compound was found to have a significantly longer duration of activity and produced a higher level of mean activity from 3.5 hr. to 4.5 hr. after administration than dextroamphetamine sulfate.

N-Phenylisopropyl-D-mannamine was synthesized and evaluated *in vitro* and *in vivo*. The compound was found *in vitro* to be stable over a 9-hr. period in both acidic and basic solutions. Solubility determinations and partitioning experiments indicated the product was relatively insoluble in chloroform and its partitioning between pH 8 buffer and chloroform was strongly in favor of the buffer. The mannamine was found to be inactive when administered orally to rats.

Comparative Cardio-Inhibitory Effects of Certain Cyclohexanol and Cyclohexylamine Derivatives

By D. C. KOSEGARTEN, J. J. DEFEO, and D. R. DEFANTI

Derivatives of cyclohexanol and cyclohexylamine were screened for cardioplegic effects on intact anesthetized rats and isolated guinea pig hearts. Evaluation of potency was based on the ability of the compounds to depress rat carotid blood pressure, and to produce reversible arrest of the isolated guinea pig heart. *trans*-2-*o*-Tolyl-*cis*-1,4-cyclohexanediol and *trans*-2-*o*-tolyl-*trans*-1,5-cyclohexanediol were equally effective and the most active compounds tested in producing a hypotensive response. *trans*-2-(*p*-Chlorophenyl)-*N*,*N*-dimethylcyclohexylamine was the least active and the only compound causing a pressor response. As a group, the cyclohexanol derivatives were more potent hypotensive agents than were the derivatives of cyclohexylamine. Conversely, the cyclohexylamines were more potent cardioplegic agents. The *cis* and *trans* isomers of 2-(*p*-chlorophenyl)-*N*,*N*-dimethylcyclohexylamine were equally the most active, with *trans*-2-*o*-tolyl-*cis*-1,4-cyclohexanediol the least active of the compounds studied. The minimum effective cardioplegic dose of 1-ethynyl-*trans*-2-*o*-tolylcyclohexanol was also the cardiotoxic dose as the heart failed to recover from arrest. Mechanism studies indicate an antagonistic effect between calcium and the negative inotropic action of these compounds.

TODAY "open-heart" surgery has changed the outlook for a great many cardiac patients, particularly those having congenital defects, who would have been labeled as hopeless cases slightly more than 10 years ago.

An important aid in the surgical treatment of intracardiac defects is the still heart. Under certain conditions, where a dry, motionless, and clearly visible operative field is desirable, an arrested and all but bloodless heart enables the surgeon to repair more accurately a particular defect.

Elective cardiac arrest has been experimentally and clinically produced by several methods; for a review see Stephenson (1). These consist chiefly of producing arrest by hypothermia, myocardial anoxia, pharmacological agent, or a combination of any or all three.

In 1959 Huitric *et al.* (2) reported that 2-(*o*-tolyl)-cyclohexanol was capable of producing reversible cardiac arrest, without affecting myocardial electrical properties. This finding stimulated the preparation of a number of cyclohexanol and cyclohexylamine derivatives by Huitric.

Previous pharmacologic studies by Smookler and DeFeo (3) and Smith (4) showed the degree of cardio-inhibitory activity to be related to the functional groups and stereochemistry of these compounds.

In continuation therefore, the present investigation was carried out on additional compounds prepared by Huitric, in an effort to determine their possible cardio-inhibitory activity and its relationship to molecular structure.

Received April 14, 1967, from the Department of Pharmacology, College of Pharmacy, University of Rhode Island, Kingston, RI 02881

Accepted for publication May 26, 1967.

Presented to the Pharmacology and Biochemistry Section, A.PH.A. Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

Based on a thesis submitted by David C. Kosegarten to the Department of Pharmacology, College of Pharmacy, University of Rhode Island, in partial fulfillment of Master of Science degree requirements.

This work was generously supported by a grant from the Rhode Island Heart Association.

EXPERIMENTAL

Materials—The cyclohexylamine hydrochloride salts (Fig. 1) were freely soluble in water. The ethynyl derivatives of cyclohexanol (Fig. 2) were practically water insoluble, while the remaining cyclohexanol derivatives (Fig. 2) were slightly water soluble. Accordingly, the ethynyl derivatives were dissolved in 50% polyethylene glycol (PEG) 400, while aqueous solutions of the remaining cyclohexanol derivatives, as well as the cyclohexylamine hydrochloride salts were used throughout the investigation.

Rat Blood Pressure—Male albino rats (260 Gm., average weight) were anesthetized with an intraperitoneal injection of 1.2 Gm./Kg. of urethan. The effects were recorded on a slowly moving smoked kymograph by direct cannulation of the right carotid artery *via* a fluid bridge of normal saline connecting the cannula to a mercury manometer. Injections of the test compounds were made intravenously and not more than six injections were made during one experiment.

Dosage was adjusted according to the results obtained, in order to determine the dose of a particular compound that would produce a 50% drop in the blood pressure. Dose and response were subjected to linear regression computations and the dose producing a 50% drop in blood pressure (ED_{50}) calculated. The ethynyl derivatives of cyclohexanol could not be tested, as the solvent used for these compounds possessed an effect of its own on the blood pressure of the intact rat.

In an effort to account for the pressor response to TH-25 the experimental procedures were modified. The preparation was allowed to stabilize for 20 min. and then the following trials were carried out at 5-min. intervals: (*a*) occlusion of the left common carotid artery for 10 sec., (*b*) 0.06 ml. of epinephrine 1:100,000, (*c*) 4 mg./Kg. TH-25, (*d*) 20 mg./Kg. i.v. hexamethonium, (*e*) 10-min. pause to allow preparation to stabilize and then repeat tests (*a*),

(*b*), and (*c*). The per cent change in blood pressure produced by TH-25 before and after the administration of hexamethonium was the index of activity studied.

Isolated Guinea Pig Heart—Guinea pigs of either sex were sacrificed by cervical dislocation. The heart was rapidly removed and was suspended after cannulation of the aorta in an Anderson-Craver perfusion apparatus. The perfusion solution used was that recommended by Chenoweth and Koelle (5), slightly modified by Smookler and DeFeo (3), and saturated with a continual flow of 95% oxygen and 5% carbon dioxide. The fluid level in the perfusion well of the apparatus was kept constant with the aid of a glass siphon tube placed in the upper end of the well. Excess fluid was thus collected with the aid of a pump and returned to the perfusion fluid reservoir. The preparation was maintained at 37.5° and the heart perfused under a head pressure of 54 cm. of water. Isotonic ventricular contractions were recorded on a slowly moving smoked kymograph. Only one compound was tested in each experiment of not more than five injections. A control dose of 50% PEG was injected at the beginning and end of each experiment involving the ethynyl derivatives of cyclohexanol.

A negative inotropic response of 95% or more was considered to be cardiac arrest and recovery was allowed to take place spontaneously. Dose and response were subjected to linear regression computations and the dose producing cardiac arrest (ED_{95}) calculated.

Isolated Rat Atria—Male albino rats were killed by cervical dislocation and hearts rapidly excised. The atria were freed of ventricular muscle and connective tissue, and suspended vertically in an 8-ml. tissue bath. The bathing solution (same as above) was continually aerated with a mixture of 95% oxygen and 5% carbon dioxide, and temperature maintained at 29° as suggested by Burn and Vane (6). Amplitude of isotonic contractions and the rate of spontaneous beat were recorded under a resting tension of approximately 0.75 Gm. on a smoked kymograph.

CH-20 and TH-27 were chosen to be tested in conjunction with a 4% calcium chloride solution, to study the mechanism involved in the cardioplegia produced by each series of compounds. At least 3 min. were allowed for the compounds to act on the suspended tissue. A minimum of three washes over a period of 5 min. were performed between trials, and the tissue allowed an additional 5-min. recovery period before proceeding to the next trial.

RESULTS AND DISCUSSION

Rat Blood Pressure—CH-21 in doses of 1.0 to 12.0 mg./Kg. produced a drop in mean blood pressure ranging from 22 to 80% of the normal. CH-14 in doses of 2.0 to 8.0 mg./Kg. produced a drop in mean blood pressure of 35 to 85%. CH-20 in doses of 2.0 to 8.0 mg./Kg. produced a drop in mean blood pressure of 42 to 63%. TH-26 in doses of 2.0 to 18.0 mg./Kg. produced a drop in mean blood pressure of 5 to 42%. TH-27 in doses of 2.0 to 14.0 mg./Kg. produced a drop in mean blood pressure of 20 to 57%.

Duration of response was not linear with the cyclohexanol derivatives, and varied from 50 to 400 sec. Conversely, the duration of the hypotensive response to the cyclohexylamine derivatives was linear from 25 to 74 sec. with 2.0 to 6.0 mg./Kg. of TH-26, and from 25 to 130 sec. with 2.0 to 8.0 mg./Kg. of TH-27.

The hypotensive ED_{50} of each of the above compounds is shown in Table I. Omitted from the table is TH-25, which in doses of 4.0 to 8.0 mg./Kg. produced a rise in mean blood pressure (Fig. 3) of 20 to 28%, with a linear duration in pressor response from 44 to 108 sec.

TABLE I—COMPARISON OF THE ED_{50} (HYPOTENSIVE) OF THE NONETHYNYL CYCLOHEXANOL DERIVATIVES AND THE CYCLOHEXYLAMINE DERIVATIVES ON THE BLOOD PRESSURE OF RATS

Compd.	Total Trials	Calcd. ED_{50}, mg./Kg.
trans-2-*o*-Tolyl-*cis*-4-hydroxy-*trans*-5-hydroxycyclohexanol (CH-21)	18	5.30
trans-2-*o*-Tolyl-*cis*-1,4-cyclohexanediol (CH-14)	11	3.95

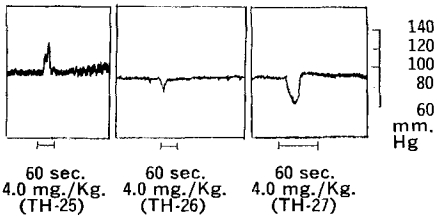

Fig. 3—Rat blood pressure response to each of the cyclohexylamine hydrochloride salts (4.0 mg./Kg.).

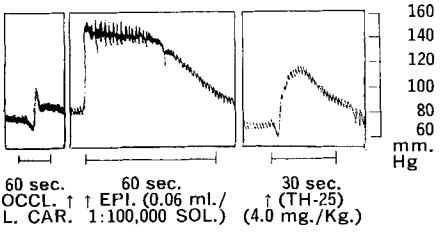

Fig. 4—The effect of trans-*2-*(p-*chlorophenyl*)-N,N-*dimethylcyclohexylamine hydrochloride (4.0 mg./Kg.) on rat blood pressure prior to hexamethonium (20 mg./Kg.).*

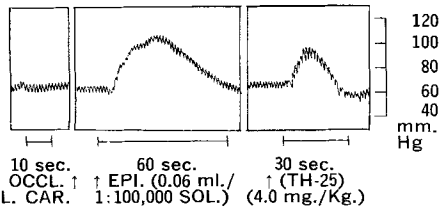

Fig. 5—The effect of trans-*2-*(p-*chlorophenyl*)-N,N-*dimethylcyclohexylamine hydrochloride (4.0 mg./Kg.) on rat blood pressure following hexamethonium (20 mg./Kg.).*

The effect of TH-25 on the rat blood pressure before and after i.v. hexamethonium is shown in Figs. 4 and 5. Prior to i.v. hexamethonium, occlusion of the left common carotid, epinephrine, and TH-25 each produced a transient pressor response of approximately 22%, 85%, and 60%, respectively.

Ten minutes after the slow i. v. injection of hexamethonium, occlusion of the left common carotid for 10 sec. failed to elicit the above-mentioned pressor response. However, second injections of epinephrine and TH-25 again produced transient pressor responses of approximately 60% and 42%, respectively.

The blood pressure results obtained with the nonethynyl cyclohexanol derivatives were typical of those previously obtained with other cyclohexanol derivatives (3). All produced an immediate transient drop in pressure. Although the magnitude of the effect was somewhat dose dependent, the duration of the effect was not. On the basis of the calculated ED_{50} (Table I), CH-20 and CH-14 were equally effective in lowering rat blood pressure. Substitution of a hydroxyl group in both the 4 and the 5 position of the cyclohexanol ring (CH-21) decreased hypotensive activity approximately 30%. It is well known that the activity and toxicity of parent compounds tend to decrease upon the introduction of hydroxyl groups into a chemical structure.

The difference in the hypotensive activity of the cyclohexylamines studied appears to be attributed to both the spatial configuration of the compounds and to the number of methyl groups substituted on the amino nitrogen. In the *trans* configuration, the secondary amine (TH-26) possessed hypotensive activity, while the tertiary amine in the *trans* configuration (TH-25), was the only compound studied that possessed pressor activity. Moreover, in the *cis* configuration, the tertiary amine (TH-27) was approximately twice as active as the secondary amine (TH-26).

Pressor activity of cyclohexylalkylamines has been reported to be due to a direct increase in peripheral vascoconstrictor activity (7, 8). In the preliminary investigation of the mechanism involved in the pressor response to TH-25, reflex vasoconstriction *via* baroreceptor activity was not demonstrated. Moreover, depletion of catecholamine stores by reserpine does not alter the pressor activity (9). Again, the compound appears to be acting directly on the peripheral vasculature.

Thus, with the exception of TH-25 and the ethynyl derivatives of cyclohexanol, the rapid and transient hypotensive response of the compounds suggested direct myocardial depression.

Isolated Guinea Pig Heart—The results obtained in the isolated heart studies are shown in Table II. Recovery to 50% of the original amplitude level was also recorded, and varied with the type of compound studied. At the minimum effective dose, CH-20 and CH-14 had the shortest mean recovery time of 21 and 87 sec., respectively; TH-25, TH-26, and TH-27 possessed intermediate mean recovery times of 202, 868, and 1205, respectively; while the longest mean recovery time of 1280 sec. occurred with AH-65. Moreover, the heart arrested by AH-64 failed to show any signs of recovery and the experiments were terminated after a minimum of 3400 sec. of systolic standstill.

TABLE II—COMPARISON OF THE ED_{95} (CARDIO-INHIBITORY) OF THE CYCLOHEXANOL AND CYCLOHEXYLAMINE DERIVATIVES ON THE ISOLATED GUINEA PIG HEART

Compd.	Total Trials	Calcd. ED_{95}, mg.
trans-2-*o*-Tolyl-*cis*-1,4-cyclohexanediol (CH-14)	15	6.80
trans-2-*o*-Tolyl-*trans*-1,5-cyclohexanediol (CH-20)	8	3.38
1-Ethynyl-*trans*-2-*o*-tolylcyclohexanol (AH-64)	11	2.52
1-Ethynyl-*cis*-2-*o*-tolylcyclohexanol (AH-65)	10	1.33
trans-2-(*p*-Chlorophenyl)-*N,N*-dimethylcyclohexylamine HCl (TH-25)	9	0.78
trans-2-(*p*-Chlorophenyl)-*N*-methylcyclohexylamine HCl (TH-26)	8	1.19
cis-2-(*p*-Chlorophenyl)-*N,N*-dimethylcyclohexylamine HCl (TH-27)	10	0.85

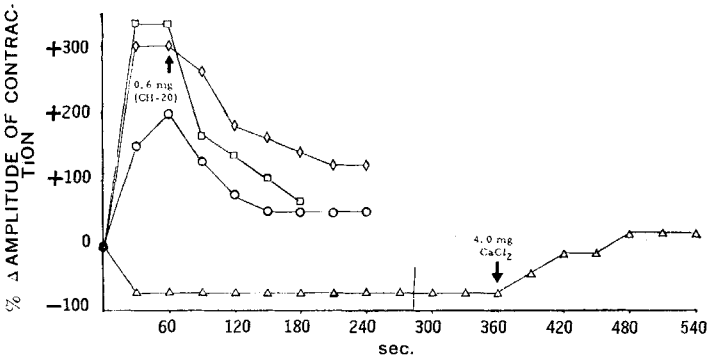

Fig. 6—The effects of trans-2-o-*tolyl* - trans - *1,5 - cyclohexanediol (0.6 mg.) and calcium chloride (4.0 mg.) on isolated rat atria. Key:* □, *4.0 mg.* $CaCl_2$; Δ, *0.6 mg. CH-20, followed by 4.0 mg.* $CaCl_2$; ◇, *4.0 mg.* $CaCl_2$, *followed by 0.6 mg. CH-20;* O, *4.0 mg.* $CaCl_2$ *and 0.6 mg. CH-20.*

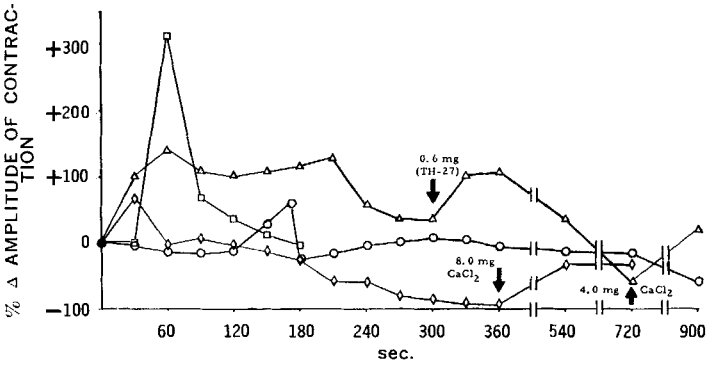

Fig. 7—The effects of cis-2-(p-*chlorophenyl*)-N,N - *dimethylcyclohexylamine hydrochloride (0.6 mg. and 1.2 mg.) and calcium chloride (4.0 mg. and 8.0 mg.) on isolated rat atria. Key:* □, *4.0 mg.* $CaCl_2$; Δ, *0.6 mg. TH-27, followed by 0.6 mg. TH-27 and 4.0 mg.* $CaCl_2$; ◇, *1.2 mg. TH-27, followed by 8.0 mg.* $CaCl_2$; O, *1.2 mg. TH-27 and 8.0 mg.* $CaCl_2$.

A 1.0-mg. quantity of CH-21 produced a mean negative inotropic effect of 10%. Due to insufficient compound, the higher dosage levels could not be investigated.

The antagonistic effect of 8 and 16 mg. of calcium chloride on the cardiac arrest produced by 1.0 mg. of AH-65 was also noted. In all cases, calcium produced a transient positive inotropic response, proportional in duration and magnitude to the concentration of calcium used, and followed by the resumption of the pre-existing cardioplegia.

The primary purpose of the investigation was to determine whether the compounds possessed cardioinhibitory activity. The results in Table II show that the cyclohexylamine derivatives were up to 8 times more active in producing cardioplegia than were the derivatives of cyclohexanol. In the latter series of compounds, it appears that hydroxyl substitution at the 5 instead of the 4 position of the cyclohexanol ring increases activity 2 times. Moreover, when this hydroxyl substituent is omitted and an ethynyl group substituted at the 1 position of the cyclohexanol ring, activity increases 3 and 5 times with the *trans* and *cis* isomer, respectively. The *trans* isomer (AH-64) possessed cardiotoxic properties as the arrested hearts failed to recover spontaneously and remained in systolic standstill until the experiments were terminated at the end of 90 min. The *cis* isomer (AH-65) did not show any signs of cardiotoxicity at the dose levels employed.

It will be recalled that the tertiary cyclohexylamine in the *trans* configuration (TH-25) possessed pressor activity. Nevertheless, both TH-25 and TH-27 were equally potent and the most active of all the compounds studied in arresting the isolated guinea pig heart. Moreover, these two isomers were approximately 25% more active than TH-26 in producing cardioplegia.

Isolated Rat Atria—The results are shown in Figs. 6 and 7. The rate of the spontaneous beat of the preparation increased 17% when 4.0 mg. of calcium chloride alone was added to the bath, and was unchanged when 0.6 mg. of CH-20 preceded 4.0 mg. of calcium chloride. The rate increased 13% if calcium preceded CH-20 and increased only 7% when both were administered simultaneously.

Conversely, 0.6 mg. of TH-27 caused a 42% reduction in the rate of atrial contraction. Moreover, a second dose of 0.6 mg. of TH-27 when added to the bath at this point led to a final reduction in rate of 67%, which was unaltered by 4.0 mg. of calcium chloride. Likewise, 1.2 mg. of TH-27 added to the bath initially caused a 65% reduction in rate which was also unaltered by a subsequent dose of 8.0 mg. of calcium chloride. A 55% reduction in rate occurred when 1.2 mg. of TH-27 and 8.0 mg. of calcium chloride were added to the bath simultaneously.

trans-2-*o*-Tolylcyclohexanol has been reported to reduce the contraction amplitude of isolated rabbit atria without affecting the rate, and calcium to restore the amplitude to a normal level (3). In the present study, CH-20 similarly affected spontaneously beating rat atria, and calcium also restored the amplitude of contraction to a control level. TH-27 produced both negative inotropic and chronotropic effects on the isolated rat atria. A positive inotropic response, the duration of which was inversely proportional to the dose employed, preceded in all instances the negative inotropic effect. Calcium was able to restore the amplitude to control level, but unable to alter the negative chronotropic

response which progressed throughout the entire tissue exposure time. If given simultaneously with either CH-20 or TH-27, the onset of the negative inotropic effect was delayed by the calcium.

SUMMARY AND CONCLUSIONS

As a group, the nonethynyl cyclohexanol derivatives were 2 to 7 times more potent than were the derivatives of cyclohexylamine in producing a hypotensive response in the intact rat. *trans*-2-*o*-Tolyl-*cis*-1,4-cyclohexanediol (CH-14) and *trans*-2-*o*-tolyl-*trans*-1,5-cyclohexanediol (CH-20) were equally effective and the most active, while the *trans* isomer of the tertiary cyclohexylamine (TH-25) was the least active and the only compound that produced a pressor response. The cyclohexylamine derivatives were up to 8 times more potent, in arresting the isolated guinea pig heart, than were the derivatives of cyclohexanol. The *trans* and *cis* isomers of the tertiary cyclohexylamine (TH-25 and TH-27) were equally effective and the most active; while *trans*-2-*o*-tolyl-*cis*-1,4-cyclohexanediol (CH-14) possessed the least amount of cardio-inhibitory activity among those compounds studied. An increase in the number of hydroxyl substituents on the cyclohexanol ring was accompanied by a decrease in both hypotensive and cardio-inhibitory activity. The minimum effective dose of 1-ethynyl-*trans*-2-*o*-tolylcyclohexanol (AH-64) in producing cardiac arrest was also the cardiotoxic dose; while the *cis* isomer (AH-65) showed the greatest cardio-inhibitory activity among the cyclohexanol derivatives studied. Spatial configuration was also significant in the blood pressure activity of the tertiary cyclohexylamines. The *cis* isomer (TH-27) produced a depressor response in contrast to the pressor response elicited by the *trans* isomer (TH-25). In the isolated atrial preparation, calcium antagonized the negative inotropic effects of *trans*-2-*o*-tolyl-*trans*-1,5-cyclohexanediol (CH-20) and *cis*-2-(*p*-chlorophenyl)-*N,N*-dimethylcyclohexylamine hydrochloride (TH-27). Moreover, calcium momentarily restored contraction of the heart arrested by 1-ethynyl-*cis*-2-*o*-tolylcyclohexanol (AH-65). In addition to its negative inotropic effect on the isolated atria, *cis*-2-(*p*-chlorophenyl)-*N,N*-dimethylcyclohexylamine hydrochloride (TH-27) also produced a negative chronotropic response which was unaffected by the administration of calcium. Decreased contraction of the myocardium appears to be responsible for the cardioplegia produced by the cyclohexanol compounds, since the pacemaker activity of the isolated atrial preparation is not affected. In addition to a decreased contraction of the myocardium, alteration of impulse formation or suppression of impulse conduction appear to be responsible for the cardioplegia produced by the cyclohexylamine derivatives. Preliminary studies of the pressor response to *trans*-2-(*p*-chlorophenyl)-*N,N*-dimethylcyclohexylamine hydrochloride (TH-25) indicate that the compound is capable of producing direct peripheral vasoconstriction.

Correlation of Dissolution Rate and Griseofulvin Absorption in Man

By B. KATCHEN and S. SYMCHOWICZ

Five different griseofulvin preparations were studied in 10 healthy subjects. Plasma levels were followed for 24 hr. after single oral 500-mg. doses. The dissolution rate of each dosage form was measured in simulated intestinal fluid and distilled water. Good correlation was seen between dissolution rates in simulated intestinal fluid and griseofulvin absorption in man.

GRISEOFULVIN is given in large amounts and is insoluble in water. Its dose in man is 125–500 mg., and its water solubility is 15 mcg./ml. at 37°. If the digestive fluids are saturated with respect to griseofulvin at all times, and griseofulvin solubility in digestive fluids is the same as in distilled water, a minimum of 33 L. of digestive fluids must be cleared for complete absorption of 500 mg. of griseofulvin as shown by the following calculation: dose (500 mg.)/solubility (15 mg./L.) = 33 L. Clearly, oral griseofulvin dosage

response which progressed throughout the entire tissue exposure time. If given simultaneously with either CH-20 or TH-27, the onset of the negative inotropic effect was delayed by the calcium.

SUMMARY AND CONCLUSIONS

As a group, the nonethynyl cyclohexanol derivatives were 2 to 7 times more potent than were the derivatives of cyclohexylamine in producing a hypotensive response in the intact rat. *trans*-2-*o*-Tolyl-*cis*-1,4-cyclohexanediol (CH-14) and *trans*-2-*o*-tolyl-*trans*-1,5-cyclohexanediol (CH-20) were equally effective and the most active, while the *trans* isomer of the tertiary cyclohexylamine (TH-25) was the least active and the only compound that produced a pressor response. The cyclohexylamine derivatives were up to 8 times more potent, in arresting the isolated guinea pig heart, than were the derivatives of cyclohexanol. The *trans* and *cis* isomers of the tertiary cyclohexylamine (TH-25 and TH-27) were equally effective and the most active; while *trans*-2-*o*-tolyl-*cis*-1,4-cyclohexanediol (CH-14) possessed the least amount of cardio-inhibitory activity among those compounds studied. An increase in the number of hydroxyl substituents on the cyclohexanol ring was accompanied by a decrease in both hypotensive and cardio-inhibitory activity. The minimum effective dose of 1-ethynyl-*trans*-2-*o*-tolylcyclohexanol (AH-64) in producing cardiac arrest was also the cardiotoxic dose; while the *cis* isomer (AH-65) showed the greatest cardio-inhibitory activity among the cyclohexanol derivatives studied. Spatial configuration was also significant in the blood pressure activity of the tertiary cyclohexylamines. The *cis* isomer (TH-27) produced a depressor response in contrast to the pressor response elicited by the *trans* isomer (TH-25). In the isolated atrial preparation, calcium antagonized the negative inotropic effects of *trans*-2-*o*-tolyl-*trans*-1,5-cyclohexanediol (CH-20) and *cis*-2-(*p*-chlorophenyl)-*N,N*-dimethylcyclohexylamine hydrochloride (TH-27). Moreover, calcium momentarily restored contraction of the heart arrested by 1-ethynyl-*cis*-2-*o*-tolylcyclohexanol (AH-65). In addition to its negative inotropic effect on the isolated atria, *cis*-2-(*p*-chlorophenyl)-*N,N*-dimethylcyclohexylamine hydrochloride (TH-27) also produced a negative chronotropic response which was unaffected by the administration of calcium. Decreased contraction of the myocardium appears to be responsible for the cardioplegia produced by the cyclohexanol compounds, since the pacemaker activity of the isolated atrial preparation is not affected. In addition to a decreased contraction of the myocardium, alteration of impulse formation or suppression of impulse conduction appear to be responsible for the cardioplegia produced by the cyclohexylamine derivatives. Preliminary studies of the pressor response to *trans*-2-(*p*-chlorophenyl)-*N,N*-dimethylcyclohexylamine hydrochloride (TH-25) indicate that the compound is capable of producing direct peripheral vasoconstriction.

Correlation of Dissolution Rate and Griseofulvin Absorption in Man

By B. KATCHEN and S. SYMCHOWICZ

Five different griseofulvin preparations were studied in 10 healthy subjects. Plasma levels were followed for 24 hr. after single oral 500-mg. doses. The dissolution rate of each dosage form was measured in simulated intestinal fluid and distilled water. Good correlation was seen between dissolution rates in simulated intestinal fluid and griseofulvin absorption in man.

GRISEOFULVIN is given in large amounts and is insoluble in water. Its dose in man is 125–500 mg., and its water solubility is 15 mcg./ml. at 37°. If the digestive fluids are saturated with respect to griseofulvin at all times, and griseofulvin solubility in digestive fluids is the same as in distilled water, a minimum of 33 L. of digestive fluids must be cleared for complete absorption of 500 mg. of griseofulvin as shown by the following calculation: dose (500 mg.)/solubility (15 mg./L.) = 33 L. Clearly, oral griseofulvin dosage

forms must be carefully designed and evaluated to insure maximum drug availability.

Several factors affecting griseofulvin plasma levels were studied (1–6) but the effect of dissolution rate on griseofulvin absorption was not measured. This study will correlate dissolution rate of griseofulvin dosage forms and griseofulvin absorption in man.

EXPERIMENTAL

Materials—Five different 125-mg. griseofulvin preparations were studied.

Methods—At 1-week intervals, 5 different griseofulvin preparations were given to 10 humans in a three-factor repeat measure design (7). Each subject took 500 mg. griseofulvin before breakfast at approximately 8:00 a.m. and ate a standard meal at 10:00 a.m. The subjects were told to avoid, for the next 24 hr., the foods and drugs which interfere with the griseofulvin plasma assay (8).

Blood was drawn at 0, 2, 4, 8, and 24 hr. postdrug and the plasma samples were assayed fluorometrically for griseofulvin (9). All plasma levels were corrected for their zero-hour values.

Mean plasma level, which was the index of absorption, was calculated by dividing the area (determined by the trapezoidal rule) under the 24-hr. plasma level curve by 24.

Dissolution rates of single 125-mg. tablets or capsules were measured (10) in either 20 L. of distilled water or 20 L. of simulated intestinal fluid (dissolve 20 Gm. of pH 7.2 phosphate buffer powder[1] and an aqueous extract of 5 Gm. of enzyme powder[2] in 20 L. of distilled water).

RESULTS AND DISCUSSION

Dissolution Rates—Table I shows the dissolution rate of four preparations in distilled water and simulated intestinal fluid. Preparation *5* could not be analyzed because its contents clogged the 40-mesh screen of the sample holder; therefore, its

dissolution rate could not be correlated with absorption of griseofulvin.

In distilled water (Table I) the dissolution rates of preparations *1*, *2*, and *3* are very low and cannot be differentiated. However, in simulated intestinal fluid, except for preparation *1*, the dissolution rates are much higher and reveal differences between preparations related to their formulations. Thus, intestinal fluid is a more sensitive tool for evaluation of griseofulvin formulations.

Plasma Levels—The individual assay data are shown in Table II. Peak plasma levels, which vary from 0.35 to 1.26 mcg./ml., occur in 2 to 4 hr. (Fig. 1) and then decline slowly for the next 20–22 hr. at varying rates. Preparations *3* and *4*, which have the highest dissolution rates in simulated intestinal fluid, decline more rapidly than preparations *1* and *2*, which have the lowest dissolution rates in simulated intestinal fluid.

The sustained low plasma level of preparation *1* suggests slow and prolonged drug release *in vivo*. In contrast, the much higher peak plasma levels and disappearance rates of preparations *3* and *4* suggest early and rapid drug release *in vivo*. An analysis of variance procedure for repeat measure designs (Table III), which assumes a fixed effects model, was applied to the plasma levels.

The analysis shows treatments, time, and the treatment × time interaction are significant factors ($p < 0.01$). Duncan's multiple range test was applied to the area/24 values (Table IV) which were calculated for each set of plasma levels in Table II. The values not connected by a common line differ significantly ($p < 0.05$).

Correlation of Dissolution Rate and Griseofulvin Absorption—Because each preparation could not be characterized with a single dissolution rate constant, the authors arbitrarily selected amount dissolved in a given time as a measure of dissolution rate. A meaningful correlation between mean plasma level and dissolution rates in distilled water could not be found because most of the griseofulvin preparations have low dissolution rates in this solvent. However, a good correlation was found between mean griseofulvin plasma level and dissolution rate in simulated intestinal fluid. The best correlation is obtained with the logarithm of the 30-min. dissolution values (Fig. 2). The correlation coefficient is 0.995 ($p = 0.01$). The 15-min. dissolution values have a correlation coefficient of 0.96 ($p = 0.05$); the 10-min. values have a correlation coefficient of 0.82 ($p = 0.10$).

The high correlation coefficients in this study were obtained with preparations that differ widely in their composition and dissolution rates. This suggests that the ability of various griseofulvin formulations to increase plasma drug levels in man (1–3) might have been due to improved dissolution rates.

Conformational Analysis of 4-Hydroxycyclohexanone Oxime by NMR Spectroscopy

By WILLIAM F. TRAGER and ALAIN C. HUITRIC

The conformational free energy of the hydroxyl group of 4-hydroxycyclohexanone oxime has been found to be 0.33 and 0.61 Kcal./mole in pyridine and D_2O, respectively. These values are intermediate to those of the hydroxyl group of cyclohexanol and 4-hydroxycyclohexanone in the corresponding solvents. Comparison of the spectrum of 4-*tert*-butylcyclohexanone-3$_{(axial)}$,5,5-d_3 oxime with that of 4-hydroxycyclohexanone oxime and utilization of the long-range deshielding effect of the oximido group has permitted assignment of the individual resonances in the spectrum of the latter compound to specific hydrogens. Moreover, the comparison of spectra and use of the oximido group long-range deshielding effect has provided an independent check on the validity of the equilibrium positions calculated herein.

THE CONFORMATIONAL free energy of the hydroxyl group ($-\Delta G°_{OH}$) in cyclohexane systems has been the subject of extensive investigations over the past 10 years and is now well established. The results are summarized by Eliel and Schroeter (1). Values of 1.25 Kcal./mole in D_2O (2) and 0.83 in pyridine (3) have been obtained for cyclohexanol. It is only recently that comparative studies have been extended to six-membered saturated ring systems containing a hetero atom (4) or a trigonal carbon (5). Since the authors have found a significant difference in the values of $-\Delta G°_{OH}$ for cyclohexanol and 4-hydroxycyclohexanone at similar concentrations in a given solvent (5)[1] it was of interest to extend the investigation to the other six-membered ring compounds containing a trigonal carbon atom. The observation of an unusually large chemical shift difference between the geminal hydrogens adjacent to the oximido group in 4-*tert*-butylcyclohexanone oxime (6) pointed to 4-hydroxycyclohexanone oxime as an attractive system to study both phenomena.

DISCUSSION

Conformational Analysis—Conformational preference of the two chair conformers 1a and 1b, Fig. 1, was determined by the signal width method (5, 7–12) as described for 4-hydroxycyclohexanone (5). The mole fraction of conformer 1a (*Na*) was obtained from w, the width of the signal of H-4 (hydrogen Z) in the mobile system, and from w_e and w_a, the widths of the signals of H-1 in the two conformationally homogeneous models *trans*- and *cis*-4-*tert*-butylcyclohexanol-3$_{(axial)}$,5,5-d_3, II and III, respectively, by the following relationship (5):

$$Na = \frac{w - w_a}{w_e - w_a}$$

From the spectrum of II in pyridine, w_e was found to be 30.0 c.p.s., Jaa = 10.7, Jae = 4.4, and J_{gem} = 12.0 c.p.s.; and the spectrum of III in pyridine gave w_a = 11.0 c.p.s., Jea $\simeq$ Jee $\simeq$ 2.7 c.p.s. (5).

In pyridine the signal of Z has a width w, of 23 c.p.s. which leads to a value of 0.63 for the mole fraction *Na* of conformer 1a and a free energy difference, $-\Delta G°_{OH}$, of 0.33 Kcal./mole at 37°. In D_2O[2] the width of the signal measured from spectrum E is 24.8 c.p.s., leading to an *Na* value of 0.73 and $-\Delta G°_{OH}$ of 0.61 Kcal./mole at 37°. The addition of about two equivalents of diethylamine in pyridine did not cause any change in the width of the signal of Z. Addition of slightly over one equivalent of NaOH in D_2O caused an increase of about 0.5 c.p.s. in w. This suggests that there is very little, if any, ionization of the oxime in pyridine under the conditions of the measurements.

Assignment of Signals to Specific Hydrogens—The assignment of the signal of the Z hydrogen is obvious in all spectra. In the 60 Mc. spectra it occurs at τ 6.05 in D_2O and τ 5.91 in pyridine. In the 100 Mc. spectrum in pyridine it occurs at τ 5.88. There is also a slight difference in the chemical shift of the X hydrogen obtained from the 60 and 100 Mc. spectra in pyridine: τ 6.73 at 60 Mc. and

[1] 0.28 Kcal./mole in D_2O and zero in pyridine for 4-hydroxycyclohexanone.

[2] The model compounds II and III are not sufficiently soluble for measurements in D_2O, and the w_e and w_a values obtained in pyridine were used. The danger of error due to variation of coupling constants with solvent in these rigid systems seems minimal because of the observation that the difference in the width of the signal of H-1 in 4-*tert*-butyl-*cis*-4-hydroxycyclohexanol-3,3,5,5-d_4 (13) measured in pyridine and 25% acetic acid in D_2O is only 0.5 c.p.s.

Conformational Analysis of 4-Hydroxycyclohexanone Oxime by NMR Spectroscopy

By WILLIAM F. TRAGER and ALAIN C. HUITRIC

The conformational free energy of the hydroxyl group of 4-hydroxycyclohexanone oxime has been found to be 0.33 and 0.61 Kcal./mole in pyridine and D_2O, respectively. These values are intermediate to those of the hydroxyl group of cyclohexanol and 4-hydroxycyclohexanone in the corresponding solvents. Comparison of the spectrum of 4-*tert*-butylcyclohexanone-3$_{(axial)}$,5,5-d_3 oxime with that of 4-hydroxycyclohexanone oxime and utilization of the long-range deshielding effect of the oximido group has permitted assignment of the individual resonances in the spectrum of the latter compound to specific hydrogens. Moreover, the comparison of spectra and use of the oximido group long-range deshielding effect has provided an independent check on the validity of the equilibrium positions calculated herein.

THE CONFORMATIONAL free energy of the hydroxyl group ($-\Delta G°_{OH}$) in cyclohexane systems has been the subject of extensive investigations over the past 10 years and is now well established. The results are summarized by Eliel and Schroeter (1). Values of 1.25 Kcal./mole in D_2O (2) and 0.83 in pyridine (3) have been obtained for cyclohexanol. It is only recently that comparative studies have been extended to six-membered saturated ring systems containing a hetero atom (4) or a trigonal carbon (5). Since the authors have found a significant difference in the values of $-\Delta G°_{OH}$ for cyclohexanol and 4-hydroxycyclohexanone at similar concentrations in a given solvent (5)[1] it was of interest to extend the investigation to the other six-membered ring compounds containing a trigonal carbon atom. The observation of an unusually large chemical shift difference between the geminal hydrogens adjacent to the oximido group in 4-*tert*-butylcyclohexanone oxime (6) pointed to 4-hydroxycyclohexanone oxime as an attractive system to study both phenomena.

DISCUSSION

Conformational Analysis—Conformational preference of the two chair conformers 1a and 1b, Fig. 1, was determined by the signal width method (5, 7–12) as described for 4-hydroxycyclohexanone (5). The mole fraction of conformer 1a (*Na*) was obtained from w, the width of the signal of H-4 (hydrogen Z) in the mobile system, and from w_e and w_a, the widths of the signals of H-1 in the two conformationally homogeneous models *trans*- and *cis*-4-*tert*-butylcyclohexanol-3$_{(axial)}$,5,5-d_3, II and III, respectively, by the following relationship (5):

$$Na = \frac{w - w_a}{w_e - w_a}$$

From the spectrum of II in pyridine, w_e was found to be 30.0 c.p.s., Jaa = 10.7, Jae = 4.4, and J_{gem} = 12.0 c.p.s.; and the spectrum of III in pyridine gave w_a = 11.0 c.p.s., Jea $\simeq$ Jee $\simeq$ 2.7 c.p.s. (5).

In pyridine the signal of Z has a width w, of 23 c.p.s. which leads to a value of 0.63 for the mole fraction *Na* of conformer 1a and a free energy difference, $-\Delta G°_{OH}$, of 0.33 Kcal./mole at 37°. In D_2O[2] the width of the signal measured from spectrum E is 24.8 c.p.s., leading to an *Na* value of 0.73 and $-\Delta G°_{OH}$ of 0.61 Kcal./mole at 37°. The addition of about two equivalents of diethylamine in pyridine did not cause any change in the width of the signal of Z. Addition of slightly over one equivalent of NaOH in D_2O caused an increase of about 0.5 c.p.s. in w. This suggests that there is very little, if any, ionization of the oxime in pyridine under the conditions of the measurements.

Assignment of Signals to Specific Hydrogens—The assignment of the signal of the Z hydrogen is obvious in all spectra. In the 60 Mc. spectra it occurs at τ 6.05 in D_2O and τ 5.91 in pyridine. In the 100 Mc. spectrum in pyridine it occurs at τ 5.88. There is also a slight difference in the chemical shift of the X hydrogen obtained from the 60 and 100 Mc. spectra in pyridine: τ 6.73 at 60 Mc. and

[1] 0.28 Kcal./mole in D_2O and zero in pyridine for 4-hydroxycyclohexanone.

[2] The model compounds II and III are not sufficiently soluble for measurements in D_2O, and the w_e and w_a values obtained in pyridine were used. The danger of error due to variation of coupling constants with solvent in these rigid systems seems minimal because of the observation that the difference in the width of the signal of H-1 in 4-*tert*-butyl-*cis*-4-hydroxycyclohexanol-3,3,5,5-d_4 (13) measured in pyridine and 25% acetic acid in D_2O is only 0.5 c.p.s.

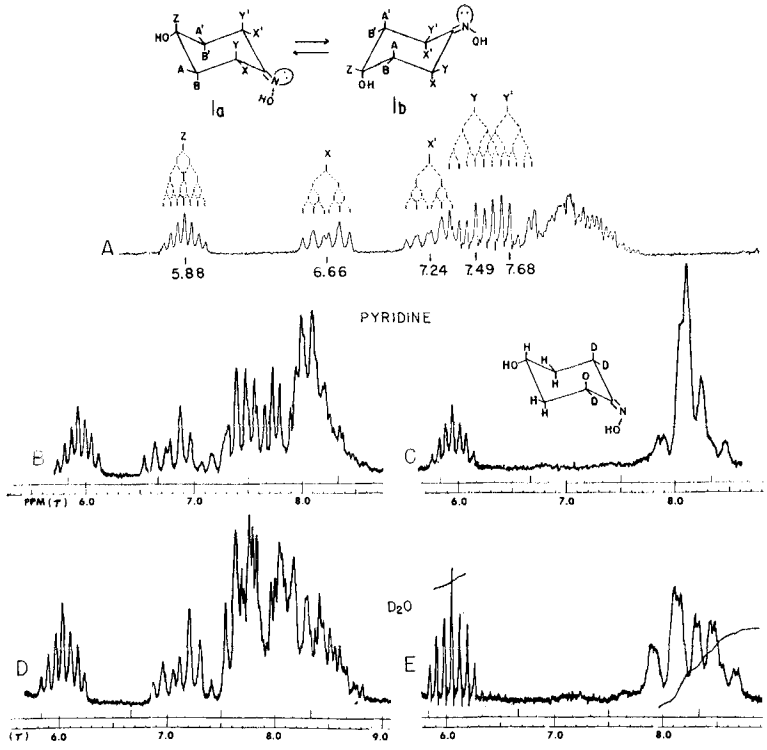

Fig. 1—NMR spectra of 4-hydroxycyclohexanone oxime (A, B, *and* D) *and the 2,2,6,6-*d_4 *analog* (C *and* E) *in pyridine and* D_2O *at 37°;* A *at 100 Mc. in pyridine,* B *and* C *at 60 Mc. in pyridine, and* D *and* E *at 60 Mc. in* D_2O.

τ 6.66 at 100 Mc. Small differences in observed chemical shifts obtained from 60 and 100 Mc. spectra are not uncommon and may arise from nonlinearity in frequency sweep with the 100 Mc. instrument, or also from nonfirst-order spectra. The 60 Mc. spectrum C of the deuterated analog shows that the difference in chemical shifts of A and B, or A′ and B′, is not sufficient to justify the first-order approximation in spectrum B (5). At 100 Mc. the complications from strong coupling and virtual coupling effects will be reduced. Comparison of spectra B and C establishes that the signals of the C-2 and C-6 hydrogens (X, X′, Y, and Y′) fall in the range between τ 6.50 and 7.85 and that the signals of the C-3 and C-5 hydrogens (A, A′, B, and B′) are above τ 7.75.

III

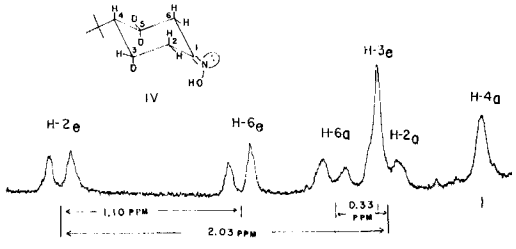

Fig. 2—NMR spectrum of 4-tert-*butylcyclohexanone-*$3_{(axial)}$,5,5-d_3 *oxime in pyridine at 100 Mc. at 37°.*

In a recent communication (6) dealing with the magnetic anisotropy of the oximido group in 4-*tert*-butylcyclohexanone-$3_{(axial)}$,5,5-d_3 oxime (IV) we have shown a large chemical shift difference between the equatorial hydrogens on C-2 and C-6 and have established the relationship between the signal of a given equatorial hydrogen at C-2 or C-6 and that of its geminal axial hydrogen. More recently experimental proof has been furnished (14) that the greatest deshielding effect of the oximido group results from the proximity of the hydroxyl group rather than from the unshared pair of electrons on the nitrogen as proposed by Saitô *et al.* (15–18). Other investigators have also presented evidence consistent with the largest deshielding effect of the hydroxyl group (19–24). On the basis of this information it is now possible to assign the signals of all hydrogens in IV as shown in the 100 Mc. spectrum measured in pyridine, Fig. 2.

The spectrum of IV, Fig. 2, provides an interesting check on the conformational equilibrium of I as calculated by the signal width method and also

permits the assignment of the signals of X, X′, Y, and Y′ in spectrum A, Fig. 1. Both spectra were measured at 100 Mc. in pyridine. In the spectrum of the conformationally homogeneous model IV there is a difference of 1.10 p.p.m. between chemical shifts of equatorial H-2 and H-6, and a difference of 0.33 p.p.m. between axial H-2 and axial H-6. The equatorial H-2 and H-6 in IV correspond to X and X′, respectively, in conformation Ia of 4-hydroxycyclohexanone oxime while in relationship to the oximido group X and X′ of conformer Ib correspond to axial H-2 and H-6, respectively, of IV. It follows, therefore, that the chemical shift difference between X and X′ should be 1.10 p.p.m. in pure conformer Ia and 0.33 p.p.m. in pure conformer Ib. In an equilibrium mixture of conformers Ia and Ib the observed spectrum at any given instant is that due to the weighted time average of the spectra arising from these two conformers. The observed difference between the chemical shifts of X and X′ in the equilibrium mixture will be a function of the populations of the two conformers. This difference for a population of 63% Ia and 37% Ib can be calculated by $[0.63(\nu_X - \nu_{X'})_{Ia} + 0.37(\nu_X - \nu_{X'})_{Ib}] = [0.63(1.10) + 0.37(-0.33)] = 0.57$ p.p.m.[3] The agreement with the observed experimental value of 0.58 p.p.m., spectrum A, is excellent.

A similar treatment for Y and Y′ yields valuable information about their relative chemical shifts and helps to unravel the complex pattern of peaks between about τ 7.35 and 7.85 resulting from the signals of Y and Y′. In conformer Ia hydrogens Y and Y′ are related to axial H-2 and H-6, respectively, of IV and their signals should be 33 c.p.s. apart, at 100 Mc., while in conformer Ib Y and Y′ are related to equatorial H-2 and H-6 of IV and their signals should be 110 c.p.s. apart. The experimental chemical shift difference between Y and Y′ in an equilibrium mixture of 63% Ia and 37% Ib should be $[0.63(\nu_Y - \nu_{Y'})_{Ia} + 0.37(Y - Y')_{Ib}] = [0.63(-0.33) + 0.37(1.10)] = 0.20$ p.p.m., or 20 c.p.s. at 100 Mc., with Y occurring at lower field. The experimental difference of 0.19 p.p.m. with the signal of Y at τ 7.49 and Y′ at τ 7.68 is in very good agreement and is consistent with the complexity of the partially overlapping signals and the relative intensities of the peaks.

Coupling Constants—Direct measurements of coupling constants from spectra A and E, Fig. 1, yield $J_{ZA} = 3.8$ and $J_{ZB} = 7.7$ c.p.s. for 4-hydroxycyclohexanone oxime in pyridine, and $J_{ZA} = 4.1$ and $J_{ZB} = 8.2$ for the deuterated analog in D_2O. The calculated values of J_{ZA} and J_{ZB}, based on the model compounds II and III, for an equilibrium mixture of 63% conformer A are:

$$J_{ZB} = 0.63\ Jaa + 0.37\ Jee = (0.63)(10.7) + (0.37)(27) = 7.7 \text{ c.p.s.}$$

$$J_{ZA} = 0.63\ Jae + 0.37\ Jea = (0.63)(4.4) + (0.37)(2.7) = 3.8 \text{ c.p.s.}$$

By similar calculations the theoretical values for an equilibrium of 73% of conformer Ia are: $J_{ZB} = 4.0$ and $J_{ZA} = 8.5$ c.p.s. The excellent agreement between observed and theoretical values suggests that in pyridine at 100 Mc. and in D_2O at 60 Mc. the difference in chemical shift between A and B is sufficient to be outside of the limits of serious complications from strong coupling effects (5) and that the first-order approximation is applicable to analysis of the Z signal. Strong coupling effects would cause a change in the relative values of observed coupling constants but would not change the sum of the coupling constants and therefore would not affect the width of the signal of Z.

Direct measurements of apparent coupling constants from the signals of X, X′, Y, and Y′ from spectrum A yield $J_{XY} = 14.2$, $J_{YB} = 9.4$, $J_{YA} = 4.0$, and $J_{XA} \simeq J_{XB} = 5.9$ c.p.s. This suggests unusual differences (26) in *Jaa*, *Jee*, *Jae*, and *Jea* between C-2 and C-3, or C-6 and C-5, vicinal hydrogens compared to the C-3 and C-4 system. The proximity of the sp^2 hydridized carbon appears to have some effect on the magnitudes of these vicinal coupling constants. The increase in geminal coupling constants by the proximity of an sp^2 carbon is reasonably well understood (27) and effects on vicinal coupling constants have been observed in α-halogenated cyclohexanone systems (9, 28–30), but in this system the chemical shift differences between the coupled hydrogens responsible for this part of the spectrum are not sufficient to truly justify the first-order approximation. This difficulty precludes speculation regarding the apparently anomalous vicinal coupling constants between hydrogens on C-2 and C-3 and on C-5 and C-6.

EXPERIMENTAL

The 60 Mc. spectra were determined on a Varian A-60 spectrometer at 37° on solutions of approximately 20% utilizing TMS as the internal standard for spectra determined in pyridine and DSS for the spectra determined in D_2O. Melting points were determined on a Fisher-Johns melting point apparatus.

4-Hydroxycyclohexanone Oxime—To a solution of 20% ammonium hydroxide (16.5 ml., 0.146 mole) was added hydroxylamine hydrochloride (4.6 Gm., 0.081 mole) with stirring. To the resulting solution was added, all at once, a solution of 4-hydroxycyclohexanone (8) (5.5 Gm., 0.048 mole) in 20 ml. of methanol. The reaction mixture was stirred for 20 min. then allowed to stand at room temperature for 22 hr. At the end of this period the reaction mixture was exhaustively extracted with ether. The ethereal extracts were combined, dried over anhydrous sodium sulfate, the mixture filtered, and the ether evaporated. The residue was taken up in ethyl acetate, treated with charcoal, then recrystallized from ethyl acetate yielding 3.4 Gm. (55%) of product, m.p 78–79°. Kahr and Berther (31) reported a boiling point of 161–164° at 11 mm. for 4-hydroxycyclohexanone oxime.

4-Hydroxycyclohexanone-2,2,6,6-d_4-oxime—This compound was obtained in a 30% yield by the slightly modified general method of Shriner, Fuson, and Curtin (32) for preparation of oximes. To a solution containing anhydrous pyridine (5 ml.), 99.8% D_2O (10 ml.), and hydroxylamine hydrochloride (1.0 Gm., 0.015 mole) was added 4-hydroxycyclohexanone-2,2,6,6-d_4 (8) (1.0 Gm., 0.0085 mole). The resulting solution was allowed to stand for 22 hr. then concentrated to approximately 2 ml. on a hot plate. The concentrated solution was extracted with 3 portions of ether, the ethereal

[3] The minus sign of $(\nu_X - \nu_{X'})_{Ib}$ results from axial H-6 being at lower field (larger ν) than axial H-2 in the model compound IV.

extracts combined, and dried over anhydrous calcium sulfate. The mixture was filtered and the ether evaporated. The residue was dissolved in a minimal amount of warm ethyl acetate, a crystal of 4-hydroxycyclohexanone oxime added, and crystallization allowed to proceed. The product was collected by filtration, m.p. 76–78°.

4 - tert - Butylcyclohexanone - $3_{(axial)}$,5,5 - d_3—This compound was obtained in 85% yield from the chromic acid oxidation of a mixture of *cis* and *trans*-4-*tert*-butylcyclohexanol-$3_{(axial)}$,5,5-d_3 (8) according to the method of Brown and Garg (33). The product was recrystallized from a water–methanol mixture, m.p. 49–50°. Ziegenbein and co-workers (34) reported a b.p. of 84–85° at 7.0 mm. and a m.p. of 49–50° for 4-*tert*-butylcyclohexanone.

4 - tert - Butylcyclohexanone - $3_{(axial)}$,5,5 - d_3-oxime—This compound was obtained in 92% yield by the slightly modified method of Ziegenbein and co-workers (34) for obtaining 4-*tert*-butylcyclohexanone oxime. To a solution of 20% ammonium hydroxide (19 ml., 0.11 mole), hydroxylamine hydrochloride (3.9 Gm., 0.056 mole), and methanol (75 ml.) was added 4-*tert*-butylcyclohexanone-$3_{(axial)}$,5,5-d_3 (5 Gm., 0.033 mole). The resulting solution was stirred for approximately 1 hr. at room temperature and then allowed to stand overnight. As the reaction progressed, the product precipitated, and after standing overnight it was collected by filtration. A second crop of product was obtained by adding water to the filtrate. The crystalline fractions were combined and recrystallized from a water–methanol mixture, m.p. 138–140°. Ziegenbein and co-workers (34) reported a m.p. of 133° for 4-*tert*-butylcyclohexanone oxime.

Octamethyleneimine in the Mannich Reaction I

Substituted β-Amino Ketones and Substituted α-Amino Alcohols

By HEINO A. LUTS, J. F. GRATTAN, S. YANKELOWITZ*, and W. L. NOBLES†

A group of Mannich bases, utilizing octamethyleneimine as the amine component, has been prepared. Their preparation and biological activities are given.

OVER A period of years, a variety of Mannich bases has been prepared (1–26) for pharmacological testing. A typical Mannich condensation of the type discussed here may be illustrated as follows:

$$R{-}\overset{\overset{O}{\|}}{C}{-}CH_3 + HCHO + R_2NH{\cdot}HCl \rightarrow RCOCH_2CH_2NR_2{\cdot}HCl + H_2O$$

Certain substituted β-aminoketones and derivatives have been reported (2, 3, 5, 7) to show both local anesthetic and antispasmodic activity. The extensive literature dealing with

† School of Pharmacy, University of Mississippi, University, MS 38677

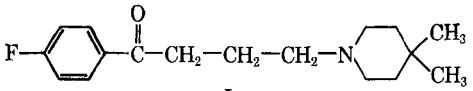
the Mannich reaction has been reviewed by Blicke (27) and later by Reichert (28).

Mannich and Lammering (2) reported that β-piperidinopropiophenone hydrochloride possesses local anesthetic activity. Denton and co-workers (7) in a series of papers described the antispasmodic activity of the Mannich bases. Under the conditions reported by these workers for determining antispasmodic activity, β-piperidinopropiophenone hydrochloride and 2-(β-piperidinopropionyl)-thiophene hydrochloride possess antispasmodic activity equal to that of β-diethylaminoethyl diphenyl acetate hydrochloride[1] and greater than that of papaverine. Burckhalter and Johnson (20) reported the antibacterial activity of certain Mannich bases derived from α,β-unsaturated ketones. Mercier and his associates indicated that the diethylamino Mannich base from acetophenone was adrenolytic, hypotensive, and ganglioplegic (10). β-Amino ketones derived from hexamethyleneimine were reported to possess CNS tranquilizing ability as well as local anesthetic activity (29, 30).

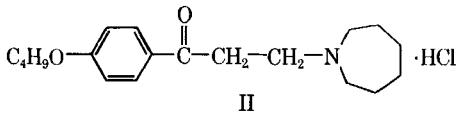
Most of the compounds prepared to the present have been alkylamino, dialkylamino, or 5- or 6-membered heterocyclic rings; only a few large ring amines have been prepared. In the last paper (26), heptamethyleneimine was used; now an attempt has been made to extend the Mannich reaction to a larger nitrogen-containing ring and to evaluate the compounds thus obtained. The authors have anticipated that the enlargement of the carbon content of the molecule would increase the lipid solubility and, because of the different shape of the amine ring (as compared to simple dialkylamines), it was felt also that these compounds might possibly exhibit different biological properties.

The demonstration that larger nitrogen-containing ring systems or highly branched amines in Mannich bases tend to elicit (26) a significant pharmacological activity which may or may not be particularly pronounced in Mannich bases containing smaller ring systems has influenced the continuation of this work. Recently, more evidence, in a degree, of this has come to our attention in the work of Simpson (31) that 4-fluoro-4-(4,4-dimethylpiperidino)butyrophenone acted as an antipsychotic agent and lowered blood cholesterol (I).



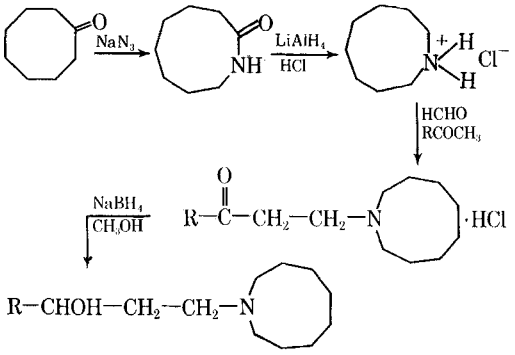
I

Zaidler and Kudrin (32) noted that 4′-butoxy-3-[hexahydro-(1*H*)azepine-1-yl]propiophenone hydrochloride has relatively high antiarrhythmic activity (II).



II

The method of preparing the octamethyleneimine was that of Blicke and associates (33). The Mannich reaction was carried out according to the original work of Tollens, in 1903 (34), and the Mannich base so obtained was reduced with sodium borohydride (35). (Scheme I.)



Scheme I

PHARMACOLOGY

The preliminary pharmacological results of these β-amino ketones and γ-amino alcohols, listed in Table I, are indicated below.

Phenylquinone Writhing Test in Mice—Good activity: 40% decrease of writhing movements as compared to untreated controls. Slight activity: 10–40% decrease of the writhing movements as compared to the untreated controls.

Hexobarbital[2] Induced Sleep in Mice—Good potentiation: 40% increase in sleeping time over the untreated controls. Slight potentiation: 10–40% increase in sleeping time over the untreated controls.

Tremorine Test in Mice—Induced tremors (T), lacrimation (L), and salivation (S). Good activity: one or more factors (T, L, S) decreased by 75–100% as compared with untreated controls. Slight activity: one or more factors (T, L, S) decreased by 50–75% as compared with untreated controls.

Compound *1* demonstrated a mild depressant effect, good activity in the phenylquinone test, possessed a transient hypotensive activity, and had an ocular anesthetic effect.

Compound *2* acted as a mild depressant and affected muscle tone. It had a good antipyretic and hypotensive activity. In the hexobarbital-induced sleep test in mice it demonstrated a good potentiation.

Compound *3* also exhibited a mild depressant

effect and an effect on muscle tone. This compound demonstrated a slight sympathomimetic activity, and elicited a good phenylquinone writhing response. It also demonstrated good activity as an analgesic in the "hot plate" test method, and activity in a reversed hexobarbital test. It was also a good antipyretic.

Compound *4* acted as a mild depressant, with some effect on muscle tone, by increasing tonus. A slight phenylquinone writhing effect and a good antipyretic effect were demonstrated. There was only transient hypotensive activity.

Compound *5* acted as a mild depressant, possessing also a slight to good phenylquinone writhing effect. Good antipyretic effect was demonstrated.

Compound *6* possessed a transient hypotensive activity with a slight anti-parkinsonism effect.

Compound *7* decreased spontaneous motor activity and demonstrated some sympathomimetic activity. It had only a slight phenylquinone writhing effect. A slight analgesic effect was elicited with the "hot plate" test. Good potentiation of hexobarbital-induced sleep was noted; only slight ocular anesthetic activity was demonstrated.

Compound *8* acted as a mild depressant but showed a slight phenylquinone writhing effect. However, good activity in hexobarbital-induced sleep potentiation was noted.

EXPERIMENTAL[3]

β-Amino Ketones—The preparation of the β-amino ketones was accomplished by the following general procedure. A solution of 0.05 mole of the appropriate acetophenone, 0.05 mole of octamethyleneimine hydrochloride, 1.5 Gm. of paraformaldehyde, and 140 ml. of absolute ethanol was refluxed for 1 hr. Three-hundred milligrams of paraformaldehyde was added, and the solution was refluxed for another hour. The ethanol was then boiled off until only 25 ml. of solution remained. After cooling to room temperature, 100 ml. of acetone and 100 ml. of anhydrous ether were added. The mixture was cooled and filtered. The crystals were twice washed with 30 ml. of anhydrous ether and recrystallized from ethanol–ether.

γ-Amino Secondary Alcohols—The preparation of the γ-amino secondary alcohols was patterned after the method of Chaikin and Brown (35). The γ-amino ketone (0.05 mole) was suspended in 100 ml. of methanol and to this was added 0.1 mole of sodium borohydride. The addition was conducted at a rate such as to maintain the temperature between 20–40°. After the evolution of hydrogen had subsided, the methanol was removed first by

[3] Microanalysis was performed by Mr. G. Roberts, Jr., Florham Park, N. J. All melting points are uncorrected.

distilling, later under vacuum. The residue was suspended in 100 ml. of distilled water and extracted with three 100-ml. portions of ether. The ether was then removed under diminished pressure and the alcohol recrystallized to analytical purity from an ethanol solution.

SUMMARY

The compounds evaluated indicate that the larger ring amine components in Mannich bases show pharmacological potentialities and should be included as amine components in series. More extensive work is in progress.

Acetylation of Acetaminophen in Tablet Formulations Containing Aspirin

By K. T. KOSHY*, A. E. TROUP, R. N. DUVALL, R. C. CONWELL, and L. L. SHANKLE

The degradation of aspirin in commercial products containing acetaminophen was found to be accompanied by the formation of diacetyl-*p*-aminophenol (DAPAP) or *p*-acetoxyacetanilid. This reaction product was not detectable using conventional acetaminophen analytical procedures, but was detected qualitatively by means of thin-layer chromatography. A procedure utilizing partition–column chromatography and gas–liquid chromatography was developed for the determination of DAPAP in products containing aspirin, acetaminophen, and caffeine. Commercial products were found to contain various levels of DAPAP up to 4 mg./tablet. Magnesium stearate was found to accelerate the reaction markedly.

THE STABILITY of aspirin *per se* in pharmaceutical dosage forms has received considerable attention and the problem is widely recognized. However, reports of the interaction of aspirin with other drugs, such as amines and phenols, have only recently begun to appear in the literature. Troup and Mitchner (1) reported that phenylephrine underwent acetylation in tablets containing aspirin. Under accelerated conditions, the mono-, di-, and triacetylated products were formed. Even at 24° the secondary amine group

Acetylation of Acetaminophen in Tablet Formulations Containing Aspirin

By K. T. KOSHY*, A. E. TROUP, R. N. DUVALL, R. C. CONWELL, and L. L. SHANKLE

The degradation of aspirin in commercial products containing acetaminophen was found to be accompanied by the formation of diacetyl-*p*-aminophenol (DAPAP) or *p*-acetoxyacetanilid. This reaction product was not detectable using conventional acetaminophen analytical procedures, but was detected qualitatively by means of thin-layer chromatography. A procedure utilizing partition–column chromatography and gas–liquid chromatography was developed for the determination of DAPAP in products containing aspirin, acetaminophen, and caffeine. Commercial products were found to contain various levels of DAPAP up to 4 mg./tablet. Magnesium stearate was found to accelerate the reaction markedly.

THE STABILITY of aspirin *per se* in pharmaceutical dosage forms has received considerable attention and the problem is widely recognized. However, reports of the interaction of aspirin with other drugs, such as amines and phenols, have only recently begun to appear in the literature. Troup and Mitchner (1) reported that phenylephrine underwent acetylation in tablets containing aspirin. Under accelerated conditions, the mono-, di-, and triacetylated products were formed. Even at 24° the secondary amine group

* Present address: The Upjohn Co., Kalamazoo, MI 49001

was found to be acetylated to the extent of 14% after 34 months of storage.

Jacobs *et al.* (2), in a study of a capsule formulation containing aspirin and codeine, observed that acetylcodeine was formed but apparently only at elevated temperatures in the presence of moisture. No acetylcodeine was detected in commercial samples stored for 32 months at room temperature.

More recently, Schwartz and Amidon (3) recognized the possibility that aspirin might react with amino groups of proteins.

Preliminary work in these laboratories had indicated the possibility of an interaction between aspirin and acetaminophen (APAP) in pharmaceutical preparations. This paper summarizes the investigation of this interaction and shows, in particular, the extent to which it is taking place in commercial products.

Initial qualitative identification of the reaction product diacetyl-*p*-aminophenol (DAPAP) or *p*-acetoxyacetanilid was accomplished by means of thin-layer chromatography. Present assay methods for APAP, such as the column-partition method of Koshy (4), or a similar method by Levine and Hohmann (5), or the N.F. XII method (6) would not distinguish between APAP and DAPAP. Colorimetric methods which depend upon hydrolysis of APAP also lack specificity since DAPAP is readily hydrolyzed to *p*-aminophenol.

A quantitative method applicable to aspirin, APAP, and caffeine mixtures containing 0.01 to 20 mg. of DAPAP per tablet was developed. The procedure consists of the removal of caffeine, aspirin, and salicylic acid by a modification of the partition-column method developed by Levine (7) and removal of APAP and *p*-aminophenol (PAP) by a silicic acid column with water as the stationary phase. The residue obtained after passing the sample through the three columns was analyzed for DAPAP content by gas-liquid chromatography.

EXPERIMENTAL

Preparation of DAPAP—Twenty-seven grams of APAP was added to a mixture of 40 ml. acetic anhydride and 40 ml. reagent grade pyridine. This was refluxed 4 hr. on a steam bath. A precipitate formed when the mixture was allowed to cool to room temperature. The precipitate was collected by filtration and washed with 500 ml. of cold water to remove the pyridine and acetic anhydride. The residue was suspended in 150 ml. of hot water and heated almost to boiling. Small amounts of methanol were added until complete dissolution occurred. The solution was allowed to cool slowly to obtain the product, m.p. 152–156°. [Lit. m.p. 151–154° (8).]

Anal.—Calcd. for $C_{10}H_{11}NO_3$: C, 62.17; H, 5.74; N, 7.25. Found: C, 62.85; H, 6.00; N, 7.54.

Qualitative Detection of DAPAP—One ground tablet was shaken thoroughly on a mechanical shaker with 10 ml. of chloroform and filtered, and the filtrate was evaporated to dryness under a stream of air. The residue was shaken with 1 ml. 3A alcohol and filtered. Twenty microliters of the filtrate was spotted on a 0.25-mm. Silica Gel G (Brinkmann Instruments, Inc.) plate previously activated by heating for 1 hr. at 105°. Twenty microliters of a reference solution of pure DAPAP (300 mcg./ml.) was also spotted for comparison. The plate was developed in a solvent mixture of chloroform–acetone–acetic acid (80:18:2) and allowed to dry. The DAPAP appeared as a yellow spot under long wavelength (350 mμ) U.V. light after about 10-min. irradiation with short wavelength (254 mμ) U.V. light.

For samples containing salicylamide the same chromatography system was used except aluminum oxide (neutral alumina AG7, Bio·Rad Laboratories) was used instead of silica gel.

Quantitative Determination of DAPAP—*Column Preparation*—All solvents used on the columns were water saturated. Three glass chromatographic columns, each 19 × 450 mm. (Fischer and Porter Co.), were used. The first column contained 10 Gm. of 100 mesh, analytical reagent grade silicic acid (Mallinckrodt Chemical Works) thoroughly mixed with 7 ml. of 4 *N* sulfuric acid. The column was washed with 100 ml. ethyl ether which had been freshly distilled over zinc and potassium hydroxide. The second column contained 10 Gm. silicic acid thoroughly mixed with 7 ml. water and was washed with 100 ml. chloroform N.F. (Allied Chemical, General Chemical Division). The third column contained 20 Gm. of diatomaceous earth[1] thoroughly mixed with 20 ml. 1 *N* sodium bicarbonate solution. The column was washed with 200 ml. chloroform N.F. It was necessary to acid wash the diatomaceous earth before it could be used. This was accomplished by adding a sufficient quantity of concentrated hydrochloric acid to the diatomaceous earth to form a thin slurry. The mixture was heated on a steam bath for about 1 hr. The diatomaceous earth was then washed free of acid with distilled water and dried for 16 hr. at 105°.

Sample Preparation—Five noneffervescent or two effervescent tablets were ground and shaken with 20 ml. of chloroform for about 5 min. The mixture was filtered through Whatman No. 541 filter paper into a 25-ml. volumetric flask and brought to volume by washing the residue with a small amount of chloroform.

Column Operation—Five milliliters of the sample solution together with 10 ml. of ether were added to the first column. When the liquid level reached the top of the silicic acid column, 10 ml. of ether was added. When the liquid level again reached the top of the silicic acid, 50 additional ml. of ether was added. The entire eluate was collected in a 150-ml. beaker. The eluate was evaporated to dryness using a current of air. (*Caution:* no heat.) The residue was dissolved in about 10 ml. of chloroform and transferred quantitatively to the second column using an additional 10 ml. of chloroform to rinse

[1] Marketed as Celite 545 by the Johns-Manville Corp., New York, N. Y.

the beaker. The rinsings were added to the column after the liquid just reached the top of the silicic acid. Another 50 ml. of chloroform was added to the column and the entire eluate was collected in a 150-ml. beaker and diluted to 100 ml. to reduce the aspirin concentration for more effective separation. The eluate was transferred quantitatively to the third column. When the solution level reached the top of the diatomaceous earth column, 100 ml. of chloroform was added in small portions. The eluate was collected in a 250-ml. beaker and evaporated down to a few milliliters on a steam bath. The concentrate was quantitatively transferred to a small vial and the evaporation was continued to dryness. The amount of DAPAP in the residue was determined by gas–liquid chromatography.

Gas–Liquid Chromatography—An F & M model 810 gas chromatograph with a flame ionization detector was used with an aluminum column $1^1/_2$-ft. by $^1/_4$-in. o.d. containing 5% Carbowax 20 M (Union Carbide Corp.) on Chromosorb G 70/80 mesh (Johns-Manville). The column temperature was 225° and both detector and injection port temperatures were 275°. Gas flow rates were: helium, 60 ml./min.; hydrogen, 65 ml./min.; and air, 300 ml./min. The sample residue was dissolved in 1–6 ml. of acetone N.F. depending upon the DAPAP content. Then, depending upon DAPAP concentration, 10 to 30 μl. of the sample was injected using a Beckman liquid sampling syringe. The amount of DAPAP was determined by comparison of sample peak height with a standard injected concurrently.

Salicylic Acid Determination—Salicylic acid was determined according to the method reported by Gold and Campbell (9).

RESULTS AND DISCUSSION

Initial qualitative evidence for the occurrence of a reaction between aspirin and APAP was obtained by thin-layer chromatography. A mixture of aspirin, APAP, and magnesium stearate with 1% water added was stored for 2 weeks at 50°. A portion of the sample was dissolved in ethyl acetate and passed through a diatomaceous earth column containing sodium bicarbonate as stationary phase to remove aspirin and salicylic acid. The effluent was evaporated to dryness using a current of air, the residue redissolved in acetone, and 20 μl. spotted on a silica gel plate. Development was with chloroform–ethyl alcohol–acetic acid (88:10:2). A spot was revealed by iodine vapor which did not correspond to salicylic acid, aspirin, or APAP. It was postulated that DAPAP was formed. Another solvent system, as described under *Experimental*, was developed which would separate DAPAP from other materials in commercial samples containing aspirin, APAP, and caffeine and two possible degradation products found in such mixtures, salicylic acid and *p*-aminophenol (PAP). Results are shown in Fig. 1. Samples 2 and 3 established that DAPAP could be separated from the other ingredients. Although the spot in sample 4 at R_f 0.52 is slightly lower than the DAPAP known, it was readily recognizable as DAPAP because of the yellow color exhibited by DAPAP under U.V. irradiation. Subsequent analysis of this same sample indicated 1.8 mg. of DAPAP per tablet.

A procedure utilizing both partition column chromatography and gas chromatography was developed for the determination of DAPAP in products containing aspirin, APAP, and caffeine. The procedure involved removal of caffeine using a silicic acid–sulfuric acid column, APAP and PAP using a silicic acid–water column, and aspirin and salicylic acid by means of a diatomaceous earth–sodium bicarbonate column. DAPAP content in the final eluate was determined by gas chromatography. It was attempted, initially, to determine DAPAP in the eluate spectrophotometrically using its absorbance at 246 mμ. However, traces of aspirin coming through in the eluate caused erratic recoveries; whereas no interference was found using gas chromatography.

Figure 2 shows the elution of APAP and DAPAP from the silicic acid–water column. When the

[a] Each mixture contained 324 mg. aspirin, 162 mg. APAP, and 33 mg. caffeine.

column is eluted with ether the DAPAP comes off first, followed closely by the APAP. However, if chloroform is used as the eluant, the DAPAP elution is sharper and the APAP is completely retained. This column could be used to determine DAPAP as a contaminant in APAP.

One discovery noted during the course of developing the assay is worthy of note. After a few inconsistent high recoveries, each step in the procedure was critically examined and it was found that DAPAP was formed during the evaporation step of the eluate from the first column since at that time a steam bath was being used. This phenomenon emphasizes that heat should be avoided prior to aspirin–APAP separation.

Recovery studies were performed on a typical formulation containing aspirin, APAP, caffeine, and various common lubricants and excipients. Known amounts of DAPAP in chloroform were added to the powder mixture prior to analysis. Results are shown in Table I. It is apparent that this analytical method is applicable to a wide concentration range of DAPAP limited only by its solubility in chloroform (about 4% w/v). The high recoveries for samples containing less than 100 mcg. may be attributed to the presence of trace impurities, since it was necessary to operate the gas chromatograph at high sensitivities for low DAPAP levels. The over-all accuracy and precision were probably as good as could be expected, especially in view of the complexity of these mixtures.

Commercial products, of unknown age, containing aspirin and APAP, were purchased from retail outlets and analyzed for DAPAP and salicylic acid (SA) content. Results are shown in Table II. As can be seen, aspirin–APAP interaction is taking place to varying extents in the samples analyzed. Product *A*, an effervescent tablet, was found to contain considerable quantities of DAPAP ranging from 1.24–4.13 mg./tablet. Product *B*, a press-coated tablet, contained lower levels of DAPAP ranging from 36–140 mcg. per tablet. Product *C*, a compressed tablet, contained only trace quantities of DAPAP. Product *D*, a compressed tablet, contained salicylamide which interfered in the analysis of salicylic acid and DAPAP. However, using the eluate from the partition–column chromatography procedure, DAPAP could be detected qualitatively using thin-layer chromatography in two samples of this product. By running various levels of a standard DAPAP solution simultaneously with the samples, the DAPAP content of the samples was estimated to be 15 mcg./tablet.

Inspection of the data in Table II indicates a relationship between the rate of formation of SA and the rate of formation of DAPAP. To study this further, tablets of product *A* from the same batch were heated for 6 weeks at 50° and analyzed weekly for SA and DAPAP content. Results, shown in Fig. 3, indicate a linear relationship between the two degradation products. The same trend exists in various samples stored at ambient conditions, although at lower SA and DAPAP levels the correlation is not so good.

The effect of various lubricants on aspirin stability has been the subject of numerous investigations. Alkaline earth stearates are reportedly responsible for poor aspirin stability in plain aspirin tablets (10) and aspirin, phenacetin, and caffeine combina-

tions (11, 12). Magnesium stearate also has been shown to accelerate the formation of acetylphenylephrine in aspirin–phenylephrine combinations (1). Consequently, the relative effects of water, stearic acid, and magnesium stearate on the rate of formation of SA and DAPAP in aspirin–APAP mixtures were studied. Powder mixtures containing (*a*) 3.25 Gm. aspirin, 1.75 Gm. APAP, and 0.05 Gm. water; (*b*) mixture (*a*) plus 0.05 Gm. stearic acid; and (*c*) mixture (*a*) plus 0.05 Gm. magnesium stearate were sealed in small bottles and stored for 4 weeks at 50°. Subsequent DAPAP analysis of these mixtures indicated 67 mcg./Gm. in (*a*), 50 mcg./Gm. in (*b*), and 48.4 mg./Gm. in (*c*). Thus, magnesium stearate had a marked accelerating effect on the rate of DAPAP formation. Consequently, this lubricant is contraindicated in such formulations.

The pharmacological significance of the presence of DAPAP in these products is not known since information in the literature concerning this compound is scanty. Stockelbach (13) disclosed in a U. S. patent that DAPAP has valuable medicinal properties particularly as an antipyretic, antineuralgic, and sedative remedy. Charlier *et al.* (14) list DAPAP as one of the compounds studied for influence on bile secretion and toxicity, but did not give any data for DAPAP.

Micellar Solubilization of Testosterone I

In Aqueous Solutions of Polysorbates

By ARVIND L. THAKKAR and NATHAN A. HALL

The solubility of testosterone in aqueous solutions of partially purified polysorbate 20, 40, and 60 was determined by measuring the area under the ultraviolet spectral peaks. There was solubilization below the critical micelle concentration. A linear relationship was observed between the amount of testosterone solubilized and the per cent polysorbate concentration. Polysorbate 60 exhibited the greatest solubilizing capacity and polysorbate 20 the least. The *Z*-value method for determining solvent polarity was employed to investigate the polarity of the environment in which testosterone was solubilized. At low polysorbate concentrations the *Z*-value was similar to that in water. As the polysorbate concentration increased, the *Z*-value decreased. This decrease in *Z*-value paralleled the increase in solubility of testosterone.

RECENT REVIEWS (1, 2) in pharmaceutical literature indicate that the phenomenon of solubilization continues to be of interest. In 1949 Ekwall and Sjöblom (3) published the first study on the solubilization of steroid hormones. They reported the solubility of testosterone in a 10% sodium oleate, 20% sodium myristyl sulfate, and 20% sodium cholate solutions. Nakagawa (4) has measured the solubility of testosterone in 20% aqueous solution of polyoxyethylene sorbitan monolaurate containing about 12 ethyleneoxide groups. Sjöblom and co-workers (5–7), in their

work with estrogens and corticosteroids, have made extensive investigations of the effect upon solubilization of modifications in the structure of the steroid solubilizate.

Although previous reports on micellar solubilization of steroids have presented information about how the nature of the solubilizate may affect solubilization, little detailed data are available on the effect of the nature of the solubilizer. As part of a study of the effect of different surfactants upon the solubilization of a single steroid, this paper deals with the study of testosterone solubilized in some nonionic surfactants of the polyoxyethylene sorbitan ester series.

It is well known that the electronic absorption spectrum of a substance is appreciably altered when the substance is in the micellarly solubilized form. Riegelman *et al.* (8) have drawn certain qualitative conclusions about the location of molecules solubilized in micellar solutions based upon the alterations in their absorption spectra. Bjaastad and Hall (9) have recently demonstrated the use of the *Z*-value method, an empirical means of solvent polarity developed by Kosower (10), for investigating the polarity of the environment of some solubilized ketones. This method is based upon the assumption that the polarity of the layers of solvent immediately surrounding a molecule or ion will differ appreciably from that of the bulk solution. Kosower has defined *Z*-value as the energy of electronic transition of 1-ethyl-4-carbomethoxy pyridinium iodide, a substance with an ultraviolet spectrum remarkably sensitive to solvent polarity. Application of this method involves determining the spectral characteristics of the solubilizate in a number of solvents of known *Z*-values and establishing a relationship between *Z*-value and the energy of transition which is readily obtained from the wavelength of maximum absorbance. From this relationship the *Z*-value of a solvent or a medium such as a surfactant solution may be derived once the wavelength of maximum absorbance of the solubilizate in the particular solvent or medium is known. Bjaastad and Hall have pointed out the assumptions which must be made in order to apply the *Z*-value method to solubilized systems.

Testosterone is a steroid of relatively simple structure. The ultraviolet absorption spectrum of this α,β-unsaturated ketone is solvent sensitive. The polarity of the environment of testosterone solubilized in aqueous solutions of polysorbates was investigated by the *Z*-value method and is reported in this paper.

EXPERIMENTAL

Materials—Three nonionic surfactants, having the same hydrophilic portion in their molecules but differing in the length of the carbon atom chain of their lipophilic portion, were selected. These were polysorbate 20, polyoxyethylene-20-sorbitan monolaurate; polysorbate 40, polyoxyethylene-20-sorbitan monopalmitate; and polysorbate 60, polyoxyethylene-20-sorbitan monostearate.[1] The commercial samples of the three nonionic agents were partially purified by partitioning between 5 *N* sodium chloride solution and ethyl acetate by the method of Weibull (11). Samples of partially purified polysorbates were dried over anhydrous sodium sulfate, placed in a 60° oven for 24 hr. to remove traces of any organic solvent, and stored in a desiccator until used. Removal of polyethylene and polyoxyethylene glycols was followed by a thin-layer chromatographic procedure (12). Solutions of polysorbates were prepared using water redistilled in the presence of alkaline permanganate from an all-glass distilling apparatus. The critical micelle concentrations of these partially purified surfactants, determined in this laboratory and elsewhere, with benzopurpurin 4B (13), have been reported as 1.0×10^{-2}, 5.5×10^{-3}, and 4.6×10^{-3} Gm./100 ml., respectively (14, 15).

Testosterone N.F.[2] was used as received. Solvents used where of reagent grade.

Solubility Determinations—To a series of screw cap vials containing 10 ml. of polysorbate solutions of known concentration, an excess of testosterone was added. The caps (lined with aluminum foil) were placed on the vials which were then rotated in a water bath[3] at 25.0° ± 0.1° for 96 hr. Although the solutions showed an initial supersaturation, all were found to attain solution equilibrium within the 96-hr. period. The contents of the vials were filtered through a Swinney filter adapter containing a 0.45 μ Millipore filter disk.[4] The ultraviolet absorption spectra were recorded with a Cary model 14 automatic recording spectrophotometer. Matched cylindrical silica absorption cells, 1 and 10 mm. light path, were used. For the determination of the concentration, ultraviolet spectra were recorded at 1 mμ/sec., from 350 mμ to 210 mμ, and the area under the spectral peak determined by multiplying the height of the peak by its width at one-half the height. The area under the peak was found to give a direct relationship to the concentration of testosterone. The observed solubility in each solution (S) was divided by the solubility in water (S_0) to give the relative solubility in the surfactant concentration.

Z-Value Determinations—In order to relate the ultraviolet absorbance of testosterone to the polarity of the solvent, the wavelength of maximum absorbance ($\lambda_{max.}$) of testosterone was determined in a number of solvents of known *Z*-values. The $\lambda_{max.}$ was first estimated from spectra scanned at 1 mμ/sec., then accurate determinations of $\lambda_{max.}$ were made by recording the spectra at 0.25 mμ/sec. for 20 mμ in the vicinity of the maxima. The reported

[1] Marketed as Tween 20, Tween 40, and Tween 60, respectively, by Atlas Chemical Industries, Inc., Wilmington, Del.
[2] Generously supplied by Schering Corp., Bloomfield, N. J.
[3] Gyrotory water bath shaker, model G76, New Brunswick Scientific Co., Inc., New Brunswick, N. J.
[4] While this work was in progress, Cahn (16) reported the presence of surfactants in Millipore filters. The experimental procedures used in this work were checked to assess the effect of the surfactant contributed by the filter. Neither the quantity of testosterone solubilized nor its ultraviolet absorption spectrum was affected by the quantity of surfactant leached from the filter disk.

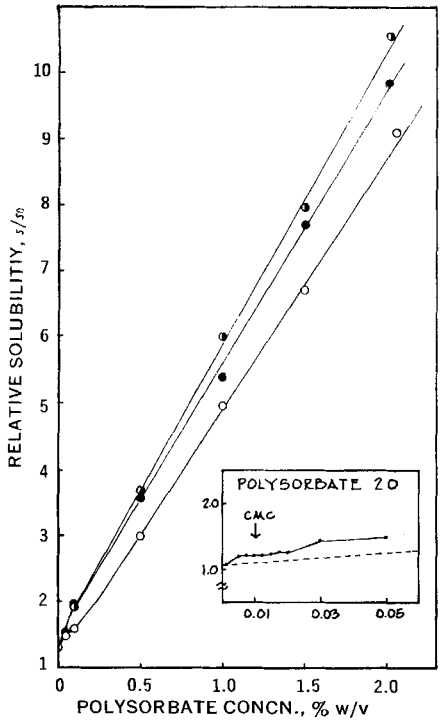

Fig. 1—Relative solubility of testosterone versus *concentration of polysorbate 20* (○), *polysorbate 40* (●), *and polysorbate 60* (◑). *Inset: polysorbate 20 solutions at low surfactant concentrations. Dashed line indicates an extrapolation of the linear portion of the larger graph.*

values of $\lambda_{max.}$ were obtained from an average of three scans and were precise to ± 0.5 mμ.

Spectral measurements for determination of $\lambda_{max.}$ of solubilized testosterone were made using undiluted solutions. In some cases, however, the saturated solutions were too concentrated to permit spectral measurements even with the cells of the shorter light path length of 1 mm. It was necessary in these cases to dilute the saturated solutions with the appropriate surfactant solution. Dilution was kept to a minimum, however. The effect of testosterone concentration upon $\lambda_{max.}$ and Z-value was investigated in some detail for solutions containing polysorbate 20.

RESULTS AND DISCUSSION

Solubility Determinations—The relationship between relative solubility of testosterone and polysorbate concentrations is shown in Fig. 1. After the initial stages of solubilization, the plots are linear, indicating that the amount of testosterone solubilized is directly proportional to polysorbate concentration. Similar observations for other steroids have been made by Sjöblom (5–7) and by Guttman *et al.* (17). The values of the slopes of the linear portions of the curves multiplied by the aqueous solubility of testosterone, in mg./100 ml., gave the solubilizing capacities of polysorbates in terms of mg. of testosterone per Gm. of polysorbate. Table I lists the solubilizing capacities on both a weight and molar basis. Since polysorbates are heterogeneous, the limitation of the significance of the molar values should be borne in mind. The results (Table I and Fig. 1) show that polysorbate 60 has the greatest capacity and polysorbate 20 the least.

The order of solubilizing capacities of the three polysorbates can be directly related to the length of their alkyl portions. In an idealized picture of spherical micelles these alkyl portions may be visualized as being directed inward. An increase in their length would result in micelles of larger size; thus polysorbate 60 micelles would have the largest relative size. It is interesting to note that the solubilizing capacities of the three polysorbates are of similar order of magnitude.

TABLE I—SOLUBILIZING CAPACITY OF POLYSORBATES FOR TESTOSTERONE AT 25°

Surfactant	Solubility: mg. Testosterone/ Gm. Surfactant	Solubility: mole Testosterone/ mole Surfactant[a]
Polysorbate 20	8.29	3.529×10^{-2}
Polysorbate 40	8.95	3.984×10^{-2}
Polysorbate 60	9.64	4.385×10^{-2}

[a] Calculated from the theoretical molecular weights of 1228, 1284, and 1312 for polysorbate 20, 40, and 60, respectively.

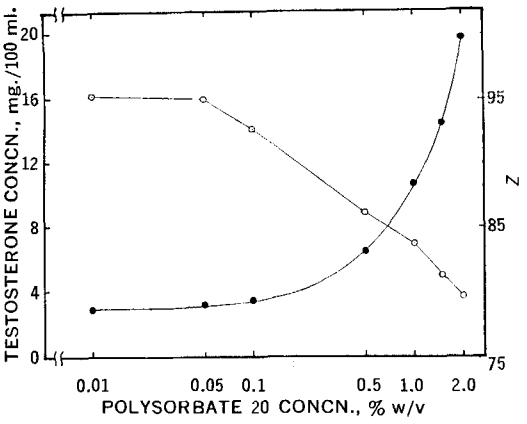

Fig. 2—The relationship between concentration of polysorbate 20 (logarithm), solubility of testosterone (●), and Z-value (○).

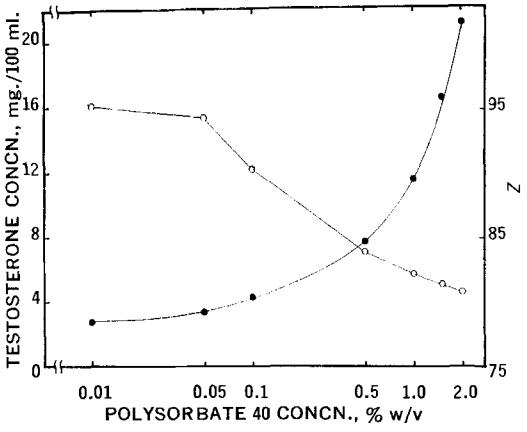

Fig. 3—The relationship between concentration of polysorbate 40 (logarithm), solubility of testosterone (●), and Z-value (○).

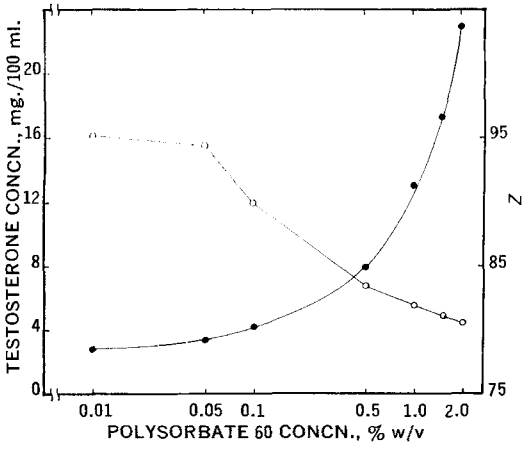

Fig. 4—The relationship between concentration of polysorbate 60 (logarithm), solubility of testosterone (●), and Z-value (○).

In general, solubilization is associated with the presence of micelles, there being little or no solubilization below the CMC. In the present study it was found that testosterone was solubilized below the CMC. This aspect was investigated in some detail with solutions of polysorbate 20 and is illustrated in the inset of Fig. 1. Moilliet *et al.* (18) have suggested that solubilization below the CMC may be explained by the formation of mixed micelles below the usual CMC due to an affinity between the surfactant and the solubilizate. In case of polysorbate 20 and testosterone such an explanation seems plausible.

Z-Value Determinations—The wavelengths of maximum absorbance of testosterone in a wide range of solvents are given in Table II.

The energy of electronic transition for testosterone was calculated from the relationship (19):

$$E_t = 2.859 \times 10^4/\lambda_{max.} \text{ in m}\mu \text{ (Kcal./mole)}$$

When a plot of Z *versus* E_t was made, a straight line with a negative slope was obtained. A negative slope indicates a $\pi \rightarrow \pi^*$ electronic transition (20). By the method of least squares, the slope and intercept were calculated and the following equation obtained for the straight line:

$$Z = -4.00\, E_t + 554.45$$

The Z-values of surfactant solutions were calculated from this equation. Since it was necessary to dilute some of the surfactant solutions saturated with testosterone, the effect of testosterone concentration upon $\lambda_{max.}$ and Z-values was investigated for solutions of polysorbate 20. This is shown in Table III.

It may be seen that any changes in $\lambda_{max.}$ due to dilution are within ± 0.5 mμ, the precision of the method. The corresponding changes in Z should not be significant. This is in agreement with previous observations made with solubilized ketones (9, 14).

Figures 2, 3, and 4 show the relationships among the concentration of polysorbate, solubility of testosterone, and Z-value. At 0.01% polysorbate concentration the Z-value is the same as that of water, and the solubility of testosterone is not appreciably greater than that in water. This concentration is approximately the CMC for polysorbate 20, and for polysorbate 40 and 60 it is higher than the CMC. With increasing polysorbate concentrations and consequent increase in testosterone solubility, the Z-value decreases, indicating an environment of decreasing polarity. The behavior is similar for the three polysorbates.

As Bjaastad and Hall (9) have pointed out, decreasing polarity might be explained by an increase in concentration and organization of micelles as the concentration of surfactant is increased. It may also be due to the solubilized testosterone encountering less polar regions of micellar interior. Guttman *et al.* (17) have suggested that the steroids, prednisolone, methylprednisolone, and fluoromethylone, are associated, by hydrogen bonding, with the polyethylene chain of the nonionic surfactant oxyethylated tertiary octylphenol formaldehyde polymer.[5] Testosterone with its hydroxyl group at C-17 should be capable of association with the ethylene oxide portion on the surface of polysorbate micelles. This would account for the high

[5] Triton WR-1339, Rohm and Haas, Philadelphia, Pa.

Z-value of low concentration polysorbate solutions in which one may expect testosterone molecules to be oriented in the hydrated polyoxyethylene surface of the micelles. The fact that the ethylene oxide chain lengths of the three polysorbates are identical and the observation that the values of testosterone solubility are nearly the same in low concentrations of all the three polysorbates support this view. The decrease in Z-value possibly results from multilayer adsorption. This proposal is substantiated by similar order of testosterone solubilization in higher polysorbate concentrations. If solubilization involved incorporation of testosterone within micellar interior, one would expect a more pronounced difference in the solubilities with a change in lipophilic moiety.

The magnitude of Z-values in 2% polysorbate solutions are comparable to those of ethanol and isopropanol, which also indicates that the environment of solubilized testosterone is quite polar. Although the hydrocarbon interior of micelles is believed to contain some water (21), its polarity might be expected to be lower than those of the alcohols.

Further studies utilizing ionic surfactants with comparable alkyl chain lengths are being conducted and will be reported in a future communication.

Steric Aspects of Adrenergic Drugs VII

Certain Pharmacological Actions of D(−)-Pseudoephedrine

By J. B. LAPIDUS, ARTHUR TYE, and P. N. PATIL

The ability of D(−)-pseudoephedrine to influence the actions of selected adrenergic drugs was examined in both *in vivo* and *in vitro* experiments. In anesthetized dogs, pretreatment with D(−)-pseudoephedrine can reduce or block the pressor effects of the other ephedrine isomers and (+)-amphetamine. Delayed potentiation was observed with norepinephrine and epinephrine. D(−)-Pseudoephedrine did not affect the pressor effects resulting from bilateral carotid occlusion, and exhibited no unique properties on the rabbit aortic strip. D(−)-Pseudoephedrine had no intrinsic activity on the isolated rat vas deferens but could block the contractions caused by tyramine or D(−)-ephedrine, and potentiate the effects of norepinephrine. D(−)-Pseudoephedrine and D(−)-ephedrine compete for α-adrenergic sites in the reserpine pretreated rat vas deferens and can protect these receptors from dibenamine blockade. It appears that D(−)-pseudoephedrine acts at both catecholamine uptake sites and at α-receptors, but apparently lacks intrinsic effects at the latter site.

In previous papers (1, 2), the authors have presented evidence that D(−)-pseudoephedrine has a unique vascular activity when compared with other isomers of ephedrine. It has virtually no pressor activity (2), yet is a diastereoisomer of D-(−)-ephedrine, the most active pressor member of the four ephedrine isomers. Certain stereochemical consequences of this relationship led to the belief that D(−)-pseudoephedrine should, in fact, be able to antagonize the pressor response to D(−)-ephedrine (1). D(−)-Ephedrine and D(−)-pseudoephedrine have the same absolute configuration at the β-carbon atom (that bearing the hydroxyl group) (Fig. 1). If the assumption is made that the amino group, the hydroxyl group, and the phenyl ring are all involved in the drug–receptor interaction (3), then these two diastereoisomers represent a

unique case in which the active groups in both molecules can occupy the same three points in space. This is not apparent from the Fischer projection formulas shown in Fig. 1, but becomes clear when the compounds are represented as in Fig. 2.

This structural relationship, coupled with the observed differences in pressor activity of these two compounds, led to the conjecture that D(−)-pseudoephedrine is capable of interacting with the same receptor(s) as D(−)-ephedrine, but apparently does so in a biologically unproductive manner. In other words, D(−)-pseudoephedrine may have affinity but very little or no intrinsic activity.

This paper is primarily concerned with the interactions of D(−)-pseudoephedrine with other isomers of ephedrine and related agents.

METHODS

In Vivo Experiments—Mongrel dogs of either sex, weighing 7–11 Kg., were anesthetized with sodium barbital, 330 mg./Kg. i.p. All experimental animals were pretreated with atropine sulfate, 1 mg./Kg. Blood pressure was recorded through the right carotid artery *via* a mercury manometer. In experiments involving bilateral carotid occlusion the femoral blood pressure was recorded and sodium pentobarbital,[1] 35 mg./Kg., was used as an anesthetic. The trachea was always cannulated. Respiration was recorded, when desired, on a kymograph through a tambour. Electrocardiograms were recorded on a Sanborn Twin Viso recorder.

[1] Nembutal, Abbott Laboratories, North Chicago, Ill.

In Vitro Experiments—Spirally cut aortic strips of the rabbit were prepared according to the method described by Furchgott and Bhadrakom (4). After the animal was rendered unconscious by a sharp blow on the head, a long incision was made on the skin and thoracic and abdominal contents were resected to expose the whole length of aorta. An incision was then made at the descending level of the aortic arch, and a long glass rod (about 3 mm. in diameter) passed gradually in it. The whole length of the aorta was thus removed from the rabbit. The fat and other connective tissue was carefully separated. During this procedure the aorta was kept moist throughout by means of Kreb's bicarbonate solution (5). The whole length of the aorta was cut spirally to give a strip 3–4 mm. wide. Strips 4 cm. in length were mounted in jacketed 10-ml. muscle chambers containing Kreb's bicarbonate at 37.5°. The contractions of the aortic strip were magnified by a lever in a ratio of 1:20, and counterbalanced to exert 4 Gm. of tension. The preparations were oxygenated by 95% O_2 and 5% CO_2 and allowed to stabilize for at least 2 hr. before any drug induced contractions were recorded *via* a frontal point lever on a slowly moving smoked kymograph. The cumulative dose-response curves were obtained as described by Van Rossum (6). No attempt was made to make two dose-response curves from the same strip. It required 10 to 15 min. to reach a plateau after addition of each dose of drug. In antagonism studies, the preparation was exposed to the antagonist for 10 min. and the dose-response curve of the agonist then obtained in presence of the antagonist.

Rats weighing 100–150 Gm. were killed by a sharp blow on the head. A vas deferens was isolated from all connective tissues and suspended in a jacketed 10-ml. muscle chamber which contained Tyrode's solution at 37–37.5°. The composition of the Tyrode's solution was as follows: NaCl, 137 m*M*; KCl, 2.68 m*M*; $CaCl_2(2H_2O)$, 1.76 m*M*; $MgCl_2(6H_2O)$, 0.88 m*M*; NaH_2PO_4, 0.36 m*M*; $NaHCO_3$, 12 m*M*; glucose, 5.5 m*M*; demineralized water was used to make the solution. A mixture of oxygen (95%) and CO_2 (5%) was bubbled through the solution. Drug-induced contractions were recorded on a smoked drum *via* a light lever (magnification: 20, tension approximately 350 mg.) which was always under the influence of low vibrations produced by a small electric motor.

Receptor protection experiments as introduced by Furchgott (7) were carried out on isolated rat vas deferens. Dibenamine (10^{-6} *M*) was selected as an irreversible α-adrenergic blocker. These experiments were carried out in the reserpine-pretreated (5 mg./Kg. i.p. 8 to 16 hr. previously) rats, because D(−)-ephedrine is classified as a mixed acting amine on isolated rat vas deferens (8). Therefore, norepinephrine liberated from the nerve endings would complicate the protection of α-adrenergic receptors by D(−)-ephedrine.

DRUGS

The optical isomers of ephedrine were prepared by the method described by LaPidus *et al.* (1). For each experiment fresh solutions of the isomers were made in physiological saline by the addition of a small amount of dilute hydrochloric acid. The following drugs were obtained from commercial

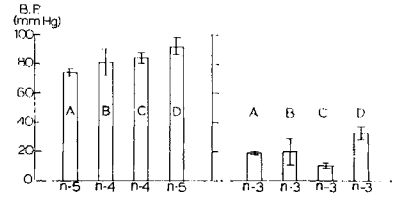

Fig. 3—Reduction of pressor effects of D(-)-ephedrine L(+)-ephedrine, D(+)-amphetamine, and L(+)-pseudoephedrine by 30-min. pretreatment with D(-)-pseudoephedrine in anesthetized dog. sources: D(+)-amphetamine sulfate, norepinephrine bitartrate,[2] reserpine phosphate,[3] epinephrine bitartrate,[4] tyramine HCl, and dibenamine HCl. All the weights given refer to free base except for amphetamine which refers to its sulfate. The terminology used for ephedrine isomers has been described previously (2).

Whenever possible the standard errors of the mean were calculated; significance between two means was tested by *t* test. Otherwise, for qualitative purposes, at least 3 observations were made in different animals. Since most of these drugs may affect the responses of one another, each observation was made in an individual animal.

RESULTS

The Effects of Pretreatment with D(−)-Pseudoephedrine—In preliminary experiments eight dogs were pretreated with D(−)-pseudoephedrine (0.33, 3.3, 9.9, 16.5 mg./Kg.) 30 min. before a challenging dose of D-(−)-ephedrine was given. [The blocking ability of D(−)-pseudoephedrine was found to be maximal when the pretreatment interval was

In the case of L(+)-ephedrine, L(+)-pseudoephedrine, and D(-)-pseudoephedrine, standard errors markedly overlapped each other.

reasonably short.] Doses of 9.9 or 16.5 mg./Kg. completely blocked the blood pressure, heart rate, and respiratory effect of D(−)-ephedrine (0.33 mg./Kg.). D(−)-Pseudoephedrine itself shows temporary depressor effects in anesthetized animals (2). Animals pretreated with 3.3 mg./Kg. of D-(−)-pseudoephedrine 30 min. before challenging with one of the following amines: D(−)-ephedrine, 0.33 mg./Kg.; L(+)-ephedrine, 0.99 mg./Kg.; L(+)-pseudoephedrine, 1.65 mg./Kg.; or D(+)-amphetamine sulfate, 0.36 mg./Kg., exhibited marked reduction of the pressor effects of these amines (Fig. 3).

At the 0.33-mg./Kg. dose level D(−)-pseudoephedrine did not significantly modify the pressor effects of epinephrine or norepinephrine. However, when the dose of D(−)-pseudoephedrine was increased to 3.3 mg./Kg., a potentiation of pressor effects was noted. This potentiation was more

TABLE I—CONTRACTION OF RABBIT AORTIC STRIPS TO 10^{-3} *M* D(−)-EPHEDRINE AFTER DOSE RESPONSE CURVES OF OTHER ISOMERS OF EPHEDRINE ARE COMPLETED

	Mean Contraction, mm. (± S.E.M.)			
	Control	After L(+)-Ephedrine	After L(+)-Pseudoephedrine	After D(−)-Pseudoephedrine

No. of observations	10	9	6	9
P value compared with control		<0.001	<0.05	<0.01

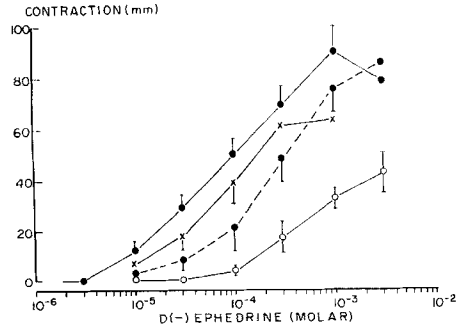

Fig. 7—Dose-response curves of D(-)-ephedrine in the presence of L(+)-ephedrine (10^{-3} M) (O—O), L(+)-pseudoephedrine (×—×) (10^{-3} M), and D(-) pseudoephedrine (10^{-3} M) (●---●). Vertical lines indicate standard errors of the mean. Average of 6, strips for each isomer.

marked 45 to 60 min. after administration (Fig. 4). The pressor effects of epinephrine (in terms of both duration and magnitude) tended to be reduced if it was given 10 to 20 min. after a dose of 9.9 mg./Kg. of D(−)-pseudoephedrine. In four experiments the average control rise in blood pressure to 0.75 mcg./Kg. of epinephrine was 29 mm. of Hg (S.E. ± 4) and that after D(−)-pseudoephedrine was 18 mm. of Hg (S.E. ± 7). Under similar conditions, the pressor effects of norepinephrine, 0.4 mcg./Kg., were not affected. In four experiments the average control rise in blood pressure was 44 mm. of Hg (S.E. ± 7), and that after D(−)-pseudoephedrine was 44 mm. of Hg (S.E. ± 18). While the intensity of the response to norepinephrine remained the same, the duration was increased.

D(−)-Pseudoephedrine was tested for its ability to modify bilateral carotid occlusion pressor effects. In doses of 3.3 or 9.9 mg./Kg. (two animals for each dose), it did not affect the carotid occlusion pressor effects up to 30 to 60 min. after injection.

When D(−)-pseudoephedrine, 3.3 mg./Kg., was given at the height of pressor responses to D(−)-ephedrine, 0.33 mg./Kg. (3 experiments), an immediate reduction in pressor response occurred in all experiments (Fig. 5). In control experiments the pressor effects of D(−)-ephedrine and D(+)-amphetamine sulfate persisted for 15 to 20 min. The increase in heart rate was not effectively antagonized.

Rabbit Aortic Strip—D(−)-Ephedrine is the only isomer which showed a marked contraction of the aortic strips. Other isomers—namely, L(+)-ephedrine, L(+)-pseudoephedrine, and D(−)-pseudoephedrine did not show any appreciable effects. The maximal effects produced by less active isomers were less than 20% of the effect produced by D(−)-ephedrine. The negative log ED_{50} of D(−)-ephedrine is 4.19 (S.E. ± 0.08) which is obtained by plotting every single dose-response curve and from log transformed values. The results are illustrated in Fig. 6.

If $10^{-3}M$ concentration of D(−)-ephedrine was added in the tissue bath after complete dose-response curves of lesser active isomers were constructed, there was a marked reduction of the maximal effects of ephedrine (Table I).

In the other series of experiments, the dose-response curves of D(−)-ephedrine were constructed in the presence of 10^{-4} *M* and 10^{-3} *M* concentrations of less active isomers. In the lower concentrations there was not any significant shift of the dose-response curve of D(−)-ephedrine. In higher concentrations, however, there was a significant shift to the right. L(+)-Ephedrine appeared to be the most effective in antagonizing the action of D(−)-ephedrine. The height of the dose-response curve of D(−)-ephedrine in the presence of 10^{-3} *M* L(+)-ephedrine was depressed (Fig. 7 and Table II).

Rat Vas Deferens—Tyramine, 10^{-4} *M*, and D(−)-ephedrine, 10^{-4} *M*, produce a maximum or near maximum contraction of rat vas deferens (9). D(−)-Pseudoephedrine, in concentrations of 10^{-4} *M* and 10^{-3} *M*, markedly antagonized the effects of tyramine and D(−)-ephedrine. D(−)-Pseudoephedrine did not show any intrinsic effects (Tables III and IV). The same concentrations of D(−)-pseudoephedrine produced a clear cut potentiation of norepinephrine (Fig. 8).

In receptor protection experiments, both D(−)-

pseudoephedrine (10^{-3} *M*) and D(−)-ephedrine (10^{-3} *M*) completely protected the α-adrenergic receptors from dibenamine blockade in the reserpine pretreated tissues. Results are summarized in Table V.

D(−)-Ephedrine produced an average 41 mm. (S.E. ± 7.8) contraction of the reserpine pretreated vas deferens. Under similar conditions, lower concentrations, 3×10^{-4} *M*, of D(−)-pseudoephedrine and D(−)-ephedrine also protected the α-adrenergic receptors to the extent of 26% (S.E. ± 11) and 44% (S.E. ± 6.9), respectively.

DISCUSSION

D(−)-Ephedrine and D(−)-pseudoephedrine are each capable of attachment to three identical points on a receptor (Fig. 2). Since the pressor effects of D(−)-pseudoephedrine are markedly inferior to those of D(−)-ephedrine (2), it was anticipated that it might antagonize the actions of the latter compound. The authors found that both *in vivo* and *in vitro* D(−)-pseudoephedrine does indeed markedly reduce the effects of D(−)-ephedrine and other "indirectly" acting sympathomimetic amines such as amphetamine and tyramine. It is interesting to note that D(−)-pseudoephedrine does not have any "intrinsic" effects on isolated rat vas deferens and at concentrations in which it antagonizes tyramine and ephedrine, potentiates the effects of norepinephrine. This led to the conclusion that D(−)-pseudoephedrine possibly acts at the catecholamine uptake sites. In other words, it has "cocaine-like" effects at the sympathetic nerve endings.

141, ± 5	0	148, ± 3	140, ± 6	150, ± 1	151, ± 4
n^d = 8		*n* = 5		*n* = 5	

[a] Controls were obtained from the contralateral side on the same rat. [b] Incubation time was 10 min., then tissue washed 4 times and 10 min. after the last wash norepinephrine was added. [c] Five minutes prior to dibenamine, D(−)-pseudoephedrine and D(−)-ephedrine were added in the tissue bath. [d] *n*, number of observations.

By using receptor protection experiments, it was possible to demonstrate that D(−)-pseudoephedrine also competes for the α-adrenergic sites. However, this effect must be very weak because the effects of exogenous norepinephrine are potentiated (*i.e.*, the competition of D(−)-pseudoephedrine at α-receptors is overcome by norepinephrine, the uptake of which is being prevented in the nerve endings). Thus, D(−)-pseudoephedrine is capable of acting at the catecholamine uptake sites and the α-adrenergic sites; however, it lacks intrinsic activity at the latter site.

The pharmacological effects of L(+)-pseudoephedrine and L(+)-ephedrine are similar on the aortic strips which support the previous report that there is a small difference between the pressor effects of these L-diastereoisomers in the dog (2).

D(−)-Ephedrine is the only isomer of ephedrine which produces a marked contraction of rabbit aortic strips. In the presence of 10^{-3} *M* concentrations of L(+)-ephedrine, L(+)-pseudoephedrine, or D(−)-pseudoephedrine, the dose-response curves of D(−)-ephedrine are shifted to the right.

On the isolated rat vas deferens D(−)-pseudoephedrine did not show any intrinsic effects. However, the contractions due to tyramine and D(−)-ephedrine were markedly antagonized by 10^{-4} *M* and 10^{-3} *M* D(−)-pseudoephedrine, while the effects of norepinephrine were potentiated. In addition, D(−)-pseudoephedrine and D(−)-ephedrine also compete for the α-adrenergic sites in the reserpine pretreated animals. D(−)-Pseudoephedrine appears to act at both the catecholamine uptake site and the α-adrenergic site, but apparently lacks intrinsic effects at the latter site.

SUMMARY

In anesthetized dogs, pretreatment (30 min.) with D(−)-pseudoephedrine, 3.3 mg./Kg., can reduce or block the pressor effects of D(−)-ephedrine, L(+)-ephedrine, L(+)-pseudoephedrine, and D(+)-amphetamine. D(−)-Pseudoephedrine also promptly reduces the pressor effects, if given during the height of response. The pressor effects of norepinephrine and epinephrine appeared to be potentiated by D(−)-pseudoephedrine. Such a potentiation was best seen 45 to 60 min. after the administration of the isomer. The pressor effects due to bilateral carotid occlusion were unaffected by D(−)-pseudoephedrine.

Differentiating Nonaqueous Titration of Salicylic Acid and Acetylsalicylic Acid Combination

By SONG-LING LIN

Synthetic mixtures of salicylic acid and acetylsalicylic acid are differentiated by potentiometric nonaqueous titration. With sodium methoxide or tetrabutylammonium hydroxide titrant and glass-calomel electrode system, dimethylformamide is found to be the best differentiating solvent. The effect of the solvent in titration and differentiation of salicylic acid and acetylsalicylic acid in water and dimethylformamide is illustrated and interpreted. Various solvent–titrant–electrode combinations are employed to explore their effects on the sensitivity of the differentiating titration. The presence of water in the titration solvent is demonstrated to be highly detrimental and undesirable on differentiation. The proposed procedure is simple, accurate, and applicable even when there is a disproportionate concentration of the components. The work suggests that by a proper combination of solvent, titrant, and electrode system, it should be possible to differentiate potentiometrically both components of acidic or basic mixtures whose dissociation constants are well below the theoretical limit of 16.

A VARIETY OF procedures (1–8) have been proposed for the analysis of acetylsalicylic acid and one of its degradation products, salicylic acid. These methods involve colorimetry, chromatography, and spectrophotometry. However, a search of the literature for titrimetric techniques applicable to differentiating salicylic acid–acetylsalicylic acid combination was not successful. It was the purpose of this study to develop such a procedure.

Although salicylic acid and acetylsalicylic acid as individual components can be readily determined by titration in nonaqueous media, the titrimetric analysis of mixtures of these compounds has not been reported. This may be due to the fact that the difference between the pKa's, in water, of salicylic acid (2.97) and acetylsalicylic acid (3.49) (9) has been considered to be too small to accomplish the differentiation, even in nonaqueous solvents.

Theoretical expressions for the titration of a mixture of two monoprotic acids can be treated as in the titration involving a single diprotic acid. Auerbach and Smolczyk (10) have shown theoretically that no inflection occurs at the first equivalence point in the potentiometric titration curve of polyfunctional acids in aqueous solvents unless the ratio of the first to the second dissociation constant is greater than 16. It is difficult, in fact, to locate the inflection accurately even at a ratio of 100. Kolthoff and Stenger (11) state that, in water, an accurate and satisfactory differentiation of acids or bases can be obtained only with a pKa (H_2O) difference of approximately 4.0. When titration is performed in nonaqueous solvents, differentiation is possible even with a pKa (H_2O) difference of about or below 2.0. Many dibasic acids which give only a single inflection in water give two sharp inflections in nonaqueous solvents. For example, the two acidic groups of succinic acid (pK_1 of 4.2 and pK_2 of 5.6) were differentiated in acetone (12). In this investigation, the resolution of acid mixtures with a pKa (H_2O) difference of only 0.52 [or with Ka (H_2O) difference of only 3] is successfully accomplished by selecting the proper combinations of titrant, solvent, and electrode system.

In this investigation, differentiating nonaqueous titration was performed with a Fisher automatic titrimeter. Various solvent–titrant–electrode combinations were employed to explore their effects on the sensitivity of differentiation. The feasibility of resolution and characteristics of titration curves are markedly different from one solvent–titrant–electrode system to another. The presence of water in the titration solvent is shown to be highly detrimental and undesirable on differentiation. The degree of water tolerance with sodium methoxide titrant is threefold as resistant as with tetrabutylammonium hydroxide titrant.

With sodium methoxide or tetrabutylammonium hydroxide in benzene–methanol as titrant and a glass–calomel electrode pair as the electrode system, dimethylformamide was found to be the best differentiating solvent. The suppression of the sharpness of the inflections for both compounds in differentiating titration as compared with the titration of individual components is realized. Acetylsalicylic acid offers sharper inflection than salicylic acid in differentiating titration, although the latter component demonstrates better inflection than its acetylated derivative when titrated individually. The proposed procedure is simple, accurate, and applicable even when there is a disproportionate concentration of the components. Preliminary treatment of the sample is unnecessary, and tedious separation and extraction techniques are obviated.

The work suggests that, by a proper combination of solvent, titrant, and electrode system, it would be possible to titrate and differentiate potentiometrically both components of an acidic and basic mixture whose dissociation constants are well below the theoretical limit of 16 proposed by Auerbach and Smolczyk (10). The findings obtained will serve as guidelines for future work on the differentiating nonaqueous titration of acetylsalicylic acid–salicylic acid–acetic acid mixtures.

EXPERIMENTAL

Apparatus—Titrations were performed potentiometrically with a Fisher automatic titrimeter, model 36, equipped with a glass electrode (Beckman No. 40498) and a sleeve-type calomel electrode (Beckman No. 40463). For this study, the calomel electrode was modified by replacing the aqueous saturated potassium chloride solution in the bridge with a saturated solution of potassium chloride in methanol. Other electrodes evaluated were platinum electrode (Fisher 13-639-102) and antimony electrode (Fisher 9-313-212). A 25-ml. automatic buret, graduated to 0.05 ml., with a titrant storage container, was used to prevent any contamination of the titrant.

Reagents and Solutions—Acetylsalicylic acid U.S.P. (Mallinckrodt) was dried at 60° for 4 hr. and was used without further purification. Analysis by the official U.S.P. assay procedure indicated a purity of better than 99.9%. This meets the U.S.P. requirements for the allowable salicylic acid content (<0.1%). The salicylic acid used was U.S.P. grade. Analysis by U.S.P. method showed a purity of 99.8%. A 0.1 *N* solution of sodium methoxide in benzene–methanol (10:1) was prepared and standardized potentiometrically against a reference standard benzoic acid dissolved in dimethylformamide. A 0.1 *N* solution of tetrabutylammonium hydroxide in benzene–methanol (10:1) was prepared by the silver oxide method and standardized potentiometrically against a reference standard benzoic acid dissolved in dimethylformamide. Both titrants were protected from the atmosphere by an Ascarite guard tube. Dimethylformamide was purified by distillation (b.p. 153°). Other chemicals and solvents used in this study were reagent grade and used as received without further purification.

Differentiating Titration of Salicylic Acid and Acetylsalicylic Acid—Approximately 0.50 meq. of salicylic acid and 0.50 meq. of acetylsalicylic acid, accurately weighed, were dissolved in 50 ml. of solvent or solvent mixture in a 150-ml. beaker covered with a rubber plate having holes for the passage of the electrodes and the buret tip. The solution, under constant stirring, was titrated potentiometrically with 0.1 *N* sodium methoxide solution or 0.1 *N* tetrabutylammonium hydroxide solution, using a modified calomel and glass electrode system. A blank titration was also performed. Titration curves were obtained by plotting the potential reading, *E*, in millivolts (mv.) *versus* volume (ml.) of titrant. The exact end point was determined by plotting $(\Delta E/\Delta \bar{V})$ *versus* ml. The titration solvents evaluated in this study included dimethylformamide, pyridine, nitromethane, nitrobenzene, acetone, methyl ethyl ketone, methyl isobutyl ketone, methanol, ethanol, isopropanol, and *tert*-butylalcohol. Prior to carrying out the differentiating titration of salicylic acid and acetylsalicylic acid in each solvent, the individual compounds were titrated separately.

Electrode Systems—The six electrode combinations employed were glass–calomel, platinum–calomel, antimony–calomel, antimony–platinum, glass–antimony, and glass–platinum. The titration solvents used in the evaluation of these electrode systems included dimethylformamide, nitromethane, acetonitrile, and methyl isobutyl ketone. The concentration of the acids, volume of solvent, and titrants were the same as above.

Variation of Salicylic Acid-to-Acetylsalicylic Acid Ratio—A series of differentiating titrations was performed in which the milliequivalent ratio of salicylic acid to acetylsalicylic acid was varied from 1 to 1 to greater than 10 to 1. Amounts of salicylic acid and acetylsalicylic acid calculated to give the desired milliequivalent ratio of components were accurately weighed and dissolved in 50 ml. of dimethylformamide. The solution was titrated potentiometrically with 0.1 *N* sodium methoxide solution or 0.1 *N* tetrabutylammonium hydroxide solution using the glass–calomel electrode system.

Effect of Varying Water Concentration in Titration Solvent on Differentiating Titration—Accurately weighed quantities of salicylic acid and acetylsalicylic acid were dissolved in 50 ml. of water–dimethylformamide solvent mixture composed of varying amounts of water. The solution was titrated potentiometrically with 0.1 *N* sodium methoxide solution or 0.1 *N* tetrabutylammonium hydroxide solution, using the glass–calomel electrode pair.

RESULTS AND DISCUSSION

An ideal solvent for the satisfactory differentiation of an acid mixture should be sufficiently weak in basicity to permit the titration of the stronger acidic component and sufficiently weak in acidity to permit the titration of the weaker acidic component. From a practical standpoint, the differentiating quality of the solvent can be realized from the characteristics of the potentiometric titration curves obtained. A well-defined inflection will be observed for the potentiometric titration of the stronger acid if the solvent is a good differentiating solvent. The better the differentiating ability of the solvent, the greater the inflection will be. In preliminary experiments a series of solvents and combinations of solvents were employed as titration solvents to test their differentiating ability. Titrations were effected potentiometrically with 0.1 *N* sodium methoxide or 0.1 *N* tetrabutylammonium hydroxide using a glass–modified calomel electrode system. Of the solvent systems tested, dimethylformamide was found to yield the most satisfactory end points in the differentiating titration of the salicylic acid–acetylsalicylic acid mixture, despite the fact that dimethylformamide has been reported to be of only limited use for the titration of acids and their mixtures because of strong acid–solvent interaction (13). The autoprotolysis constant for this solvent, as determined from potentiometric measurements, was found to be 10^{-18} (14).

When an electrically neutral acid (HA) is dissolved in the solvent (SH), species with various charges are formed upon the ionization of the solvent:

$$SH + HA \rightleftarrows A^- + SH_2^+ \qquad \text{(Eq. 1)}$$

The reaction is not solvent-independent since reactants and products differ significantly in their charge densities, and therefore, in their ability to accept hydrogen bonds or form ion pairs in the solvent. The effect of the solvent in titration and differentiation of salicylic acid and acetylsalicylic acid in water and dimethylformamide is illustrated in Schemes I–III.

It was observed that salicylic acid and acetylsalicylic acid, alone or in combination, are readily dissolved in dimethylformamide but slowly dissolved in water. This may be explained by the important role of the nature of the solvent molecule on the strength of the solute–solvent interactions. The nature of the solution also varies with the solvent. Ions and molecules have a tendency to achieve the lowest possible energy state, and the formation of certain structure in the solution process is one way of attaining this. The greater the solvation, the lower the resulting energy of the solute, and its stability in solution is increased. This is achieved when a charged species is surrounded by suitably oriented dipoles of a solvent of high dielectric constant. In water, both anions and cations are well solvated and thus shielded from each other because of van der Waal forces and other intermolecular attractions. Anions, because of their great solvation energies, are well stabilized in solution, and the forward reactions of Scheme I (*a* and *b*), are greatly favored. In other words, since the anion is much more densely charged than the electrically neutral solvent molecule, the strong anion–solvent interactions due to hydrogen bonding lower the energy of anion relative to the electrically neutral solvent molecule. As a result, the equilibrium in water is shifted further to the right as compared to a solvent incapable of forming hydrogen bonding with the anions. Upon the addition of alkoxide ion as titrant during the titration, the solvated proton reacts quantitatively with alkoxide ion as shown in Scheme II(*a*). Consequently, salicylic acid and acetylsalicylic acid can be titrated individually in water as shown in Fig. 1 (curves 1 and 2). Parker (15) and Buckingham (16) have shown that anions are solvated to a greater extent

than cations in water and small anions are much more solvated than large anions. However, in water, the difference in energy between anions of salicylic acid and acetylsalicylic acid might not be great enough to permit the successful differentiation of a salicylic acid–acetylsalicylic acid mixture as evidenced by Fig. 1, curve 3.

When dimethylformamide replaced water as the solvent, the situation was changed. This is due to the fact that dimethylformamide and water possess different solvent characteristics. (*a*) Water is amphiprotic in nature, while dimethylformamide donates electrons but does not accept them. (*b*) The strongest base that can exist in water is the solvated hydroxide ion, while on the other hand, a much stronger base system is possible in dimethylformamide. (*c*) The dielectric constants of water and dimethylformamide are 80 and 36, respectively, and the higher the dielectric constant of a solvent, the lower the electrostatic interaction and less will be the chance for the dissolved species bearing an opposite charge to interact. (*d*) The positive charge on the small hydrogen atoms of water can come much closer to an anion than can a positive charge on an atom other than hydrogen. Hence, the possible interaction in dimethylformamide is of the weaker ion–dipole interaction, neither hydrogen bonding nor ion-pairing being operative. Consequently, the anions in dimethylformamide are much less solvated and more reactive than those in water. In other words, solute molecules dissolved in dimethylformamide yield anions which have much greater free energies than the anions produced from solutes dissolved in water. As illustrated in Scheme I (*c* and *d*), the forward reaction becomes less favorable relative to the backward

Key: 1, acetylsalicylic acid; 2, salicylic acid; 3, salicylic acid and acetylsalicylic acid.

reaction when water is replaced with dimethylformamide. The equilibrium in dimethylformamide, therefore, does not lie as far to the right as it does in water. As the result, a greater sensitivity in end point detection was noted for the individual components with water (curves 1 and 2, Fig. 1) than with dimethylformamide (curves 1 and 2, Fig. 2) as titration solvent. Zaugg (17), Prue and Sherrington (18), and Parker (15) have pointed out that in dimethylformamide anions are much less solvated than cations, and large polarizable anions may be slightly more solvated than small anions. Even more important is the fact that the difference in energy between anions of different sizes and charge densities is much greater in dimethylformamide than in water. Consequently, differentiating titration of a salicylic acid–acetylsalicylic acid mixture can be readily achieved in dimethylformamide (curve 3, Fig. 2), but not in water (curve 3, Fig. 1). When the combination of drugs was titrated in dimethylformamide, two distinct inflections were obtained, the first corresponding to the salicylic acid content and the second representing the acetylsalicylic acid end point. In this connection, Kolthoff *et al.* (19) have emphasized that, in the interpretation of difference in acid strength in different solvents, one must consider the degree of anion solvation and the formation and dissociation of ion pairs in addition to the basic characteristics and dielectric constant of the solvent. Additional studies are presently underway concerning the basic behavior of salicylic acid and acetylsalicylic acid in water and dimethylformamide; the results will be presented in a future publication (20).

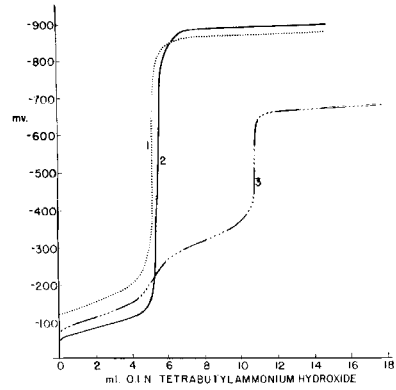

Fig. 3—Typical curves for the titration of salicylic acid and acetylsalicylic acid dissolved in dimethylformamide, individually and in combination, with 0.1 N tetrabutylammonium hydroxide in benzene–methanol (10:1), using glass-modified calomel electrode system. Key: 1, acetylsalicylic acid; 2, salicylic acid; 3, salicylic acid and acetylsalicylic acid.

With dimethylformamide as the titration solvent, the titration curves in Fig. 2 were obtained with sodium methoxide, whereas those in Fig. 3 were obtained with tetrabutylammonium hydroxide as the titrant. The sharp breaks in the titration curves (curves 1 and 2, Figs. 2 and 3) indicated excellent quantitative recoveries of acetylsalicylic acid and salicylic acid when titrated individually. As would be expected, a greater sensitivity in end point detection was realized for the individual components with the more basic titrant, tetrabutylammonium hydroxide, than with sodium methoxide titrant. A comparison of the sharpness of the inflection, as shown in Table I by the magnitude of $(\Delta E/\Delta \bar{V})_{max.}$, expressed in mv./ml., indicates that for acetylsalicylic acid the sharpness of the inflection was doubled when the quaternary ammonium hydroxide titrant replaced the alkoxide titrant. The steeper inflection given by salicylic acid over acetylsalicylic acid in dimethylformamide is predictable from their respective dissociation constants in water. When the combination of drugs was titrated (curve 3, Figs. 2 and 3), satisfactory differentiation was obtained with either titrant. When sodium methoxide was substituted by tetrabutylammonium hydroxide as titrant, as indicated in

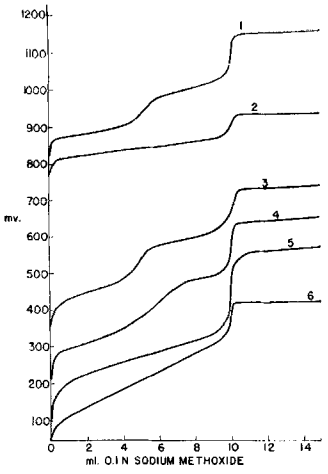

Fig. 4—Typical curves for differentiating titration of salicylic acid and acetylsalicylic acid in various solvents. Key: 1, dimethylformamide; 2, pyridine; 3, nitromethane; 4, nitrobenzene; 5, alcoholic solvent; 6, ketonic solvent. The titrant was 0.1 N sodium methoxide in benzene–methanol (10:1).

Table I, the sharpness of the inflection remained fairly unchanged for salicylic acid, while the sharpness of the inflection for acetylsalicylic acid was more than tripled. This may be explained, at least in part, by the fact that when tetrabutylammonium hydroxide is used as titrant, the potential span available is two to three times larger than when sodium methoxide is employed. The suppression of the sharpness of the inflections during differentiating titration of mixtures, as compared with the titration of individual components, is further shown from the data in Table I. With sodium methoxide as the titrant, the magnitude of $(\Delta E/\Delta \bar{V})_{max.}$ obtained during differentiation is suppressed about twentyfold for salicylic acid and approximately twofold for acetylsalicylic acid. When the mixture was titrated with tetrabutylammonium hydroxide, a more drastic suppression of the magnitude of $(\Delta E/\Delta \bar{V})_{max.}$ was observed with salicylic acid, giving a 35-fold reduction of the sharpness of potential break during differentiation as compared with the value obtained from the titration of salicylic acid alone. It is interesting to note that acetylsalicylic acid offers a sharper inflection than salicylic acid during the differentiating titration, in spite of the fact that salicylic acid demonstrates better inflection than its acetylated derivative when titrated individually.

Using a glass–methanol modified calomel electrode system, the effect of various solvents on the sensitivity of differentiation was investigated with either sodium methoxide (Fig. 4) or tetrabutylammonium hydroxide (Fig. 5) as the titrant. Basic solvents other than dimethylformamide, such as pyridine, while excellent for the individual components, do not permit differentiation in the case of acetylsalicylic acid–salicylic acid mixture. Figure 4, curve 2, indicates a single end point corresponding to the total acid present when titration is performed in pyridine. An explanation of this is that both acids react nearly completely with the pyridine which tends to level all acids so that their strengths become indistinguishable. This phenomenon has been termed the "leveling effect" (21). When sodium methoxide was used as the titrant, no resolution was observed in acetonitrile, the ketones, and alcohols. Using tetrabutylammonium hydroxide as titrant, similar results were obtained in these solvents with the exception of *tert*-butyl alcohol (curve 5, Fig. 5). When the titration is performed in nitromethane, differentiation is readily accomplished with the sodium methoxide titrant (curve 3, Fig. 4) but not with tetrabutylammonium hydroxide titrant (curve 4, Fig. 5). On the contrary, when the titration is carried out in *tert*-butyl alcohol, resolution is realized with tetrabutylammonium hydroxide titrant (curve

5, Fig. 5) and not with the sodium methoxide titrant (curve 5, Fig. 4). Although it is possible to differentiate the acids in nitrobenzene (curve 4, Fig. 4), a smaller and less well-defined inflection is obtained for the stronger acid in the mixture. Consequently, the importance of the proper selection of the solvent–titrant combination for a successful differentiating titration is clearly exemplified by the plots in Figs. 4 and 5.

Pifer *et al.* (22) point out that the inclusion in the titration solvent system of an excess of a solvent having a low dielectric constant can increase markedly the sensitivity in the detection of the end point. This useful principle has been applied satisfactorily to the titration of acetophenetidin (23) and the differentiation of acetophenetidin–caffeine mixture (24). However, an attempt to sharpen the end points by the incorporation of an excess of benzene or chloroform in dimethylformamide, nitrobenzene, or nitromethane was not successful with sodium methoxide as the titrant. Although quantitative recoveries, as reported in Table II, were obtained for both components dissolved in nitromethane and mixed solvents containing a large excess of chloroform or benzene in nitromethane, the sharpness of the inflection remains fairly unaltered. The incorporation of an excess of a solvent having a low dielectric constant in dimethylformamide or nitrobenzene not only prevented the differentiation, but a single end point corresponding to the total acid present in the system was obtained.

The effect of six electrode combinations on the resolution of salicylic acid and acetylsalicylic acid was explored, using either sodium methoxide or tetrabutylammonium hydroxide as titrant. Dimethylformamide and nitromethane were employed as the titration solvents. The electrode systems and the number of end points subsequently observed for the differentiating titration are listed in Table III. It was observed that the feasibility of the differentiation and the characteristics of titration curves were markedly different from one titrant–solvent–electrode system to another. For example, with dimethylformamide as the titration solvent and sodium methoxide as the titrant, various degrees of differentiation were observed with six electrode couples investigated. As depicted in the family of curves on the left side of Fig. 6, two distinct inflections were obtained with the glass–calomel (curve 1) and the antimony–platinum (curve 4) electrode pairs, one potential break representing total acid was realized with the antimony–calomel (curve 3) electrode system, no discernible inflection was attainable with the platinum–calomel (curve 2) electrode couple, and abnormal titration curves near the second equivalent points were encountered with the antimony–glass (curve 5) and the platinum–glass (curve 6) electrode combinations. When tetrabutylammonium hydroxide replaced sodium methoxide as titrant, as shown in the family of curves on the right side of Fig. 6, all electrode systems, with the exception of the antimony–platinum (curve 4) electrode pair, gave satisfactory but different degrees of resolution for the salicylic acid–acetylsalicylic acid mixture dissolved in dimethylformamide. When titration was performed

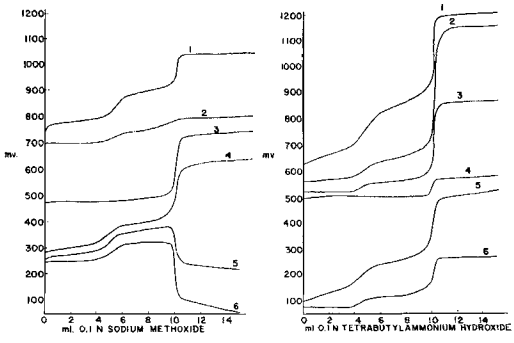

Fig. 6—Effect of electrode combination on sensitivity of differentiating titration of salicylic acid and acetylsalicylic acid dissolved in dimethylformamide. Right series of curves were obtained with sodium methoxide as titrant, whereas the left series of curves were obtained with tetrabutylammonium hydroxide. The numbers above the curves correspond to those in Table III.

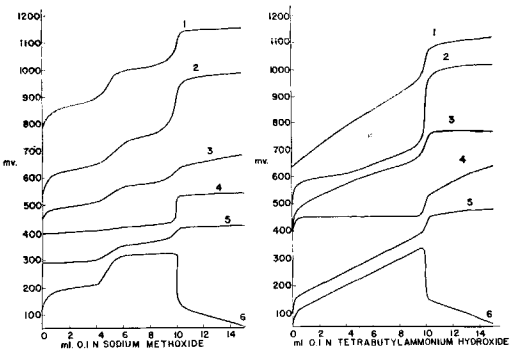

Fig. 7—Effect of electrode combination on sensitivity of differentiating titration of salicylic acid and acetylsalicylic acid dissolved in nitromethane. Left series of curves were obtained with sodium methoxide as titrant, and the right series of curves were obtained with tetrabutylammonium hydroxide. The numbers above the curves correspond to those in Table III.

in nitromethane, tetrabutylammonium hydroxide proved unsuitable as a differentiating titrant. As shown in the family of curves on the right side of Fig. 7, tetrabutylammonium hydroxide titrant did not permit the differentiation in any of six electrode combinations studied, whereas the sodium methoxide titrant allowed the differentiation to be accomplished in four out of the six electrode systems investigated, the exceptions being the antimony–platinum (one end point representing the total acid) and the glass–platinum (abnormal titration curve) electrode couples as demonstrated in the family of curves on the left side of Fig. 7. Lin and Blake (25, 26) reported the same phenomenon in the differentiating titration of acetylsalicylic acid and barbiturate combinations dissolved in methyl isobutyl ketone, using glass–calomel or antimony–calomel electrode pairs. They found that resolution was achieved with the sodium methoxide titrant but not with tetrabutylammonium hydroxide as the titrant. Further studies were performed using sodium methoxide as the titrant and acetonitrile as the titration solvent or using tetrabutylammonium hydroxide as the titrant and methyl isobutyl ketone as the titration solvent. However, no differentiation of salicylic acid–acetylsalicylic acid mixtures was observed with any of the six electrode systems investigated.

Quantitative recoveries, together with the corresponding maximum potential change per unit volume of titrant added, for both salicylic acid and acetylsalicylic acid obtained in various titrant–solvent–electrode combinations are tabulated in Table IV. Excellent results were obtained for all combinations. For each titrimetric condition, acetylsalicylic acid offers a sharper potential break than salicylic acid in the differentiating titration, although salicylic acid shows better inflection than acetylsalicylic acid when it is titrated separately. In general, the tetrabutylammonium hydroxide titrant gave sharper inflections than the sodium methoxide titrant for acetylsalicylic acid, the weaker acid presented in the acid mixture to be differentiated, while only slight differences in the sharpness of the inflections for salicylic acid was noted between the two titrants. Another example to illustrate the importance of the suitable solvent–titrant combination on the successfulness of the resolution can be easily deduced from Table III. With the antimony–calomel electrode system, for example, differentiation is readily achieved with a combination of dimethylformamide–tetrabutylammonium hydroxide or nitromethane–sodium methoxide but is unsuccessful with the dimethylformamide–sodium methoxide or nitromethane–tetrabutylammonium hydroxide system.

Since salicylic acid is one of the hydrolytic degradation products of acetylsalicylic acid, the effect of varying the ratio of concentrations of the components on the sensitivity of the differentiating titration was studied. The data for a series of titrations in which the milliequivalent ratio of salicylic acid to acetylsalicylic acid was varied from 1 to 1 to about 12 to 1 are reported in Table V. Typical titration curves obtained with the sodium methoxide titrant are shown in Fig. 8 and those obtained with tetrabutylammonium hydroxide titrant are depicted in Fig. 9. With sodium methoxide as the titrant, two discernible inflections in the titration curve were obtained when the milliequivalent ratio of salicylic acid to acetylsalicylic acid was not greater than about 5 to 1. When the ratio was greater

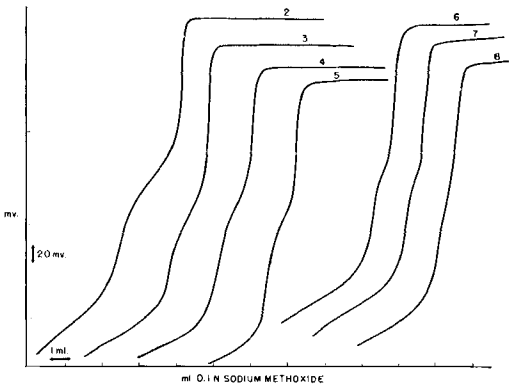

Fig. 8—Effect of salicylic acid-to-acetylsalicylic acid ratio on sensitivity of differentiating titration of salicylic acid and acetylsalicylic acid dissolved in dimethylformamide. The numbers above the curves correspond to those in Table V. The titrant was 0.1 N sodium methoxide in benzene–methanol (10:1).

than this, only one end point representing total acid was realized. The curves in Fig. 8 demonstrate clearly the effect of the ratio on the resolution of the two end points. With tetrabutylammonium hydroxide as the titrant, satisfactory resolution was realized when the salicylic acid-to-acetylsalicylic acid ratio was as high as 7 to 1. However, the salicylic acid inflection began to blend with the acetylsalicylic acid inflection at an 11 to 1 ratio. In Fig. 9, curve 8, two end points are clearly defined and recoveries of both components are quantitative. However, in curve 9, only one end point corresponding to the total acid is discernible. Conceivably these ratios could be extended in dimethylformamide by using either more diluted titrants or larger sample sizes.

Water is present as a common impurity in nearly all nonaqueous solvents. The presence of water in the titration solvent can interfere in the titration of acids in protophilic (basic) solvents, of bases in protogenic (acidic) solvents, and of acids and bases in inert solvents. This is due to the amphiprotic nature of water. However, the presence of water in the quaternary ammonium titrant has shown to exhibit a profound stabilizing action on the titrants at a sacrifice of its basic strength (27). The weak acid properties of water are evident in basic solvents, such as dimethylformamide (28, 29), pyridine (30), and ethylenediamine (28). In this investigation, the effect of adding varying quantities of water into the dimethylformamide titration solvent on the sensitivity of differentiation was examined. Equal milliequivalent concentrations of salicylic acid and acetylsalicylic acid were used for all titrations. This requirement was necessary in order to prevent any concentration effect (31). A suitable quantity of water or dimethylformamide was delivered from microburets into the beaker containing accurately weighed samples of the acids. Since a well-defined inflection will be realized for the potentiometric titration of the stronger acid if the solvent employed has good differentiating power, a new and simple method was employed to define the resolution power of the solvent system. This is depicted in Fig. 10 for sodium methoxide titrant and in Fig. 11 for tetrabutylammonium hydroxide titrant. Only a representative set of curves obtained are shown for clarity. The magnitude of the inflection for the stronger acid which is the determining factor for satisfactory differentiation was determined by extrapolating the two straight portions of the

titration curve and then drawing a straight line through the end point and verticle to the extrapolated line to obtain interception points A and B. The distance of the line AB = d is measured in cm. The magnitude of d obtained in various water–dimethylformamide solvent mixtures is reported in Table VI. The higher the concentration of water in the solvent mixture, the smaller the d value, and the weaker the differentiating ability of the solvent mixture. As expected, water has a detrimental effect on the differentiation. The presence of only a small percentage in the solvent is sufficient to reduce markedly the size and sharpness of the inflections obtained. The potential jump for salicylic acid was reduced gradually upon the progressive addition of water. This is well illustrated in Figs. 10 and 11. Although the recovery is quantitative for both components in the mixture, higher recoveries were obtained when the solvent mixture contained higher water concentrations. However, this is coincided with the increasing blank obtained as the water concentration is increased. When the magnitude of inflection of the stronger acid was plotted *versus* per cent v/v of water in the water–dimethylformamide mixed solvent, Fig. 12 was obtained. At the same concentration of water, larger d values were obtained with the tetrabutylammonium titrant than with the sodium methoxide titrant. This indicates that relatively larger inflections were obtained with the former titrant than with the latter titrant at any particular level of water concentration in the mixed solvent. A linear relationship exists up to 15% of water when the sodium methoxide titrant was employed, as compared to 8% of water when the quaternary ammonium hydroxide titrant was used. The slope of the linear portion of the curve for the quaternary

ammonium titrant is approximately three times steeper than that of the sodium methoxide titrant. This correlation demonstrates that the rate of water tolerance with the sodium methoxide titrant is threefold as resistant as with the quaternary ammonium hydroxide titrant. Since this investigation was designed to provide potentiometric differentiating data for analytical purposes rather than accurate fundamental data, the volume shrinkage during mixing of the solvents and the dielectric constants of such solvent mixtures were not precisely controlled. It is possible that the dielectric constants of such mixtures as measured in the ordinary manner do not represent the effective dielectric constant in the immediate surroundings of the ions. The greater polarity of the water as compared to the dimethylformamide may cause the titration in the immediate vicinity of the ions to be richer in water than the bulk of the solution (32–34). The qualitative pictures obtained in Table VI and Fig. 12 indicate that a progressive increase of dielectric constant with increasing water concentration has a harmful effect on the sensitivity of differentiation.

The proposed nonaqueous differentiating procedures make possible the simple and accurate determination of the combination of acetylsalicylic acid and salicylic acid. Preliminary treatment of the sample is unnecessary, and tedious separation and extraction techniques are obviated. The differentiating titration is achieved in various solvent–titrant–electrode combinations. The technique is applicable even when there is a disproportionate concentration of the components. This work suggests that, by a proper combination of solvent, titrant, and electrode system, it should be possible to titrate potentiometrically both components of acidic or basic mixture whose dissociation constants not only approach but are well below the theoretical limit of 16 proposed by Auerbach and Smolczyk (10).

Emulsifying Properties of a New Polysaccharide Gum

By OSCAR E. ARAUJO

A recently developed polysaccharide gum produced by bacterial fermentation, now commercially available, was investigated as a potential emulsifying agent for pharmaceutical systems. Mineral oil emulsions having a fixed oil to water ratio were prepared using concentrations of the new gum ranging from 0.1 to 0.9 per cent. Emulsions containing 5 to 40 per cent acacia were also prepared and served as a basis for comparison. Rheological measurements, particle size studies, and organoleptic observations were performed on all the emulsions. A Stormer viscosimeter was used to obtain the flow properties, while a standard microscopic technique was employed for the particle size analysis. The results showed the plastic nature of the emulsions prepared with the new gum and the existence of a definite yield value. These emulsions showed good over-all stability over a period of 6 months, with little change in viscosity or particle size. The general appearance of the emulsions containing the new gum was creamier than that of those prepared with acacia, and the emulsions containing more than 0.2 per cent of the polysaccharide exhibited no phase separation after 6 months.

THE EVALUATION of potential suspending and emulsifying agents which would increase the stability and cosmetic elegance of heterogeneous pharmaceutical systems has been the object of much investigation.

In recent years, research by the U. S. Department of Agriculture resulted in the production of a heteropolysaccharide from the bacterial fermentation of glucose by *Xanthomonas campestris* (1). Jeanes *et al.* (2) reported several of the properties of what was at the time referred to as polysaccharide B-1459: this xantham gum has since been produced commercially.[1] These authors had shown upon analysis that the major constituents of the new polysaccharide were D-mannose, D-glucose, and D-glucuronic acid present as the potassium salt.

A study of the acute toxicity of and the skin sensitivity to the gum was carried out and no evidence of either was found (3). Government clearance for food and drug use is still pending final FDA approval.

Carnie (4) discussed some of the properties of solutions of the gum and the effects of heating, pH, concentration, and homogenization on these preparations. Kabre *et al.* (5, 6) studied the rheological characteristics of this xantham gum and evaluated it as a suspending agent for zinc oxide and sulfamethazine.

The above studies along with preliminary experimentation revealed certain unusual properties of this polysaccharide which indicated its potential as an emulsifying agent and led to the present investigation. Emulsions using acacia, a well-known naturally occurring polysaccharide, served as the basis for comparison.

Received April 14, 1967, from the Department of Pharmacy, College of Pharmacy, University of Florida, Gainesville, FL 32601

Accepted for publication June 21, 1967.

EXPERIMENTAL

Preparation of Emulsions—All the emulsions were prepared using a 4:6 mineral oil to water ratio. The xantham gum was used in concentrations of 0.1 to 0.9%, in increments of 0.1%, and acacia in concentrations of 5 to 40%, in increments of 5%. The carefully measured liquids were placed in a Waring blender, the emulsifying agent added to the surface of the liquids, and the entire mixture blended for 4 min. The resulting emulsions were passed twice through a hand homogenizer to further standardize the products. The distilled water used to prepare all emulsions contained 0.2% benzoic acid as a preservative. All emulsions were allowed to equilibrate for 2 hr. before any measurements were made.

pH Measurements—A Photovolt electronic pH meter model 110 was used to measure the pH of the emulsions.

Rheological Measurements—A Stormer viscosimeter equipped with the modified cup and bob as described by Fischer (7) was employed. A weight hanger with various slotted weights provided the shearing stress. Calibration data obtained with a standard oil were used to calculate the instrumental constant, K_v, from the expression:

$$K_v = \eta \frac{\text{r.p.m.}}{W} \qquad \text{(Eq. 1)}$$

where W represents the shearing stress in Gm., r.p.m., the rate of shear, and η, the viscosity of the standard oil in cps.

The plastic viscosity was calculated according to the expression:

$$U = K_v \frac{W - W_f}{\text{r.p.m.}} \qquad \text{(Eq. 2)}$$

where W_f is the extrapolated yield value intercept in Gm., and U is the plastic viscosity in cps.

The yield value was obtained from the expression:

$$f = \frac{2\pi}{60} \times K_v \times W_f \times \frac{1}{2.303 \log R_c/R_b} \qquad \text{(Eq. 3)}$$

All rheological measurements were performed at 20 ± 0.1°.

Organoleptic Observations—The emulsions were examined as to appearance, odor, and texture; any

change in these characteristics over a period of 6 months was noted.

Particle Size Analysis—The diluting medium used to prepare the slides for the microscopic analysis consisted of a 75% aqueous glycerin solution. Several other vehicles were tried, including propylene glycol as suggested by Knoechel (8); the medium selected provided the best contrast and least particle mobility.

One milliliter was withdrawn from well below the surface of the emulsion by means of a syringe equipped with an 18 gauge, 3.5 in. length needle. The sample was then introduced into a 100-ml. volumetric flask containing approximately 50 ml. of the diluting fluid, mixed thoroughly and brought to a volume of 100 ml. One drop of the diluted emulsion was then placed on a glass slide and a cover slip carefully placed over the liquid. Approximately 15 min. was permitted to elapse to allow the particles to rise and assume a fixed position on the slide.

The particle count was performed with the aid of a standard microscope equipped with a 43× objective, a 10× ocular, a movable micrometer stage, and a micrometer eyepiece. The latter contained a movable cross hair, the traverse of which was measured by a revolving drum marked into 100 divisions. By proper calibration each division was then equivalent, under the above conditions, to a fraction of a micron.

The number of particles counted for each sample varied from 400 to 1600 depending on the range of particle distribution. A preliminary scan of the entire slide provided an over-all picture of the spread of particle size, helping to establish the number to be counted. The degree of aggregation or clustering was also noted in this examination.

Using the movable micrometer stage and a table of random numbers, "coordinates" were chosen to insure a random selection of fields and to prevent duplicate measurements. The size frequency tally obtained from these counts was used to calculate the arithmetic mean diameter, d_m, the geometric mean diameter, d_g, and the volume-surface mean diameter, d_{vs}, according to the following expressions:

$$d_m = \frac{\Sigma n_i d_i}{\Sigma n_i} \qquad \text{(Eq. 4)}$$

$$d_g = \frac{\Sigma n_i \ln d_i}{\Sigma n_i} \qquad \text{(Eq. 5)}$$

$$d_{vs} = \frac{\Sigma n_i d_i^3}{\Sigma n_i d_i^2} \qquad \text{(Eq. 6)}$$

where n_i is the number of globules having a class diameter of d_i in microns (7, 9).

RESULTS AND DISCUSSION

Preliminary Studies—In order to evaluate effectively the emulsifying ability of the xantham gum, it was necessary not only to prepare the emulsions in exactly the same manner each time, but also to maintain a constant oil–water ratio. These precautions would eliminate all the variables affecting the quality of the emulsions except the nature and concentration of the emulsifier.

Preliminary experiments were performed to establish the range of concentrations of the new gum to be used in the study. The results showed that a 1.0% aqueous mucilage of xantham gum was a firm gel, while those mucilages containing less than 0.1% were too dilute. Therefore, the range of concentrations selected was 0.1 to 0.9%.

Emulsions of castor, cod liver, and mineral oils were prepared using equal parts of oil and water; 0.25 and 0.5% of the xantham gum served as the emulsifier. Mineral oil was selected for the investigation on the basis of the over-all appearance of the emulsions.

The oil–water ratio selected for the detailed experimentation was the result of an appraisal of the general appearance of mineral oil emulsions prepared with ratios of 2:8, 3:7, 4:6, 5:5, 6:4, 7:3, and 8:2. Again the xantham gum was used in concentrations of 0.25 and 0.5%. Emulsions having a 4:6 oil–water ratio were chosen by the above criterion for use throughout the study.

Since emulsions containing acacia were to be used for the purpose of comparison, it was necessary to determine if the 4:6 ratio also provided satisfactory emulsions with acacia. Accordingly, a trial mineral oil emulsion with acacia was prepared and judged satisfactory.

Having established the range of concentrations of xantham gum to be used in the investigation, similar preliminary experiments were conducted with acacia, resulting in the selection of concentrations ranging from 5 to 40%.

Organoleptic Qualities—The emulsions prepared with the new gum exhibited a creamy white appearance. The lone exception involved the product containing 0.1% which appeared to be incompletely emulsified; this observation was confirmed by examining the emulsion under a microscope, which clearly showed large oil lakes throughout the sample, making a globule count impossible. No unpleasant odor developed in any of the emulsions during a 6-month shelf-life. The general texture when applied to the skin was smooth, leaving no gummy residue. This quality would seem to be important from a lotion formulation standpoint. The preparations having concentrations above 0.5% had a gel-like consistency easily broken up by shaking. Creaming was observed to a slight degree only with the 0.2% emulsion after storage of 6 months.

The emulsions prepared with acacia did not have a creamy appearance and possessed an off-white coloration. A gummy film characteristic of acacia preparations remained on the skin upon drying. The acacia emulsions having concentrations of 25% and less showed creaming after a period of 6 months, the extent of which increased with decreasing concentration.

pH Considerations—The pH of each emulsion was taken initially and after 6 months. The pH of the emulsions with the xantham gum ranged from 3.5 to 4.0 while that of those prepared with acacia varied from 4.2 to 4.4. The measurements indicate essentially no change in the pH of the emulsions prepared with either emulsifier.

Rheological Observations—The emulsions prepared with the new gum showed certain unusual rheological characteristics. Figure 1 clearly indicates the plastic nature of the emulsions and the existence of a definite yield value. As the shearing stress is increased, a value is reached for each of the emulsions above which a constant plastic viscosity is given by the linear portion of

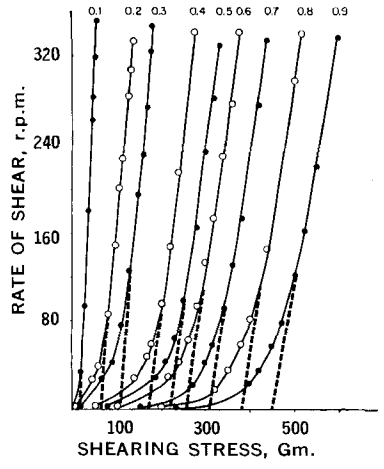

Fig. 1—Rheograms of emulsions containing various per cent concentrations of xantham gum.

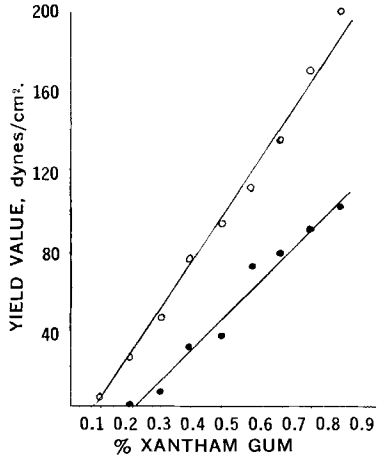

Fig. 2—Yield values of emulsions containing the xantham gum. Key: ●, minimum yield value; ○, Bingham yield value.

the rheogram. Extrapolation of this linear segment to the shearing stress axis gives the Bingham yield value, in Gm.

A minimum yield value was established for each of the xantham gum emulsions by determining the minimum number of Gm. which produced rotation of the bob on the Stormer viscosimeter. Each emulsion, except the 0.1% semiemulsified product, displayed a minimum yield value, thereby precluding any pseudoplasticity.

The minimum and extrapolated yield values for the various concentrations of the xantham gum are shown in Fig. 2. There appears to be a linear relationship between concentration and both yield values over the range studied. In addition, the Bingham yield value for the most concentrated emulsion is less than 200 dynes/cm.², well within the range of the stress of a hand-shaken bottle.

Figure 3 indicates that the plastic viscosities increase with increasing concentrations of the gum, as did the yield values. The increase, however, appears to decrease exponentially so that the overall range of plastic viscosity was only 25 to 86 cps. Consequently, the 0.9% xantham gum emulsion which has the highest plastic viscosity still has sufficient mobility upon agitation to be easily poured from a bottle.

Rheologically, the ideal emulsifying agent should possess the same qualities as those of the ideal suspending agent: high viscosity at the negligible shear of shelf storage and low viscosity upon agitation, causing the preparation to be free-flowing and easily spread on the skin (10).

The new polysaccharide appears to lack one desirable feature of an emulsifying agent, that of thixotropy. Since the upcurve and downcurve of the rheograms were found to be coincidental, there was no time-dependence in the rheological reconstitution of the emulsions upon removal of the shearing stress. This property held true for all concentrations of gum but only affects pourability in those emulsions of concentrations above 0.6%, where agitation must be maintained to remove the contents from the bottle.

The rheograms for the acacia emulsions are shown

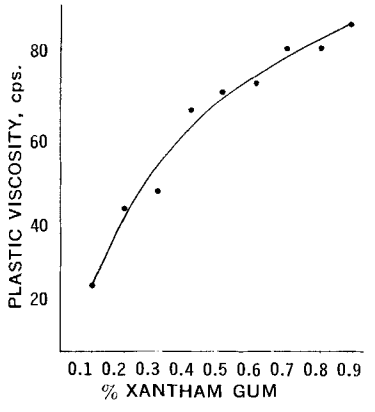

Fig. 3—Plastic viscosities of emulsions containing xantham gum.

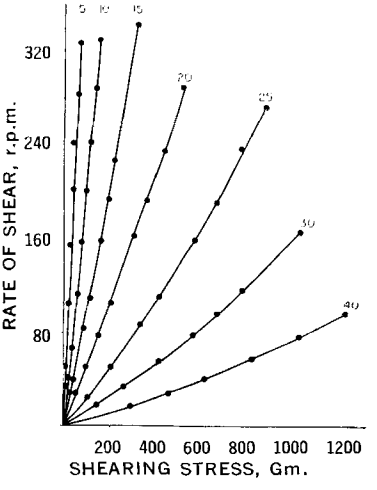

Fig. 4—Rheograms of emulsions containing various per cent concentrations of acacia.

TABLE I—PARTICLE SIZE OF EMULSION GLOBULES

% Xantham Gum	Diam., μ			% Acacia	Diam., μ		
	d_m	d_g	d_{vs}		d_m	d_g	d_{vs}
0.2	1.38	1.13	11.1	5	7.53	5.33	19.7
0.3	1.46	1.18	12.1	10	6.47	5.37	11.6
0.4	1.81	1.21	25.9	15	5.81	4.40	13.7
0.5	2.00	1.27	28.9	20	2.39	2.10	3.60
0.6	2.08	1.24	33.3	25	2.05	1.84	2.84
0.7	2.26	1.30	31.5	30	1.83	1.72	2.26
0.8	2.52	1.38	27.2	40	<1.00	...	...
0.9	3.19	1.55	26.4				

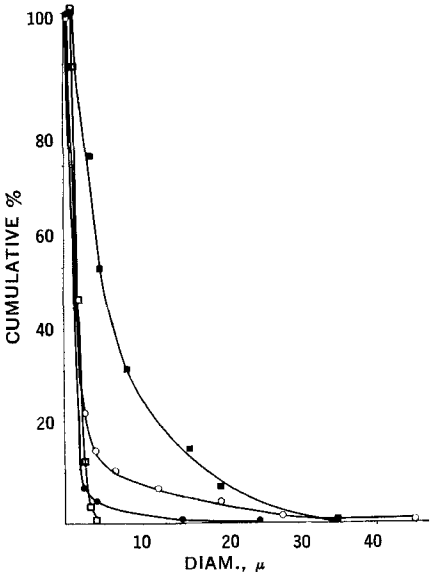

Fig. 5—Particle size distribution of emulsions containing extremes of concentration of acacia and xantham gum. Key: ■, 5% acacia; □, 30% acacia; ●, 0.2% xantham gum; O, 0.9% xantham gum.

in Fig. 4. The quasi-Newtonian characteristics of the dilute emulsions and the pseudoplastic nature of the more concentrated ones are evident. The rheological pattern is quite similar to that of the aqueous mucilages of the gum (11).

Regardless of the emulsifying agent used or its concentration, the products showed no significant change in rheological properties after a 6-month shelf-life, indicating good consistency stability.

Particle Size Studies—Table I gives the mean globule diameters for all the emulsions prepared in this study. The ranges of the arithmetic and geometric mean diameters of the emulsions prepared with the xantham gum from low to high concentration are narrower than those for the acacia emulsions. However, the emulsion containing 40% acacia contained only particles of 1 μ and smaller; no larger particles were observed even when the entire slide was scanned.

The volume-surface mean diameters are much larger for the emulsions prepared with the new polysaccharide, indicating the presence of a number of particles in the 25 to 45 μ range. However, in Fig. 5, which shows the cumulative frequency distribution curves for the extremes of concentration of both emulsifiers, it can be seen that the xantham gum emulsions have a considerably larger percentage of 1-μ diameter globules than do the acacia emulsions.

Figure 6 shows the log normal plots for the emulsions prepared with acacia. Whereas these emulsions appeared to follow a log normal distribution, those prepared with the new gum did not. This may be explained by the fact that in most cases more than 90% of the globules in the xantham gum emulsions had a diameter of less than 1 μ.

Interestingly, the emulsions with xantham gum increase in particle diameter and in the number of very large globules as the concentration is increased; the acacia emulsions, on the other hand, show a decrease in globule size with an increase in concentration. The explanation is probably involved in the rheological nature of the two emulsifying agents. The xantham gum may produce a strong film around the globules and as the concentration is increased, the well protected particles resist breakdown by the blender and homogenizer. At lower concentrations of the new gum, where the film may be more vulnerable, the larger particles may be broken down, producing a lower mean diameter. It was further noted that samples of the xantham gum emulsions, when viewed microscopically, show clusters of globules which remained in this aggregated state without coalescing. Some globule coalescence was observed with the acacia emulsions, as two globules in close proximity would eventually merge, sometimes within 24 hr. There did not appear to be as many clusters of particles in the

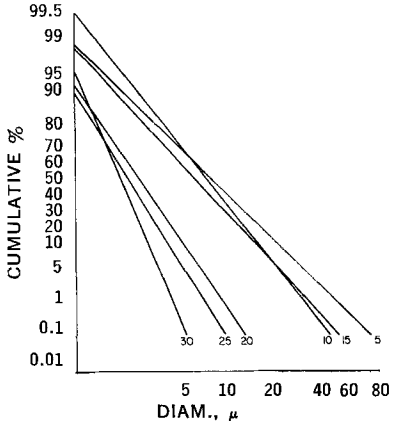

Fig. 6—Log probability plot of particle size distribution of emulsions containing various per cent concentrations of acacia.

acacia emulsions. Regardless of the emulsifier used, re-examinations of all emulsions showed no significant change in globule pattern or over-all mean diameters after 6 months on the shelf. These results were corroborated by the previously mentioned rheological stability of the emulsions after 6 months. If a general increase in particle size due to coalescence had occurred, the over-all viscosity of the emulsions would have decreased (12).

The above findings further contribute to the belief that thickness and strength of the emulsifier film adsorbed at the globule surface play a more important role in the stability of emulsions than does the initial particle size distribution.

SUMMARY

Mineral oil emulsions with a 4:6 oil to water ratio were prepared using various concentrations of a new polysaccharide.

The emulsions prepared with the new xantham gum demonstrated desirable rheological characteristics from a stability standpoint. The plastic nature of the xantham gum emulsions, as well as the corresponding yield values, were examined in detail. Their particle size distribution was broader in general than the emulsions prepared with acacia. Globule coalescence of the emulsions containing the xantham gum appeared to be minimal.

The emulsions containing more than 0.2% of the new gum did not exhibit creaming after 6 month's storage. The xantham gum did not leave a tacky film on the skin after drying. There appeared to be no evidence of bacterial decomposition in any of the emulsions, as evidenced by no significant change in pH or viscosity.

A much lower concentration of xantham gum than of acacia was required to produce stable emulsions. As a result of this investigation, it was felt that the new polysaccharide showed good potential as an emulsifier. For the mineral oil emulsions prepared in this study, the optimum concentration of the xantham gum appeared to be 0.4 to 0.5%.

Effect of Probenecid on Riboflavin Absorption and Excretion in Man

By WILLIAM J. JUSKO and GERHARD LEVY*

An oral dose of probenecid given 1 hr. prior to oral administration of riboflavin or riboflavin-5′-phosphate (FMN) to normal humans produced a marked decrease in the excretion rate of the vitamin during the early excretion phase but had no significant effect during the later (post-absorptive) phase. Oral administration of probenecid prior to intramuscular injection of FMN increased the apparent "half-life" of the initial rapid phase of riboflavin excretion. The urinary recovery of riboflavin following oral or intramuscular administration of the vitamin was usually somewhat decreased by probenecid. These results are consistent with our earlier suggestion that riboflavin is excreted in part by renal tubular secretion. It appears that probenecid also inhibits the specialized transport process responsible for the intestinal absorption of riboflavin in man. The complex kinetics of riboflavin distribution and elimination in man are discussed and additional evidence is presented in support of enterohepatic cycling of the vitamin.

THE AUTHORS have shown recently that riboflavin and riboflavin-5′-phosphate (FMN) are absorbed from the gastrointestinal tract of man by a site-specific and saturable specialized transport process rather than by passive diffusion (1, 2). An analysis of published data has led also to the conclusion that the renal excretion of riboflavin occurs not only by glomerular filtration but apparently also by renal tubular secretion (3).

The purpose of the study to be described here was to determine the effect of probenecid on the excretion of riboflavin. Probenecid inhibits a

* To whom requests for reprints should be directed.

number of specialized renal tubular transport processes (4, 5). An effect of this drug on the excretion of riboflavin would constitute additional support for the suggestion that riboflavin excretion involves active tubular secretion.

Some of the results of this study have bearing also on the absorption, distribution, and disposition of riboflavin and provide additional support for our earlier suggestion that riboflavin is subject to enterohepatic cycling (2).

EXPERIMENTAL

Seven healthy male volunteers, 24 to 38 years of age, served as test subjects. They received 1 Gm. of probenecid[1] (0.5 Gm. in one instance) in the morning after an overnight fast and then ate a standard breakfast. Exactly 1 hr. after probenecid administration, three subjects received 10 to 150 mg. riboflavin or FMN[2] dissolved in 200 ml. of water. Four of the subjects were given an intramuscular injection of approximately 30 mg. of riboflavin as FMN[3] 1 hr. after probenecid administration. The exact amount of FMN injected was determined by direct analysis of an equivalent volume of the parenteral solution measured in the same syringe used for the injection. The injected amounts averaged 28.4 mg. riboflavin equivalent. Similar experiments were carried out without preadministration of probenecid. The order of experiments was randomized with an interval of at least 2 weeks between them.

Urine was collected at frequent intervals for 24 to 48 hr. The standard breakfast, urine collections, and other details of the protocol were essentially the same as described in previous reports (1, 2).

Analyt cal Methods—Riboflavin and FMN in the urine were determined fluorimetrically by the method of Burch *et al.* (6) and by a modified U.S.P. assay procedure (7) using the Turner fluorometer, model 111, with primary filter 47-B and secondary filter 2A-12. The modifications of the two assays have been described in a previous publication (1).

At least two 24-hr. blank urine collections were carried out in each subject and all data were corrected for blank values. The data reported in the tables and figures are based on results obtained with the modified U.S.P. assay. Probenecid and probenecid metabolites (in urines collected after probenecid administration) were found to have no effect on the riboflavin assays.

RESULTS AND DISCUSSION

In the first part of this study, three subjects received various doses of riboflavin or FMN 1 hr. after oral administration of 1 Gm. probenecid. Typical examples of the effect of probenecid on the excretion of riboflavin after oral administration of FMN are shown in Figs. 1 and 2. Probenecid produced a pronounced decrease in the excretion rate of riboflavin during the early phase of riboflavin excretion, but had no detectable effect during the later (post-absorptive) phase of excretion. The effect of probenecid on the early excretion rates and on the total urinary recovery of riboflavin after oral administration of various doses of the vitamin is summarized in Table I for all experiments. In each instance, probenecid produced not only a marked decrease in the excretion rate of riboflavin during the first 2 to 3 hr. after administration of the vitamin, but caused also a statistically significant decrease in the total urinary recovery of the vitamin ($p < 0.05$, paired comparisons).

Bahal (5) found that 1 Gm. probenecid inhibited the elimination of sulfisomidine and procainamide for at least 8 hr. This is consistent with the reported plasma half-life of probenecid which, though

apparently dose-dependent, is around 6 hr. for a 1-Gm. dose (8). The fact that riboflavin excretion was inhibited only during the first 2 to 3 hr. after administration of probenecid suggested to the authors that the latter inhibits the absorption rather than the excretion of riboflavin. While there appears to be no previous report of an intestinal absorption inhibiting effect of probenecid in man, it is of interest that Binder and co-workers have found recently that probenecid inhibits the active intestinal transport of certain amino acids in the hamster (9).

It was desirable, in view of the results obtained from oral administration of riboflavin, to determine the effect of probenecid on the elimination of parenterally administered riboflavin. A typical example of the effect of probenecid on the excretion rate of riboflavin as a function of time after intramuscular administration of FMN is shown in Fig. 3. The time course of riboflavin excretion observed in these experiments is similar to that found in previous studies (1, 2) where it was noted that the excretion of the vitamin exhibits an initial rapid and a subsequent slow phase. In addition, secondary excretion rate maxima are evident in Fig. 3. These maxima were found in about one-half of the experiments and have been noted also and consistently after oral administration of large doses of the vitamin (2). These secondary maxima are thought to

TABLE II—EFFECT OF PROBENECID ON URINARY RECOVERY AND INITIAL APPARENT HALF-LIFE OF RIBOFLAVIN AFTER INTRAMUSCULAR INJECTION OF FMN[a]

[c] Figures in parentheses represent the number of "half-lives" during which the residuals yielded a straight line when plotted in semilogarithmic form.

be due to enterohepatic cycling of riboflavin. The possiblity that the secondary peaks observed in the previous study were due to delayed gastric emptying of a portion of the orally administered FMN is ruled out by the occurrence of secondary peaks in this study where the vitamin was administered parenterally. The secondary peaks are not due to absorption of additional riboflavin from dietary sources since the urinary excretion of riboflavin by subjects deriving the vitamin only from dietary sources is very much lower than that observed in the present study. It is of interest however that excretion rate maxima are observed after meals even in subjects receiving only dietary riboflavin (Fig. 4). The excretion rate maxima observed in the latter instance are at least one order of magnitude lower than those shown in Fig. 3. Similar pronounced secondary maxima have been observed recently in the serum levels of dipyridamole and have been ascribed also to enterohepatic cycling (10). The occurrence of such enterohepatic cycling precludes a rigorous pharmacokinetic analysis of riboflavin absorption, distribution, and elimination.

An effect of probenecid on riboflavin excretion after FMN injection becomes evident upon resolving a semilogarithmic plot of the amount of riboflavin unexcreted as a function of time after drug administration into two components by backward projection of the apparently linear terminal portion of the excretion curve. A good example of this is shown in Fig. 5. A semilogarithmic plot of the residuals was linear in all instances up to the time of occurrence of a secondary excretion rate maximum. As a matter of convenience, the rate of decline of the initial linear portion of the semilogarithmic plot of the residuals is described in terms of an "initial apparent half-life." It must be emphasized, however, that this designation is without rigorous pharmacokinetic basis since the actual kinetic model describing the distribution and elimination of riboflavin is considerably more complex than one involving only two parallel unidirectional exponential processes.

The initial apparent "half-lives" and urinary recoveries of riboflavin obtained with and without pre-administration of probenecid are listed in Table II. In all subjects, the initial apparent "half-life" of riboflavin was increased by probenecid but this difference was slightly short of statistical significance ($p > 0.05$; < 0.1). Also, in three of the four subjects, the urinary recovery of the vitamin was decreased by probenecid.

A comparison of the results obtained by the modified U.S.P. and Burch methods, which gives an indication of the relative concentrations of riboflavin and FMN in the urine (2), showed that probenecid had no noticeable effect on the metabolic fate of the vitamin. As noted in the previous study, the urine contained mainly free riboflavin regardless of the form or route of administration.

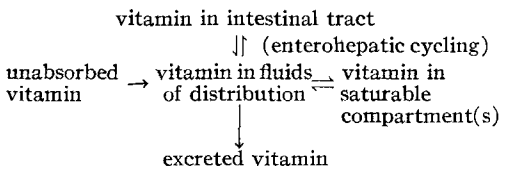
The results of the parenteral study suggest that probenecid does have an inhibitory effect on the renal excretion of riboflavin, presumably by inhibiting an active tubular secretory process (3). While the duration of this effect appears to be relatively short, it is believed unlikely to be due to a decreased rate of absorption of FMN from the site of injection since no such effect of probenecid is known to the authors. On the other hand, Rennick has found an active renal tubular secretory process for riboflavin in the chicken and noted that this process is inhibited by probenecid (11). She suggested that the vitamin shares the transport system for organic bases since the renal tubular secretion of riboflavin was inhibited also by tolazoline. In addition, Markkanen has found that probenecid decreases the basal riboflavin excretion in man and rabbits whose riboflavin intake was limited to that derived from the normal diet (12).

The incomplete recovery of riboflavin observed in most experiments in the present and in previous studies (1, 2), and the decreased urinary recovery of parenterally administered vitamin upon pre-administration of probenecid suggest that the elimination of riboflavin involves at least two parallel pathways.[4] One of these is the urinary excretion of riboflavin; the other process may involve biotransformation, extra-renal excretion, and/or a reversible association of the vitamin with proteins resulting in the formation of certain flavoproteins. The occasional complete urinary recovery of parenterally administered riboflavin (*Reference 13* and subject *M* in the present study) implies that biotransformation and extra-renal excretion may be either quantitatively unimportant or nonexistent. This is consistent with recent evidence that riboflavin is not degraded in rat tissues (14). The third suggested route, namely the reversible association[5] of riboflavin with certain proteins, must be treated kinetically as a bi-directional process involving a compartment of limited capacity. This concept is supported by the fact that nutritionally deficient subjects retain a large fraction of a small test dose of riboflavin (15) and that subjects in

[4] The various phosphorylation-dephosphorylation cycles to which riboflavin is subject in the body have been discussed in a previous publication (2) and are neglected in the present discussion.

[5] This refers to the formation of covalent bonds between riboflavin and proteins in extravascular tissues rather than complex formation with plasma proteins.

negative nitrogen balance (*i.e.*, during excessive catabolism of tissue proteins) show an increased basal excretion of the vitamin (16). These considerations lead to the kinetic model for riboflavin shown in Scheme I.



Scheme I

Even this model, though of considerable complexity, neglects certain additional processes such as phosphorylation-dephosphorylation cycles, formation of FAD, and synthesis of the vitamin by intestinal microorganisms. The time course of riboflavin elimination, as found in this and previous studies in this laboratory (1, 2), is qualitatively similar to that of bromosulfophthalein and rose bengal for which similar reversible multiple compartment models of limited capacity have been suggested (17, 18).

It is reasonable to assume that the saturable compartment is near capacity in subjects who are in exceptionally good nutritional status with respect to riboflavin. Subject *M* of the present study professed to have been taking 5 mg. of riboflavin a day in the form of multiple vitamin tablets four or five times weekly. He discontinued this regimen about 1 week prior to the first parenteral injection of riboflavin. At this time his basal excretion of riboflavin (1.4 mg./day) was indicative of an exceptionally good nutritional status with respect to the vitamin since the usual basal excretion rate is about 1.0 mg./day. (His basal excretion decreased to this level about 3 weeks after the first parenteral injection of riboflavin. During this time he did not use the dietary supplement.) This subject excreted 102% of the first intramuscular dose of FMN which was given without probenecid. It is conceded that this represents very limited evidence but it is noteworthy that none of the other subjects used vitamin preparations prior to the study and that the urinary recovery of riboflavin in these subjects was always incomplete.

The results of this study suggest that probenecid inhibits the urinary excretion of riboflavin. This is consistent with the previous conclusion that the renal excretion of riboflavin apparently involves active tubular secretion (3). It appears also that probenecid inhibits the active intestinal transport of riboflavin although the evidence is by no means unequivocal. This latter point must be established by appropriate animal experiments which await the development of suitable experimental methods since classical techniques used in active transport studies do not appear to be satisfactory for riboflavin (unpublished data). Efforts in this direction are presently being pursued in this laboratory.

ADDENDUM

Effect of Probenecid on Plasma Protein Binding of Riboflavin—Ultrafiltration studies, using human plasma containing 0.1 mg.% riboflavin or FMN alone and with 10 mg.% probenecid, respectively, showed that probenecid has no measurable effect on the plasma protein binding of the vitamin. Details of the binding of riboflavin and FMN by plasma proteins will be reported in a future communication. The concentrations of vitamin and probenecid used in this study reflect the maximum concentration in the plasma obtained upon administration of 30 mg. FMN intramuscularly and 1 Gm. probenecid orally (3, 8, 13). The lack of effect of probenecid on the plasma protein binding of riboflavin suggests that probenecid does not affect the distribution of the vitamin in the body.

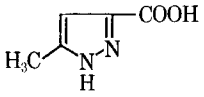
Absorption, Metabolism, and Excretion of 5-Methylpyrazole-3-carboxylic Acid in the Rat, Dog, and Human

By DAVID L. SMITH, JOHN G. WAGNER, and GEORGE C. GERRITSEN

5-Methylpyrazole-3-carboxylic acid is completely absorbed and rapidly excreted in the rat, dog, and human. After 1- or 9-mg./Kg. doses to the rat, the urinary excretion half-life was 1.0 hr., with 57 per cent of the dose excreted unchanged and the remainder as an acidic conjugate. Pretreatment of rats with high doses of the drug did not significantly alter the absorption, metabolism, or excretion of the drug. After oral and intravenous administration of about 7 mg./Kg. to the dog, all of the drug was excreted unchanged with a half-life of 1.8 hr. (average of blood and urine data). After oral and intravenous doses of 37.5 mg. to six human volunteers, the average half-life for the excretion of radioactivity was 1.9 hr. At this dose the human converts an average of 31 per cent of the drug to the same metabolite produced by the rat. In the human, the following averages were not statistically different after oral and intravenous administration: total urinary excretion, urinary excretion half-life, total fecal excretion, half-life of disappearance from plasma, apparent volume of distribution, area under the plasma curve, and percentage of drug metabolized. The human data have been summarized by general equations, which were derived for a simple kinetic model. The average first-order rate constants ($hr.^{-1}$) for the six humans were as follows (average of oral and intravenous data): over-all loss, 0.32; excretion of drug, 0.22; formation of metabolite, 0.10; excretion of metabolite, 1.5.

IN PREVIOUS studies (1) 5-methylpyrazole-3-carboxylic acid (I) was isolated as a metabolite



I

from the urine of rats treated with 3,5-dimethylpyrazole and was shown to be 116 times more potent than tolbutamide as a hypoglycemic agent in the intact, fasted, glucose-primed rat (2).

Studies in the rat with ^{14}C-labeled 3,5-dimethylpyrazole (3) showed the oral dose to be completely absorbed and rapidly excreted as four metabolites: 5 - methylpyrazole - 3 - carboxylic acid (13%), conjugated 5-methylpyrazole-3-carboxylic acid (14%), conjugated 4-hydroxy-3,5-dimethylpyrazole (71%), and an unidentified metabolite (1%).

All of the hypoglycemic activity of 3,5-dimethylpyrazole in the rat appeared to be due to I, its active metabolite. Unlike 3,5-dimethylpyrazole, I stimulates glucose utilization by adipose tissue *in vitro* and depresses blood sugar of eviscerated rats (2). It was not known whether the human would metabolize 3,5-dimethylpyrazole to the active carboxy metabolite and, if so, how much would be produced. It was therefore decided to undertake the development of the active metabolite as an antidiabetic agent. As part of this research effort, ^{14}C-labeled I (also referred to as the drug) was prepared, and its absorption, metabolism, and excretion compared in the rat, dog, and human.

EXPERIMENTAL

Materials—^{14}C-labeled I[1] was prepared from ethyl acetopyruvate-4-^{14}C and hydrazine (4). Its chemical and radiochemical purity was established by melting point, elemental analysis, infrared spectroscopy, and paper and thin-layer chromatography.

Rat Studies—Charles River CD male rats, weighing 140–200 Gm., were used. They were fasted overnight prior to the experiment (water was allowed *ad libitum*), and were housed individually in stainless steel metabolism cages. Rats *1–3* were dosed orally with 1.315 mg. (9 mg./Kg.) of labeled I (specific activity: 1.33 μc./mg.), dissolved in 0.5 ml. of 0.25% sterile methylcellulose (MC) vehicle. Sequential urine samples were collected from each rat at 2, 4, 6, 8, 15, 24, 48, and 72 hr. Since biological studies suggested that tachyphylaxis to the drug develops in rats (unpublished results) and since a change in the metabolism of the drug could explain this phenomenon, rats *10–15* were treated orally with 25 mg./Kg. of unlabeled I dissolved in 0.5 ml. of 0.25% MC vehicle twice daily for 3 days and 3 times on the fourth day. The rats were fasted on the fourth night and dosed orally with 0.184 mg. (1.0 mg./Kg.) of labeled drug (specific activity: 0.57 μc./mg.)

Received February 6, 1967, from the Control Analytical Research and Development Department, The Upjohn Co., Kalamazoo, MI 49001

Accepted for publication June 13, 1967.

The authors thank the following individuals: R. C. Thomas for the synthesis of the ^{14}C-labeled drug, R. L. Johnston for assistance with the dog studies, A. L. Pulliam for analytical assistance, J. I. Northam, R. H. Baker, Jr., and C. M. Metzler for statistical and interpretive analysis of the data, and A. K. Herd and L. H. MacDonald for preparation of the dosage forms for human use.

[1] This compound was prepared by Dr. R. C. Thomas, The Upjohn Co.

in 4.6 ml. of physiological saline on the morning of the fifth day. The controls (rats *4–9*) were treated exactly like rats *10–15* except that they received only vehicle on days 1 through 4. Rats *4–15* were hydrated by oral administration of 25 ml./Kg. of physiological saline on the afternoon of the fourth day. Sequential urine samples were collected from rats *4–15* at 0.5, 1, 2, 3, 4, 6, 7, 8, and 24 hr. after oral administration of the ^{14}C-labeled drug.

Dog Studies—The ^{14}C-labeled I was administered both orally and intravenously in crossover fashion to two fasted beagles (one male, one female). One week was allowed between the oral and intravenous doses. In each case the dose was approximately 7.5 mg. (10 μc.). The oral dose was given as a powder in a soft gelatin capsule and the intravenous dose was dissolved in 5 ml. of water. Several blood and sequential urine samples were collected for 72 hr. The urine was collected by catheter.

Human Studies—Oral and intravenous doses of ^{14}C-labeled I were administered to six adult male volunteers in crossover fashion. Three of the subjects received the drug intravenously and the other three received it orally on the first week and then, after a 2-week rest period, the drug was administered again with the routes of administration crossed over. The ages and weights of the volunteers are given in Table V. The intravenous dose was 10 ml. of a 3.75 mg./ml. sterile aqueous solution of the labeled drug (specific activity: 1.33 μc./mg.). The oral dose was 37.5 mg. of the drug (1.33 μc./mg.) mixed with lactose in a mortar (average particle size about 70 μ; all particles less than 107 μ), and packed in capsules. The volunteers were fasted overnight and for 6 hr. after drug administration. To facilitate urine collection, each subject received 8 fl. oz. of water 1 hr. prior to drug administration and at 0, 1.5, 4, 6.5, and 10 hr. Plasma and sequential urine samples were collected for 3 days as indicated in Tables II and III. Fecal samples were collected at 24, 48, and 72 hr.

General Counting Techniques—The samples were counted in duplicate using Packard Tri-Carb liquid scintillation spectrometers, models 314EX-2A and 314X; corrections for counting efficiency were made using ^{14}C-toluene as the internal standard. Urine was counted directly by dissolving 0.1 to 0.5 ml. in 15 ml. of diotol counting solution, which was prepared by the procedure of Herberg (5). Plasma and homogenized fecal samples (0.5 to 0.9 Gm.) were placed in sample sacs made from dialysis tubing, and dried overnight. The dried samples were burned by the Schöniger technique, and the evolved $^{14}CO_2$ trapped in a 1 *M* solution of 2-phenylethylamine in methanol. For counting, an aliquot of the latter was mixed with an equal volume of a solution consisting of 4.6 Gm. PPO and 8 mg. POPOP per liter of toluene.

Paper Chromatography—The following paper chromatographic systems were employed, using Whatman No. 2 paper: BAW system, *n*-butanol–acetic acid–water (2:1:1; R_f values: I, 0.76; metabolite, 0.72); BPW system, *n*-butanol–piperidine–water (81:2:17; R_f values: I, 0.37; metabolite, 0.32). The radioactive zones were measured with a 4π paper-strip scanner, Vanguard model 880. The percentage of the total radioactivity represented by each peak was determined by cutting out the peaks and weighing them.

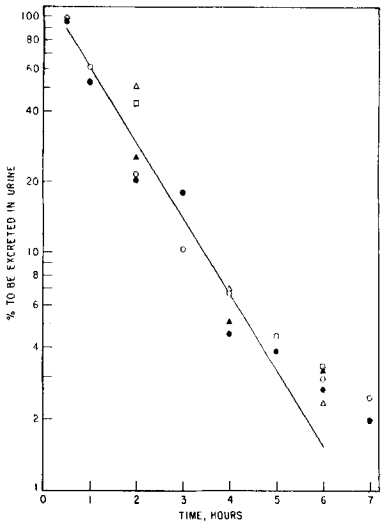


Fig. 1—Rate of urinary excretion of equivalents of 5-methylpyrazole-3-carboxylic acid-^{14}C in the rat. Key: △, rat 1; ▲, rat 2; □, rat 3; ○, rats 4–9; ●, rats 10–15. Average $t_{1/2}$ = 1.0 hr.

RESULTS

Rat Studies—After oral administration of the ^{14}C-labeled drug to three rats at a dose of 9 mg./Kg., 88.4% of the radioactivity was found in the urine and 0.2% in the feces. By paper chromatography, an average of 57% of the urinary radioactivity was unchanged drug while the remainder was a single metabolite. The excretion of radioactivity in the urine by the rat obeyed first-order kinetics with a half-life of about 1.0 hr. (Fig. 1).

The six drug-pretreated rats excreted an average of 98.8% of the dose in the urine with 54.0% unchanged. The six nonpretreated rats given the 1-mg./Kg. dose excreted an average of 100.3% of the dose in the urine with 59.7% as unchanged drug. For these two groups there was no significant difference in average percentage of radio-

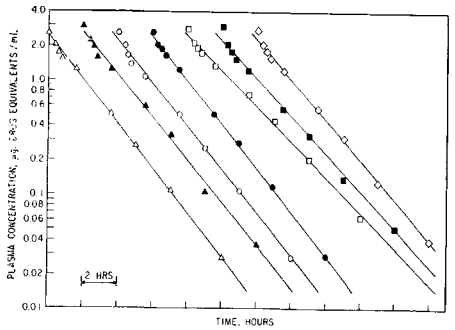

Fig. 3—Plasma levels of equivalents of 5-methylpyrazole-3-carboxylic acid-^{14}C in humans after a 37.5-mg. intravenous dose (log scale). Each curve is displaced 2 hr. from the one preceding it, and the last point on each curve is at 12.0 hr. Key: △, subject No. 1; ▲, No. 2; ○, No. 3; ●, No. 4; □, No. 5; ■, No. 6; ◇, average of No. 1–6.

activity represented by unchanged drug in each of the urine collection intervals. For example, in the first 30 min. 63.7 ± 3.0% (±S.D.) of the radioactivity excreted by the nonpretreated rats was unchanged drug, whereas 61.8 ± 1.5% of the total excreted during this interval by the pretreated rats was unchanged. Therefore, pretreatment with drug for 4 days did not alter the excretion pattern of labeled drug given on the fifth day. Both the rate of excretion (Fig. 1) and the total amount of labeled drug excreted were essentially identical in both the pretreated and nonpretreated groups.

Dog Studies—*Intravenous Dose*—After intravenous administration of approximately 7 mg./Kg. to two dogs, 104.6% of the dose was recovered in the urine and 0.3% in the feces. By paper chromatography, all of the urinary radioactivity was unchanged drug. The whole blood concentrations are plotted in Fig. 2. In the case of one dog, both the whole blood and plasma levels of radioactivity were measured. The plasma levels, which paralleled the blood levels, averaged 28% higher. The elimination of drug from the blood of both dogs obeyed first-order kinetics with half-lives of 1.40 and 2.15 hr. for the female and male dog, respectively (Fig. 2, A and C). No radioactivity was detected in the blood of either dog at 24 hr. The urinary excretion of radioactivity into the urine also obeyed first-order kinetics with half-lives of 1.65 and 2.15 hr. for the female and male dog, respectively (Fig. 2, B and D).

Oral Dose—After oral administration of approximately 7 mg./Kg. to two dogs, an average of 100.2% of the dose was recovered in the urine, and 0.1% in the feces. By paper chromatography all the urinary radioactivity was unchanged drug.

In both dogs the peak levels of radioactivity in the blood were attained within 1 hr. after the oral dose (Fig. 2). The elimination of radioactivity from the blood obeyed first-order kinetics with half-lives of 1.25 and 1.75 hr. for the female and male dog, respectively (Fig. 2, A and C). After the oral dose, urinary excretion of the radioactivity obeyed first-order kinetics with half-lives of 1.45 and 1.95 hr. in the female and male dog, respectively (Fig. 2, B and D).

The half-lives calculated from the blood and urine levels after oral and intravenous doses in the dog are summarized in Table I.

Human Studies—*Intravenous Dose*—The average concentrations of drug equivalents in plasma and their standard errors at several time intervals after the 37.5-mg. intravenous dose are summarized in Table II, and the data for the individual subjects are plotted in Fig. 3. The log plasma concentration time curves show two segments, the first representing rapid equilibration with body fluids (average half-life ~7 min.); the second segment is rate-determining, having an average half-

TABLE III—CUMULATIVE URINARY EXCRETION OF DRUG EQUIVALENTS AFTER ADMINISTRATION OF A 37.5-mg. DOSE OF 5-METHYLPYRAZOLE-3-CARBOXYLIC ACID-^{14}C TO HUMANS

Time, hr.	mg. ± S.E.M. i.v. Route	Oral Route

life (±S.E.M.) of 1.66 ± 0.05 hr. in the six subjects.

The urinary excretion of drug equivalents following the intravenous dose is presented in Table III. The urine data for the individual subjects are plotted in Fig. 4. The average half-life (±S.E.M.) for the excretion of drug equivalents in urine after the intravenous dose was 1.91 ± 0.15 hr.

An average (±S.E.M.) of 71.4 ± 2.8% of the urinary radioactivity was found to be unchanged drug (Table IV); the remainder (28.6 ± 2.8) was present as a metabolite, which corresponded by

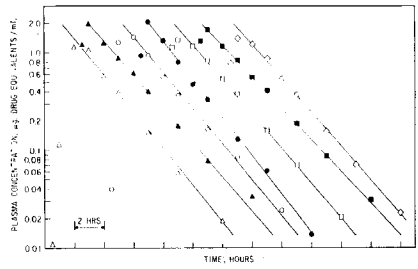

Fig. 5—Plasma levels of equivalents of 5-methylpyrazole-3-carboxylic acid-^{14}C in humans after a 37.5-mg. oral dose (log scale). The displacement of the curves from the origin and the subject identification are the same as in Fig. 3.

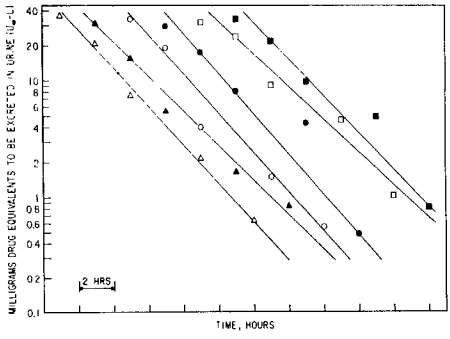

Fig. 6—Urinary excretion of equivalents of 5-methylpyrazole-3-carboxylic acid-^{14}C by humans after a 37.5-mg. oral dose. The displacement of the curves from the origin is the same as Fig. 4. Subject identification is the same as that in Fig. 3.

paper chromatography to the same metabolite excreted by the rat.

An average cumulative total (±S.E.M.) of 0.003 ± 0.002, 0.009 ± 0.002, and 0.009 ± 0.002 equivalents of the intravenous 37.5-mg. dose was found in the feces at 24, 48, and 72 hr., respectively.

Oral Dose—The average concentrations of drug equivalents and their standard errors in plasma at several time intervals after the 37.5-mg. oral dose are summarized in Table II and the data for the individual subjects are plotted in Fig. 5. The average plasma half-life (±S.E.M.) for the six subjects was 1.71 ± 0.05 hr. The average plasma levels beyond about 2 hr. were actually higher after the oral dose than after the intravenous dose.

The urinary excretion of drug equivalents following the oral dose is presented in Table III, and the data for the individual subjects are plotted in Fig. 6. The average (±S.E.M.) half-life for the excretion of drug equivalents into the urine after the oral dose was 2.22 ± 0.20 hr.

Following the oral dose, an average (±S.E.M.) of 66.3 ± 3.2% of the radioactivity recovered in the urine was unchanged drug, and the remainder was excreted as the metabolite (Table IV).

An average (±S.E.M.) cumulative total of 0.016 ± 0.014, 0.052 ± 0.038, and 0.058 ± 0.038 equivalents of the oral 37.5-mg. dose was found in the feces at 24, 48, and 72 hr., respectively.

[a] Using these fitting constants, the urinary excretion data for each subject may be fitted to the equation: $U = U_\infty[1 - e^{-K(t-t_0)}]$, where U = the milligrams of drug equivalents excreted at time, t, in hours. [b] $t_{1/2}$ (hr.) = 0.693/K.

DISCUSSION

Absorption—The drug is very efficiently absorbed in the rat, dog, and human as shown by the essentially quantitative recovery of the dose in the urine after oral administration. In the dog the drug was absorbed so rapidly that the blood levels after oral administration were essentially identical to those after intravenous administration (Fig. 2). The superimposition of the oral and intravenous blood level curves does not mean, however, that oral absorption was complete in the 20 sec. that was required for intravenous administration, but rather that the oral absorption rate and excretion rate counterbalance each other, *i.e.*, since the intravenous dose gets in faster, a larger fraction is being excreted sooner.

The drug was absorbed very rapidly in the human. The absorption rate could not be estimated even though the first blood sample was taken 0.5 hr. post-drug administration. Nearly quantitative absorption of the oral dose in the human is shown by the fact that the total urinary excretion (Table III) and the areas under the plasma curves (Table V) were not significantly different after oral and intravenous administration. Based on the drug equivalents excreted in the urine (Table VI), the average per cent absorbed was 92.7% of the oral dose. This is a minimum estimate since this method of calculation gives only 89.0% absorbed estimated from the intravenous data.[2]

[2] The fact that the urinary excretion is lower after the intravenous dose than after the oral dose may indicate nonquantitative intravenous administration.

The per cent absorbed is 88.1 and 105.7% calculated from oral/intravenous ratios of the areas under the plasma curves and urinary output, respectively. Since the 72-hr. fecal excretion averaged only about 0.2% of the oral dose, the actual absorption may be as high as 99.8% of the dose.

Distribution—The apparent volumes of distribution (V_d) of the drug in the male and female dogs, after both routes of administration, are summarized in Table I. The apparent volumes are based on the plasma concentrations. Expressed as per cent of body weight, the V_d was very similar in the two dogs and was essentially identical after oral and intravenous administration. The average V_d (40.5% of body weight) is about twice the volume of extracellular water, but is less than total body water.

In the human, the early portion of the plasma curves after the intravenous dose reveals a rapid disappearance phase, having an average half-life (estimated from residuals) of about 7 min. in the six subjects, which undoubtedly reflects distribution and equilibration of the drug in body fluids. The apparent volumes of distribution of the drug in the six subjects, after both routes of administration, are summarized in Table V. The apparent volumes of distribution are independent of route of administration. The average V_d in the six subjects was found to be 15.2 L. (21.5% of their average body weight). This volume corresponds (perhaps fortuitously) to extracellular fluid volume as determined by insulin and sucrose (6).

Metabolism—The dog excreted all of the drug

TABLE VII—CALCULATED CONSTANTS[a] FROM URINARY EXCRETION DATA: INFINITE URINARY EXCRETION (U_∞), RATE CONSTANTS (K), AND LAG TIMES (t_0) FOR THE DRUG AND ITS METABOLITES

		Drug			Metabolite

[a] Using these fitting constants, the urinary excretion of drug and metabolite for each subject may be fitted to the equation: $U = U_\infty[1 - e^{-K(t-t_0)}]$, where U = mg. of drug equivalents excreted at time t. [b] Expressed as drug equivalents.

unchanged; two paper chromatographic systems revealed only a single zone corresponding to intact drug. The 15 rats excreted an average of 57% of the drug unchanged and the remainder as an acidic metabolite. The percentage of drug metabolized was essentially identical at the 1-mg./Kg. and 9-mg./Kg. dose levels. This metabolite can be converted to the free drug with acid but not with sulfatase or glucuronidase and is therefore believed to be a glycine conjugate. The R_f values of this metabolite correspond to one of the metabolites of 3,5-dimethylpyrazole in two paper chromatographic systems (2).

In the human, an average (±S.E.M.) of 71.4 ± 2.8% of the intravenous dose and 66.3 ± 3.2% of the oral dose was excreted as unchanged drug. The remainder of the dose in the human was excreted as a metabolite, which corresponded by paper chromatography to the one excreted by the rat. The distribution of the drug and its metabolite in each sequential urine sample from the rat and human was also determined, in order to calculate the individual rates of excretion of the drug and its metabolite (*vide infra*).

Effect of Pretreatment with Drug on Its Absorption and Metabolism in the Rat—The data strongly suggest that tachyphylaxis to the drug in rats is not due to altered metabolism. Absorption from the gastrointestinal tract was also not altered with repeated administration. Paper chromatography indicated that the metabolite was identical in both the pretreated and nonpretreated groups and the amounts of metabolite excreted were essentially the same in the two groups. Since no alteration in metabolism occurs, tachyphylaxis cannot be explained on the basis of drug metabolism.

Excretion—The average half-life for the excretion of radioactivity by the rats was 1.0 hr. Excretion by the dog was slightly slower; the half-lives obtained from blood level and urine data were essentially identical, averaging about 1.8 hr. in the two dogs.

The over-all (plasma and urine) half-life for the excretion of drug equivalents in the six subjects was essentially identical to that found in the dog, averaging 1.9 ± 0.1 hr. The plasma levels and rates of elimination of drug equivalents from the plasma were remarkably uniform in the humans. The half-lives for the appearance of radioactivity in the urine of the humans were obtained by fitting the data by the method of least squares to the first-order equation (Eq. 1):

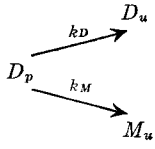
$$U = U_\infty[1 - e^{-K(t - t_0)}] \qquad \text{(Eq. 1)}$$

where U is the milligrams of drug equivalents excreted to time t, U_∞ is the amount excreted at infinite time, K is the observed rate constant for excretion ($t_{1/2} = 0.693/K$), and t_0 is a "lag time" which corrects for the delays caused by absorption, metabolism, and distribution.

Kinetics of Metabolism and Excretion in the Human—Since the over-all rate constant for the loss of radioactivity in the human was known to be a composite of the rates of excretion of the unchanged drug and the formation of its metabolite, it seemed desirable to assay for each of these compounds in all of the sequential urine collections. Hopefully, the individual rate constants could then be estimated. The percentages of radioactivity as metabolite in each of the sequential human urine samples, determined by quantitative paper chromatography, are presented in Table IV. After the first hour, the average ratio of drug to metabolite remained constant within the error of the assay. From the distribution of radioactivity in each sample, the cumulative excretion and the 24-hr. distribution[3] of the drug and its metabolite were calculated. The cumulative excretion data and Eq. 1 were used to estimate the over-all rate constant for the appearance in the urine of the drug and its metabolite. The constants of Eq. 1 which were obtained by this procedure are summarized in Table VII.

[3] The 24-hr. distribution obtained by this procedure was in excellent agreement with that found by paper chromatography of a pooled sample consisting of one-tenth of every sequential urine sample.

Model I—After both oral and intravenous administration, the average rate constant for the appearance of drug in the urine is not significantly different from the corresponding average constant for the appearance of metabolite (Fig. 7), *i.e.*, the ratio of drug to metabolite remains relatively constant with time. This suggests the following simple model:



where D_p is the amount of drug in the body and D_u and M_u are the amounts of drug and metabolite excreted in the urine. This model describes the data only in the mathematical sense; it ignores at least one of the rate constants involved in the transfer of drug in the plasma to metabolite in the urine. The over-all rate constant (K) for the appearance of drug or metabolite in the urine is equal to the sum of k_D and k_M. This model requires that the experimentally determined ratio of D_u to M_u be constant with time and equal to the ratio of k_D to k_M. Also, according to this model, the over-all rate constant (K) for the appearance of drug in the urine must be equal to the rate constant for the appearance of metabolite in the urine as well as to the rate constant for the disappearance of drug from the plasma. The model is described by the following equations (7):

$$D_p = D_0 e^{-Kt} \quad \text{(Eq. 2)}$$

$$D_u = (k_D D_0/K)(1 - e^{-Kt}) \quad \text{(Eq. 3)}$$

$$M_u = (k_M D_0/K)(1 - e^{-Kt}) \quad \text{(Eq. 4)}$$

$$K = k_D + k_M \quad \text{(Eq. 5)}$$

where D_0 is a constant equal to the amount of drug absorbed, and t is the time. The elimination of drug from the plasma data obeys Eq. 2 and the excretion of drug into the urine after the intravenous dose obeys Eq. 3, but the appearance of both drug and metabolite after the oral dose are described best by Eqs. 6 and 7, which include the correction term, t_0:

$$D_u = (k_D D_0/K)[1 - e^{-K(t - t_0)}] \quad \text{(Eq. 6)}$$

$$M_u = (k_M D_0/K)[1 - e^{-K(t - t_0)}] \quad \text{(Eq. 7)}$$

Fitting the average human urine data to Eqs.

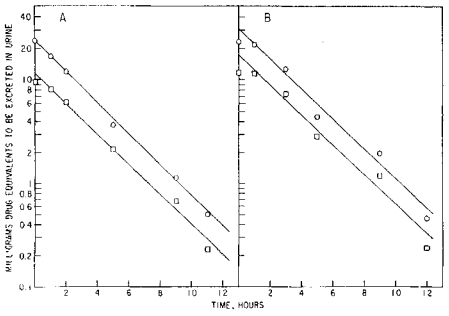


Fig. 7—Urinary excretion of 5-methylpyrazole-3-carboxylic acid-^{14}C and its metabolite (log scale) as determined by paper chromatography. Average of 6 subjects. Key: A, *37.5-mg. i.v. dose;* B, *37.5-mg. oral dose;* O, *drug;* □, *metabolite.*

[a] From Eqs. 8–11.

TABLE IX—ESTIMATES OF PARAMETERS OF MODEL *II* FOR METABOLISM AND EXCRETION OF 5-METHYLPYRAZOLE-3-CARBOXYLIC ACID AFTER INTRAVENOUS ADMINISTRATION

Parameter	Subject 1	2	3	4	5	6	Av.
k_m (hr.$^{-1}$)	0.111	0.108	0.139	0.130	0.051	0.081	0.103
k'_m (hr.$^{-1}$)	1.14	1.76	1.41	1.31	0.618	2.21	1.32
k_D (hr.$^{-1}$)	0.377	0.325	0.251	0.222	0.084	0.332	0.256
V_d (L.)	13.4	13.5	16.6	15.5	38.9	14.3	15.2

6 and 7 (the oral and intravenous doses were treated separately), gave the following constants for excretion of the drug and metabolite:

	Intravenous Dose	Oral Dose
D_0 (mg.)	32.95	34.76
K (hr.$^{-1}$)	0.339	0.305
k_D (hr.$^{-1}$)	0.242	0.202
k_M (hr.$^{-1}$)	0.097	0.103

The cumulative excretion of drug and metabolite after the 37.5-mg. intravenous and oral doses is described, therefore, by Eqs. 8–11.

i.v. dose

$$D_u = 23.52\,[1 - e^{-0.34(t\,-\,0.06)}] \quad \text{for } t \geq 0.06 \text{ hr.} \quad \text{(Eq. 8)}$$

$$M_u = 9.49\,[1 - e^{-0.34(t-0.56)}] \quad \text{for } t \geq 0.56 \text{ hr.} \quad \text{(Eq. 9)}$$

oral dose

$$D_u = 23.02\,[1 - e^{-0.31(t-0.83)}] \quad \text{for } t \geq 0.83 \text{ hr.} \quad \text{(Eq. 10)}$$

$$M_u = 11.78\,[1 - e^{-0.31(t-0.98)}] \quad \text{for } t \geq 0.98 \text{ hr.} \quad \text{(Eq. 11)}$$

The experimental data are compared with the values calculated from Eqs. 8–11 in Table VIII. The deviation of the average cumulative urinary excretion of the six humans from that calculated from the above equations averaged less than 1.3% of the dose.

Model II—Although model *I* yields equations which give a satisfactory mathematical description of the data, it has an obvious defect. The appearance of the metabolite in the urine must be effected by *at least* two rate processes, first the formation of the metabolite with a rate constant k_m, and second, its excretion with a rate constant k'_m, *viz.*:

$$\begin{array}{l} \overset{k_D}{\longrightarrow} D_u \\ D_p \xrightarrow{k_m} M_p \xrightarrow{k'_m} M_u \end{array}$$

Since first-order kinetics are nearly obeyed (Figs. 3–6), one of these processes must be much faster than the other.

Since rapid metabolism followed by slow excretion of the metabolite would not be consistent with the observed ratio of drug to metabolite, the rate-determining step is undoubtedly the formation of the metabolite (k_m). Therefore, the rate constant k_M in model *I* must be essentially equal to k_m. Since the rate constant for excretion of metabolite is larger than the rate constant for formation, the plasma levels of metabolite are undoubtedly quite low compared to plasma levels of drug, *i.e.*, the plasma half-life obtained by measurement of total radioactivity (Table III) reflects primarily intact drug.

The magnitude of k'_m, the rate constant for the excretion of the metabolite, was determined by both analog and digital computer techniques. Using the above constants for D_0, K, and k_D, and setting k_m equal to k_M, the analog computer[4] gave an excellent fit for both the intravenous and oral data when k'_m was set at approximately 1.5 hr.$^{-1}$, *i.e.*, when the half-life for the excretion of the metabolite is about 28 min. An analog computer plot of the intravenous data is presented in Fig. 8.

The digital computer was also used as a tool for the fitting of the data to model *II*. A digital computer program,[5] which simultaneously fits both the urine and plasma data, was used to estimate the rate constants. Equations 3, 12, and 13, which describe model *II* for the intravenous dose, were incorporated into the computer program.

$$C_D + C_M = D_0[(K - k'_m)V_d]^{-1} [(k_D - k'_m)e^{-Kt} + k_m e^{-k'_m t}] \quad \text{(Eq. 12)}$$

$$M_u = k_m D_0 K^{-1}[1 + k'_m(K - k'_m)^{-1} e^{-Kt} - K(K - k'_m)^{-1} e^{-k'_m t}] \quad \text{(Eq. 13)}$$

where C_D and C_M represent the concentrations of drug and metabolite in the plasma, and the other terms have already been defined. These equations satisfactorily describe not only the average data, but also the data of the individual subjects. The parameters obtained are presented in Table IX. The average values do not differ significantly from those obtained by the use of the analog computer. For the best fit of the oral data, at least one more rate constant (representing gastrointestinal absorption) would have to be introduced into model *II*.

Determination of Terpin Hydrate by Gas Chromatography

By LEON KURLANSIK, CAROLYN DAMON, and EDWARD F. SALIM

Two gas chromatographic procedures have been developed for the determination of terpin hydrate using dodecyl alcohol as an internal standard. Methods involving direct chromatographic comparison of the two materials as well as formation and measurement of the corresponding trimethylsilyl (TMS) ethers have been tested. Agreement between the methods is ±1 per cent.

TERPIN HYDRATE, *cis-p*-menthane-1,8-diol hydrate, has been the subject of several analytical investigations including acetylation (1–3) and aquametry (4). The latter procedure is an example of the application of Karl Fischer reagent to quantitative determination of organic functional groups.

Gas-liquid chromatography has been applied to the separation of terpin hydrate from oils and perfumes (5, 6). Volatility of the compound at relatively low temperatures is conducive to gas chromatographic analysis. Two quantitative methods for the determination of terpin hydrate are presented which incorporate the highly desired essentials of simplicity, specificity, and accuracy. Method *A* is a direct chromatographic comparison of terpin hydrate to dodecyl alcohol as an internal standard and method *B* is the formation and chromatographic measurement of terpin hydrate and dodecyl alcohol as their trimethylsilyl ether derivatives.

EXPERIMENTAL

Reagents—Hexamethyldisilazane (HMDS) (Matheson Coleman & Bell), trimethylchlorosilane (TMCS) (Eastman Kodak), and dodecyl alcohol (Analabs, Inc.) were used without purification.

Terpin Hydrate Reference Standard—Terpin hydrate N.F. was recrystallized twice from water–alcohol (5:1). The material was analyzed by differential scanning calorimetry (99.86%) and nuclear magnetic resonance (99.92%). The analytical evaluations are calculated on an anhydrous basis using the water content determined by Karl Fischer titrimetry.

Apparatus—An F & M model 810 dual column gas chromatograph with a dual flame ionization detector and a Minneapolis Honeywell recorder was used.

Received March 29, 1967, from the Drug Standards Laboratory, AMERICAN PHARMACEUTICAL ASSOCIATION FOUNDATION, Washington, DC 20037

Accepted for publication June 6, 1967.

The authors thank Candace Plato and Dr. Arthur Jacobson for analytical evaluations of the terpin hydrate reference standard.

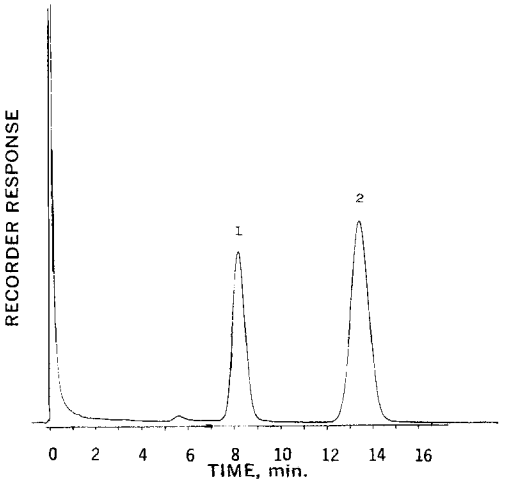

Fig. 1—Chromatogram of an alcohol solution of terpin hydrate and dodecyl alcohol on a Carbowax 20M column. Key: 1, dodecyl alcohol; 2, terpin hydrate.

Method *A*

Columns—Stainless steel columns (6 ft. × 1/8 in.) packed with 10% Carbowax 20 M on Diatoport S, 60–80 mesh (prepared by F & M Scientific Co.).

Chromatography Conditions—Column temperature, 170°; injection port temperature, 170°; detector temperature, 170°; amplifier gain 5 × 10^8 ohms at an attenuation of 2; helium flow, 40 ml./min.; hydrogen 44 ml./min.; air, 360 ml./min.

Internal Standard Solution—Dissolve about 1 Gm. of dodecyl alcohol, accurately weighed, in 100.0 ml. of absolute alcohol.

Procedure—Transfer about 200 mg. of terpin hydrate, accurately weighed, into a 50-ml. volumetric flask and dissolve in about 30 ml. of absolute alcohol. Add 10.0 ml. of internal standard solution, dilute to volume with absolute alcohol, and mix. A 0.5-μl. portion of this solution was injected into the chromatograph. A typical chromatogram is shown in Fig. 1.

Calculation—The per cent of anhydrous terpin hydrate is calculated by the formula:

$$H \times \frac{C \times V}{W} \times F \times 100$$

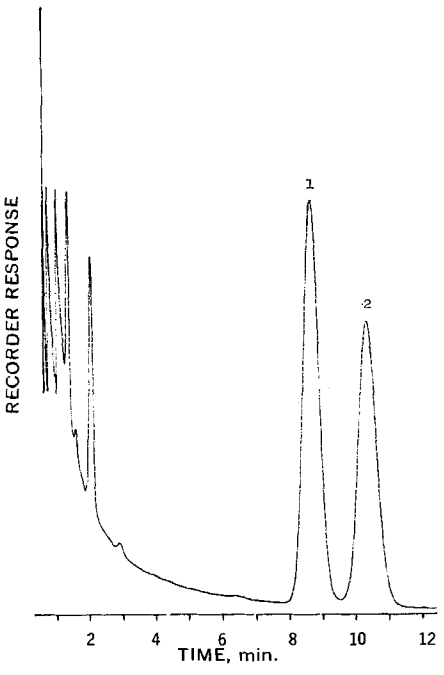

Fig. 2—Chromatogram of ether derivatives of terpin hydrate and dodecyl alcohol on a SE-30 column. Key: 1, terpin hydrate (TMS derivative); 2, dodecyl alcohol (TMS derivative).

in which H = peak ht. of terpin hydrate / peak ht. of internal std.

C = concentration, in mg./ml., of internal standard preparation,

V = volume, in ml., of internal standard added in procedure,

W = weight, in mg., of terpin hydrate taken calculated on an anhydrous basis using a water content determined by Karl Fischer titrimetry,

F = relative response of equal weights of dodecyl alcohol (DDA) and terpin hydrate (TH) standard as determined by peak height measurement (DDA/TH).

Method *B*

Columns—Stainless steel columns (6 ft. × 1/8 in.) packed with 10% SE-30 on Diatoport S, 60–80 mesh (prepared by F & M Scientific Co.)

Chromatography Conditions—Column temperature, 140°; injection port temperature, 145°; detector temperature, 150°; amplifier gain 5 × 10^8 ohms at an attenuation of 1; helium flow, 65 ml./min.; hydrogen, 58 ml./min.; air, 370 ml./min.

Internal Standard Solution—Dissolve about 2 Gm. of dodecyl alcohol, accurately weighed, in 100.0 ml. of pyridine.

Procedure—Transfer about 200 mg. of terpin hydrate, accurately weighed, into a 50-ml. volumetric flask and dissolve in about 25 ml. of pyridine. Add 10.0 ml. of internal standard solution, dilute to volume with pyridine, and mix. Transfer 1.0 ml. to a screw-cap vial, add 0.3 ml. of hexamethyldisilazane, 0.2 ml. of trimethylchlorosilane, stopper the vial, and shake vigorously for 1 min. Allow to stand for 1 hr. and inject 0.4 μl. of supernatant liquid into the chromatograph. A typical chromatogram is shown in Fig. 2.

Calculation—The formula given in method *A* may be used for calculation of terpin hydrate recoveries. However, for this procedure H is the ratio of the peak heights for the corresponding trimethylsilyl esters of terpin hydrate and dodecyl alcohol, and F is the relative response determined for the TMS ethers.

Table I—Recovery of Terpin Hydrate for Commercial Samples by Method *A*

Sample	Terpin Hydrate, mg. Added	Terpin Hydrate, mg. Found	Recovery, %[a] (Anhydrous)
A	201.5	180.2	98.8

	202.7	182.5	99.4
	...	...	99.2[b]

[a] Water contents used for calculation included in Table I. [b] Average of 5 determinations of S.D. ± 0.20.

RESULTS AND DISCUSSION

Series of tests were conducted to determine the stability of terpin hydrate and its TMS derivative at various component temperatures. Results of the investigations showed that terpin hydrate could be chromatographed directly at a temperature not exceeding 175° and terpin hydrate bis-trimethylsilyl ether could be exposed to a temperature of about 300° before thermal decomposition was evidenced. Additional studies produced the instrument parameters established for methods *A* and *B*. Results obtained for commercial samples of terpin hydrate by each method are summarized in Tables I and II, respectively.

The method is specific for the determination of terpin hydrate in the presence of its dehydration products. A sample of terpin hydrate was boiled in dilute sulfuric acid, the mixture steam distilled, the water immiscible portion distilled, and an alcoholic solution of the distillate chromatographed

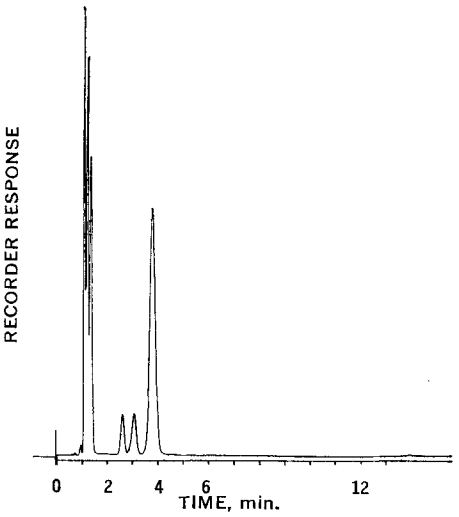

Fig. 3—Chromatogram of dehydroxylated terpin hydrate in alcohol solution on a Carbowax 20M column.

on a Carbowax 20 M column. The resultant chromatogram, shown in Fig. 3, indicates the low retention times for the reaction products which include terpinene, terpineol, and eucalyptol. The distillate also was subjected to etherification using the conditions stated under *Method B* and the chromatogram produced showed the absence of any significant peaks after a retention time of 4 min.

Dodecyl alcohol was selected as an internal standard based on a similarity in molecular weight to terpin hydrate, reactivity to form a trimethylsilyl ether, and ready availability of the material in a high state of purity. General use of the internal standard method has the advantage of minimizing sampling variation as a source of error in gas chromatographic procedures.

Terpin hydrate and dodecyl alcohol exhibited a linear response between the ratios of 0.5 to 3.0 (DDA/TH standard) in the range of 70 mg. to 200 mg. of either compound. An analogous study with the TMS ethers indicated a linear response between essentially the same ratios as the parent compounds. Average values for the relative response factor F were determined to be 1.75 for method A and 0.64 for method B.

Determination of Terpin Hydrate in Elixirs by Gas Chromatography

By LEON KURLANSIK, CAROLYN DAMON, HANNAH KLEIN, and EDWARD F. SALIM

A previous paper describes the determination of terpin hydrate by gas chromatographic analysis. The method has been extended to the assay of terpin hydrate in official elixirs after isolation of the drug in relatively pure form. The procedure is considered to be an improvement over existing methods in specificity and reproducibility.

TERPIN HYDRATE is used extensively as an ingredient in the preparation of cough suppressing elixirs. The most common formulations are terpin hydrate elixir, terpin hydrate and codeine elixir, and terpin hydrate and dextromethorphan hydrobromide elixir which are official in N.F. XII (1).

Literature reports on determinations of terpin hydrate in elixirs are confined to gravimetric (2–4) and colorimetric (5–7) procedures. Spectrophotometric assays in the visible region are due to the formation of molybdenum blue, a reduction product of the phosphomolybdic acid reagent.

Received April 13, 1967, from the Drug Standards Laboratory, AMERICAN PHARMACEUTICAL ASSOCIATION FOUNDATION, Washington, DC 20037
Accepted for publication May 25, 1967.

A previous paper by the authors deals with gas chromatographic analysis of terpin hydrate by two techniques (8). A method is presented for the isolation of terpin hydrate from the elixirs in relatively pure form and application of the gas chromatographic procedures developed for the drug substance.

EXPERIMENTAL

The gas chromatograph, columns, chromatography conditions, reagents, and terpin hydrate reference standard employed are described in a previous paper (8).

Isolation of Terpin Hydrate—Transfer 10.0 ml. of the elixir into a separator, add 25 ml. of saturated sodium acetate solution, shake for 1 min.,

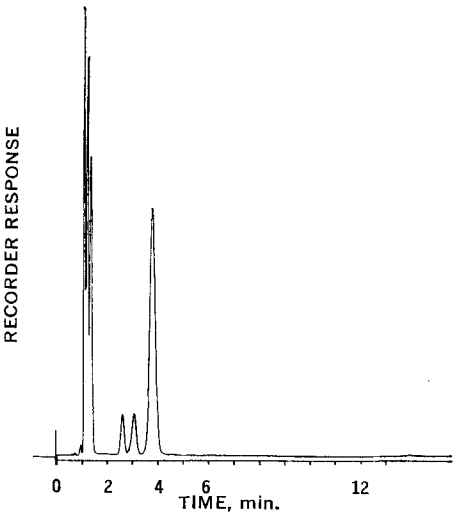

Fig. 3—Chromatogram of dehydroxylated terpin hydrate in alcohol solution on a Carbowax 20M column.

on a Carbowax 20 M column. The resultant chromatogram, shown in Fig. 3, indicates the low retention times for the reaction products which include terpinene, terpineol, and eucalyptol. The distillate also was subjected to etherification using the conditions stated under *Method B* and the chromatogram produced showed the absence of any significant peaks after a retention time of 4 min.

Dodecyl alcohol was selected as an internal standard based on a similarity in molecular weight to terpin hydrate, reactivity to form a trimethylsilyl ether, and ready availability of the material in a high state of purity. General use of the internal standard method has the advantage of minimizing sampling variation as a source of error in gas chromatographic procedures.

Terpin hydrate and dodecyl alcohol exhibited a linear response between the ratios of 0.5 to 3.0 (DDA/TH standard) in the range of 70 mg. to 200 mg. of either compound. An analogous study with the TMS ethers indicated a linear response between essentially the same ratios as the parent compounds. Average values for the relative response factor F were determined to be 1.75 for method A and 0.64 for method B.

Determination of Terpin Hydrate in Elixirs by Gas Chromatography

By LEON KURLANSIK, CAROLYN DAMON, HANNAH KLEIN, and EDWARD F. SALIM

A previous paper describes the determination of terpin hydrate by gas chromatographic analysis. The method has been extended to the assay of terpin hydrate in official elixirs after isolation of the drug in relatively pure form. The procedure is considered to be an improvement over existing methods in specificity and reproducibility.

TERPIN HYDRATE is used extensively as an ingredient in the preparation of cough suppressing elixirs. The most common formulations are terpin hydrate elixir, terpin hydrate and codeine elixir, and terpin hydrate and dextromethorphan hydrobromide elixir which are official in N.F. XII (1).

Literature reports on determinations of terpin hydrate in elixirs are confined to gravimetric (2–4) and colorimetric (5–7) procedures. Spectrophotometric assays in the visible region are due to the formation of molybdenum blue, a reduction product of the phosphomolybdic acid reagent.

Received April 13, 1967, from the Drug Standards Laboratory, AMERICAN PHARMACEUTICAL ASSOCIATION FOUNDATION, Washington, DC 20037
Accepted for publication May 25, 1967.

A previous paper by the authors deals with gas chromatographic analysis of terpin hydrate by two techniques (8). A method is presented for the isolation of terpin hydrate from the elixirs in relatively pure form and application of the gas chromatographic procedures developed for the drug substance.

EXPERIMENTAL

The gas chromatograph, columns, chromatography conditions, reagents, and terpin hydrate reference standard employed are described in a previous paper (8).

Isolation of Terpin Hydrate—Transfer 10.0 ml. of the elixir into a separator, add 25 ml. of saturated sodium acetate solution, shake for 1 min.,

and allow to stand for 30 min. with occasional shaking. Extract with four 25-ml. portions of chloroform, filtering each portion through chloroform-saturated cotton into a beaker. Concentrate the solution to about 10–15 ml. by warming on a steam bath with the aid of a current of air, and evaporate the remaining solvent without heat using a gentle current of air.

Method *A*

Internal Standard Solution—Dissolve about 1 Gm. of dodecyl alcohol, accurately weighed, in 100.0 ml. of absolute alcohol.

Procedure—Dissolve the residue from the elixir extract in about 15 ml. of absolute alcohol and transfer quantitatively to a 50-ml. volumetric flask containing 10.0 ml. of internal standard solution. Dilute to volume with absolute alcohol, and mix. A 0.5-μl. portion of this solution was injected into the chromatograph.

Calculation—The quantity of terpin hydrate N.F. in the elixir, in mg. per ml., is calculated by the formula:

$$\frac{H \times (C \times V) \times F \times 1.104}{10}$$

in which

H = $\frac{\text{peak ht. of terpin hydrate}}{\text{peak ht. of internal std.}}$

C = concentration, in mg. per ml., of internal standard solution,

V = volume, in ml., of internal standard solution taken,

F = relative response of equal weights of dodecyl alcohol (DDA) and terpin hydrate (TH) standard as determined by peak height measurement (DDA/TH),

1.104 = factor to convert anhydrous terpin hydrate to terpin hydrate N.F.

The per cent recovery of terpin hydrate is obtained by the expression

$$\text{terpin hydrate found } \frac{(\text{mg./ml.}) \times 100}{17}$$

in which the denominator represents the theoretical amount of terpin hydrate, in mg. per ml. of official elixirs.

Method *B*

Internal Standard Solution—Dissolve about 2 Gm. of dodecyl alcohol, accurately weighed, in 100.0 ml. of pyridine.

Procedure—Dissolve the residue from the elixir extract in about 15 ml. of pyridine and transfer quantitatively to a 50-ml. volumetric flask containing 10.0 ml. of internal standard solution. Dilute to volume with pyridine, and mix. Transfer 1.0 ml. to a screw-cap vial, add 0.3 ml. of hexamethyldisilazane, 0.2 ml. of trimethylchlorosilane, stopper the vial, and shake vigorously for 1 min. Allow to stand for 1 hr. and inject 0.4 μl. of supernatant liquid into the chromatograph.

Calculation—The formulas given in method *A* may be used for calculation of terpin hydrate recoveries. However, for this procedure H is the ratio of peak heights for the corresponding trimethylsilyl ethers of terpin hydrate and dodecyl alcohol, and F is the relative response determined for the TMS ethers.

Table I—Analysis of Terpin Hydrate in Elixirs

Elixir	Recoveries, % Method *A*	Method *B*
Terpin hydrate[a]	99.7 ± 0.22[c]	99.8 ± 0.27[c]
Terpin hydrate[b]	100.2	102.0
	100.9	101.1
Terpin hydrate and codeine[b]	102.4	103.1
	103.3	103.3
Terpin hydrate and dextromethorphan HBr[b]	102.6	100.9
	103.4	101.4

[a] Prepared in this laboratory according to N.F. XII. [b] Commercial products. [c] Based on 10 determinations.

RESULTS AND DISCUSSION

Isolation of terpin hydrate in the elixirs is achieved by salting the material out of solution and subsequent extraction with chloroform. This has been found to be necessary due to the similarity of terpin hydrate solubility in water and chloroform. Several saturating agents were investigated and sodium acetate was selected on the basis of reproducibility of initial assays. Recoveries obtained for terpin hydrate, terpin hydrate and codeine, and terpin hydrate and dextromethorphan hydrobromide elixirs through the addition of saturated sodium acetate solution are summarized in Table I. Satisfactory results may be obtained by the addition of a saturated magnesium sulfate solution. However, on occasion it has been observed that gel formation occurs during the prescribed waiting period. This effect may be eliminated by adding 1–2 ml. of water and gentle mixing.

Care must be exercised in the evaporation of solvent following extraction of terpin hydrate with chloroform. Terpin hydrate is fairly volatile and can be vaporized under the influence of excess heat or air. The preferred handling is to concentrate the solution and remove the last portion of chloroform without the application of heat.

Chromatograms produced by injections of sample solutions are basically the same as those obtained from previous gas chromatographic analyses of terpin hydrate. One extraneous peak is noted at a retention time of about 2 min. This peak has been assigned to a component in orange oil by preparation and injection of an alcoholic solution of orange oil U.S.P. and does not interfere with the dodecyl alcohol or terpin hydrate peaks which have a much longer retention time.

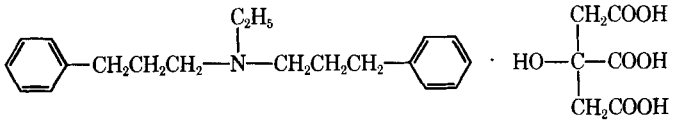
Qualitative and Quantitative Tests for Alverine Citrate

By EDWARD F. SALIM* and WILLIAM R. EBERT†

Provisional, unofficial monographs are developed by the Drug Standards Laboratory, in cooperation with the manufacturers of the drug concerned, for publication in the *Journal of Pharmaceutical Sciences*. The ready availability of this information affords discriminating medical and pharmaceutical practitioners with an added basis for confidence in the quality of new drug products generally, and of those covered by the monographs particularly. Such monographs will appear on drugs representing new chemical entities for which suitable identity tests and assay procedures are not available in the published literature. The purity and assay limits reported for the drugs and their dosage forms are based on observations made on samples representative of commercial production and are considered to be reasonable within expected analytical and manufacturing variation.

BIS-γ-PHENYLPROPYLETHYLAMINE CITRATE; $C_{26}H_{27}N \cdot C_6H_8O_7$; mol. wt. 473.57. The structural formula of alverine citrate may be represented as:



Physical Properties—Alverine citrate occurs as a white to off-white powder having a sweet odor and a slightly bitter taste, m.p. 100–102° (U.S.P. class I). It is slightly soluble in water and in chloroform, sparingly soluble in alcohol, and very slightly soluble in ether. The pH of a solution of alverine citrate in carbon dioxide-free water (1 in 200) is between 3.5 and 4.5.

Identity Tests—A 1 in 1500 solution of alverine citrate in 0.1 *N* hydrochloric acid exhibits ultraviolet absorbance maxima at about 253 mμ, 258 mμ [absorptivity (*a*) about 0.9], and 267 mμ and absorbance minima at about 233, 255, and 265 mμ. The spectrum is shown in Fig. 1.

The infrared spectrum of a 0.5% dispersion of alverine citrate in potassium bromide, in a disk of about 0.82 mm. thickness, is shown in Fig. 2.

Suspend about 500 mg. of alverine citrate in 10 ml. of water, add a slight excess of sodium hydroxide to liberate alverine base, allow to stand 5 min. with occasional swirling, and filter: the clear filtrate responds to the U.S.P. tests for citrate.

Purity Tests—Dry about 1 Gm. of alverine citrate, accurately weighed, at 80° for 2 hr.: it loses not more than 0.5% of its weight.

Char about 1 Gm. of alverine citrate, accurately weighed, cool the residue, add 1 ml. of sulfuric acid, heat cautiously until evolution of sulfur trioxide ceases, ignite, cool, and weigh: the residue does not exceed 0.1%.

Assay—Transfer about 360 mg. of alverine citrate, accurately weighed, to a separator, add 25 ml. of water, 5 ml. of sodium hydroxide T.S., and extract with four 25-ml. portions of chloroform. Wash the combined extracts with 10 ml. of water and filter the chloroform solution through a layer of chloroform-moistened anhydrous sodium sulfate contained on a pledget of cotton, collecting the filtrate in a titrating beaker. Wash the aqueous phase with 10 ml. of chloroform and filter as before into the beaker. Add methanolic methyl red T.S. and titrate with 0.1 *N* perchloric acid in dioxane. Perform a blank determination, and make any necessary correction. Each milliliter of 0.1 *N* perchloric acid is equivalent to 47.36 mg. of $C_{26}H_{27}N \cdot C_6H_8O_7$. The amount of alverine citrate found is not less than 99% and not more than 102%.

DOSAGE FORMS OF ALVERINE CITRATE

Alverine Citrate Tablets

Identity Test—Powder a suitable number of tablets and transfer an amount equivalent to about 120 mg. of alverine citrate to a 200-ml. volumetric flask. Add about 100 ml. of 0.1 *N* hydrochloric acid, allow to stand unstoppered until effervescence ceases, stopper and shake for 30 min., dilute to volume with the acid, and mix. Filter a portion of the solution, discarding the first 20 ml. of filtrate. The filtrate exhibits ultraviolet absorbance maxima and minima at the same wavelengths as the bulk drug as shown in Fig. 1.

Assay—Weigh and finely powder not less than 20 alverine citrate tablets. Weigh accurately a portion of the powder, equivalent to about 360 mg. of alverine citrate, and transfer to a separator. Add 5 ml. of water and 5 ml. of sodium hydroxide T.S., swirl occasionally for 5 min., and extract with four 25-ml. portions of chloroform. Wash the combined extracts with 10 ml. of water and filter the chloroform solution through a layer of chloroform-moistened anhydrous sodium sulfate contained on a pledget of cotton, collecting the filtrate in a titrating

beaker. Wash the aqueous phase with 10 ml. of chloroform and filter as before into the beaker. Add methanolic methyl red T.S., and titrate with 0.1 *N* perchloric acid in dioxane. Perform a blank determination, and make any necessary correction. Each milliliter of 0.1 *N* perchloric acid is equivalent to 47.36 mg. of $C_{20}H_{27}N \cdot C_6H_8O_7$. The amount of alverine citrate found is not less than 95% and not more than 105% of the labeled amount.

DISCUSSION

U.S.P. and N.F. terminology for solubility, melting range, reagents, *etc.*, has been used wherever feasible.

Alverine citrate[1] is a non-narcotic, smooth-muscle antispasmodic which is approximately 3 times as potent as papaverine and with a longer duration of action. It is neither an anticholinergic nor a derivative of atropine and adverse reactions commonly associated with anticholinergics are not manifest.

Identity Tests—Alverine citrate may be identified by the preparation of an oxalate salt. The free base is isolated by extraction with ether from basic solution and is reacted with oxalic acid in aqueous solution to form the oxalate. The derivative when dried at 55° in vacuum melts between 139° and 142°.

Quantitative Tests—The nonaqueous titration of the extracted base with perchloric acid gave an average value of 100.4 ± 0.3%.[2] Alternatively, alverine citrate may be dissolved in glacial acetic acid and titrated directly with 0.1 *N* perchloric acid. With crystal violet indicator, the color change from blue to blue-green corresponds to the midpoint of the inflection obtained by simultaneous potentiometric measurement. Montequi *et al.* (1) have assayed alverine citrate by formation of a reineckate and subsequent bromometric determination. The method is reported to be accurate to within 1%. Titrimetric analyses of commercial tablets gave an average value of 97.3 ± 1.0%[2] of the labeled amount of alverine citrate.

Rheological Estimation of the Spreading Characteristics of Pharmaceutical Semisolids

By JAMES C. BOYLAN

A Ferranti-Shirley cone and plate viscometer was utilized to characterize the spreading properties of white petrolatum U.S.P., white ointment U.S.P., and anhydrous lanolin U.S.P. Data were obtained for structural breakdown during repetitive cycling and for structural breakdown at constant shear. The problem of slippage at the revolving cone/sample interface is discussed. An attempt is made to relate rheological differences and molecular structure.

THE EASE of application of a pharmaceutical semisolid to the skin is an important factor in consumer product acceptance. Realizing that each individual applies ointment-like materials to the skin with a slightly different motion, stroke, and rate, any rheological estimation of this process, however good, involves some degree of error. However, good approximations of the shearing rates involved in spreading can still be made. Kostenbauder *et al.* (1, 2) estimated the shearing rates for a pharmacist compounding an ointment with a spatula and for a consumer spreading ointment on a surface (such as skin) as 200 sec.$^{-1}$ and 120 sec.$^{-1}$, respectively. Interestingly, it was recently shown that for ointments comprised mainly of white petrolatum or white ointment, 120 sec.$^{-1}$ represented the point of greatest resistance to flow at low rates of shear (3). In addition, it was clear from this study that the shearing region of 0 to 250 sec.$^{-1}$ would be important when characterizing the spreading properties of the 13 pharmaceutical semisolids studied.

In recent years significant progress has been made in the area of rheologically defining the spreading and extrusion properties of pharmaceutical ointments and lotions. In particular, Kostenbauder and co-workers (1, 2) and Wood and associates (4–6) have published useful information in this area.

Kostenbauder and Martin (1) after consultation with several dermatologists, grouped pharmaceutical ointments into 3 classes. Ophthalmic ointments, the softest products, constituted class I. The common medicated ointments, such as ammoniated mercury ointment and boric acid ointment, comprised class II. These products are soft, but stiff enough to remain at the point of application. Class III consisted of protective ointments, such as zinc oxide paste, which are hard and stiff enough to remain at the site of moist, ulcerated areas. Rheological evaluation of various bases selected by dermatologists for these classes indicated that the values in Table I were acceptable guideposts.

Wood and co-workers (4–6) used several techniques to measure a variety of properties concerned with the rheology of pharmaceutical semisolids and lotions. They were able to measure the force required to extrude products from a plastic bottle as a function of bottle design, wall thickness, type of orifice, and rheological character of the contents (4). In another study (5), they used a modified Castor-Severs extrusion rheometer to extrude samples from collapsible tubes and to measure the shear rates involved in simulated high speed tube filling. Wood and his associates (6) also evaluated the increase in tackiness that occurs in some lotions and ointments as they dry. An empirical test was devised that directly measured the cohesive-adhesive capability of skin surface during absorption after rub-in.

The Ferranti-Shirley cone and plate viscometer has instrumental advantages that make it worthwhile to evaluate its usefulness in studying the spreading properties of semisolid materials. These advantages are: the direct recording of a continuous, rather than a multipoint-rheogram, the ease of maintaining a constant shearing rate for an indefinite period of time, and a shearing geometry that (*a*) closely duplicates that of ap-

plying materials with a circular motion and (*b*) subjects all portions of the sample to uniform shearing stress (see Fig. 1).

It is the purpose of this paper to illustrate the advantages and limitations of the Ferranti-Shirley cone and plate viscometer for the evaluation of pharmaceutical semisolids in the shearing region between 0 and 270 sec.$^{-1}$ and, also, to present rheological procedures for estimating the spreading properties of semisolid materials using this instrument.

EXPERIMENTAL

Materials—The semisolids studied were white petrolatum U.S.P. and anhydrous lanolin U.S.P. These substances were chosen for this study because they are widely used in formulating pharmaceutical and cosmetic products and because they are dissimilar in their spreading characteristics. The white petrolatum was also used to prepare white ointment U.S.P. Storage of all samples was at room temperature.

Rheological Evaluation—The viscometer used in this study was a Ferranti-Shirley cone and plate viscometer[1] equipped with a 400 Gm.-cm. spring, an automatic gap setting device, an *x-y* recorder,[2] and a constant-temperature water bath.[3] The use of this viscometer has been described elsewhere (7). Calibration of the instrument was carried out using N.B.S. standard viscosity oils. The sample to be evaluated (about 1 ml.) was gently put on the plate of the viscometer with a spatula. The plate was immediately raised into position with the cone. The sample then remained undisturbed for 5 min. (to allow temperature equilibration at 30 ± 0.1°) before obtaining the rheogram. All rheograms were obtained using a truncated cone having an angle of 33 min. 26 sec. and a radius of 2 cm.

Procedure A—This procedure was designed to measure the amount of slippage at the cone/sample interface. The instrument was set to achieve a maximum of 100 r.p.m. (1074 sec.$^{-1}$). Using a fresh sample of white petrolatum each time, rheogram upsweep times (0–100 r.p.m.) were 10, 20, 40, 60, 120, 240, 480, and 600 sec. The downsweep time was identical to the upsweep time in each instance.

Procedures B, C, and D—These procedures were designed to measure the amount of structural breakdown at a constant rate of shear (see Table II).

Procedure E—This procedure was designed to measure structural breakdown as a result of repetitive cyclic shearing. The instrument was set to achieve a maximum of 11 r.p.m. (120 sec.$^{-1}$) in 13.3 sec. (instrument sweep time setting of 120 sec.). The downsweep time was identical. Immediately upon completion of the first cycle, the cycle was repeated on the same sample 4 additional times. Then a 6th cycle was immediately run utilizing a maximum r.p.m. of 100 (1074 sec.$^{-1}$).

Procedure F—This procedure was identical to procedure *E* in every respect except one—25 r.p.m. (270 sec.$^{-1}$) was the maximum r.p.m. for the first 5 cycles, instead of 11 r.p.m.

Tackiness—None of the procedures used was intended to measure tackiness. For this, special instrumentation, such as the modified tackmeter described by Wood and Lapham (6), is needed.

RESULTS AND DISCUSSION

Slippage—Evidence of slippage between the rotating member of the viscometer and the sample, resulting in reproducible artifacts, has been observed by several authors working with pharmaceutical substances. To minimize this problem, Kostenbauder and Martin (1) found it necessary to have a grooved bob prepared for the modified Stormer viscometer. Likewise, Wood and coworkers (4) "ribbed" the bobs for their Hercules Hi-Shear viscometer.[4] Wood attributes this artifact to the development of slippage planes at the wall-sample interface (artifact) and compares it with internal sample slippage planes (true yield value). Bruss (8) advocates the use of a star-shaped rotor. A star-shaped rotor is commercially available with the Haake Rotovisco viscometer.[5]

The Ferranti-Shirley viscometer used in this study offers another approach to the solution of this problem. The portions of rheograms shown in Figs. 2 and 3 illustrate the dramatic effect that the speed at which the shearing rate is increased can have on the rheogram. These data were obtained by procedure *A*. A comparison of Figs. 2 and 3 shows also that interpretation of the upcurve suffers more severely than does interpretation of the downcurve. The downcurve patterns show that shearing to 1074 sec.$^{-1}$ has destroyed most of the structure and also the rotating cone has been able to "catch up" and minimize any slippage effect.

It is felt that when using the Ferranti-Shirley cone and plate viscometer with semisolids, proper

sweep time selections can overcome serious slippage artifacts. Accordingly, it was not felt advisable to score the cone used for this study. However, the warning is clear. Each laboratory must recognize that this problem exists and determine how serious a problem it is for their particular instrument and samples, and deal with it accordingly.

Structural Breakdown at Constant Shear—Procedures *B*, *C*, and *D* were used to gather data on structural breakdown at constant shear. Two approaches were tried. Procedure *B* permitted a very slow increase in shearing rate in an attempt to minimize cone/sample slippage during measurement. Procedures *C* and *D* relied on a minimum of time being spent in the interval 0 to 120 sec.$^{-1}$ or 0 to 270 sec.$^{-1}$ to minimize prebreakdown of structure before the 120 sec.$^{-1}$ or 270 sec.$^{-1}$ constant shear rate. It was recognized that procedures *C* and *D* would be subject to cone/sample slippage artifacts, but it was felt that this could be taken into account when interpreting the rheograms. Typical results are shown in Figs. 4 and 5.

Procedure *B* was disappointing as a technique. It was readily apparent from Fig. 4 that when using procedure *B* much structural breakdown had occurred before reaching 120 sec.$^{-1}$.

The information gained from procedures *C* and *D* (Fig. 5) illustrates the importance of maintaining a constant maximum r.p.m. for reproducible and comparative results. Slippage is very evident in this figure. To follow structural breakdown from figures similar to Figs. 4 and 5, while at the same time eliminating slippage artifacts, the reduction in dynes/cm.^{2} was ignored for the constant shear interval 0–10 sec. The data obtained with procedures *C* and *D* are shown in Fig. 6. From Fig. 6 it can be seen that, as shearing continues (10–20 sec., 20–30 sec., 30–40 sec.) breakdown becomes proportionately less (*i.e.*, most structural breakdown occurs early).

When using the 400 Gm.-cm. torque spring, only white petrolatum and white ointment could be measured satisfactorily at 270 sec.$^{-1}$. In Fig. 6 it is interesting to compare the 270 sec.$^{-1}$ and the 120 sec.$^{-1}$ curves for these semisolids. The 270 sec.$^{-1}$ curves do not follow an apparent first-order

pattern, whereas the 120 sec.$^{-1}$ curves do. In both instances the white ointment has a greater resistance to flow and in both instances an approximately equal difference is maintained between the white ointment and white petrolatum for the interval 10–40 sec. This can be explained by the fact that while the white wax in the ointment is dispersed throughout the petrolatum it does not contribute to chemical structure, only to stiffness. Furthermore, microscopic examination shows the white wax particles to be unaffected as a result of shearing.

One feature of the curves in Fig. 6 for white ointment and white petrolatum that at first glance appears unusual is that apparently less structural breakdown occurs at 270 sec.$^{-1}$ than at 120 sec.$^{-1}$. Intuitively it would be expected that the higher constant shearing rate would cause a greater breakdown of structure. This is not so and can best be explained by referring to Fig. 7. Here it can be seen that for white petrolatum and white ointment much structural breakdown has already occurred by the time 270 sec.$^{-1}$ has been reached.

Also from Fig. 6 it is readily seen that even after 40 sec. of shearing at 120 sec.$^{-1}$ anhydrous lanolin is still over twice as stiff as white ointment or white petrolatum were after only 10 sec. of shearing.

This type of information regarding structural breakdown is among the most useful data obtainable from a rheological study.

Structural Breakdown by Repetitive Cyclic Shearing—Procedures *E* and *F* were used to gather data on structural breakdown by repetitive cyclic shearing. It was quickly evident that the 25 r.p.m. used in procedure *F* was sufficient to destroy most of the structure on the first cycle. Consequently, the data were collected using procedure *E* (11 r.p.m. maximum). Typical results obtained for white petrolatum are shown in Fig. 8. For all 3 ointment bases studied the trend is similar; namely, the major structural change occurs during the first cycle. Breakdown continues linearly, but very slowly, as cycling continues (Fig. 9). Finally, when the 6th cycle (0–100 r.p.m.) is run, it nearly coincides with portions of the 1 cycle 0–100 r.p.m. rheogram for white petrolatum (Fig. 8, dotted line). Figure 8 is an excellent example of the effect previous sample shearing can have on results and why it is

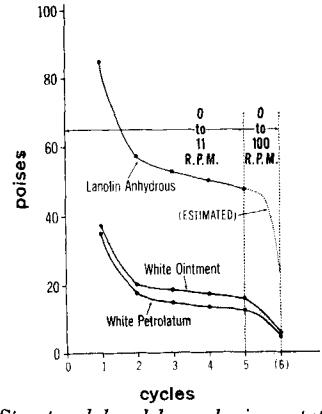

Fig. 9—Structural breakdown during repetitive cyclic shearing. Data obtained using procedure E.

TABLE III—FATTY ACIDS OF LANOLIN ISOLATED BY WEITKAMP (12)

Series	Structural Formula	n
Normal	$CH_3—(CH_2)_{2n}—COOH$	4 to 12 incl.
2-Hydroxyl	$CH_3—(CH_2)_{2n-1}—\underset{\displaystyle OH}{\underset{\vert}{CH}}—COOH$	6, 7
iso	$CH_3—\underset{\displaystyle CH_3}{\underset{\vert}{CH}}—(CH_2)_{2n}—COOH$	3 to 11 incl.
Anteiso	$C_2H_5—\underset{\displaystyle CH_3}{\underset{\vert}{CH}}—(CH_2)_{2n}—COOH$	2 to 13 incl.

essential to run samples that have been equilibrated with respect to structure as well as temperature.

The data obtained using procedure *E* are shown in Fig. 9. This figure clearly shows that although structural breakdown during repeated cycling with anhydrous lanolin occurs at a faster rate than with either white petrolatum or white ointment, it still possesses more than twice the viscosity of either other vehicle. This agrees well with data obtained under constant shear conditions (Fig. 6).

Structural Changes with Shear—*White Petrolatum*—Despite the widespread use of white petrolatum, much remains unknown regarding its composition. Franks (9) attributes this lack of knowledge to the formidable problems of analysis and the general familiarity and satisfaction with the material.

Variation from lot to lot of white petrolatum may be due to several factors. These include (9): (*a*) the type of crude oil started with, (*b*) the extent to which the volatile oils are removed during distillation, (*c*) whether any refining is done before dewaxing, (*d*) the type of process used for separating waxy constituents, (*e*) the viscosity and other characteristics of the oil used to soften the crude petrolatum before refining to U.S.P. specifications by filtration.

Schulte and Kassem (10) separated petrolatum into *n*-, iso-, and cyclic paraffin fractions. Their experiments showed that the rheological properties of petrolatum are determined by the ratio of these constituents to each other, the best pharmaceutical petrolatums containing a low content of *n*-paraffins. During mechanical strain, structural collapse of iso-paraffins is less than *n*-paraffins. Schulte and Kassem feel a principal reason for this is because iso-paraffins form a finer crystallite gel structure. A fine crystallite structure is less susceptible to mechanical strain than is a large crystallite structure. Also, as the crystallite size decreases, the viscosity of the petrolatum increases.

An explanation for the "bulge" in the upcurve of the rheograms of white petrolatum and white ointment and also the breakdown at constant shear rates for these products may be as follows. At rest, the petrolatum structure is probably a three-dimensional gel comprised of *n*-, iso-, and cyclic paraffins attached through random entanglement and chemical bonding. As the shear rate increases the *n*-paraffins tend to align in the direction of shear, whereas the iso and cyclic paraffins cannot align as readily and serve to retain some of the three-dimensional character of the system. As the shear rate further increases, the paraffins become further aligned concurrent with rupture of some of the entangled paraffin chains. At this point, the difference between the upcurve and downcurve becomes minimal.

Anhydrous Lanolin—Since lanolin is a product of animal synthesis, it shows a great deal of variation due to differences in heredity, environment, and age of the animal, time of shearing, age and storage conditions of the greasy wool, and variations in lanolin processing (11).

Purified anhydrous lanolin contains approximately 96% esters, 2% free alcohols, 1% free fatty acids, and 1% hydrocarbons (11). The alcohols that result from saponification of the esters of lanolin, and the free alcohols, can be classified as aliphatic, triterpene, or sterol. The aliphatics comprise about 23% of the total alcohols. Most of these are normal (C_{18}–C_{26}) or branched (C_{17}–C_{26}) chain alcohols. Triterpene alcohols, principally lanosterol and dihydrolanosterol, constitute about another 25%. Sterols (mostly cholesterol) comprise about 30% of the alcohols in lanolin. At present about 20% of the lanolin alcohols remain unclassified (11).

Weitkamp (12) formed the methyl esters of lanolin fatty acids, fractionated them by vacuum distillation, and identified 32 acids. Table III summarizes his results.

As was the case with white petrolatum, it is difficult to visualize what is occurring when anhydrous lanolin is mechanically sheared. There is undoubtedly some alignment of long-chain molecules in the direction of shear and some rupturing of weak chemical bonds at higher shear rates. Any additional speculation is hindered by the unknown constitution and complexity of lanolin.

Recommended Plan of Approach for Evaluating Spreading Properties—On the basis of the findings discussed above, it is apparent that when a user applies white petrolatum or anhydrous lanolin to the epidermis, or a pharmacist levigates these materials, the first few seconds of shearing stress serve to destroy much of the structural integrity, making the use of these materials much easier. This is desirable from a user's acceptance viewpoint. In addition, differences among the common ointment bases studied are great enough to allow a ranking of formulas. The following procedure would appear to be useful when using the Ferranti-Shirley cone and plate viscometer to evaluate the spreading properties of pharmaceutical semisolids.

(*a*) Establish a semisolid material as a standard of acceptable spreadability. This should involve the judgment of several experienced people.

(*b*) Evaluate the rheological characteristics of the standard material utilizing the hysteresis loop and procedures *C* and *E*.

(*c*) Relate the semisolid formulation under study to the standard material using the hysteresis loop and procedures *C* and *E*. It would be wise to make the comparison at several points in the temperature range 20 to 35° to simulate most temperatures of use.

SUMMARY

1. Some of the advantages and limitations of the Ferranti-Shirley cone and plate viscometer for the evaluation of pharmaceutical semisolids in the shearing region between 0 and 270 sec.$^{-1}$ are discussed.

2. Rheological procedures by which the spreading properties of pharmaceutical semisolids can be reproducibly measured are presented.

3. The usefulness of the data in the cases of white petrolatum U.S.P., white ointment U.S.P., and anhydrous lanolin U.S.P. is discussed.

4. The problem of slippage between the revolving cone and the sample is discussed.

5. Structural breakdown at constant shear, structural breakdown during repetitive cycling, and the structural theory possibly involved in some of the observed rheological changes are discussed.

Color Stability of Ascorbic Acid Tablets Measured by Light Reflectance

By ROBERT B. WORTZ

The effect of eight commonly used lubricants and glidants on the color stability of ascorbic acid tablets was studied. Light reflectance measurements were used to measure color change after an accelerated aging test. Lubricants low in metallic ion content, such as stearic acid and hydrogenated vegetable oil, conferred maximum color stability to ascorbic acid tablets. The alkaline lubricants such as magnesium and calcium stearate and minerals such as talc and hydrated sodium silico-aluminate were shown to cause excessive color reversion. The importance of humidity control when accelerated test conditions are used to measure the stability of pharmaceutical tablets is shown. Color stability was found to be closely related to chemical stability.

IT IS WELL known that ascorbic acid tablets discolor during storage under normal conditions of temperature and humidity. In fact, tablets stored in closed amber bottles at room temperature will gradually age from a white to a yellowish-brown color. The color stability of ascorbic acid in tablet form is not only affected by conditions of humidity and temperature, but can be influenced by the fillers, lubricants, and binders which are usually found in tablet formulations (1, 2).

Pharmaceutical tablets are often subjected to accelerated aging tests at elevated temperatures and humidities so that color stability may be ascertained rapidly. The end point of most such studies has been visual examination of tablets for color change. However, this type of evaluation is dependent on the judgment of the individual making the observation. No physical measurement is recorded and further deterioration or destruction of sample tablets makes it impossible to compare new samples prepared at a later date.

Light reflectance measurements are widely used by the pulp and paper industry to measure discoloration. The standard brightness test used for evaluating the discoloration of paper measures reflectance in the blue range at 458 mμ (3, 4). This wavelength is considered to give the best measure of yellow color. Such a light reflectance test should be useful in evaluating discoloration of ascorbic acid tablets. Gunsel and Lachman have used light reflectance measurements in comparing formulations containing conventionally processed and spray-dried lactose (5).

The purpose of this study was to determine the effects of lubricants and glidants commonly used in pharmacy on the color stability of ascorbic acid

IT IS WELL known that ascorbic acid tablets discolor during storage under normal conditions of temperature and humidity. In fact, tablets stored in closed amber bottles at room temperature will gradually age from a white to a yellowish-brown color. The color stability of ascorbic acid in tablet form is not only affected by conditions of humidity and temperature, but can be influenced by the fillers, lubricants, and binders which are usually found in tablet formulations (1, 2).

Pharmaceutical tablets are often subjected to accelerated aging tests at elevated temperatures and humidities so that color stability may be ascertained rapidly. The end point of most such studies has been visual examination of tablets for color change. However, this type of evaluation is dependent on the judgment of the individual making the observation. No physical measurement is recorded and further deterioration or destruction of sample tablets makes it impossible to compare new samples prepared at a later date.

Light reflectance measurements are widely used by the pulp and paper industry to measure discoloration. The standard brightness test used for evaluating the discoloration of paper measures reflectance in the blue range at 458 mμ (3, 4). This wavelength is considered to give the best measure of yellow color. Such a light reflectance test should be useful in evaluating discoloration of ascorbic acid tablets. Gunsel and Lachman have used light reflectance measurements in comparing formulations containing conventionally processed and spray-dried lactose (5).

The purpose of this study was to determine the effects of lubricants and glidants commonly used in pharmacy on the color stability of ascorbic acid

tablets. The filler used in most cases was microcrystalline cellulose.

EXPERIMENTAL

Materials—Ascorbic acid used in this study was either the coated, fine crystal, or fine powder grade.[1] The diluents used included microcrystalline cellulose,[2] cornstarch,[3] and spray-dried lactose.[4] Lubricants included in the study were hydrogenated vegetable oil,[5] stearic acid,[6] magnesium stearate,[6] and calcium stearate.[6] The glidants used were submicroscopic pyrogenic silicas,[7] hydrated sodium silico aluminates,[8] and talc.[9]

Sample Preparation—Mixtures of microcrystalline cellulose and ascorbic acid were dry blended with the various lubricants and glidants. Formulations containing starch and lactose were granulated with a 10% starch paste, air dried, and ground through a 30-mesh screen on a Wiley mill. Fifteen grams of each formulation was pressed into 2.25-in. disks using a Carver[10] test cylinder at a pressure of 20,000 p.s.i. The disks were pressed on a Drake hydraulic press.[11] The 2.25-in. disks were used rather than tablets to obtain the necessary surface area for reflectance measurements.

Storage Conditions—The accelerated test conditions used to store the samples were 2 weeks at 40° and 75% relative humidity. Selected samples were also stored for 16 to 32 weeks at 6 different conditions of humidity and temperature. The various humidity conditions were established by storing the samples in closed desiccators containing the saturated salt solutions listed in Table I (6). The

Table I—Storage Conditions

Saturated Salt Soln.	Temp., °C.	% R.H.
$KC_2H_3O_2$	24	23
$Ca(NO_3)_2$	24	51
NaCl	24	75
KF	40	23
NaBr	40	52
NaCl	40	75

variations in temperature were ±1°. All disks were stored in the absence of light.

Assay of Ascorbic Acid—The ascorbic acid concentrations were determined by the U.S.P. XVI method (7).

Reflectance Measurements—The light reflectance of the disks was measured with a tristimulus reflectometer both before and after the 14-day stability test. A Gardner precision reflectometer exposure head[12] and a Gardner automatic photometric unit were used for the reflectance measurements. Measurements were made using blue, amber, and green light.

RESULTS AND DISCUSSION

The ascorbic acid formulations listed in Table II were pressed into disks and stored for 14 days at 40° and 75% relative humidity. Table III compares the initial and final reflectance values of the disks using green, amber, and blue light. The per cent change in reflectance or the per cent reversion was calculated by the formula:

$$\% \text{ reversion} = \frac{\text{initial reflectance} - \text{final reflectance}}{\text{initial reflectance}} \times 100$$

Calculation of the per cent color reversion enables direct comparison of data without having to compensate for differences in the initial reflectance of each sample.

The color of the disks after the accelerated stability test ranged from off-white to a yellowish-brown color. In all cases the greatest change in reflectance was detected with the blue light. The per cent reversion obtained with the green and amber light was less than one-half the magnitude of that obtained with the blue light. The blue light was also much more sensitive to small color changes. For example, formulation *5* showed a reversion of 8.9% with blue light while reversions of only 2.4 and 1.4% were detected with the green and amber lights. Due to the increased sensitivity of the blue light to color change as the tablets aged, only blue light reflectance values are reported for the remainder of the paper.

The change in reflectance units that could be detected by visual observations was determined. Disks prepared from the same tableting formulation were removed from the oven at close intervals to obtain samples having similar reflectance values. Disks having blue light reflectance values of 89.7, 88.3, 85.9, 84.2, and 82.5 were examined. Five observers arranged the samples in order of decreasing reflectance values. The data demonstrate that a change in reflectance as small as 1.4 units could be detected by visual examination. When this is expressed in terms of per cent color reversion, a change as small as 1.6% could be detected by visual examination. Several observers were able to distinguish between the samples having a reflectance difference as small as 0.8 units. The reproducibility limit of the reflectance measurements was approximately ±0.3 reflectance units.

The data listed in Table III demonstrate a definite relationship between tablet color stability and the lubricants and glidants present in the tablet. Formulations *1*, *2*, *3*, and *4* which contained either magnesium stearate, hydrated sodium silico aluminates, or talc displayed excessive color reversion. However, formulations *5* and *6*, with either stearic acid or hydrogenated vegetable oil as lubricants and pyrogenic silica as a glidant, displayed the same discoloration as the control (formulation *8*).

The formulations described in Table II were assayed for ascorbic acid before and after storage for 2 weeks at 40° and 75% R.H. In Table IV, the assay and the per cent color reversion obtained with blue light are listed. Color stability is shown to be closely related to chemical stability.

To study the separate effect of various lubricants and glidants, blends were made up to contain 69% fine powder ascorbic acid, 30% microcrystalline

Pyrogenic silica	95.1	87.9	7.6

[a] Tablets contained 69% fine powder ascorbic acid, 30% microcrystalline cellulose, and 1% lubricant or glidant. Stored 2 weeks at 40° and 75% R.H.

cellulose, and 1% of the tested material. Data listed in Table V indicate that formulations containing stearic acid, hydrogenated vegetable oil, or pyrogenic silica displayed approximately the same discoloration as the ascorbic acid–microcrystalline cellulose control sample. Discoloration increased markedly over the control when magnesium stearate, calcium stearate, talc, or hydrated sodium silico aluminates were used.

The effect of lubricant concentration on color stability is shown in Table VI. Color reversion increased with lubricant concentration when magnesium stearate and talc were used. However, with stearic acid and hydrogenated vegetable oil, the degree of discoloration was independent of lubricant concentration.

Blaugh, Chakravarty, and Lach (1) have indicated that precoating ascorbic acid with ethylcellulose and granulating with ethylcellulose helped protect against decomposition due to metallic contamination. Coated ascorbic acid is prepared by granulating ascorbic acid with an alcoholic solution of ethylcellulose. To determine if the use of coated ascorbic acid improved color stability in tablets prepared by direct compression, formulations were prepared both with the coated and uncoated ascorbic acid. Various lubricants and glidants were added separately to formulations containing 75 parts ascorbic acid and 33 parts microcrystalline cellulose. Data listed in Table VII demonstrate that, in most cases, no improvement in color stability is gained by using coated ascorbic acid. In fact, formulations with stearic acid or hydrogenated vegetable oil showed greater stability with the regular ascorbic acid. The only significant improvement in color stability with the coated ascorbic acid was in the formulation containing hydrated sodium silico aluminates. There is no apparent explanation for the increased discoloration in the formulations containing coated ascorbic acid.

TABLE VI—EFFECT OF LUBRICANT OR GLIDANT CONCENTRATION ON COLOR STABILITY[a]

[a] Amount of each ingredient listed as the weight per cent. Stored 2 weeks at 40° and 75% R.H.

Table VIII compares the color stability of tablets containing starch and lactose fillers with those containing microcrystalline cellulose. Since microcrystalline cellulose by itself requires no lubrication in direct compression it is possible to use the less efficient lubricants such as hydrogenated vegetable oil or stearic acid. Formulations *9* and *10* in Table VIII resemble those found in commercial ascorbic acid tablets. The tableting formulation with microcrystalline cellulose as the filler was markedly more stable to color reversion than those containing lactose and starch.

The relationship between the color reversion

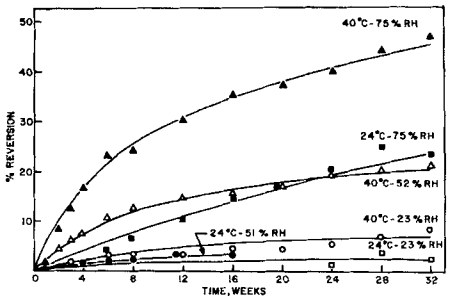

Fig. 1—Per cent color reversion plotted versus *storage time for formulation containing 60% ascorbic acid, 38.5% microcrystalline cellulose, 2% stearic acid, and 0.5% pyrogenic silica.*

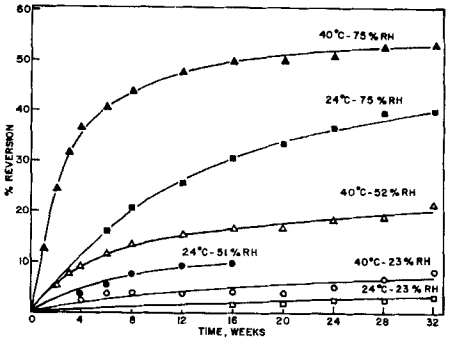

Fig. 2—Per cent color reversion plotted versus *storage time for formulation containing 60% ascorbic acid, 38.5% microcrystalline cellulose, 1% magnesium stearate, 0.5% pyrogenic silica.*

obtained under accelerated test conditions with that obtained at room temperature was determined. Three formulations that displayed varying degrees of color stability were stored for 16 to 32 weeks under 6 different conditions of temperature and humidity. In Figs. 1, 2, and 3 the per cent color reversion is plotted against storage time. The storage times required for each sample to display a reversion of

TABLE IX—STORAGE TIMES REQUIRED FOR THE FORMULATIONS IN FIGS. 1–3 TO SHOW REVERSIONS OF 10%

Storage Conditions	Storage Time, Days Fig. 1	Fig. 2	Fig. 3
40°, 75% R.H.	5	2	14
40°, 50% R.H.	34	11	42
40°, 23% R.H.	...	50	..
24°, 75% R.H.	25	11	67
24°, 51% R.H.	112	64	..

TABLE X—STORAGE TIMES EQUIVALENT TO 2 WEEKS AT 40° AND 75% R.H.

Storage Conditions	Time, Wk.
40°, 50% R.H.	6–11
40°, 23% R.H.	50
24°, 75% R.H.	8–11
24°, 51% R.H.	45–64

10%, at each condition of temperature and humidity was extracted from the figures and listed in Table IX. These data were used to determine storage times that were equivalent to 2 weeks at 40° and 75% R.H. (See Table X.)

The importance of humidity control, when accelerated test conditions are used to measure color stability, is clearly shown. At a constant temperature, color reversion increased markedly with increasing relative humidity. For example, after 12 weeks' storage at 40°, the formulation listed in Fig. 2 had color reversions of 4, 15, and 47% at relative humidities of 23, 52, and 75%, respectively. The formulations shown in Figs. 1 and 3 displayed approximately the same color reversion when stored at 40° and 52% R.H. or at 24° and 75% R.H. Very little color change was detected in samples stored at 24° and 23% R.H. The accelerated test conditions used, 2 weeks at 40°, and 75% R.H., were shown to be equivalent to approximately 1 year of storage at 24° and 51% R.H.

SUMMARY AND CONCLUSIONS

The light reflectance values of ascorbic acid tablets were measured before and after aging with a tristimulus reflectometer using amber, green, and blue light. The blue light reflectance values were found to be most effective for detecting small color changes in ascorbic acid tablets as they degraded from a white to a yellowish-brown color. The blue light reflectance values correlated closely with color changes detected by visual examination. Color stability was found to be closely related to chemical stability.

The color stability of ascorbic acid tablets was shown to be affected by the lubricants and glidants present in the tablet. Of the seven lubricants and glidants studied, stearic acid, hydrogenated vegetable oil, and pyrogenic silica were found to confer maximum stability to formulations of ascorbic acid. Tablets containing alkaline stearates such as magnesium or calcium stearate and minerals such as talc or hydrated sodium silico aluminate all displayed excessive color reversion. Use of ethylcellulose coated ascorbic acid did not improve color stability of tablets prepared by direct compression.

The importance of humidity control when accelerated stability tests are used to determine tablet stability is clearly shown. At a constant temperature color reversion of ascorbic acid tablets increased dramatically with increasing relative humidities. Two weeks' storage at 40° and 75% R.H. was found to be equivalent to storage for approximately 1 year at 25° and 50% R.H.

The use of reflectance measurements to measure tablet color stability greatly improved the reliability and usefulness of data obtained from accelerated stability tests.

Effect of Additives and Formulation Techniques on Controlled Release of Drugs from Microcapsules

By LOUIS A. LUZZI* and ROBERT J. GERRAUGHTY

The objectives of this study were to evaluate the effects of polysorbate 20 and a polyelectrolyte dispersing agent on the release of solids from microcapsules and to formulate microcapsules which, when subjected to gastrointestinal fluids, would release the encapsulated material at a predictable rate. Samples of microcapsules were subjected to simulated gastric fluid for 0.5 hr. and transferred to simulated intestinal fluid for an additional 2-hr. period. The filtered gastrointestinal fluids were compared spectrophotometrically to known absorption spectra in order to determine the quantity of solid released after each time interval. Results showed that the additives generally increased the release rate and that a large differential in release rate could be obtained without additives.

PREVIOUS WORK carried out by these authors and reported in *J. Pharm. Sci.* (1, 2) has indicated that the release of materials encapsulated by the process of complex coacervation could be controlled to make the encapsulated material available at a relatively predictable rate.

It was reported (1) that certain surfactants, when added to the system, would decrease the protection offered to the encapsulated substance. In this case, the encapsulated substance was mineral oil and the extracting substance was ethyl ether.

In another work (2) it was reported that solid particles (pentobarbituric acid) had been encapsulated in the same system and that a certain amount of control of the release rate of the solid to gastrointestinal fluids could be attained when conditions used in the encapsulation process were varied. The variables included: starting pH, starting temperature, ratio (dry weight) of solid to encapsulating material, quantity of formaldehyde added, and final pH.

With the above in mind, it became desirable to determine the effect of surfactants on microencapsulation as well as to attempt the formulation of fast and slow release microcapsules.

EXPERIMENTAL

Preparation of Microcapsules—The method of preparation of microcapsules followed that of Green and Schleicher (3, 4), as modified by Luzzi and Gerraughty (1). A previously described method of including solids (2) was incorporated into the process. Changes in pH were brought about by the addition of either 20% sodium hydroxide or diluted hydrochloric acid U.S.P.

Polysorbate 20[1] and a polyelectrolyte dispersing agent[2] were added in various quantities to the aqueous phase prior to the addition of the solid. In order to minimize the degradation of pentobarbituric acid, the temperature at which the capsules were dried was reduced from 50° to 40°.

The conditions incorporated into the formulation of fast release microcapsules are as follows: the starting pH was 5.0, the starting temperature was 34°, the ratio (dry weight) of pentobarbituric acid to encapsulating agents was 20/6; 4 ml. of formaldehyde solution U.S.P. was added for each 100 ml. of 3% gelatin solution, and the final pH was 8.8.

Samples for slow release microcapsules were prepared using the following conditions: the starting pH was 6.0, the starting temperature was 37°, the ratio of pentobarbituric acid to encapsulating agents was 4/6; 8 ml. of formaldehyde solution was added for each 100 ml. of 3% gelatin solution, and the final pH was 6.5.

The conditions accompanying the addition of both polysorbate 20 and the dispersing agent were as follows. The starting pH was 6.0, the starting temperature was 40°, the ratio of pentobarbituric acid to encapsulating agents was 8/6; 10 ml. of formaldehyde solution for each 100 ml. of 3% gelatin solution was added, and the final pH was 7.5. In addition samples of microcapsules containing the dispersing agent were prepeard where the lowest encapsulating pH values were 4.8 and 3.5 rather than the usual 4.0.

Method of Evaluation of Microcapsules—The method used to evaluate the microcapsules formed with the additives and for fast and slow release follows the method outlined by Luzzi and Gerraughty (2). The dried capsules were immersed in simulated gastric fluid and shaken for 0.5 hr. after which they were transferred to intestinal fluid and assayed after 1 and 2-hr. periods.

The assay method consisted of spectrophotometrically comparing the properly diluted, filtered extracts to known absorption spectra.

Photography—Photomicrographs of the wet microcapsules, taken prior to drying, were made to determine any visual peculiarities of the various formulations. The microscope slides were prepared for photography by placing 1 drop of slurry on a slide and covering it with a cover slip. The slurry was taken from the preparation while it was being filtered.

Polysorbate 20 (0.0071%) was added to the system shown in Fig. 1. In this photograph both

encapsulated and unencapsulated particles are visible. Photographs of a system containing less surfactant were prepared and, although not shown, suggested a progressive interference with encapsulation as the per cent of surfactant was increased.

Figure 2 is a photograph made of capsules containing 0.019% of the dispersing agent. It can be seen that the particles were not well dispersed and that large groups of particles seem to have gathered together to form a large group or groups of capsules. Figure 3 is a photograph prepared from microcapsules to which 0.029% of the dispersing agent had been added and shows elongated capsules filled with solid particles. The elongation of capsules seemed to be typical when moderate quantities of this dispersant were used. A comparison of the shell thickness of the over-all capsules to the shell thickness of capsules with no additive seemed to

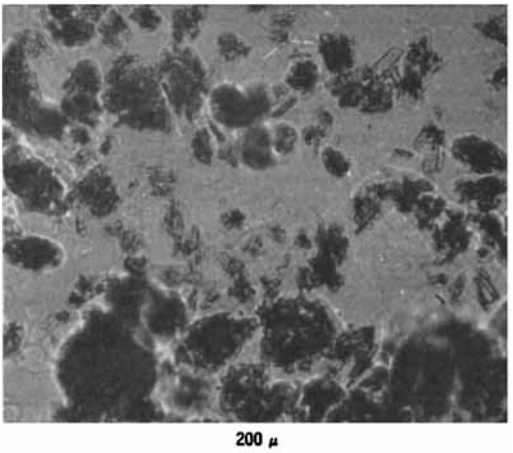

Fig. 4—Photograph of well dispersed microcapsules to which 0.116% of dispersant had been added.

indicate that high concentrations of the dispersant tend to decrease the wall thickness.

Figure 4 is a photograph of microcapsules to which 0.0071% polysorbate 20 had been added and was made at a slightly reduced enlargement. With this as a consideration, it can still be seen that the solids are in smaller groups, that the walls are quite thin, and that some capsules are not filled.

RESULTS

Effect of Polysorbate 20 on Microcapsules—Luzzi and Gerraughty (1) showed that polysorbate 20 in concentrations of 2% completely inhibited the encapsulation of mineral oil; it was thought that the orientation of polysorbate 20 molecules at the oil–water interface acted to prevent shell forming coacervate droplets from becoming oriented at the interface of the oil. The preparation of a series of microcapsules was undertaken in an attempt to establish the effect on microencapsulation of polysorbate 20 in systems employing solid rather than liquid particles.

In this series the per cent of polysorbate 20 included in the aqueous phase was varied from zero to 0.0142%. Table I shows that, under the conditions described, there was no significant change in the per cent of pentobarbituric acid released except at the highest concentration of polysorbate 20.

Effect of Dispersant on Microcapsules—Since the solid particles of pentobarbituric acid tended to settle out of suspension and were at times difficult to disperse, the dispersing agent was added to three separate series. Also, since preliminary work indicated that the dispersant was basic (pH 8.5–9.0) in the concentrations used, it was desirable to determine what effect changing the lowest pH would have on microcapsules as well as on the activity of the dispersant. The three series differed in that the lowest pH's attained during the encapsulating process were 4.0, 4.8, and 3.5, respectively.

The samples of Table II were prepared in an identical manner to those in the polysorbate 20 series (Table I), the only difference being that the dispersing agent rather than polysorbate 20 was added. At the lowest concentrations of the dispersant there seemed to be less acid extracted by the gastrointestinal fluids than in those samples prepared with no dispersant: thereafter, the per cent of acid released became greater with increasing additions of the dispersant.

Where the samples of Table III correspond to the dispersant concentrations of those in Table II, they are identical, with the exception that the lowest pH in the former was 4.8 rather than 4.0. Table III shows that there was a greater release of pentobarbituric acid as the concentration of the dispersant was increased and also that all of the samples of Table III released a greater percentage of acid than the corresponding members of Table II.

All of the samples within the series found in Table IV were also prepared in a manner similar to those of the polysorbate 20 group with the exception that the lowest pH was at 3.5 rather than at 4.0. Table IV shows that samples were not collectable until the second increment of the dispersant had been added; with the addition of the second increment of the dispersant, they become collectable.

TABLE I—EFFECT OF POLYSORBATE 20 ON THE PER CENT OF PENTOBARBITURIC ACID EXTRACTED FROM MICROCAPSULES EXPOSED TO GASTROINTESTINAL FLUIDS[a]

Formulation of Fast and Slow Release Microcapsules—Using the information gathered from a previous work by the authors of this paper (2), an attempt was made to formulate microcapsules which would release all or nearly all of the pentobarbituric acid which they contained. An attempt was also made to formulate microcapsules which would retain more than 50% of this original content of acid after 2.5-hr. exposure to gastrointestinal fluids. Samples of both formulations were prepared, and they were subjected to the gastrointestinal fluids as previously described (2).

The results of assays for fast release microcapsules revealed that 47.3% of the drug was extracted after 0.5-hr. exposure to gastric fluid. After being transferred to intestinal fluid and remaining immersed for 1 hr., an additional 30.1% was extracted and during the second hour in intestinal fluid 1.1% of the original quantity of acid was released; for a total of 78.5% released after 2.5-hr. exposure to gastrointestinal fluids.

The results of assays for slow release microcapsules revealed that 37.7% of the drug was released during 0.5-hr. exposure to gastric fluid. After being transferred to intestinal fluid and remaining immersed for 1 hr., an additional 13.0% was extracted, and during the second hour in intestinal fluid 5.5% of the original quantity of acid was released for a total of 56.2% released after 2.5-hr. exposure to gastrointestinal fluids.

In the fast release samples there was a difference of 1.1% in total per cent acid extracted between 1- and 2-hr. exposure periods to intestinal fluid, whereas there was a difference of 5.5% acid extracted under the same conditions for slow release samples.

Although the per cent of pentobarbituric acid released after the 2.5-hr. assay period fell somewhat short of the goal of this experiment, there seemed to be a significant difference in the per cent of acid released between the two types of samples.

DISCUSSION

Reasoning concerning the effect of starting pH, starting temperature, ratio, and quantity of formaldehyde on the strength or stability of capsule walls when in contact with gastrointestinal fluids has been given elsewhere (1, 2). That is, the starting pH will affect the coacervation already present at low pH values (*i.e.*, 5) or to the salt present (in the case of pentobarbituric acid) at high pH values; the starting temperature will affect the mobility of the micromolecules or the formed coacervate droplets thus limiting encapsulation; the ratio of solid encapsulating agents may affect the shell thickness; the quantity of formaldehyde may be insufficient to cause stable droplets to form or may possibly cause cracking of the shell when present in excess.

Combination of those conditions contributing to optimum shell strength were incorporated into the slow release microcapsules and selected conditions (those where collection of samples could be made) away from the optimum were incorporated into the fast release microcapsules. It seems likely that the reasoning which applied to the individual variables would also apply to the combined conditions.

Polysorbate 20 may have interfered with encapsulation because of its orientation at the solid–liquid interface (1). However, this may not be the case with the dispersing agent. Here it seems likely that the increased release of solid from the capsule was due to an increase in the number of particles which resulted from better dispersion of the solid and thus in more individual capsules having been formed. (See Fig. 4.) With the increased number of particles present, it would seem that the ratio of solid surface to encapsulating agents has been increased. As shown previously, this too would decrease the capsule strength.

Studies are now being carried out in order to determine the degree to which surface orientation and particle dispersion or size affect capsule strength.

CONCLUSIONS

Polysorbate 20, in the higher concentration used, seems to enhance the release of pentobarbituric acid to simulated gastrointestinal fluids.

Photomicrographs indicate that the polyelectrolyte dispersing agent aids in the dispersion of solid containing microcapsules and that at higher concentrations the encapsulations are sometimes incomplete.

It is possible to control the rate of release of pentobarbituric acid to gastrointestinal fluids by varying certain conditions in the encapsulation process.

Infrared Studies of Some New Azlactones

By P. K. SHARMA and S. S. DAVE

The infrared spectra of five azlactones possessing the trimethoxy benzene structure are discussed, and an attempt is made to draw some structural inferences from the data reported.

FIVE AZLACTONES having the trimethoxy benzene structure were synthesized previously, and their central nervous system depressant actions have already been reported (1). The present communication deals with the infrared studies (Table I) and interpretation of those azlactones.

TABLE I—CHEMICAL STRUCTURE AND INFRARED ABSORPTION PEAKS OF SOME AZLACTONES

No.	Compd.	Structure	Absorption Peaks, cm.$^{-1}$	Intensity	Structural Inference
I	Azlactone of 3,4,5-trimethoxy benzoyl amino cinnamic acid		1750–1770	Strong	5-Membered cyclic ketone
			1240–1280	Variable	C=O (stretching)
			1650–1680	Variable	C=N (stretching)
			1130–1170	Weak	3,4,5-Trisubstituted aromatic ring
II	Azlactone of 3,4,5-trimethoxy benzoyl α-amino p-dimethyl-amino cinnamic acid		1770	Strong	5-Membered cyclic ketone
			1240	Strong	C=O stretching
			1680–1690	Strong	C=N (stretching)
			1130–1170	Weak	3,4,5-Trisubstituted aromatic ring
			1630	Variable	Dimethylamino group
III	Azlactone of α-acetyl amino 2,3,4-trimethoxy cinnamic acid		1750	Strong	5-Membered cyclic ketone
			1260	Variable	C=O (stretching)
			1260–1670	Variable	C=N (stretching)
			1000–1170	Strong	1,2,3-Trisubstituted aromatic ring
			1350–1370	Strong	C—CH_3 (CH deformation)
IV	Azlactone of α-acetyl amino 2,4,5-trimethoxy cinnamic acid		1750–1770	Strong	5-Membered cyclic ketone
			1260–1280	Variable	C=O (stretching)
			1650–1680	Variable	C=N (stretching)
			1020–1040	Strong	2,4,5-Trisubstituted aromatic ring
			1350	Strong	C—CH_3 (CH deformation)
V	Azlactone of 3,4,5-trimethoxy benzoyl α-amino 2,4,5-trimethoxy cinnamic acid		1730	Strong	5-Membered cyclic ketone
			1250	Variable	C=O (stretching)
			1660	Strong	C=N (stretching)
			1020	Strong	2,4,5-Trisubstituted aromatic ring
			1140	Weak	3,4,5-Trisubstituted aromatic ring

All of the five azlactones give absorption bands of variable intensity in the region of 1750 to 1770 cm.$^{-1}$. This peak suggests the existence of a 5-membered saturated cyclic ketone (2). To lend support to the above fact a C=O stretching mode appears between 1240 and 1280 cm.$^{-1}$ with strong intensity, indicating the presence of a cyclic anhydride type C—O—C structure. Moreover, since all of these compounds are azlactones, the presence of C=N in the structure is essential, as shown by the C=N stretching vibrations of variable intensity at frequencies 1680 and 1690 cm.$^{-1}$.

Received August 4, 1966, from the Department of Physiology and Biochemistry, Medical College, Ajmer, Raj, India. Accepted for publication May 5, 1967.

Compound I gives the two characteristic bands at 1170 cm.$^{-1}$ and 1130 cm.$^{-1}$ of weaker intensity due to the presence of the 3,4,5-trisubstituted aromatic ring. Compound II shows in its spectra two bands at 1170 and 1130 cm.$^{-1}$ of the 3,4,5-trisubstituted aromatic ring, and the peak at 1630 cm.$^{-1}$ of weak intensity is due to the presence of the aromatic tertiary amine structure in the molecule. Compound III, being a 1,2,3-trisubstituted aromatic compound, shows absorption bands at 1000 and 1170 cm.$^{-1}$. Since there is a C-methyl group in the molecule, a peak at 1350 cm.$^{-1}$ due to CH deformation is observed. Compound IV, being a 2,4,5-trisubstituted derivative, gives absorption bands at 1000 and 1150 cm.$^{-1}$ and CH deformation for the C—CH_3 group at 1350 cm.$^{-1}$. With compound V, the bands of absorption at frequencies 1130 and 1000 cm.$^{-1}$ and 1170 to 1130 cm.$^{-1}$ clearly reveal that this compound contains two aromatic nuclei, both of which are trisubstituted.

Synthesis and Chemotherapeutic Effects of Ethyl Bis-(2,2-dimethyl)-ethylenamido Phosphate. A Preliminary Report

By Z. F. CHMIELEWICZ, T. J. BARDOS, A. MUNSON, H. L. BABBITT, and J. L. AMBRUS

The title compound, a new analog of the experimental anticancer agent, AB-132, was synthesized and tested against a spectrum of transplanted animal tumors. It was found to have significant chemotherapeutic activity in all of the tumor systems studied. In these assays, the new compound was a much more effective antitumor agent than AB-132.

ETHYL BIS(2,2 - DIMETHYL - 1 - AZIRIDINYL)PHOSPHINYL CARBAMATE (AB-132) was synthesized in this laboratory several years ago (1). This compound, although only moderately effective against various transplanted tumors in rodents, nevertheless showed promising therapeutic activity in the clinical testing against various forms of human cancer, particularly, in conjunction with X-irradiation (2–5). In view of these results, it appeared of interest to synthesize the title compound (I), in which the urethan moiety of AB-132 is replaced by an ethoxy group.

RESULTS AND DISCUSSION

Ethyl bis(2,2-dimethyl)ethylenamido phosphate (I), designated as AB-163, was synthesized by the reaction of ethyl dichlorophosphate with 2,2-dimethylaziridine (in the presence of triethylamine) and purified by distillation under high vacuum, as described under *Experimental*. (Scheme I.)

The compound, a colorless, viscous oil, is readily soluble in water but, like other 2,2-dimethylaziridine derivatives, it undergoes rapid hydrolysis; it gradually decomposes even on exposure to air (humidity and carbon dioxide) and has to be stored in sealed containers. Its NMR spectrum shows the characteristic β-phosphorus splitting of the methylene protons, both in the aziridine rings and the ester group, and a singlet for the methyl substituents of the tertiary ring carbon.

In chemical alkylation studies, using 4-(*p*-nitrobenzyl)pyridine as a model nucleophile (6), AB-163 demonstrated a higher initial rate of alkylation compared to AB-132 (Fig. 1). Its higher chemical reactivity was paralleled by its greater toxicity. The LD_{50} of AB-163 in mice was 159 mg./Kg. (i.p.), in comparison to the 600 mg./Kg. LD_{50} value for AB-132.

The results of some of the antitumor studies are shown in Figs. 2–5. Details of the methods used in the animal assays will be published elsewhere.

Figure 2 shows the effects of various doses of AB-163 against Ehrlich ascites tumor in ICR/Ha mice. Treatment was started 24 hr. after inoculation, and the drug was administered intraperitoneally for 9 consecutive days. The animals were sacrificed on the 10th day and tumor cell counts were taken. Tumor inhibition was expressed as the per cent difference between the mean number of cells in the control group and the test group. At the optimal dose level (30 mg./Kg.), 95% inhibition was observed.

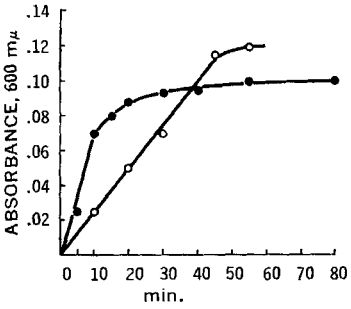

Fig. 1—Comparative reaction rates of ethyl bis(2,2-dimethyl-1-aziridinyl)phosphinyl carbamate (AB-132) and ethyl bis(2,2-dimethyl)ethylenamido phosphate (AB-163) with 4-(p-nitrobenzyl)pyridine, at 80°. Standard initial concentrations: compound, 0.2 μmole/ml.; reagent, 240 μmole/ml. Key: O, AB-132; ●, AB-163.

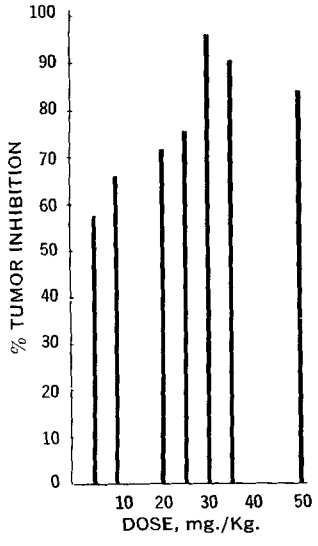

Fig. 2—Effect of AB-163 against Ehrlich ascites tumor (E-2) in ICR/Ha mice.

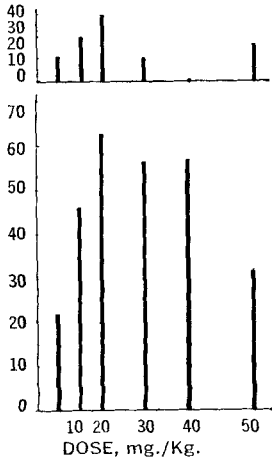

Fig. 3—Effect of AB-163 against sarcoma 180 in ICR/Ha mice. Top: per cent of animals without tumor, at various dose levels indicated on bottom abscissa. Bottom: per cent tumor inhibition in the remaining animals, at each of these dose levels.

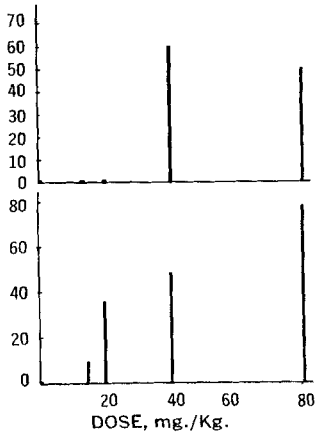

Fig. 4—Effect of AB-163 against adenocarcinoma 755 in 57B16 mice. Top: per cent of animals without tumor, at various dose levels indicated on bottom abscissa. Bottom: per cent tumor inhibition in the remaining animals, at each of these dose levels.

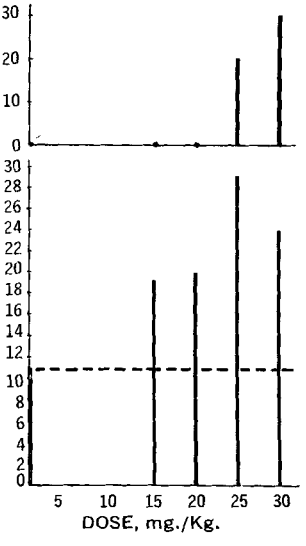

Fig. 5—Effect of AB-163 against leukemia L1210 in BDF1 mice. Top: per cent of animals surviving for 45 days, at various dose levels indicated on bottom abscissa. Bottom: per cent mean survival time of the remaining animals, at each of these dose levels. (Drug administered 1–11 days.)

Figure 3 shows the effect of the compound against sarcoma 180 in ICR/Ha mice. The drug was administered intraperitoneally for 7 consecutive days starting 24 hr. after tumor implantation. At the optimal dose range (15–25 mg./Kg.), 20–30% of the animals did not develop tumors while in the rest of the animals the tumors were 57–63% smaller (by weight) as compared to the controls.

Figure 4 illustrates the results obtained against adenocarcinoma 755 in 57B16 mice. Treatment was continued daily from day 1 to 11 following tumor implantation. At 40–80 mg./Kg. dose levels, 55–60% of the treated animals had no tumors

while the rest of the treated animals showed 48–77% inhibition of tumor growth as compared to the controls.

Figure 5 shows the effect of AB-163 against leukemia L1210 in BDF1 mice. In this experiment treatment was continued daily from day 1 to 11 post-inoculation. At optimal dose range, 25–30 mg./Kg., 20–30% of the animals survived for more than 45 days and are considered "cures." The remaining animals showed an average increase of survival time of 107–170%.

These results demonstrate that AB-163 is a much more effective compound against a spectrum of transplanted tumors than was AB-132(2).

EXPERIMENTAL

Into a 1-L. round-bottom flask equipped with a mechanical stirrer, pressure equalized addition funnel, thermometer, and a calcium chloride drying tube was introduced a solution of 15.6 Gm. (0.22 mole) of 2,2-dimethylaziridine, 22.2 (0.22 mole) of triethylamine in 350 ml. of toluene. The content of the flask was cooled to 0° by immersion in a mechanically refrigerated bath maintained at −3° to 0°, and a solution of 16.3 Gm. (0.1 mole) of ethyl dichlorophosphate in 100 ml. of toluene was slowly added. The reaction mixture was stirred for 24 hr. and then slowly warmed to room temperature and filtered. The precipitate contained nearly the theoretical amount of pure triethylamine hydrochloride. The filtrate was concentrated in a flash evaporator under reduced pressure, and the crude product was obtained as a viscous oil. The material was purified by high vacuum distillation and the analytically pure sample was obtained by collecting the fraction boiling at 70–71°/0.03–0.04 mm.; yield 17.3 Gm. (74%). This distillation had to be conducted with care because of the tendency of the material to decompose on overheating.

Anal.—Calcd. for $C_{10}H_{21}N_2O_2P$: C, 51.72; H, 9.05; N, 12.07. Found: C, 51.60; H, 9.18; N, 11.94.

Infrared absorption bands (Beckman IR-8): $\nu_{max.}^{CHCl_3}$ 2990, 1460 (broad), 1385, 1375, 1340, 1265, 1210 (broad), 1145, 1105, 1035, 960, 840 cm.$^{-1}$.

NMR absorption bands (in CCl_4, with tetramethylsilane as internal standard): 8.78 triplet (ester CH_3); 8.65 singlet (CH_3 ring-substituents); 8.05 doublet, P_H = 14 cps. (ring CH_2); 6.05, multiplet (ester CH_2).

Alkylation Studies—Comparative alkylating activities of I and AB-132 were determined at 80° by a previously described method (6).

Determination of Ephedrine, Phenobarbital, and Theophylline in Tablets by Gas Chromatography

By MILTON ELEFANT, LESTER CHAFETZ, and JOSEPH M. TALMAGE

A gas chromatographic procedure is described for the rapid, specific, and precise determination of ephedrine, phenobarbital, and theophylline in tablets. Ephedrine is converted to benzaldehyde by periodate oxidation prior to chromatography, while the phenobarbital and theophylline are chromatographed directly after simple tablet disintegration in a co-solvent. Adaptation of the method to single tablet analysis is described.

THE PROBLEM of devising a convenient and accurate assay for combinations of ephedrine, a barbiturate, and theophylline or its complexes has become classical in the literature of pharmaceutical analysis. The literature has been reviewed by Connors (1) and, more recently, by Foreman and Blake (2). Most of the solutions described so far require lengthy and tedious liquid–liquid extractions, ion-exchange chromatography, and/or liquid–liquid partition chromatographic separations followed by quantitation of the separated drugs by gravimetry, titrimetry, or spectrophotometry. Since gas chromatography combines separation with quantitation, it appeared to be a singularly attractive means for assay of a tablet declaring ephedrine HCl, phenobarbital, and theophylline.

Gas chromatographic methods have been successfully applied to assay of barbiturates (3–7) and ephedrine (8–11); however, mixtures of ephedrine, phenobarbital, and theophylline present more difficulties in gas chromatography than the assay of the individual drugs because of their differences in functionality, polarity, and dose. The polar, strongly basic amine, ephedrine, tails badly on columns which give good separation and symmetrical peaks for the weakly acidic barbiturate and xanthine drugs. Ephedrine is quantitatively oxidized by periodate, and this observation has been made the basis of quantitative assays of the alkaloid by Wickström (12), who determined the acetaldehyde formed by colorimetry, and by Chafetz (13),

while the rest of the treated animals showed 48–77% inhibition of tumor growth as compared to the controls.

Figure 5 shows the effect of AB-163 against leukemia L1210 in BDF1 mice. In this experiment treatment was continued daily from day 1 to 11 post-inoculation. At optimal dose range, 25–30 mg./Kg., 20–30% of the animals survived for more than 45 days and are considered "cures." The remaining animals showed an average increase of survival time of 107–170%.

These results demonstrate that AB-163 is a much more effective compound against a spectrum of transplanted tumors than was AB-132(2).

EXPERIMENTAL

Into a 1-L. round-bottom flask equipped with a mechanical stirrer, pressure equalized addition funnel, thermometer, and a calcium chloride drying tube was introduced a solution of 15.6 Gm. (0.22 mole) of 2,2-dimethylaziridine, 22.2 (0.22 mole) of triethylamine in 350 ml. of toluene. The content of the flask was cooled to 0° by immersion in a mechanically refrigerated bath maintained at −3° to 0°, and a solution of 16.3 Gm. (0.1 mole) of ethyl dichlorophosphate in 100 ml. of toluene was slowly added. The reaction mixture was stirred for 24 hr. and then slowly warmed to room temperature and filtered. The precipitate contained nearly the theoretical amount of pure triethylamine hydrochloride. The filtrate was concentrated in a flash evaporator under reduced pressure, and the crude product was obtained as a viscous oil. The material was purified by high vacuum distillation and the analytically pure sample was obtained by collecting the fraction boiling at 70–71°/0.03–0.04 mm.; yield 17.3 Gm. (74%). This distillation had to be conducted with care because of the tendency of the material to decompose on overheating.

Anal.—Calcd. for $C_{10}H_{21}N_2O_2P$: C, 51.72; H, 9.05; N, 12.07. Found: C, 51.60; H, 9.18; N, 11.94.

Infrared absorption bands (Beckman IR-8): $\nu_{max.}^{CHCl_3}$ 2990, 1460 (broad), 1385, 1375, 1340, 1265, 1210 (broad), 1145, 1105, 1035, 960, 840 cm.$^{-1}$.

NMR absorption bands (in CCl_4, with tetramethylsilane as internal standard): 8.78 triplet (ester CH_3); 8.65 singlet (CH_3 ring-substituents); 8.05 doublet, P_H = 14 cps. (ring CH_2); 6.05, multiplet (ester CH_2).

Alkylation Studies—Comparative alkylating activities of I and AB-132 were determined at 80° by a previously described method (6).

Determination of Ephedrine, Phenobarbital, and Theophylline in Tablets by Gas Chromatography

By MILTON ELEFANT, LESTER CHAFETZ, and JOSEPH M. TALMAGE

A gas chromatographic procedure is described for the rapid, specific, and precise determination of ephedrine, phenobarbital, and theophylline in tablets. Ephedrine is converted to benzaldehyde by periodate oxidation prior to chromatography, while the phenobarbital and theophylline are chromatographed directly after simple tablet disintegration in a co-solvent. Adaptation of the method to single tablet analysis is described.

THE PROBLEM of devising a convenient and accurate assay for combinations of ephedrine, a barbiturate, and theophylline or its complexes has become classical in the literature of pharmaceutical analysis. The literature has been reviewed by Connors (1) and, more recently, by Foreman and Blake (2). Most of the solutions described so far require lengthy and tedious liquid–liquid extractions, ion-exchange chromatography, and/or liquid–liquid partition chromatographic separations followed by quantitation of the separated drugs by gravimetry, titrimetry, or spectrophotometry. Since gas chromatography combines separation with quantitation, it appeared to be a singularly attractive means for assay of a tablet declaring ephedrine HCl, phenobarbital, and theophylline.

Gas chromatographic methods have been successfully applied to assay of barbiturates (3–7) and ephedrine (8–11); however, mixtures of ephedrine, phenobarbital, and theophylline present more difficulties in gas chromatography than the assay of the individual drugs because of their differences in functionality, polarity, and dose. The polar, strongly basic amine, ephedrine, tails badly on columns which give good separation and symmetrical peaks for the weakly acidic barbiturate and xanthine drugs. Ephedrine is quantitatively oxidized by periodate, and this observation has been made the basis of quantitative assays of the alkaloid by Wickström (12), who determined the acetaldehyde formed by colorimetry, and by Chafetz (13),

Received March 10, 1967, from the Pharmaceutical Research and Development Laboratories, Warner-Lambert Research Institute, Morris Plains, NJ 07950
Accepted for publication June 8, 1967.

Table I—Analysis of a Production Lot of Tablets

	Ephedrine HCl	Phenobarbital	Theophylline
Declared, mg./tablet	24.0	8.0	130.0

who measured the benzaldehyde produced on oxidation by ultraviolet spectrophotometry.

Gas chromatography of the benzaldehyde produced by oxidation of ephedrine provided sharp peaks suitable for quantitation on a chromatographic column useful for phenobarbital and theophylline. Benzaldehyde conveniently chromatographed at 80° while the ureides are chromatographed at 250°. Moreover, it was difficult to find an oxidation medium for ephedrine which would serve also as a good solvent for eluting phenobarbital and theophylline from tablets. For these reasons, separate sample preparations and separate determinations were performed for ephedrine and the other two drugs. The use of separate chromatograms allowed use of closely resolved internal standards, with an advantage in precision and accuracy over programmed temperature technique. A procedure for assay of the three drugs in individual tablets is described.

EXPERIMENTAL

Instrumental Conditions—A Perkin-Elmer model 801 gas chromatograph equipped with dual flame ionization detectors and a Honeywell-Brown Electronik recorder was used. The column employed was a 6-ft. glass helix, 0.25 in. o.d., packed with 3% HI-EFF 8 BP on 100/120 mesh Gas Chrom Q (Applied Science Laboratories, Inc., State College, Pa.). Gas flow rates of 30 ml./min. for hydrogen and 40 ml./min. for helium were used.

Phenobarbital and Theophylline Assay—*Internal Standard*—Use an approximately 0.6 mg./ml. solution of 4,4′-methylene-bis-(*N*,*N*-dimethylaniline) (Eastman Organic) in equal volumes of chloroform and methanol.[1]

Mixed Standard—Dissolve accurately weighed amounts of about 13 mg. of phenobarbital and 200 mg. of anhydrous theophylline in 25.0 ml. of the internal standard solution.

Sample Preparation—Determine the average weight of not less than 10 tablets, and reduce the sample to a fine powder. Weigh accurately the equivalent of one average tablet weight of the composite sample, and transfer it to a 50-ml. glass-stoppered centrifuge tube. Add exactly 15.0 ml. of internal standard solution, stopper the mixture, and shake vigorously for 5 min. Centrifuge the mixture and use the clear supernatant solution for chromatography.

[1] The compound should be stored under nitrogen after opening to protect it from oxidation.

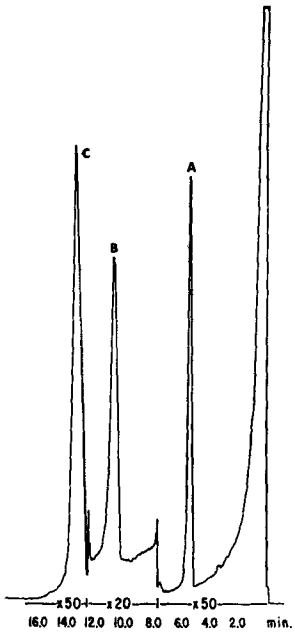

Fig. 1—Key: A, *internal standard;* B, *phenobarbital;* C, *theophylline.*

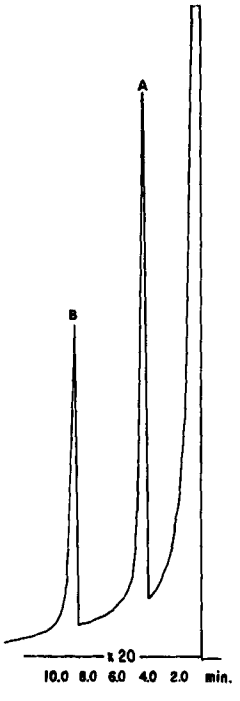

Fig. 2—Key: A, *benzaldehyde;* B, *internal standard.*

Procedure—Set the injector temperature at 325° and the column temperature at 250°. Inject in turn 2-μl. volumes of the sample and standard solutions at preselected attenuation settings.

Ephedrine Determination—*Internal Standard*—Use a solution of 0.06 ml. of benzyl alcohol in 100 ml. of ethyl acetate.

Standard Preparation—Dissolve approximately 65 mg. of ephedrine HCl, accurately weighed, in 25.0 ml. of saturated sodium bicarbonate solution.

TABLE II—ASSAY OF INDIVIDUAL TABLETS

Trial	Ephedrine HCl	Phenobarbital	Theophylline
1	23.6	7.7	127.0
2	23.2	7.6	128.0
3	24.1	7.7	127.0
4	23.9	7.6	127.0
5	23.8	7.7	127.0
6	23.8	7.6	127.0
7	23.6	7.8	130.0
8	23.6	7.8	126.0
9	23.4	7.7	126.0
10	23.8	7.8	126.0
Av.	23.7	7.7	127.0
Relative S.D.	1.1%	1.0%	0.9%

Pipet 10.0 ml. into a glass-stoppered centrifuge tube.

Sample Preparation—Accurately transfer the equivalent of one average tablet weight of composite sample into a glass-stoppered centrifuge tube. Add exactly 10.0 ml. of saturated sodium bicarbonate solution.

Procedure—Add 2.0 ml. of 10% sodium metaperiodate to the sample and standard preparations and shake 5 min. Pipet 10.0 ml. of internal standard solution into each tube, stopper, and shake for 3 min. Centrifuge the mixtures, and use the clear upper phases for chromatography.

Set the injector block temperature at 175° and the column temperature at 80°, and inject approximately 0.5 μl. of sample and standard solutions in turn. Program the column temperature at 6°/min. to a final temperature of 130° immediately after injection of each sample.

Assay of Individual Tablets—The procedures described above were employed with one modification; the single tablet was dispersed in the appropriate solvent by immersing the centrifuge tube in an ultrasonic cleaning bath (Maxomatic Ultrasonic, L. & R. Manufacturing Co., Kearny, N.J.).

Quantitation—Peak heights were employed according to the method described by Celeste and Turczan (14).

Sample—A commercially available tablet,[2] which has a label declaration of 24 mg. ephedrine HCl, 8.0 mg. phenobarbital, and 130 mg. of theophylline, was the only test preparation employed.

[2] Tedral is a registered trademark of Warner-Chilcott Laboratories, Morris Plains, N.J.

RESULTS

A production lot of tablets was analyzed by the gas chromatographic procedure, and the results were compared with values obtained by the conventional quality control methods. The data are presented in Table I. Figures 1 and 2 show typical chromatograms for phenobarbital and theophylline and for ephedrine, respectively.

The method was employed with equal success for the assay of individual tablets. The data obtained from assay of 10 individual tablets are presented in Table II. The average results and the relative standard deviations obtained do not differ appreciably from those obtained from powdered composite tablets.

SUMMARY

A gas chromatographic method has been developed for the determination of ephedrine, phenobarbital, and theophylline, and its application to the assay of composite and individual tablets has been described for a commercial tablet dosage form. Ephedrine is chromatographed after quantitative periodate oxidation to benzaldehyde at a lower temperature than the ureide drugs; thus, the method requires two sample preparations, two chromatograms, and one chromatography column. The procedure provided relative standard deviations of about 1% for each of the components of individual tablets, and it is rapid and selective.

Chemical Study of the Latex, Stems, Bracts, and Flowers of "Christmas Flower" (*Euphorbia pulcherrima*) I

By XORGE A. DOMINGUEZ, JESUS GARCIA DELGADO, MA. DE LOURDES MAFFEY, JOSÉ G. MARES, and CARLOS ROMBOLD

The latex, stems, bracts, and flowers of *Euphorbia pulcherrima* Willd were chemically studied. Each part was extracted separately with petroleum ether. All the extracts contained germanicol, β-amyrin, and pseudotaraxasterol. From the latex was obtained a new sterol, $C_{24}H_{40}O$, pulcherrol. From the extracts of the stems were isolated an octaeicosanol and β-sitosterol.

In Mexico and Central America there are many native members of the *Euphorbiaceae*, particularly of the genus *Euphorbia* (which has over 1600 species) (1, 2), among them the *Euphorbia pulcherrima* Willd, called "flor de pascua" (Christmas flower). The bracts of this plant were used as galactopoietic and abortive agents by the Aztecs and they are still used for both purposes in medicine popular in some parts of Mexico (3, 4). Because of its colorful red bracts, the *E. pulcherrima* is actually cultivated in many parts of the world, being used as a flower arrangement at Christmastime, but there are only a few chemical studies of this plant. It has been reported that the ethanolic extracts of its petals have insecticidal properties and that its leaves contain alkaloids (5). Asen (6, 7) has identified by chromatographic and spectrophotometric methods four anthocyanins present in its bracts. The purpose of this work was to look for compounds with possible hormonal activity in different parts of the plant. From the petroleum extracts of the latex, bracts, and stems, β-amyrin, germanicol, and pseudotaraxasterol were isolated. In addition to these compounds, the latex provided a new steroid, $C_{24}H_{40}O$, for which the name, pulcherrol, is proposed. Also, in the extracts of the stems an octaeicosanol and β-sitosterol were identified.

EXPERIMENTAL

Melting points (uncorrected) were determined on a Kofler hot stage. Infrared spectra were taken on a Beckman IR-8 spectrophotometer and NMR spectra were obtained on a Varian A-60 instrument,[1] with tetramethylsilane as an internal standard and deuterochloroform as a solvent. Thin-layer chromatograms (TLC) were run on Silica Gel G (Merck), according to Stahl (8), and the system benzene–chloroform (7:1) (v/v) was used as solvent *A*.

Authentic specimens of triterpenoids were kindly supplied by Dr. Guy Ourisson and Dr. G. Poinsinet, Strasbourg University, and Dr. P. De Mayo, University of Western Ontario, Canada, whose assistance is acknowledged.

Microanalysis was by Dr. A. Bernhardt, Milheim/Ruhr, Germany. Identification methods and reactions were those described by Cheronis (9), and for the triterpenoids the methods used have been described by Steiner (10).

Plant Materials—The aerial part (stems, bracts, and flowers) and latex of *E. pulcherrima* were collected around Monterrey, Nuevo León, Mexico, in December 1963, 1964, and 1965.

Extraction of the Latex—The stems and terminal twigs were cut, and the flowing milky latex was collected. The latex (15 Gm.) was refluxed 12 hr. with methanol (150 ml.) and KOH (6 Gm.). The suspension was evaporated under reduced pressure, and the gummy residue was extracted five times with 50-ml. portions of ethyl ether. To the residue, water (100 ml.) was added, and a rubber-like material (9.8 Gm.) was obtained. The water solution was acidified with 5% HCl and an oily suspension (10.8 Gm.) was obtained; its principal component was palmitic acid which was isolated and identified by its physical constants and the melting point of its anilide (9). The combined ethyl ether solutions were washed with water and dried with Na_2SO_4. On TLC (solvent *A*) seven spots were detected with iodine vapors and also with 20% $SbCl_3$ in chloroform. The residue (2.8 Gm.), obtained on the removal of the ether, was dissolved in hot methanol–chloroform (20:1). On standing overnight, colorless crystals (1.45 Gm.) of crude pulcherrol were obtained, m.p. 110–116°. The mother liquors produced six spots on TLC; then the filtrate was evaporated and the residue (1.0 Gm.) was chromatographed on silica gel (150 Gm.). The substances were eluted successively by benzene, benzene–chloroform, and chloroform. A total of 36 fractions were collected; their composition was monitored by TLC. After rechromatography of several fractions and the corresponding recrystallization of the eluates, germanicol (23.5%), β-amyrin (9%), and pseudotaraxasterol (22%) were obtained.

Identification of the Known Substances (11)—Germanicol recrystallized from methanol, m.p. 178–180°; $[\alpha]_D^{24}$ +8°. [Reported (12) m.p. 180–181°; $[\alpha]_D^{24}$ +7°.] Acetylation with acetic acid anhydride in pyridine (12) produced an acetate, m.p. 276–280°; $[\alpha]_D^{24}$ +11°. [Reported (12) m.p. 279–280°; $[\alpha]_D^{24}$ +18°.] Mixed melting points with authentic germanicol and its acetate showed no depression.

β-Amyrin recrystallized from methanol, m.p. 197–199°; $[\alpha]_D^{24}$ +82°. [Reported (11) m.p. 199–200°; $[\alpha]_D^{24}$ +88°.] Acetylation with acetic acid anhydride in pyridine produced an acetate, m.p. 238–241°; $[\alpha]_D^{24}$ +81°. [Reported (11) m.p. 241°; $[\alpha]_D^{24}$ +81°.] Mixed melting point with an authentic β-amyrin showed no depression.

Received February 27, 1967, from the Institute of Technology of Superior Studies, Monterrey, N. L., Mex.
Accepted for publication June 6, 1967.
This work was supported by a grant from the Research Corporation of New York.
Presented to the Meeting of Plant Phenolics Group of North America, Austin, Tex., April 17, 1966.
[1] Spectra obtained by Dr. Roger Ketcham, School of Pharmacy, University of California, whose assistance is gratefully acknowledged.

Pseudotaraxasterol, recrystallized from ethanol, melted at 220–222°; $[\alpha]_D^{24}$ +46°. [Reported (11) m.p. 220–221°; $[\alpha]_D^{24}$ +50°.] Acetylation with acetic acid anhydride in pyridine (12) produced an acetate, m.p. 244–246°; $[\alpha]_D^{24}$ +50.4°. [Reported (11) m.p. 246–247°; $[\alpha]_D^{24}$ +53°.] Mixed melting point with an authentic pseudotaraxasterol showed no depression.

Purification of Pulcherrol—Pulcherrol was recrystallized from ethanol–chloroform and colorless needles, m.p. 115–116°, were obtained. It produced a single spot on TLC and gave positive results for the Liebermann-Burchard test for steroids and the tetranitromethane test for unsaturation. Negative results were obtained from the selenium dioxide–acetic acid test, for Δ^7 steroids (13); $[\alpha]_D^{24}$ (in $CHCl_3$) +35°. No absorption in the U.V.; infrared absorption: $\nu_{max.}^{CHCl_3}$ 3600, 2950, 2850, 1470, 1370, 1010 cm.$^{-1}$.

Anal.—Calcd. for $C_{24}H_{40}O$: C, 83.65; H, 11.70; O, 4.64. Found: C, 83.73; H, 11.59; O, 4.68.

The NMR spectrum: 5.2 (multiplet), 6.52 τ (singlet), 7.9–9.2 τ (38H, complex with five singlet signals).

Pulcherryl Acetate—Pulcherrol (100 mg.) was mixed with acetic anhydride (5 ml.) and pyridine (1.0 ml.). After it stood at room temperature for 12 hr., the mixture was diluted with water. The crude acetate was collected and recrystallized several times from methanol. The bright plates melted at 228–229°. I.R. spectrum: $\nu_{max.}^{CHCl_3}$ 2950, 2850, 1720, 1465, 1455, 1370, 1250, 1200, 1100, 1020, 980 cm.$^{-1}$. The NMR spectrum: 2.5 τ (multiplet) 7.9 τ (singlet, 3H), 3.1–9.2 τ (38H complex).

Anal.—Calcd. for $C_{26}H_{42}O_2$: C, 80.77; H, 10.95; O, 8.28. Found: C, 80.66; H, 10.74.

Oxidation of Pulcherrol—Pulcherrol (100 mg.) in pyridine (1 ml.) was mixed with 4 ml. of chromic acid–pyridine–acetic acid complex (14), and the temperature was held at 0° for 1 hr. Methanol (2 ml.) was added, then the mixture was diluted with water, and the ketone was recovered as usual. On recrystallization from methanol, needles (80 mg.), m.p. 151–152°, were obtained. I.R. spectrum: $\nu_{max.}^{CHCl_3}$ 2950, 2850, 1700, 1465, 1460, 1380, 1110, 1005 cm.$^{-1}$.

Anal.—Calcd. for $C_{24}H_{38}O$: C, 84.15; H, 11.18; O, 4.67. Found: C, 84.33; H, 11.28.

Epoxide of the Pulcherryl Acetate—A chloroform solution of pulcherryl acetate (50 mg.) was mixed with 50 mg. of *m*-chloroperbenzoic acid and 5 ml. of chloroform. The mixture stood at room temperature for 12 hr. Then, 5% NaOH solution (25 ml.) was added. The chloroform layer was rinsed with water, dried with Na_2SO_4, and evaporated. The residue was recrystallized from methanol–chloroform, m.p. 267–269°.

Anal.—Calcd. for $C_{24}H_{40}O_2$: C, 79.94; H, 11.19; O, 8.88. Found: C, 80.07; H, 11.26; O, 8.69.

Extraction of Stems—Dried stems (1400 Gm.) of *E. pulcherrima* were extracted in a Soxhlet apparatus with petroleum ether (b.p. 30–60°) for 100 hr. The green solution was evaporated and the greenish residue (7.0 Gm., yield 0.5%) was saponified as described for the latex, but the unsaponifiable material was extracted with several portions of chloroform. The chloroform solutions were mixed and added to a column of alumina (Merck). The elutions were obtained in the usual way (10) with benzene, chloroform, ethyl acetate, and ethanol. From the first fraction was obtained an aliphatic alcohol, 326 mg., which after recrystallization from chloroform–methanol melted at 63–65°.

Anal.—Calcd. for $C_{28}H_{58}O$: C, 81.87; H, 14.23; O, 3.90. Found: C, 81.53; H, 14.12; O, 3.86.

Also there were eluted and identified, as mentioned for the latex, germanicol, 370 mg., m.p. 177–179°; β-amyrin, 825 mg., m.p. 198–200°; pseudotaraxasterol, 263 mg., m.p. 237–240°; and β-sitosterol, 108 mg., m.p. 134–136°; $[\alpha]_D^{CHCl_3}$ −37°, from which β-sitosteryl acetate was produced by acetylation, in the usual manner (11); it melted at m.p. 125–127°. There was no depression of the melting point when each compound was mixed with an authentic specimen.

Extraction of Bracts and Flowers—Dried flowers and bracts (1700 Gm.) were extracted with petroleum ether (b.p. 30–60°) in a Soxhlet apparatus during 160 hr. The solution, containing 22.85 Gm. of solids, and showing five spots on TLC, was chromatographed on alumina (Merck). The fractions were eluted by benzene, chloroform, and ethanol. The crude ester mixtures, detected by I.R. spectroscopy on several fractions, were saponified with KOH in methanol as usual (10). The unsaponifiable material was extracted with ethyl ether and the solution was chromatographed on alumina. From the eluates there was obtained and identified germanicol (1.32 Gm.); β-amyrin (0.386 mg.); pseudotaraxasterol (649 mg.); the same aliphatic alcohol of 28 carbons isolated from the stems (64 mg.); and an aliphatic hydrocarbon, melting at 75–77°.

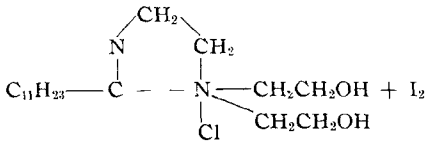
Toxicology of the Iodophor, Imidecyl Iodine

By T. A. FAKOUHI*, C. GRIFFIN†, R. S. McCUTCHEON‡, and J. F. BONE

The iodophor imidecyl iodine is relatively nontoxic in rats, guinea pigs, rabbits, and dogs. In rats, calculated oral LD_{50} for males was 14.0 ± 2.1 mg./Kg., and for females 11.0 ± 1.5 mg./Kg. Dermal, eye, skin, and chronic toxicity studies were essentially negative. Urinary bladder studies in rabbits terminated fatally in two animals given undiluted and 1:2 dilutions in water. Dilutions of from 1:10 to 1:64 were progressively decreasing local irritants. Microscopic lesions in LD_{50} studies included pulmonary emphysema, ascites, distended stomach, hyperemia, and parenchymal damage in the liver and kidneys. Lesions in rabbits were compatible with shock. Lesions in chronic studies were mainly mild kidney damage. Three dogs fed imidecyl iodine for 3 to 5 months were unaffected.

FOR MANY YEARS, iodine has been used as a topical germicide and antiseptic. Although it is highly effective against fungi, bacteria, and viruses, it also has some detrimental attributes in the elemental form (1). It is irritating to body tissues and has objectionable odor and staining properties, and thus has given way to other antiseptics with less offensive side effects.

The combination of iodine with certain detergents greatly reduces objectionable side effects while retaining most of the desirable qualities of iodine (2). One such preparation, the iodophor imidecyl iodine[1] is a germicidally effective combination of iodine with an amphoteric detergent possessing the approximate structural formula:



There appears to be a positive chemical interaction between the detergent and the elemental iodine which results in a nearly complete loss of the caustic, corrosive, staining, and physically unstable properties of the halogen. The toxicity of this compound, however, has not been completely investigated.

This paper deals with the toxicological properties of imidecyl iodine and its effect upon various tissues in several species under various conditions and routes of administration. Specifically the studies involve determination of the LD_{50} in rats, dermal toxicity in rats, intradermal sensitivity reactions in guinea pigs, toxicity to ocular tissues of adult and newborn rabbits, toxicity when instilled into the urinary bladder of adult rabbits, and chronic toxicity feeding trials in dogs.

METHODS

LD_{50} in Rats—The oral LD_{50} was determined for each sex of adult Wistar rats in good physical condition. The animals were starved for 24 hr. and then given graduated solutions of imidecyl iodine *via* stomach tube. One hour after receiving the drug, the animals were allowed food and water *ad libitum*. Controls were run with each group and surviving animals closely observed for 14 days. LD_{50} values were calculated by the method of Reed and Muench (3). Fatalities were examined postmortem and outstanding lesions were noted. Results are shown in Table I.

TABLE I—ORAL LD_{50} OF IMIDECYL IODINE

Species and Sex	Dose, ml./Kg.	Observed Deaths	Calcd. LD_{50}, ml./Kg.
Rat, male	4.0	0/5	14.0 ± 2.1
	10.0	1/5	
	12.5	2/5	
	15.0	3/5	
	25.0	5/5	
Rat, female	4.0	0/5	11.0 ± 1.5
	10.0	2/5	
	15.0	4/5	
	25.0	5/5	

Acute Dermal Toxicity—The abdomens and backs of five Wistar rats of both sexes were shaved and the skin abraded. Specially fitted rubber sleeves were placed over the lesions to prevent the loss of material from the skin areas being tested. Five milliliters of imidecyl iodine in various concentrations, *e.g.*, undiluted, 1:5, and 1:10, was placed under the sleeves, and 5 ml. of saline applied in the same manner served as the control. The animals were observed at 1, 4, 24, and 48-hr. intervals after the application for signs of edema, erythema, vesiculation, and other signs of irritation.

Guinea Pig Sensitization—Five adult female guinea pigs were used to determine sensitivity. Concentrations of undiluted, 1:10, and 1:15 of imidecyl iodine in distilled water were injected intradermally. One animal was kept as control. Each animal received 0.05 ml. of imidecyl iodine intradermally as the first dose, followed by a dose of 0.125 ml. daily for 10 days. The sensitizing injection (0.05 ml.) was given 10 days after the last dose.

Eye Toxicity—*Adult Rabbits*—Twelve adult male domestic rabbits were used to determine if local eye irritation was produced by imidecyl iodine. Four strengths of the drug were employed, *e.g.*, undiluted, 1:10, 1:15, 1:25. One instillation of 0.3 ml. was made in the left eye; the right eye received 0.3 ml. of normal saline and served as control. The corneas, irises, and conjunctivae of each animal were observed for erythema, vesiculation, edema, or other signs of irritation at 1 hr., 24 hr., 96 hr., and 168 hr. after instillation. The degree of toxicity was evaluated by the method of Draize *et al.* (4).

Newborn Rabbits—Three drops of 1:64 dilution of

1:25	Cornea	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0
	Iris	0	0	0	0	0	1	2	0	0	0	2	2	0	0	0
	Conjunctiva	0	1	0	0	0	4	4	0	0	0	4	4	1	0	0

imidecyl iodine was instilled in the left eye of five newborn rabbits (7–10 days old) four times daily for 5 days. The right eye served as a control. The corneas, irises, and conjunctivae were observed for erythema, vesiculation, edema, and other signs of irritation during the days of administration and daily thereafter for 2 months. The degree of toxicity was evaluated by the method of Draize *et al.* (4).

Rabbit Bladder Toxicity—Fifteen milliliter solutions of the following strengths of imidecyl iodine, *e.g.*, undiluted, 1:2, 1:10, 1:20, and 1:40 were each used in two animals and a dilution of 1:64 was used in four animals and of 1:128 in two animals. In each case the solutions were placed in an empty bladder of male and female adult domestic rabbits through a urethral catheter. The solutions were kept in the bladder for 30 min., after which the bladder was evacuated by catheter if urination was not spontaneous. Three animals given equal volumes of saline were used as controls. Each animal received three treatments at intervals of 24 hr., and 24 hr. after the last treatment, was killed and examined grossly and microscopically for abnormalities.

Chronic Toxicity—A group of three mature male dogs maintained on a basic diet of Purina laboratory chow (Ralston-Purina, St. Louis, Mo.) were given 1:15 dilutions of imidecyl iodine four times weekly. Dosage level was based on extrapolation of the calculated LD_{50} for rats. During the course of this experiment, the animals were examined daily for appearance, behavior, weight gain, and food consumption (5). After 90 days, one animal was sacrificed. At autopsy the entire carcass was examined grossly and the heart, lung, liver, kidney, spleen, and brain were removed and weighed, and portions of these organs were prepared for histological examination. The two other animals were sacrificed and examined in the same way at the end of 5 months.

RESULTS

The median lethality (LD_{50}) of imidecyl iodine for rats is given in Table I. The deaths were usually very rapid; nearly all fatalities were found within 18 hr. after dosage. No deaths occurred in treated animals after the ninth day. Prior to death, the rats showed depression, piloerection, and a crouched attitude indicative of abdominal pain. Immediately prior to death, each animal went into mild convulsions and regurgitated a small amount of brownish material. The survivors were lethargic for periods of 1 to 3 days after administration of the drug.

On postmortem the viscera contained a fairly uniform pattern of lesions which included mild thoracic and abdominal ascites, pulmonary emphysema, and petchiation, and grossly distended stomachs filled with a mixture of gas, food, and a dark greenish-brown fluid. Other lesions included gassy distention of the intestines, cloudy swelling and congestion of the liver, engorgement of the myocardial vessels, hyperemia, and tubule damage in the kidneys. Scattered and insignificant damage was found in other organs. The pattern of lesions was indicative of a toxic reaction affecting the vascular system. Death probably occurred from a combination of pulmonary lesions and distention of the abdominal viscera resulting in respiratory collapse and suffocation, perhaps partly due to the large volumes used.

The administration of such a large (10 ml.) quantity of solution *via* stomach tube apparently caused pylorospasm since no drug was found in the intestinal tract. Regurgitation, which is not a normal phenomenon in rats, occurred immediately prior to death. This was probably the result of gas pressure in the stomach overcoming the resistance of the distal esophagus to dilation in the moribund animals.

Acute Dermal Toxicity—The different concentrations of imidecyl iodine failed to cause any significant dermal reactions with the exception of reddening which disappeared shortly after removal of the agent.

Guinea Pig Sensitization—The challenging dose of imidecyl iodine failed to cause any abnormal or unique reactions at the time of injection or afterward.

Eye Toxicity—*Adult Rabbits*—The results of instillation of imidecyl iodine in the eyes of adult rabbits are reported in Table II. With all dilutions, the eyes were back to normal by 96 hr. after each instillation of the maximum concentration. There were no signs of damage in the corneas of any of the animals. Sixty days after the tests, the eyes of these animals were still normal.

Newborn Rabbits—Imidecyl iodine concentration of 1:64 failed to produce any clinical evidence of ocular irritation during treatment or within the 2-month period following treatment.

Rabbit Bladder Toxicity—Gross and microscopic examination of the urinary bladders and viscera of rabbits treated with various concentrations of imidecyl iodine indicated that dilutions up to and including 1:64 were tissue irritants. Dilutions stronger than 1:64 were accompanied by effects ranging from mild toxicosis to sudden death. The deaths occurred in the animals given undiluted and 1:2 dilutions of imidecyl iodine in water. At a dilution of 1:128 there were no gross or microscopic lesions that could be attributed to the iodophor. Dilutions of 1:10 or greater produced local lesions in the bladder. The lungs of the animals receiving up to 1:64 dilutions of imidecyl iodine contained congested areas and small areas of emphysema and consolidation. The extent and severity of the lesions dropped markedly between 1:40 and 1:64 dilutions. However, there was no correlation between dosage levels and extent and severity of lesions in the 1:10 through 1:40 dilutions. In the kidneys, glomerular and tubular damage compatible with toxicosis, *e.g.*, nonsupportive nephritis, epithelial and glomerular swelling, and edema were seen in a majority of the animals receiving dilution through 1:64 of the iodophor. Other accompanying lesions ranged through a wide spectrum that had no uniformity and were more compatible with naturally occurring lesions in conventional animals than with iodophor toxicity.

In dilutions up to 1:10, death occurred shortly after injection. The lungs were congested, but the lesions were not sufficient to account for the collapse of the animals. Death was probably the result of shock.

Dilutions of 1:10 through 1:40 produced urinary bladder lesions consisting mainly of edema and local hemorrhage. In these animals, the bladder was empty at the time of examination. There were no other significant lesions except in the lungs, and these could be attributed to the manner in which the animals were killed (*e.g.*, Na pentobarbital intracardially) rather than to the imidecyl iodine. Dilutions of 1:40 were, at least as far as postmortem evidence is concerned, on the borderline toxic level.

Two rabbits receiving the 1:64 dilution were killed by pentobarbital intracardially, and the remaining two by concussion. The two killed by pentobarbital had appreciable pulmonary congestion; one of the other two had inflammatory lesions and the second had minimal congestion. The bladders of all animals were slightly edematous, but the lesions were minimal.

Dilutions of 1:128 produced no visible lesions in the urinary bladder, nor any lesions elsewhere in the body which could be attributed to imidecyl iodine toxicity. At this dilution the drug exercised no observable effect upon the viscera. Lesions present were evaluated as conditions existing prior to the experiment and were not apparently related to the iodophor.

Chronic Toxicity—There was no clinical evidence of adverse effects in the dogs continuously fed imidecyl iodine. Gross and microscopic postmortem examination showed no lesions which could be attributed to imidecyl iodine. All organs and structures were examined grossly. Organs examined microscopically were the heart, lungs, liver, kidneys, and urinary bladder.

SUMMARY

The LD_{50} potential toxic effects of sublethal doses of imidecyl iodine were investigated. Oral lethal dosage in rats, skin sensitization, and dermal reaction in guinea pigs, corneal, and urinary bladder reaction in rabbits, and the effect of chronic sublethal dosage in dogs were studied. LD_{50} values measured by oral administration to male and female Wistar rats were, respectively, 14.0 ± 2.1 and 11.0 ± 1.5 ml./Kg. Corneal reactions, skin sensitization, and dermal reactions were transient or negative.

Dilutions of 1:64 infused into the urinary bladder of rabbits produced edema of the bladder musculature. Dilutions of 1:40 and below were accompanied by lung and kidney damage in addition to the bladder lesions. Full strength and 1:2 dilution produced collapse and death, probably from shock. Dogs fed diets containing imidecyl iodine over a period of 5 months exhibited no toxic lesions or symptoms

Mechanism and Stereochemistry of Epoxy Ether Formation and Cleavage IV

By HARSHADKUMAR PATEL* and GILBERT HITE

An independent proof of the mechanism and stereochemistry of epoxy ether formation from (−)-1-methyl-3-benzoyl-3-chloropiperidine[(−)-I] is presented.

IN PREVIOUS PAPERS on this subject (1–5) the anomalous racemization observed in the sequence, (−)-I → (−)-II → (±)-III (1) was rationalized on the basis of an asymmetric induction at the carbonyl carbon followed by halide ejection with concomitant participation of the free electron pair on nitrogen and α-C-symmetrization (*cf.* IV). This requires formation of identical amounts of the two possible diastereoisomeric epoxy ethers, epimeric at the spiro carbon, both arising from IV. The antipodal intermediate formed in the asymmetric induction would give rise to the remaining two diastereoisomeric epoxy ethers, also epimeric at the spiro carbon, but enantiomorphic to the first set. Since the product must then be a unique mixture consisting of identical quantities of erythro and threo epoxy ethers in identical degrees of optical purity, the optical activity of II must be attributed to the ketal carbon and not to the carbon common to both rings.

The *total* optical specificity of the reaction sequence, α-(+)-I $\xrightarrow{O}$ β-(−)-II → β-(+)-III (2,3) in which participation of the electron pair on nitrogen is obviated, has made possible this study. The interjection of an analogous but symmetrical cyano blocking group, following epoxy ether [(−)-II] formation, permitted observation of the opticochemical course of the conversion of (−)-I to (−)-II. (Scheme I.)

After treatment of (−)-1-methyl-3-benzoyl-3-chloropiperidine [(−)-I] with sodium methoxide in methanol, the total levorotatory mixture containing 2 - methoxy - 2 - phenyl - 5 - methyl - 1 - ox - 5 azaspiro[2.5]octanes (II) was isolated and was allowed to react with cyanogen bromide in order to effect demethylation. The total, dextrorotatory, benzene soluble fraction, containing 2-methoxy-2-phenyl-5-cyano-1-ox-5-azaspiro[2.5]octanes (V), was treated with dilute aqueous acid to give racemic 1-cyano-3-benzoyl-3-hydroxypiperidine (VI).

Since this epoxy ether cleavage is analogous to the totally optically specific transformation of β-(−)-II to β-(+)-III (2, 3), it is clear that the carbon common to both rings in (+)-V, and thus in (−)-II, must be present in both configurations, *equally*. Accordingly, the previously proposed (1) salient features of epoxy ether [(−)-II] formation from (−)-I are unequivocally established.

EXPERIMENTAL[1]

(−) - 2 - Methoxy - 2 - phenyl - 5 - methyl - 1-ox-5-azaspiro[2.5]octanes [(−)-II]—This was prepared, as described earlier (1), from (−)-I, $[\alpha]_D^{25}$ (ethanol) −4.2° (c 15.00).

(+) - 2 - Methoxy - 2 - phenyl - 5 - cyano - 1-ox-5-azaspiro[2.5]octanes [(+)-V]—A solution of 4.67 Gm. (20 mmoles) of (−)-II, $[\alpha]_D^{28}$ (ethanol) −1.28° (c 15.32), in 20 ml. of dry benzene was slowly added to a solution of 8.5 Gm. (60 mmoles) of cyanogen bromide in 30 ml. of dry benzene. The mixture was heated to 50° and stirred for 48 hr. The insoluble salts (0.8 Gm.) were filtered off

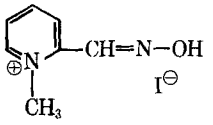
Synthesis of Aldoxime Analogs of Arecoline as Reactivators of Organophosphorus Inhibited Cholinesterase

By J. N. WELLS, J. N. DAVISSON, I. BOIME, D. R. HAUBRICH, and G. K. W. YIM

A series of arecoline-like aldoximes were synthesized and evaluated as potential reactivators of organophosphate-inhibited cholinesterase. These arecoline analogs were patterned after the potent quaternary oximes 2-PAM and TMB-4 and were synthesized by sodium borohydride reduction of the corresponding pyridinium aldoxime. Biological results show that although these aldoximes are less toxic than the quaternary aldoximes, they are much less effective as reactivators. They did exhibit weak muscarinic activity (1/60 that of arecoline) on dog blood pressure and guinea pig ileum.

THE EFFICIENT reactivating property of 2-pyridine aldoxime methiodide (2-PAM) has been attributed to the affinity of its quaternary nitrogen for the anionic site of cholinesterase (1). This affinity could cause the nucleophilic aldoxime oxyanion to be in a favorable position for reactivating phosphorylated cholinesterase.



2-PAM

The cholinergic agent arecoline contains a tertiary amine. Since the muscarinic activity of arecoline has been shown to be dependent on its protonated cationic nitrogen (2), the arecolinium ion might also possess a marked affinity for the anionic site of cholinesterase. Therefore, aldoxime analogs of arecoline, which should enter the CNS readily, might be expected to provide good reactivation of phosphorylated cholinesterase in the brain.

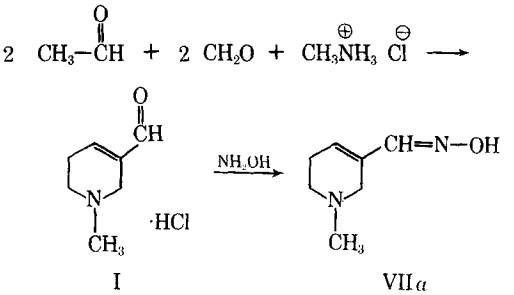
DISCUSSION

The authors have prepared a few 1,2,5,6-tetrahydropyridine aldoximes and report here the chemistry and pharmacological data. 1-Methyl-1,2,5,6-tetrahydropyridine-3-aldoxime (VII*a*) has been prepared by the reaction of formaldehyde, methylamine hydrochloride, and acetaldehyde to give 1-methyl-1,2,5,6 - tetrahydropyridine - 3 - carboxaldehyde (I) which was isolated as the oxime (3). (Scheme I.)



Scheme I

This reaction is quite laborious and gave poor yields of impure VII*a*. Thus, a more general method was sought which would be applicable to 1-alkyl-1,2,5,6-tetrahydro-3- and 4-aldoximes.

Potassium borohydride has been shown to reduce *N*-methylpyridinium iodide (II) to 1-methyl-1,2,3,6-tetrahydropyridine (III) (4). Similarly, the reduction of methyl nicotinate methiodide (IV) with

and the benzene and cyanogen bromide were removed under reduced pressure. The residual oil was dissolved in dry benzene and treated with carbon. The mixture was filtered through sintered glass. The solvent was removed under reduced pressure (0.01 mm. Hg/24 hr.) to give a colorless oil, 3.04 Gm. (12.3 mmoles, 61.5%), $[\alpha]_D^{28}$ (benzene) +2.1° (c 3.04), exhibiting a band at 2208 cm.$^{-1}$ (film) (C≡N) in the infrared spectrum. There were no bands in the —OH or C=O region.

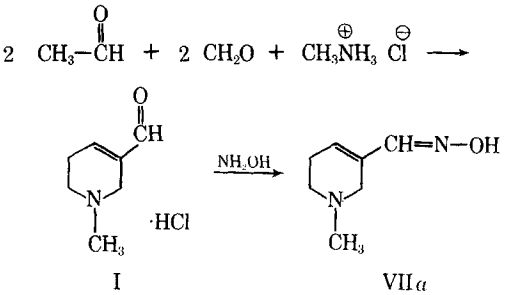
DISCUSSION

The authors have prepared a few 1,2,5,6-tetrahydropyridine aldoximes and report here the chemistry and pharmacological data. 1-Methyl-1,2,5,6-tetrahydropyridine-3-aldoxime (VII*a*) has been prepared by the reaction of formaldehyde, methylamine hydrochloride, and acetaldehyde to give 1-methyl-1,2,5,6 - tetrahydropyridine - 3 - carboxaldehyde (I) which was isolated as the oxime (3). (Scheme I.)

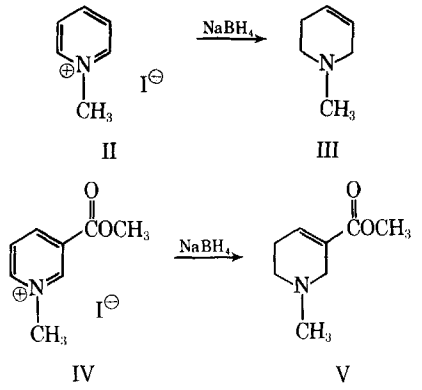


Scheme I

This reaction is quite laborious and gave poor yields of impure VII*a*. Thus, a more general method was sought which would be applicable to 1-alkyl-1,2,5,6-tetrahydro-3- and 4-aldoximes.

Potassium borohydride has been shown to reduce *N*-methylpyridinium iodide (II) to 1-methyl-1,2,3,6-tetrahydropyridine (III) (4). Similarly, the reduction of methyl nicotinate methiodide (IV) with

sodium borohydride has been shown to give arecoline (V) (5). The conditions of these reactions seemed applicable to these systems. (Scheme II.)

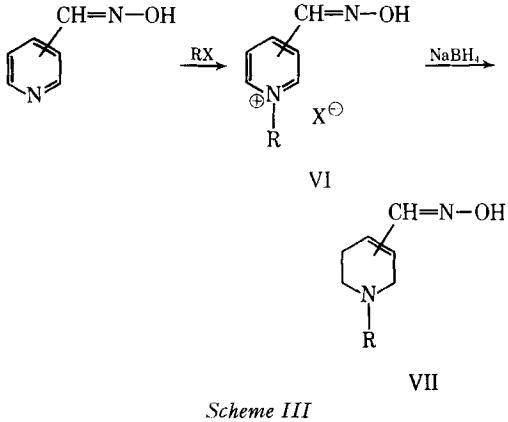


Scheme II

The quaternary pyridine aldoximes (VI) were prepared by reacting the pyridine aldoxime with an appropriate alkyl halide. Reduction of the resulting pyridinium aldoxime with sodium borohydride in methanol or ethanol gave the 1-substituted 1,2,5,6-tetrahydropyridine-3- or 4-aldoxime (VII) in 50–74% yield (Table I). (Scheme III.)

TABLE I—1-SUBSTITUTED-1,2,5,6-TETRAHYDROPYRIDINE-3- OR 4-ALDOXIMES

	Position of Aldoxime	*n*	R	% Yield from Reduction
VII*a*	3	1	CH_3	59
VII*b*	4	1	CH_3	50
VII*c*	4	2	$(CH_2)_3$	74



Scheme III

Elemental analysis of these compounds (VII) indicated that the tetrahydropyridine system had been formed but the position of the double bond had to be established.

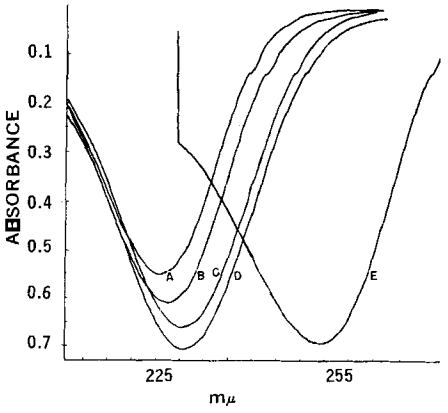


Fig. 1—Ultraviolet absorption spectrum of tetrahydropyridine aldoximes. Key: A, *VII*b *in 0.05* N *HCl;* B, *VII*a *in 0.05* N *HCl;* C, *VII*b *in water;* D, *VII*a *in water;* E, *VII*b *in base (pH 11.5). Bausch & Lomb model 505 spectrophotometer.*

Infrared and NMR spectra were consistent with the Δ-3 system but were not stringent proof. Another point of confusion arose from the fact that Mannich reported the melting point of VII*a* hydrochloride to be 240–242° (3), while the product (VII*a* hydrochloride) from the sodium borohydride reduction melted at 261.5–262°.

The ultraviolet spectrum of compound VII*b* in water showed $\lambda_{max.}$ 226 mμ; ϵ = 17,700. The $\lambda_{max.}$ 226 mμ is consistent with that expected of an α, β-unsaturated aldoxime (6). The molar absorptivity clearly indicates conjugation. Since very little shift was noted when the spectrum was obtained from an acidic solution of any of the compounds (VII*a* or *b*), conjugation with the amino nitrogen may be ruled out in all cases (see Fig. 1). The slight shift to shorter wavelengths in acidic solution must have been due to suppression of ionization of the oxime hydroxyl. The U.V. spectrum of VII*a* in water gave $\lambda_{max.}$ 226 mμ; ϵ = 17,100. Again a conjugated oxime is indicated. Of the two possibilities for location of the double bond, only the 3–4 position should give the same $\lambda_{max.}$ as compound VII*b*. If the double bond of VII*a* were in the 2–3 position one would also see a contribution from the amine electrons which would give rise to absorption at a longer wavelength.

The results of the pharmacological evaluation of compounds VII*a*, *b*, and *c* are summarized in Table II. Only 6–20% reactivation of the TEPP inhibited erythrocyte cholinesterase was obtained with these aldoximes, whereas 60–75% reactivation was observed with even lower concentrations of 2-PAM. In agreement with this weak *in vitro* activity was the lack of protection afforded by the tetrahydropyridine aldoximes against TEPP toxicity in mice. In contrast, 2-PAM afforded 80% protection, and all six mice injected with 20 mg./Kg. TMB-4 survived the TEPP treatment. Only one mouse survived of 22 control mice that were injected with the 1 mg./Kg. dose of TEPP.

Compound VII*a* showed definite muscarinic activity. It caused contractions of the isolated

[a] Bovine erythrocyte ChE, inhibited with $10^{-7}M$ TEPP, was incubated with the aldoximes for 55 min. ChE activity was measured manometrically (Umbreit *et al.*, 1964). [b] Swiss albino mice weighing 25–35 Gm. were used. [c] Aldoximes were given 6–8 min. prior to TEPP; TEPP killed 21 of 22 control mice. [d] Dissociation constants were determined potentiometrically by titration of 0.01 *M* solutions of the compounds with 0.1 *N* KOH according to the method of Albert and Serjeant (1962).

guinea pig ileum, gave depressor responses in the anesthetized cat, and induced salivation, urination, and defecation in mice. These actions were readily antagonized by atropine. When atropine was combined with the aldoxime pretreatment, the mice were still not protected from the lethal effects of TEPP. Thus, it is unlikely that beneficial effects of possible reactivation induced by the aldoximes were masked by the toxic muscarinic effects of the aldoximes.

The ionization data offer a feasible explanation for the low activity of the tetrahydropyridine aldoximes. The pKa values of compounds VII*a* and VII*b* (8.04 and 8.15, respectively) were close to the dissociation constant of the basic ring nitrogen of arecoline, and were therefore attributed to the dissociation of the basic ring nitrogens. Similarly, the pKa values of compounds VII*a* and VII*b* (10.84 and 10.91, respectively) were close to the dissociation constant of the aldoxime group of compound VIII (the methiodide of VII*a*) and were attributed to the dissociation of the aldoxime groups. The data in the last column indicate that, as predicted, the ring nitrogen of the tetrahydropyridine aldoximes would be sufficiently protonated at physiological pH to form the cationic head which could be attracted to the anionic site of the phosphorylated enzyme. The aldoxime groups of compounds VII*a* and VII*b* were almost completely unionized, as contrasted to the 30% ionization of the aldoxime group of 2-PAM. Thus, the weak reactivating activity of the tetrahydropyridine aldoximes can be attributed to insufficient ionization of the oxime group to the active oximate form. The importance of the steric configurations of 2-PAM and the nonaromatic aldoximes could not be ascertained from the present study.

EXPERIMENTAL

1 - Methyl - 1,2,5,6 - tetrahydropyridine - 4-aldoxime (VIIb)—To a solution of pyridine-4-aldoxime methiodide (7) (10.6 Gm., 0.04 mole) in 200 ml. of methanol was added 6.0 Gm. (0.16 mole) of sodium borohydride in small portions. The reaction was stirred continuously and the temperature was maintained between 25–30°. The solution was stirred for an additional 0.5 hr. at room temperature after the addition was completed.

The solution was concentrated *in vacuo* to 50 ml. and diluted with 200 ml. of water. The aqueous solution was saturated with Na_2CO_3 and extracted with ether. The ether solution was dried over K_2CO_3 and then removed *in vacuo* to give 2.8 Gm. (50% yield) of white crystalline solid, m.p. 156–158°.

The hydrochloride was prepared and recrystallized from ethanol, m.p. 241–242°.

Anal.—Calcd. for $C_7H_{12}N_2O \cdot HCl$: C, 47.59; H, 7.42. Found: C, 47.43; H, 7.48.

1 - Methyl - 1,2,5,6 - tetrahydropyridine - 3-aldoxime (VIIa)—Pyridine-3-aldoxime methiodide (7) (8.6 Gm., 0.03 mole) was reduced with 4.7 Gm. (0.12 mole) of $NaBH_4$ using the same conditions as for VII*b* except that ethanol (200 ml.) was used as solvent. Using the work-up described for VII*b*, 2.5 Gm. (59% yield) of VII*a* was obtained. The hydrochloride was prepared and recrystallized from ethanol, m.p. 261.5–262°. [Lit. (3) m.p. 240–242°.]

Anal.—Calcd. for $C_7H_{12}N_2O \cdot HCl$: C, 47.59; H, 7.42. Found: C, 47.73; H, 7.26.

The methiodide (VIII) was prepared by reaction of VII*a* with methyl iodide in acetone, m.p. 181–182°.

1,3 - Bis(4 - formyl - 1,2,5,6 - tetrahydropyridyl)-propane Dioxime (VIIc)—To a solution of 7.0 Gm. (0.02 mole) of 1,3-bis(4-formylpyridinium bromide)-propane dioxime (8), in 200 ml. of methanol, was added portionwise 4.8 Gm. (0.13 mole) of sodium borohydride. A precipitate formed as the reaction proceeded. The solid was collected and dissolved in 20 ml. of 6 *N* hydrochloric acid. Ethanol (100 ml.) was added. It was necessary then to add a small quantity of ether to initiate crystallization. After recrystallization from ethanol, 2.6 Gm. (77% yield) of white crystalline solid was obtained, m.p. 246–247° dec.

Anal.—Calcd. for $C_{15}H_{24}N_4O_2 \cdot HCl$: C, 49.32; H, 7.12. Found: C, 49.08; H, 7.25.

Effect of Griseofulvin Upon Lipid Films at the Air-Water Interface

By RONALD P. QUINTANA, ANDREW LASSLO, and SANDRA L. OUSLEY

The effect of griseofulvin upon monomolecular films of stearic acid and cholesterol has been determined by comparing the pressure-area curves obtained when these film-forming materials were spread on a redistilled water substrate and one consisting of a solution of griseofulvin in redistilled water.

IN CONNECTION with studies on the structural requirements and physicochemical characteristics associated with a compound's capacity for anchoring to dermal tissue constituents or for enhancing its localization in the latter, the authors sought to determine the effects of griseofulvin upon monomolecular films of two representative lipid dermal constituents (1), *i.e.*, stearic acid and cholesterol.

EXPERIMENTAL

Materials—Stearic acid was obtained in purity greater than 99%, m.p. 71.1–72.0°.[1] Chromatographically pure cholesterol (99 +%) was procured (Sigma Chemical Co.), m.p. 148.8–149.4°. Griseofulvin was recrystallized from benzene, yielding white needles, m.p. 220.5–221.4°; $[\alpha]_D^{26}$ +331.03° (c 1.015 in acetone); $\lambda_{max.}^{EtOH}$ 215 mμ (ε 23,107), 235 (22,754), 292 (23,636), 330 (5,644); $\lambda_{max.}^{CHCl_3}$ 5.85 μ (C=O), 6.02 (COC=C). Its properties were consistent with those reported in the literature (2, 3).

Anal.[2]—Calcd. for $C_{17}H_{17}ClO_6$: C, 57.88; H, 4.86; Cl, 10.05. Found: C, 57.79; H, 4.78; Cl, 10.30.

The substrate water was obtained by redistillation through a 45-cm. Vigreaux column from aqueous permanganate (4). It had a pH of 6.0, and gave a value of 0.15 p.p.m. in conductometric measurements of ionizable substances expressed as sodium chloride. Solutions of griseofulvin (20 mcg./ml.; $5.7 \times 10^{-5} M$) were prepared by boiling the substrate water to which griseofulvin had been added (5); the absorbance at 295 mμ for the solutions prepared in this manner (5) was 1.35 ± 0.02.

Instrumentation and Methods—The surface balance utilized is a refinement of the commercially available Hydrophil balance (Central Scientific Co.) (see Fig. 1). The trough and all Teflon parts of the apparatus which come into contact with the substrate and monolayer were thoroughly cleaned with reagent grade benzene followed by rinsing with spectro-grade benzene and redistilled water. The equipment was assembled and used within an isolation cabinet (Kewaunee Scientific Equipment). All experiments were carried out at room temperature (substrate temperature, 24 ± 2°).

After the cleanliness of the substrate surface was checked, the compression barrier was positioned (initial area, 490–560 cm.²), and the film-forming material was applied to the surface of the substrate by means of an Agla micrometer-syringe (Burroughs Wellcome & Co.), in spectro-grade benzene (0.125–0.176 μmole/0.05–0.10 ml.). Following a period of 20 min. during which the solvent evaporated, the compression barrier was moved slowly toward the float. Usually 2-mm. decrements were employed, starting about 3 cm. before pressure was first observed; as the pressure increased rapidly with a small decrease in area, 1-mm. decrements were used. In each case, there was a 1-min. interval between the time when the barrier was stopped and that when the reading of surface pressure was made.

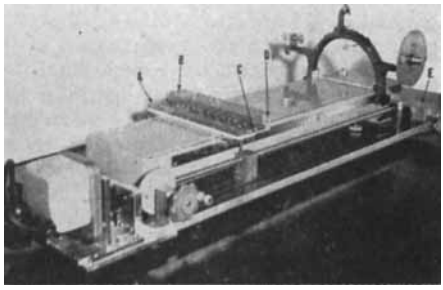

Fig. 1—The modification of the surface balance. The trough is Teflon coated, and the float and end piece systems, patterned after those of Mann and Hansen (6), are constructed of Teflon. Key: A and B, compression barrier units (solid Teflon attached to solid brass) transported at uniform rates by motor-driven operation; C, restraining arm for part B; D, scale pointer; E, switch providing automatic cessation of barrier movement.

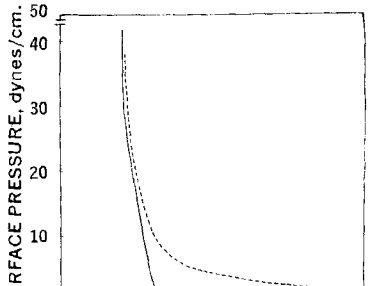

Fig. 2—Surface pressure vs. *area per molecule for stearic acid spread on: redistilled water (———); 5.7 × 10⁻⁵ M solution of griseofulvin in redistilled water (– – – –). In the latter case the corrected surface pressure is shown.*

Received April 12, 1967, from the Department of Medicinal Chemistry, College of Pharmacy, University of Tennessee, Memphis, TN 38103

Accepted for publication June 7, 1967.

This investigation was supported by research contract DA-49-193-MD-2636 from the U. S. Army Medical Research and Development Command, Washington, D. C.

The authors acknowledge valuable discussions with Dr. Herman E. Ries, Jr., American Oil Co., and with Dr. Robert G. Crounse, Johns Hopkins University School of Medicine. The authors also acknowledge the work of Mr. W. A. Frase, who constructed the modifications incorporated in the surface balance, and that of Mr. B. Carpenter, who prepared the Teflon end piece system. The authors thank Dr. K. E. Avis for conductometric measurements, and Dr. R. J. Grabenstetter, Procter and Gamble Co., for the stearic acid, and Mr. G. R. Goetchius, Ayerst Laboratories, for the griseofulvin employed in this investigation.

[1] Melting points are corrected; they were determined with a Büchi melting point apparatus.

[2] Analyses were performed by Drs. G. Weiler and F. B. Strauss, Oxford, England.

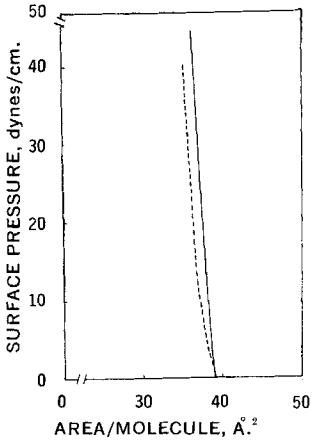

Fig. 3—Surface pressure vs. *area per molecule for cholesterol spread on: redistilled water (———); 5.7 × 10⁻⁵ M solution of griseofulvin in redistilled water (- - - -). In the latter case the corrected surface pressure is shown.*

After the film collapsed, a check was made for monolayer leakage.

RESULTS AND DISCUSSION

Each of the pressure-area isotherms (Figs. 2 and 3) was obtained by averaging the results of three independent experiments; the experimental points deviated from the curve average generally by no more than 0.2 Å.² per molecule, at a given surface pressure. It should be noted that the pressure-area curves for stearic acid and cholesterol spread on water agree well with those reported by Walker and Ries (7) and Taylor and Haydon (8). The surface pressure values for stearic acid and cholesterol, spread on the aqueous solution of griseofulvin, are corrected.[3] This permitted direct comparison with values obtained when the substrate was redistilled water.

The broken line in Fig. 2 indicates that griseofulvin was incorporated into the monolayer, and that, as the pressure increased, most of it was forced out of the film. The collapse pressure for this curve was slightly lower than that for pure stearic acid; this appears to be consistent with the observation (10) that the presence of irregularly shaped molecules in films of regularly oriented molecules renders the film less stable.

[3] The correction factor (8, 9) was determined to be 0.6 dyne/cm. using a du Nouy tensiometer and employing the ring method by procedures previously described (4).

The curve for cholesterol spread on the solution of griseofulvin (Fig. 3) is displaced slightly toward a lower area per molecule compared with that spread on redistilled water. This suggests that griseofulvin either facilitates a closer packing of the cholesterol molecules than that in the film of the pure substance, or that griseofulvin causes some of the cholesterol molecules to leave the area-determining positions in the surface; the latter may be, possibly, due to a process of interfacial dissolution (10).

The data indicate a somewhat limited but unequivocally significant affinity of griseofulvin for stearic acid. This is interesting in the light of evidence (5, 11) that the presence of lipid material in skin tissue may be associated with uptake of griseofulvin. While the authors are aware of the fact that a response to a given compound *in vitro* cannot be interpreted as evidence of the latter's corresponding involvement *in vivo*, even without conclusive causal connection, one should not underestimate the importance of leads of this nature. In the instance of the interactions observed in the cholesterol monolayer, one is tempted to interpret the isotherm also in terms of a type of affinity; it is possible to visualize that some of the cholesterol molecules shifted from their area-determining positions toward the aqueous phase because of their affinity for the griseofulvin.

Studies concerned with the affinity of a series of grisan derivatives for stearic acid and other lipid constituents have been recently completed (12, 13). They are expected to be supplemented with complementary studies.[4]

Investigations of Philippine Plants for Alkaloids, Antimalarial Agents, and Antineoplastic Agents

By F. D. POPP, J. M. WEFER, G. ROSEN, and A. C. NOBLE

Extracts of 28 different Philippine plants were prepared and the extracts tested for alkaloids. The extracts were also screened, in many cases, for antimalarial and antineoplastic activity. In some cases preliminary fractionation into petroleum ether soluble and ethanol soluble extracts were made.

THE IMPORTANCE of screening plant materials for various chemical constituents of medicinal importance is well established. Plants have provided many drugs which are being used for the prevention or cure of diseases or which have been the basis for synthetic drugs. This work was directed to the search for new drugs which may find application as antineoplastic agents or as antimalarial agents.

EXPERIMENTAL

Materials—All plant materials were collected, identified, and supplied in the air-dried state by Dr. Demetrio Mendoza, Philippine National Museum, Manila.

Received April 21, 1967, from the Department of Chemistry, Clarkson College of Technology, Potsdam, NY 13676
Accepted for publication June 12, 1967.
The authors thank Dr. D. Mendoza, the National Museum, Manila, for assistance in obtaining the plant materials and for many helpful suggestions and Dr. L. Rane and Dr. J. L. Hartwell for assistance in having the extracts screened.
This investigation was supported in part by grant T-234 from the American Cancer Society and grant CA-07891 from the National Cancer Institute, U. S. Public Health Service, Bethesda, Md.

TABLE II—MALARIA SCREENING DATA[a]

No.[b]	Dose,[c] mg./Kg.	Survival Time, Days[d] Test	Control	Notes
2a	160	6.4	6.1	Toxic at 640 mg./Kg.
3	640	8.0	6.2	Some toxicity

[a] Samples sent to Dr. L. Rane, University of Miami, for screening; results received from Walter Reed Army Medical Center. Screening against *Plasmodium berghei* in mice infected with a lethal dose 3 days prior to administration of the extract. [b] Refer to Table I. [c] At least three different doses were given for each extract, the highest nontoxic dose is recorded here. [d] A compound is considered to be active when the survival time of the test is more than twice the survival time of the control.

Preparation of Extracts—The air-dried plant materials were ground and extracted in a Soxhlet extractor until a fresh extract had relatively little color to it. All plant materials were extracted with 80–90% ethanol and the ethanol extract was concentrated to dryness *in vacuo*. The residue from this concentration was tested for alkaloids and submitted for screening.

In selected cases a fresh batch of air-dried plant materials were extracted first with petroleum ether (naphtha) and then with 80–90% ethanol. These individual extracts were concentrated as noted above.

Screening—Most of the concentrated extracts were submitted to Dr. J. L. Hartwell, Cancer Chemotherapy National Service Center (CCNSC), for anticancer screening under the CCNSC standard protocol, and the anticancer results included in this paper were supplied by the CCNSC. Many extracts were also submitted to Dr. L. Rane, University of Miami, for screening against *Plasmodium berghei* in mice. The antimalarial results included in this paper were supplied by the Walter Reed Army Medical Center.

Alkaloid Tests—The concentrated extract (0.1 Gm.) was dissolved in 10 ml. of 0.5% hydrochloric

[a] Screening results received from Cancer Chemotherapy National Service Center (CCNSC), National Institutes of Health. All screening done by CCNSC contract screeners according to standard CCNSC screening protocol. [b] Refer to Table I. [c] ED_{50}, dose that inhibits growth to 50% of control growth. Slope, difference in result for a tenfold difference in dose. [d] L-1210 lymphoid leukemia. [e] Sarcoma 180. [f] Dunning leukemia (solid). [g] Walker carcinosarcoma 256 (intramuscular). [h] Lewis lung carcinoma.

acid and 1 ml. of this solution was added to each of the standard alkaloid test reagents used.

RESULTS AND DISCUSSION

Since many substances can interfere with the alkaloid test reagents these should be taken only as an indication of the possible presence of alkaloids. Ten of the 28 plants examined had four or five positive alkaloid tests out of the five run and it would appear that these materials almost certainly contain alkaloids (Table I.). Seven additional plant extracts had three positive tests and thus these could be considered as having a high probability of containing alkaloids. As might be expected, the petroleum ether extracts contained no alkaloids and thus the petroleum ether extract followed by an ethanol extract provides a good preliminary separation of some of the nonalkaloid components from the alkaloids.

Based on the standards of activity set by the Walter Reed Army Medical Center, none of the extracts tested could be considered as being active against *P. berghei* in mice (Table II.). Only 4 of the 13 extracts screened for antimalarial activity extended the survival time more than 1 day beyond the control and the most active, *Cinnamomum mercadoi vidal*, had only about one half the extension in survival time needed to be considered an active compound.

Five (serial No. 2, 4, 5, 23, and 25) of the original ethanol extracts had an activity worthy of note against the KB cell culture (Table III.). In the case of *Sphaeranthus africanus*, this activity was also present in the petroleum ether extract but not in the ethanol extract which followed the petroleum ether extract. With *Anona squamosa* the activity was not present in the petroleum ether extract, while both *Calophyllum blancoi* and *Straphanthus cumingii* had activity in the ethanol extract which followed the petroleum ether extraction. None of the extracts had outstanding activity against any of the animal tumors but five (serial No. 2, 9, 16b, 23, and 28a) had at least moderate activity against two animal systems each. Two (serial No. 21 and 28b) had moderate activity against one system each. It is of interest to note that only two of the compounds active in the cell culture screen had any appreciable activity in animal screens, *A. squamosa* and *Phaseolus aureus*.

SUMMARY

Of 28 Philippine plants studied, between 10 and 17 could be considered to contain alkaloids.

None of the extracts screened had any appreciable antimalarial activity, although one had a slight indication of activity.

Five of the plants were active against KB cell culture, and a number had moderate activity against a variety of animal cancers.

Improvement of the Color Stability of Parenteral Solutions of Papaverine Hydrochloride

By D. E. GRIFFITH

Disodium ethylenediaminetetraacetate (EDTA) 0.005 per cent successfully inhibits color formation in parenteral papaverine hydrochloride solutions.

PAPAVERINE HYDROCHLORIDE, one of the alkaloids of opium, is used primarily as an antispasmodic for smooth muscle, including arterial (1). It has also been prepared synthetically, and is chemically the hydrochloride of 6, 7, 3′, 4′-tetra-methoxy-1-benzylisoquinoline (1).

The chemical stability at room temperature of papaverine hydrochloride injection, as determined by the N.F. XII alkaloid extraction method, is extremely good. There is no detectable loss in potency in 4 years. However, an amber color starts to form within 1 year at 25° and within 1 month at 37°.

Disodium ethylenediaminetetraacetate (EDTA or sodium edetate) is a sequestering agent which has been used in medicine primarily as a binding agent in heavy metal poisonings; the usual dose being 75 mg./Kg. of body weight of a 20% solution (2). Salk poliomyelitis vaccine has been stabilized with sodium edetate, 7 : 20,000.[1]

Received March 22, 1967, from the Research and Development Laboratories, Eli Lilly & Co., Indianapolis, IN 46206

Accepted for publication June 19, 1967.

[1] Eli Lilly and Co.

The use of sodium edetate to prevent discoloration of pharmaceuticals is recorded several times in the literature (3–8). Discoloration has been prevented in morphine, phenylephrine, sodium sulfacetamide, procaine, and ajmaline solutions. Amounts of sodium edetate used vary from 0.005–0.04% in the references cited.

The purpose of this study was to inhibit the color formation of papaverine hydrochloride injection without changing the chemical stability. The approach was through use of sodium edetate while controlling all pertinent variables.

EXPERIMENTAL

The experiments were designed to determine the effect on papaverine hydrochloride color stability of (*a*) various concentrations of sodium edetate, (*b*) the container, (*c*) light and atmosphere, and (*d*) different papaverine hydrochloride raw material lots.

The experimental solutions were formulated with conventional laboratory apparatus, reagent grade chemicals, and water for injection U.S.P. The solutions were sterilized by either autoclaving or sterile filtration by Selas 02 candles. The glass-sealed ampuls and rubber-stoppered vials were flint type I glass. They were washed on conventional ampul washing machines and sterilized by

acid and 1 ml. of this solution was added to each of the standard alkaloid test reagents used.

dry heat. The glass-sealed ampuls were sealed by pull-type seals. The rubber-stoppered vials were sealed with West natural rubber stoppers and aluminum seals. Aging tests were conducted at room temperature and in ovens at 37° and 50°. Light exposure consisted of exposure to direct sunlight in a window facing south, and also by exposure on a shelf to fluorescent lights approximately 10 ft. away. Color was noted visually by observing against a white background. The N.F. XII assay procedure for papaverine hydrochloride was used in all cases. Samples of papaverine hydrochloride containing 0%, 0.005%, 0.01%, and 0.02% sodium edetate were formulated.

Samples of papaverine hydrochloride with 0.005% and no sodium edetate were stored in glass-seal ampuls and rubber-stoppered vials. Two lots of papaverine hydrochloride raw material were used for the experiments. Some ampuls of each section were exposed to light. Some contained a nitrogen atmosphere. All sections were exposed to 25, 37, and 50° temperatures. The samples were observed weekly to 2 months, then monthly to the point of discoloration.

DATA AND RESULTS

Oxygen in the air and light detract from color stability of papaverine hydrochloride solutions. The effect, however, is considerably less for sodium edetate formulations. Temperature has less effect on discoloration with the sodium edetate formulations, but still is a significant factor. It was found that color inhibition was maximum at 0.005% sodium edetate and was not improved by increasing the concentration of sodium edetate. The discoloration noted in glass-seal ampuls and rubber-stoppered vials was the same, indicating no effect from the package. No difference was seen between either of the lots of papaverine hydrochloride raw material. The type of sterilization (filtration *versus* autoclave) did not affect color formation. The amount of improvement of color stability can be seen in Table I.

CONCLUSIONS

Disodium ethylenediaminetetraacetate (sodium edetate or EDTA) successfully inhibits color formation in injectable solutions of papaverine hydrochloride at a concentration of 0.005%. Protection from light and oxygen offer additional protection. Chemical potency is still at 100% at 37° at 18 months. It is believed that the mechanism of protection is through sequestering trace quantities of heavy metals present, such as iron, which may react with chloride ions in the solution at the low pH (3.0–4.0) of these solutions. That this is so was determined by adding a tiny piece of iron oxide to each of several vials of papaverine hydrochloride which turned dark amber soon after.

New Compounds: Mannich Bases from 2-Phenylindolizines II. 3-Dialkylaminomethyl Derivatives

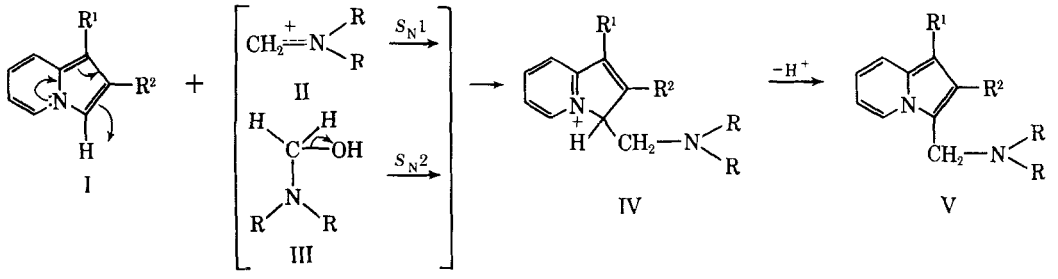
By WILLIAM B. HARRELL* and ROBERT F. DOERGE

In continuing the search for new therapeutic agents in the indolizine series, eight new Mannich bases derived from 1,2-diphenylindolizine have been synthesized. In addition, 1-(2-hydroxyethyl)-2-phenylindolizine, a new indolizine, and its 3-pyrrolidinomethyl derivative have been synthesized. The mechanism by which 1,2-disubstituted indolizines participate in the Mannich reaction has been discussed and alternate S_N1 and S_N2 routes have been proposed.

IN A PREVIOUS PAPER (1) the authors described the synthesis of a series of Mannich bases with the dialkylaminomethyl substituent at the C-1 position of the indolizine ring. The purpose of this investigation was to continue the search for useful therapeutic agents by synthesizing a series of 3-dialkylaminomethyl-1,2-diphenylindolizines. Eight new compounds were prepared in this series. In addition, a new indolizine, 1-(2-hydroxyethyl)-2-phenylindolizine, was synthesized and its 3-pyrrolidinomethyl derivative was prepared by the Mannich reaction (2). These compounds are currently being evaluated for possible activity on the central nervous system. If interesting activity is found, a study of the relationship of chemical structure with activity will be conducted.

DISCUSSION

The successful preparation of Mannich bases derived from indolizines in which the dialkylaminomethyl substituent occurs at the C-3 position has not been reported previously in the literature. In part I of this study the authors proposed a mechanism by which indolizines, based on their eneamine nature (3), participate in the Mannich reaction to form the 1-dialkylaminomethyl derivatives. Scheme I illustrates how this mechanism can be expanded to include the preparation of Mannich bases with the dialkylaminomethyl substituent occurring at the C-3 position. Alternate S_N1 and S_N2 routes are proposed.



Scheme I

EXPERIMENTAL

All melting points were taken on a Thomas-Hoover capillary melting point apparatus and are uncorrected. Elemental analyses were provided by Weiler and Strauss Microanalytical Laboratory, Oxford, England. Results of pharmacological screening will be reported elsewhere.

Materials—The starting indolizines were prepared by the Chichibabin synthesis (4) which involved condensing phenacyl bromide with the appropriate 2-substituted pyridine and heating the resulting pyridinium bromide in aqueous sodium bicarbonate. The preparation of 1,2-diphenylindolizine (I) has been reported previously (5).

Preparation of Mannich Bases from 1,2-Diphenylindolizine—The following general procedure was employed in the synthesis of these compounds. A mixture containing formaldehyde (0.05 mole), the secondary amine (0.05 mole), and 20–30 ml. of *N,N*-dimethylformamide (DMF) was stirred with a magnetic stirrer at room temperature for 30 min. The indolizine (0.01 mole) was then dissolved in the mixture and stirring was continued for 2 to 3 hr. In all cases except one, the product crystallized out during the stirring process. In the case of the 3-morpholinomethyl derivative, crystallization occurred after allowing to stand at room temperature for 24 hr. The preparation of 3-diethylaminomethyl-1,2-diphenylindolizine is described in the following section and is typical of the experimental procedures employed.

3 - Diethylaminomethyl - 1,2 - diphenylindolizine—To a 125-ml. conical flask equipped with a Teflon coated magnetic stirrer was added 4 ml. of 37% aqueous formaldehyde (0.05 mole), 3.7 Gm. diethylamine (0.05 mole), and 20 ml. DMF, and the mixture was stirred at room temperature for 30 min. To the mixture was added 2.7 Gm. 1,2-diphenylindolizine (0.01 mole) and stirring was continued for 3 hr. The product began to crystallize about 1 hr. after the addition of the indolizine.

I*h*	$C_{26}H_{27}N_3$			36–137	84	Ethyl acetate	C, 81.85 H, 7.13 N, 11.01	82.00 7.09 10.70
II*a*	$C_{21}H_{24}N_2O$	$HOCH_2CH_2$—		122–124	62	DMF–water	C, 78.72 H, 7.55 N, 8.74	78.65 7.54 8.72

Upon completion of the crystallization, the flask was placed in the refrigerator overnight. The product was filtered, washed with 25% ethanol, recrystallized from hot ethanol, and yielded 3.1 Gm. (87.5%), m.p. 114.5–115.5°.

Anal.—Calcd. for $C_{25}H_{26}N_2$: C, 84.71; H, 7.39; N, 7.90. Found: C, 84.32; H, 7.35; N, 7.82.

2 - (3 - Hydroxypropyl) - 1 - phenacylpyridinium Bromide—To a 1-L. conical flask, equipped with a magnetic stirrer and cooled in an ice bath was added 99.5 Gm. phenacyl bromide (0.5 mole) dissolved in 300 ml. ether. To the well-stirred ethereal solution was added dropwise 110 Gm. (0.8 mole) of 3-(2-pyridyl)-1-propanol over a 10-min. period. The temperature of the surrounding ice water bath was allowed to rise gradually to room temperature and stirring was continued for an additional 10 to 12 hr. The crystalline product was collected and washed with ether. Recrystallization from ethanol yielded 131 Gm. (78%), m.p. 138–140°. The identity of this new intermediate was confirmed by the successful ring closure to 1-(2-hydroxyethyl)-2-phenylindolizine in the Chichibabin reaction.

1 - (2 - Hydroxyethyl)-2-phenylindolizine—In a 2-L. beaker was placed 79 Gm. (0.24 moles) of 2 - (3 - hydroxypropyl) - 1 - phenacylpyridinium bromide and 1200 ml. of water. The beaker was placed in a water bath on a magnetic stirrer hot plate. The temperature of the reaction mixture was raised to about 60°, and 120 Gm. sodium bicarbonate was then added in small portions over a 10-min. period. After the addition, the temperature of the reaction mixture was gradually raised and maintained in the range of 80–85° with constant stirring for 2 hr. Foaming occurred during the reaction and was controlled by supplemental manual stirring with a glass rod. At the end of the reaction period, the crystalline product was filtered off while

hot by suction and washed with warm water. The air-dried product was immediately recrystallized from hot ethanol and yielded 51 Gm. (92%), m.p. 101.5–102.5°.

Anal.—Calcd. for $C_{16}H_{15}NO$: C, 80.98; H, 6.37; N, 5.90. Found: C, 81.10; H, 6.40; N, 5.81.

1 - (2 - Hydroxyethyl) - 2 - phenyl - 3 - pyrrolidinomethylindolizine—Six milliliters of 37% aqueous formaldehyde (0.075 mole) and 5.34 Gm. of pyrrolidine (0.075 mole) were combined with 30 ml. of dioxane and allowed to stand for 15 min. at room temperature. 1-(2-Hydroxyethyl)-2-phenylindolizine, 3.57 Gm. (0.015 mole), was dissolved in the mixture which was then allowed to stand at room temperature for 24 hr. The reaction mixture was transferred to an evaporating dish and the solvent was removed by blowing cold air over the surface. Scratching with a glass rod during evaporation failed to induce crystallization and a viscous oil was obtained. The oil was transferred to a 50-ml. conical flask with the aid of about 3 ml. of ethanol and placed in the freezer compartment of the refrigerator. The product crystallized after 1 week in the refrigerator. The crystals were removed by filtration, washed with 50% ethanol, and recrystallized from hot DMF–water. The yield was 2.9 Gm. (62%), m.p. 122–124°.

Anal.—Calcd. for $C_{21}H_{24}N_2O$: C, 78.72; H, 7.55; N, 8.74. Found: C, 78.65; H, 7.54; N, 8.72.

New Compounds: Amides Derived from 2-(2-Pyridyl)ethylamines

By JOSEPH SAM*

Basic amides containing the pyridylethyl- and piperidylethylamino groups have been prepared either from 2-vinylpyridines, 2-(2-aminoethyl)pyridines, or from substituted 2-(2-aminoethyl)piperidines. The amides possess some of the structural characteristics of the phenothiazine tranquilizers.

Amides, in general, exhibit a depressant effect on the central nervous system. Phenacetin, an analgesic amide, and barbital, an hypnotic amide derivative, were forerunners of many other biologically active amides (1).

Based on (*a*) the general CNS depressant properties of amides, (*b*) the presence of the 1,3-propylenediamine entity in many biologically active compounds, and (*c*) the similarity of the reactions of the NH of the phenothiazine ring to the NH of amides, it was of interest to prepare some amides (I) possessing structural characteristics of the phenothiazine tranquilizers (II).

some 2-aminobenzenethiol derivatives (IV) related to the phenothiazine tranquilizers and to reserpine. Perron and Sam (4) noted tranquilizing properties in the 3,4,5-trimethoxybenzamide (V) of 2-(2-pyridyl)ethylamine; Lewis (5) observed analgesic properties with the phthalimide (IX) $R^1 = R^2 = H$; and VI was prepared as an intermediate to bis-quaternary hypotensive agents (6). Compounds possessing structure I are closely related to potent analgesic amides (VII and VIII, respectively) described by Fancher and associates (7) and Carabateas and co-workers (8).

The procedures described by Reich and Levine (9) and Shapiro and associates (2) were employed for the preparation of the phthalimides (IX) and pyridylethylanilines (XII). The preparation of the *N*-methylpiperidine derivative (XV) was accomplished *via* hydrogenation of XIII followed by methylation, whereas XVII was obtained from IX *via* the methiodide (XVI) followed by reduction. The amides (XI) were prepared by reacting X with the appropriate acid chloride. (Scheme I.)

Several related compounds possessing structures XVIII and XIX were prepared for comparison purposes. The latter compounds are related to analgesic anilides described by Wright and Brabander (10).

Preliminary pharmacological evaluation did not indicate any pronounced biological activity in the compounds that were studied.

EXPERIMENTAL[1]

2-(2-Aminoethyl)-5-ethylpyridine—The procedure described by Magnus and Levine (12) for the preparation of 2-(2-aminoethyl)pyridine was followed. A mixture of 214 Gm. (4 moles) of ammonium chloride, 266 Gm. (2 moles) of 5-ethyl-2-vinylpyridine, 300 ml. of water, and 400 ml. of methanol was refluxed for 3 days. The methanol was distilled *in vacuo*. The aqueous solution was cooled, poured into ice water, and neutralized with excess 40% sodium hydroxide. The oily layer was extracted with chloroform and dried over anhydrous potassium carbonate. Distillation of the solvent and then the residual oil gave 192 Gm. (64%) of distillate, b.p. 90–95° (2 mm.).

Anal.—Calcd. for $C_9H_{14}N_2$: C, 71.9; H, 9.38; N, 18.76. Found: C, 72.1; H, 9.56; N, 18.55.

Amides (Table I)—*Method A*—A mixture of 0.2 mole of amine, 40.4 Gm. (0.4 mole) of triethylamine, 0.4 mole of acid chloride, and 600 ml. of dry benzene was refluxed on a steam bath for 18–24 hr. Thereafter, the mixture was cooled, washed with water, and 10% sodium hydroxide, respectively, and dried over anhydrous potassium carbonate. The benzene solution was distilled and the residual material either recrystallized or distilled.

Method B—A mixture of 0.5 mole of the desired vinylpyridine and 73.6 Gm. (0.5 mole) of phthalimide was treated with 0.5 mole of a surfactant[2] and heated slowly and carefully to 175–180° and kept at this temperature for 3 hr. The oil, consisting of a single phase, was cooled and treated with 100 ml. of chloroform and filtered. The filtrate was concentrated and the residual oil crystallized.

Method C—A mixture of 24.1 Gm. (0.2 mole) of 2-(2-aminoethyl)pyridine (11) and 0.2 mole of anhydride was heated at 170–180° for 2 hr. and then cooled. The residual solid was recrystallized from a suitable solvent.

Method D—A mixture of 24.5 Gm. (0.2 mole) of 2-(2-aminoethyl)pyridine and 0.2 mole of ester was heated on a steam bath for 20 hr. and then vacuum distilled.

1 - (2,4 - Dichlorobenzoyl) - 5 - ethyl - 2 - (2 - morpholinoethyl)piperidine—The procedure described under *Method A* was followed. From 22.6 Gm. (0.1 mole) of 5-ethyl-2-(2-morpholinoethyl)-piperidine and 21 Gm. (0.1 mole) of 2,4-dichlorobenzoyl chloride there was obtained 31 Gm. (77%) of product, b.p. 234–236° (0.7 mm.) (13).

A methiodide was prepared in 87% yield as described under *Method E* and was recrystallized from methanol, m.p. 235–236° (13).

1 - (2,4 - Dichlorobenzoyl) - 5 - ethyl - 2 - (2 - pyrrolidinoethyl)piperidine—The procedure described under *Method A* was followed. From 19 Gm. (0.09 mole) of 5-ethyl-2-(2-pyrrolidinoethyl)-piperidine and 21 Gm. (0.1 mole) of 2,4-dichlorobenzoyl chloride there was obtained 28 Gm. (81%) of product, b.p. 218–220° (1.0 mm.) (13).

A methiodide was prepared in 98% yield as described under *Method A* and recrystallized from methanol, m.p. 205–207° (13).

Quaternary Ammonium Iodides—*Method E*—A solution of 0.02 mole of the requisite tertiary amine in 50 ml. of acetonitrile was treated with 14 Gm. (0.1 mole) of methyl iodide and refluxed on a steam bath for 4 hr. The solution was either filtered to remove the product or concentrated to dryness and then recrystallized from a suitable solvent.

2 - [2 - (p - Ethoxyanilino)ethyl] - 5 - ethylpyridine—The procedure described by Reich and Levine (9) was followed using 133 Gm. (1.0 mole) of 5-ethyl-2-vinylpyridine, 137 Gm. (1.0 mole) of *p*-phenetidine, 60 Gm. (1.0 mole) of acetic acid, and 300 ml. of methanol. One hundred and ninety grams of product, boiling at 168–176° (0.1 mm.), was obtained.

Anal.—Calcd. for $C_{17}H_{22}N_2O$: C, 75.51; H, 8.20. Found: C, 75.70; H, 8.38.

N - [2 - (1 - Methyl - 2 - piperidyl)ethyl]phthalimide Hydriodide—A mixture of 39 Gm. (0.1 mole) of 1-methyl-2-(2-phthalimidoethyl)pyridinium iodide, 200 ml. of methanol, and 0.4 Gm. of platinum oxide catalyst was hydrogenated at 60 p.s.i. at 50° for 18 hr. The resulting mixture was treated with 800 ml. of methanol, heated to reflux, filtered, and cooled. The product (30 Gm., 75%) was removed by filtration, m.p. 230–231°.

Anal.—Calcd. for $C_{16}H_{21}IN_2O_2$: C, 48.01; H, 5.29. Found: C, 48.20; H, 5.29.

N - (p - Ethoxyphenyl) - N - [2 - (5 - ethyl - 2-piperidyl)ethyl]isobutyramide—A solution of 40 Gm. (0.12 mole) of *N*-(*p*-ethoxyphenyl)-*N*-[2-(5-ethyl-2-pyridyl)ethyl]isobutyramide in 150 ml. of glacial acetic acid was hydrogenated at 58 p.s.i. in the presence of 0.4 Gm. platinum oxide catalyst for 30 hr. The catalyst was removed by filtration and the filtrate concentrated under reduced pressure. The residual material was treated with 100 ml. of concentrated sodium hydroxide solution. The oily layer was extracted with ether and dried over anhydrous potassium carbonate. Distillation of the ether solution gave 36 Gm. (88%) of product, b.p. 200–205° (1.0 mm.); n_D^{26} 1.5161.

Anal.—Calcd. for $C_{21}H_{34}N_2O_2$: C, 72.79; H, 9.89. Found: C, 72.80; H, 9.70.

N - (p - Ethoxyphenyl) - N - [2 - (5 - ethyl - 1-methylpiperidyl)ethyl]isobutyramide—To 25 Gm. (0.07 mole) of *N*-(*p*-ethoxyphenyl)-*N*-[2-(5-ethyl-2-piperidyl)ethyl]isobutyramide, cooled in an ice bath, was added 7.8 Gm. (0.17 mole) of 98% formic acid. The mixture was allowed to warm slightly and then cooled while 7 ml. of 37% formaldehyde

[1] All melting points were taken on a Fisher-Johns melting point apparatus and are uncorrected. Boiling points are uncorrected.

Quantitative Determination of Sympathomimetic Amines Using Interference Refractometer

Sir:

Interference refractometry, the phenomenon of light interference which is used to measure differences in the refractive index of liquids (and gases), has been used as a means for quantitative analysis of solutions, and a method for the determination of concentration of protein in blood serum has been established (1) using this technique.

In the present investigation, quantitative determination of some sympathomimetic amines has been carried out using a Carl Zeiss laboratory interferometer and a 80-mm. cell.

Very dilute solutions of the amines in various solvents were prepared, and the measuring process followed directly after the determination of the zero point in the instrument. This means that the zero point must be determined at the beginning of the experiment and before each individual series. For this purpose the solvent to be used for the solution under measurement is placed in the twin-cell, and the zero reading is taken. The reference substance is then removed from one half of the cell and the test sample is poured into it and allowed to stand until the temperature has become equalized (approximately 20 min.), because at this stage only the lower interference band can be seen, the upper band of the band system having been displaced laterally due to the filling cell.

The actual measurement process is to determine the amount of this displacement. The reading, less the zero point reading, is the required result.

The purity of the amines used was detected, before use, by thin-layer chromatography, melting point determination, and infrared spectra analysis.

Using solutions of amphetamine sulfate (National Biochemical Corp.) in water, a linear relationship between the various solutions of the amine and the interference refractive index was observed, and this relationship was found to be concentration dependent (Fig. 1). An unknown amount of the amine, measured under the same conditions, can be then estimated.

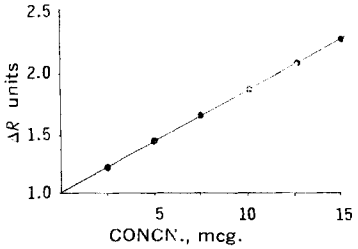

Fig. 1—Relation between differential refractive index (ΔR) and concentration for amphetamine sulfate in water solution.

Similar results were obtained using aqueous solutions of nordefrin hydrochloride (Mann Research Laboratories, Inc.) and phenylephrine hydrochloride (K & K Laboratories, Inc.).

Due to the high precision of the instrument (with monochromatic light, an accuracy of $\pm 1 \times 10^{-7}$ to $\pm 1 \times 10^{-8}$ can be obtained), the method is regarded as being very accurate even for microgram quantities of the amines.

A complete picture of the results, including all amines and solvents used, and a full discussion of the method will be cited in a definite publication.

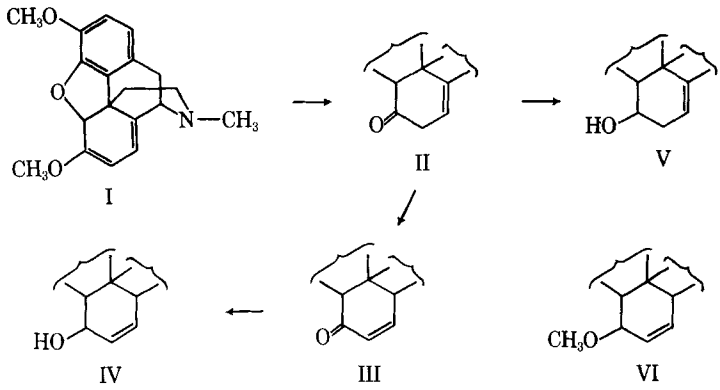
Biosynthetic Conversion of Thebaine to Codeine and Role of Codeine Methyl Ether

Sir:

The mechanism by which thebaine (I) is converted to codeine in the opium poppy has been postulated to involve demethylation to the ketone neopinone (II), rearrangement to codeinone (III), followed by reduction to codeine (IV) (1–3). This scheme also explains the presence in the plant of the alkaloid neopine (V) as a reduction product of neopinone. In 1965 codeine methyl ether (VI) was isolated from the crude mother liquor obtained during the commercial production of morphine (4).



The suggestion was made that this substance might conceivably be a biosynthetic intermediate between thebaine and codeine if the reduction step preceded demethylation. It was therefore decided to test these hypotheses by feeding experiments with radioactively labeled codeinone and codeine methyl ether and by demonstrating whether these two substances exist as genuine alkaloids in the fresh plant. This investigation had been completed when Blaschke, Parker, and Rapoport (5) described experiments with generally labeled materials of a similar nature and with similar results. Our work with specifically labeled codeinone, which provides independent evidence for the role of this compound in the biosynethetic conversion of thebaine to codeine, is published elsewhere (6). However, we want to report here on our experiments with codeine methyl ether and the conclusions which may be drawn from these.

Codeine *N*-oxide (3-$^{14}CH_3$) was prepared as described by Chang *et al.* (7). It was methylated with dimethyl sulfate, and reduced with sulfur dioxide to codeine (3-$^{14}CH_3$) methyl ether which was purified by preparative thin-layer chromatography and crystallization from ether–petroleum ether, m.p. 142° (micro K), specific activity 1.35 mc./mmole. The substance was shown to be chromatographically pure by thin-layer and gas chromatography. Autoradiograms (7 days' exposure) from thin-layer chromatograms with two solvent systems (8) revealed only one radioactive spot corresponding to codeine methyl ether. In July 1965, 56 mg. (0.241 mc.) of this substance was administered to 5 opium poppies by a technique described before (9). The plants were harvested 3 days later, extracted with methanol, and the nonphenolic alkaloid fraction isolated. An autoradiogram of this fraction showed radioactive codeine and codeine methyl ether, while thebaine was inactive. Preparative thin-layer chromatography on silica gel GF (benzene–ethanol, 8 : 2, triple development) gave codeine (41 mg.), codeine methyl ether (48 mg.), and thebaine (56 mg.). Codeine was purified by repeated crystallization, first as the picrate, then as the free base, until the activity remained constant (liquid scintillation counting). Total incorporation of radioactivity from the methyl ether was 2.5%. A Zeisel *O*-demethylation showed that all activity resided in the *O*-methyl group. Although these results were encouraging, it was felt that the amount of precursor which had been fed was too large for the number of plants, possibly resulting in a swamping of the biosynthetic pool. Second, the feeding time of 3 days might have been too short for efficient incorporation since most of the methyl ether was recovered unchanged. The feeding experiments were, therefore, repeated in May 1966 with 5 mg. of labeled codeine methyl ether for 10 plants and a 7-day feeding period. This resulted in an incorporation into codeine of 15.8% of the total radioactivity. Thus, it is clear that

the opium poppy is capable of demethylating codeine methyl ether. However, this did not prove that the methyl ether is a required intermediate. It would be necessary to show (*a*) that this substance is present in the fresh plant, and (*b*) that it is formed directly from thebaine. The biosynthetic pathway leading from reticuline to thebaine is now well established (10–12). Radioactively labeled (±)-reticuline-3-^{14}C (0.045 mc.) (10) was administered to 9 opium poppies. The plants were harvested 2 weeks later, and 100 mg. of radioinactive codeine methyl ether was added to the plant mash during extraction. It was recovered by isolation and separation of the nonphenolic alkaloids and was found to be practically inactive (0.0004% incorporation). This suggested that codeine methyl ether is not produced in the plant by way of thebaine, nor is it derived from codeine. The latter point was also confirmed by addition of the unlabeled methyl ether to an extract from 20 opium poppies which had been fed 2,6-^{3}H-codeine (0.108 mc.) (6). Again the isolated codeine methyl ether was essentially inactive (0.0003% incorporation). We, therefore, conclude that codeine methyl ether is not a genuine opium alkaloid, at least not in the varieties of *P. somniferum* which we have used.

When the isolation of codeine methyl ether was reported, the possibility of this substance being an artifact was considered (4). During large-scale production of morphine, reducing agents such as sulfur dioxide, bisulfite, or hydrosulfite are usually added as antioxidants. It now appears reasonable to believe that the small amounts of codeine methyl ether present in the mother liquors were actually produced by reduction of thebaine during the isolation and purification of morphine.

Review Article

Drug-Induced Cardiomyopathies

By DUANE G. WENZEL

WHILE FREQUENT REFERENCE is made to the toxicity of drugs for the myocardium, and at least one major symposium has dealt with the subject of cardiomyopathies (1), there has been no general review of the drug-induced condition. The lack of well-defined and universally-employed criteria for cardiomyopathies necessitated some latitude when interpreting reports of myocardial drug toxicity. For the purpose of this review the terms degeneration, fatty degeneration, necrosis, primary myocardial disease, myocardial injury or lesions, calcification, fibrosis, or myocarditis were accepted as being synonymous with a cardiomyopathy. Obviously, some of these are not necessarily related to a true cardiomyopathy. Myocarditis, for example, while frequently preceding, accompanying, or following degeneration, is essentially an inflammatory rather than a degenerative process. While drugs acting primarily on the coronary vasculature were included in this review, the mechanism was indicated whenever it was apparent. Alterations in biochemical, electrical, or hemodynamic functions may accompany, or even precede, morphologic evidence of injury to the myocardium, but such changes were not included as cardiomyopathies unless accompanied by evidence of physical alterations.

Degeneration of the heart muscle can result from a wide variety of causes. In this country the most common causes are cardiovascular diseases which result in acute or chronic impairment of coronary circulation. These include coronary artery disease, hypertension, heart-lung disease (*corpulmonale*), valvular heart disease, and congenital heart disease. As practically all adult males in the United States are believed to have some degree of coronary artery disease, the incidence of minimal myocardial degeneration must be considerable. For this reason an assessment of drugs in human degenerative heart disease must include the possibility of an interaction with impaired coronary circulation. While it is possible to experimentally distinguish between drugs producing primary toxic or allergic lesions of the myocardium and those producing similar end effects through alterations in coronary blood flow, such differentiation is often not possible on the basis of clinical reports. In fact, some drugs, of which the catecholamines are an outstanding example, probably produce their degenerative effects through both mechanisms.

Primary myocardial disease may also result from a variety of infections, nutritional and metabolic disturbances, and allergies, and in some cases may have a genetic component. Once again, superimposing the effect of a drug upon such underlying conditions would be expected to intensify the response. Most drugs which produce primary cardiomyopathies are believed to interfere with the metabolic activity of the cell, probably by poisoning enzyme systems. The remaining drugs act through an allergic mechanism, either by a direct effect on the myocardium or secondary to coronary vasculitis. In addition to the possibility that some drug cardiomyopathies seen in the human are related to predisposing

Received from the School of Pharmacy, University of Kansas, Lawrence, KS 66044

factors, it may be argued that myocardial lesions may occur with almost any drug if administered in a large enough dose and for a sufficient length of time. Despite the use of unphysiologic doses in many of the reported animal experiments, these data were included in order to present a complete picture. Drugs having a low order of intrinsic activity on the normal heart would be expected to demonstrate their toxicity on hearts already damaged or otherwise rendered susceptible.

SYMPATHOMIMETIC AMINES

The earliest evidence relating the sympathomimetic amines to necrotic lesions of the myocardium as cause and effect was in a report on epinephrine by Josué in 1907 (2). Since then this observation has been repeated many times with epinephrine and other sympathomimetic amines. A variety of mechanisms have been postulated to explain the pathogenesis of these lesions. Proposed mechanisms include: a direct oxygen wasting action (3–29); altered permeability of the myocardial cell membrane through elevation of plasma nonesterified fatty acids (30); impairment of venous drainage of the heart (31); potassium depletion (32); constriction of the coronary arteries (33); dilatation of precapillary shunts between coronary arteries and veins (34); damage to the coronary endothelial cells (35); increased myocardial oxygen requirements plus alterations of systemic circulation (36); and combinations of three different effects including myogenic, physical, and metabolic mechanisms (37).

Raab and his co-workers were the earliest and have been the principal proponents of a mechanism by which the amines increase myocardial oxygen consumption and cardiac work without a corresponding increase in energy production (3–29). It has been repeatedly demonstrated that following administration of the catecholamines the oxygen consumption of the heart greatly exceeds the normal energy requirements (38–46). Raab not only proposed a mechanism by which endogenous neurohormones or administered sympathomimetic amines produce myocardial degeneration, but he seriously challenged the classical concept of occlusive coronary artery disease as *the* cause of myocardial degeneration. It is notable that even in defining the term infarction, as applied to the myocardium, recognition is now given to the fact that arterial obstruction or insufficiency is not the sole cause (47). Since the early study of Herrick (48), demonstrating the effects of coronary occlusion, and the subsequent emphasis by Keefer and Resnik (49) on the role of myocardial oxygen deprivation in the symptoms of angina pectoris, relatively little attention has been given to the nonocclusive mechanisms. While there can be little doubt that coronary occlusion is a major factor in the production of myocardial necrosis, it is also probable that the primary cardiomyopathies constitute a significant factor.

Of the known mechanisms by which the sympathomimetic amines may act, oxygen wastage is at least of theoretical importance. This mechanism appears to be related to mitochondrial function. Following the admnistration of catecholamines the mitochondria become swollen (50) and undergo uncoupling of oxidative phosphorylation (51). This effect is apparently unrelated to hypoxia, congestive heart failure, or the accumulation of free fatty acids, and does not occur when catecholamines are added to the mitochondria *in vitro* (51). The lack of an *in vitro* action suggests a preliminary *in vivo* effect. Possible *in vivo* mechanisms include the reduction of myocardial potassium by the catecholamines (52, 53) because potassium has an essential role in mitochondrial metabolism (54). Still another possible explanation is the *in vivo* conversion of catecholamines to adrenochrome, a metabolite with a demonstrated capacity to uncouple oxidative phosphorylation in mitochondria (55). Some investigators have concluded that the catecholamine-induced increase in myocardial oxygen consumption is the result of hemodynamic changes rather than of a direct metabolic action (56). To reach this conclusion, the heart was arrested by potassium, which in addition to preventing hemodynamic changes would also modify any potassium-depleting effect of the catecholamines. In the isolated rat heart it was shown, however, that the increase in oxygen uptake produced by epinephrine still occurred following arrest by potassium (57), citrate, or procainamide (57, 58). These results suggest that if uncoupling of oxidative phosphorylation is the cause of the observed increase in oxygen consumption, the uncoupling is not the result of potassium depletion. Hauge and Øye (58) concluded that part of the effect of epinephrine on the arrested heart was due to an increased utilization of ATP by several separate reaction systems. They found that this increase in oxygen consumption was blocked by a β-adrenergic receptor blocking agent, propranolol, but not by phentolamine, an α-adrenergic receptor blocking agent.

While the relative importance of the various mechanisms is still unresolved, there is direct evidence that the adrenergic receptors responsible for the myocardial toxicity of the catecholamines are alpha in character rather than beta. The intravenous administration of epinephrine to dogs has been shown to produce a fatty degeneration of the

myocardium associated with elevated serum levels of several myocardial enzymes (59–61). These effects are prevented by the administration of an α- receptor blocking agent (62–64). In a study with rats, it was found that the myocardial damaging effects of epinephrine, norepinephrine, or phenylephrine were prevented by the α-adrenergic receptor blocking agent, phentolamine, but the β-adrenergic receptor blocking agent, pronethalol, did not add to the effectiveness of the phentolamine, nor was it effective alone (65). In fact, with low doses of isoproterenol and with high doses of epinephrine the pronethalol added to the toxicity. The β-receptor blocking agents prevent phosphorylase activation and hyperglycemia (66) without affecting hyperkalemia (67). Alpha-receptor blocking agents, on the other hand, prevent the loss of myocardial potassium without appreciably affecting hyperglycemia (68). As previously suggested, potassium depletion is a likely causal mechanism by which the catecholamines are toxic to the heart. Among the known consequences of potassium depletion is interference with mitochondrial metabolism (54, 69). It has been suggested that this effect is based upon the importance of potassium in transphosphorylation reactions (70) as shown by the potassium dependence of enzymes involving phosphate transfer, such as fructokinase (71, 72), pyruvic phosphoferase (73–75), phosphotransacetylase (76), and acetate activating enzyme (77). Still other potential potassium-related effects are the requirements for high concentrations of this element in protein synthesis (78) and the fall in muscle pH produced by potassium deficiency (79). Numerous studies have demonstrated the production of myocardial necrosis by potassium depletion as well as the loss of potassium following myocardial injury (80–85). The extent to which hemodynamic effects are responsible for the myocardial lesions produced by the sympathomimetic amines is still conjectural. To summarize the vascular effects of the three principal catecholamines: isoproterenol is almost entirely a vasodilator; epinephrine produces both vasoconstriction and vasodilation; while norepinephrine is almost entirely a vasoconstrictor. It has been suggested that at least part of the toxicity of isoproterenol for the myocardium is related to the marked decrease in systemic blood pressure (86, 87). Just as a marked fall in peripheral vascular resistance may result in embarrassment to the myocardial circulation, an intense rise in peripheral pressure produced by the pressor amines would be expected to produce an increase in the myocardial work load.

The role of the coronary vessels in the production of myocardial necrosis by the sympathomimetic amines may be significant yet variable. The cardiovascular effects of the catecholamines are usually accompanied by marked compensatory dilatation of the coronary vessels, provided that they are not sclerotic (88, 89). The nature of the response appears to depend upon vessel size and the amount of catecholamine. Norepinephrine was found to produce good relaxation of the small coronary arteries, but somewhat less relaxation resulted from equal doses of epinephrine (90). This dilatation was blocked by pronethalol. Larger coronary vessels tend to be contracted by the catecholamines, and this effect is blocked by phenoxybenzamine hydrochloride[1] (90). The over-all myocardial circulation, as measured by coronary flow, is improved by epinephrine or norepinephrine, while after β-adrenergic receptor blockade these same sympathomimetic amines produce coronary constriction (91). The predominant effects of low doses of catecholamines are seen upon the myocardium and coronary circulation, while large doses produce greater peripheral effects (92). Furthermore, isoproterenol in large doses actually produces a pressor response which is blocked by α-adrenergic receptor blocking agents (93).

A factor of great importance in the action of sympathomimetic amines as myocardial necrotizing agents is their interaction, either as drugs or hormones, with other agents capable of producing cardiomyopathies. Because such unplanned interactions are probably common in the human, results obtained with sympathomimetic amines in normal animals may give an unrealistic impression of a low order of toxicity.

Epinephrine—Myocardial injury ranging from edema to massive necrosis can be produced by the injection of epinephrine. The nature of these effects and their severity are dependent upon the dose of epinephrine and the species tested. Cats appear to be most susceptible, demonstrating necrosis after the intravenous administration of moderate doses (94, 95). Larger doses are usually necessary to produce equivalent lesions in dogs (60, 61, 96, 99), rabbits (100), and rats (65, 86, 101–103). The importance of interacting factors is demonstrated by the fact that a dose of epinephrine producing no lesions alone (104, 105) consistently causes myocarditis when combined with low doses of caffeine (104–108), sparteine, or strophanthidin (105–106). A similar interaction with caffeine has been observed with guinea pigs (109) and dogs (104, 110). While the sensitivity of the human

[1] Trademarked as Dibenzylamine by Smith Kline & French Laboratories, Philadelphia, Pa.

myocardium is not known, large doses of epinephrine have been reported to produce functional evidence of lesions (111).

Norepinephrine—High mortality rates resulting from the use of norepinephrine in the treatment of cardiogenic shock or shock-like states prompted the initial studies of its myocardial toxicity (112). It was found that patients dying after treatment with norepinephrine or those with pheochromocytoma presented evidence of morphologic changes in the myocardium similar to those obtained by treating dogs with therapeutic doses of norepinephrine (113, 114). Lesions observed ranged from myocarditis to necrosis and/or focal fibrosis. It has been suggested that the mortality in cardiogenic shock would be reduced if lower doses of norepinephrine were employed (115). A hazard in the use of norepinephrine was demonstrated by the marked cardiac toxicity resulting from its administration to patients receiving iproniazid (116).

Focal myocarditis, patchy, fatty, degenerative changes, necrosis, and hemorrhages of the myocardium were produced in dogs by the intravenous administration of therapeutic doses of norepinephrine (60, 61, 112, 113). Rats were similarly susceptible to single or repeated subcutaneous injections (65, 86, 117–123). Doses producing minimal lesions when administered alone resulted in severe lesions when combined with dihydrotachysterol and calcium acetate (120), with a low potassium diet (121) or with cold stress (117).

Isoproterenol—In terms of the extent of its use, isoproterenol has become the reference standard for producing experimental myocardial necrosis. The rat has generally been the species of choice. Since the first studies (87, 124) using isoproterenol to produce lesions resembling those resulting from human myocardial infarction, a wide variety of factors have been studied in order to determine the pathogenesis of cardiopathies in general. The significance of such factors has been reviewed (125). Different strains of rats, as well as animals from the same strain but from different colonies, have significantly altered sensitivities to isoproterenol (126). Large animals were found to be more susceptible than small ones, while age and sex were not significant factors in this study as long as body weights were equal (126). Treatment of rats with conjugated equine estrogen or progesterone (125), ACTH (127), or glucocorticoids (127) failed to influence the cardiotoxicity of isoproterenol. Factors increasing isoproterenol-induced necrosis were: estrone (125), testosterone (125), hyperthyroidism (128), mineralocorticoids (127), a low-potassium diet (52), a high-sodium diet (52), isolation or cold stress (129), increased body fat (130), and nicotine (131). Factors providing some protection were: hypothyroidism (128), a high potassium diet (52), a low sodium diet (52), starvation (125), and, contrary to a report indicating a potentiation of the effects of norepinephrine in the human (116), monoamine oxidase inhibitors (132–134).

The hamster has also been used in studies to determine the mechanism by which isoproterenol affects the heart (33, 34). From these studies it was initially concluded that isoproterenol produced its effects by dilating the precapillary shunts of the coronary arteries (34); however, it was later concluded that the effects were those of ischemia resulting from coronary vasoconstriction (33).

Other studies of isoproterenol to follow were performed with rats unless otherwise indicated. These studies demonstrated: histochemical and electron microscopic changes (50); the relationship of the lesions to the loss of myocardial aspartate aminotransferase (135); the effect of adrenergic blocking agents on isoproterenol-induced biochemical changes in the myocardium (65, 136, 137); the similarity of isoproterenol-induced myocardial lesions to those occurring naturally in breeder rats (138); hemodynamic changes during the acute (139) and chronic (140) phases of the myocardial damage; the presence of impaired venous drainage as a possible cause of myocardial injury (31); the rate at which necrotic areas heal (36); a correlation of the lesions with hemodynamic and electrocardiographic changes in the dog (141); comparative effects with other sympathomimetic amines (86); a correlation between the disappearance of myocardial glycogen and potassium (142); detailed histological effects (143, 144); lack of protection from cardiac glycosides, monoamine oxidase inhibitors (145), or adrenergic blocking agents (65, 145); and a series of studies in which hemodynamic and metabolic effects were correlated with the histopathologic responses of rats to several sympathomimetic amines including isoproterenol (30, 37, 146).

Other Sympathomimetic Amines—Surprisingly few studies have been performed to evaluate the potential of other sympathomimetic amines in the production of cardiomyopathies. In early studies the oral administration of ephedrine each day for 1 to 2 years produced foci of calcification in the myocardium of guinea pigs (147). Following treatment with xanthine compounds in rabbits, ephedrine was found to produce myocarditis (106). Obviously ephedrine is much less potent in terms of its capacity to produce myocardial necrosis than are the catecholamines. The amount of ephedrine required to produce minimal

gross myocardial lesions in the rat is approximately 1,000 times the amount of epinephrine required, 700 times that of norepinephrine, and 4,400 times that of isoproterenol (86). Ephedrine also failed to produce myocardial injury when it was repeatedly injected in chickens and rabbits, both with and without the administration of sparteine (148).

Tyramine has also been shown to produce myocarditis in rabbits following administration of xanthine alkaloids (106). Methamphetamine administered daily for long periods to mice or rabbits resulted in myocardial degeneration (149). Phenylephrine, a sympathomimetic amine usually regarded as a specific stimulant for α-adrenergic receptors, produced myocardial necrosis, accompanied by loss of myocardial aspartate aminotransferase activity in rats, equivalent to the changes produced by epinephrine or norepinephrine when given in approximately twice the dose (65).

Nicotine—Nicotine has notable pharmacodynamic activities other than those of an indirect-acting sympathomimetic amine, but its principal effects upon the heart are probably mediated through stimulation of the sympathetic nervous system and the release of epinephrine and norepinephrine. Tobacco has long been suspect as a major etiologic factor in the increased mortality from cardiovascular disease of smokers, and nicotine is probably the active agent (150). Chronic administration of nicotine to rats (151–155), or rabbits (156, 157) did not produce myocardial lesions when used by some workers, yet others have produced ischemic changes (158) and necrotic areas of the myocardium (159) with rats. As large doses of nicotine produce death by respiratory arrest, it is not expected that myocardial necrosis would be seen with acute nicotine poisoning, yet myocardial effects have been seen in humans (160, 161) and horses (162). As was suggested from evidence with the catecholamines, however, there are indications that nicotine may owe much of its potential myocardial toxicity to interactions with other agents. It was observed, for example, that while nicotine or bovine serum administered daily to rabbits did not produce myocarditis, this effect resulted when the two agents were combined (163–167). Similarly, nicotine administered to the rat in doses approximating the intake of an average smoker does not produce lesions of the myocardium, yet it significantly intensifies the lesions produced by isoproterenol (131) or corticosteroid–electrolyte-stress treatment (53). Furthermore, when nicotine, ergometrine, and a hypercholesterolemic diet were administered to rabbits, as separate treatments or as any pair of treatments, there was no evidence of morphologic damage to the myocardium. When the three treatments were combined, fatty degeneration of the myocardium accompanied by thickening and fibrosis of the coronaries resulted (168, 169). Because of the multiplicity of the direct and indirect effects of nicotine on the myocardium, the nature of its interacting mechanism(s) can only be speculative at this time.

CORTICOSTEROIDS

In 1942 Miller and Darrow administered repeated doses of desoxycorticosterone to rats and produced necrosis of the myocardium which was indistinguishable from that produced by a low potassium diet (170). These effects were preventable by the administration of potassium chloride in the drinking water. Darrow later observed that a low potassium diet intensified the necrosis produced by this steroid (171). Others have reproduced these effects with desoxycorticosterone (172, 173), and have further observed that the coadministration of sodium chloride potentiates its damaging action (174–184). It was also demonstrated that the myocardial lesions were intensified by experimental hypertension (180, 182), uninephrectomy (177, 181, 183, 184), adrenalectomy (185), growth hormone (176), methandriol (186), digitalis in patients with congestive heart failure (187), hydrocortisone and calciferol (183), and cortisone or hydrocortisone (188). The lesions produced by desoxycorticosterone were reported to be reduced or prevented by promethazine (174), adrenalectomy (185), corticotropin or cortisone (177), or a sodium-free diet (182). Contrary to previous reports concerning the potentiation of the effect of desoxycorticosterone by sodium chloride, the administration of sodium chloride has also been reported to prevent the lesions in unilaterally nephrectomized and adrenalectomized rats (189). A further conflicting report is that the coadministration of cortisone does not influence the response to desoxycorticosterone (190). The guinea pig was also shown to be sensitive to the steroid-induced necrosis (191) as were humans treated for arthritis (192).

Not only are necrotic lesions of the myocardium produced by injections of desoxycorticosterone, but by corticotrophin (193–197, 206), cortisone (188, 194, 198–203), hydrocortisone (195, 201, 204, 205), corticosterone (206), and prednisone (207). The toxic effects of corticotropin for the myocardium were reported in the treatment of asthma (193, 194) and when used in conjunction with tetanus antitoxin (197). Prednisone produced myocardial infarctions in two of 63 tuber-

culous patients treated with average doses of prednisone and antitubercular drugs (207). The toxicity of the glucocorticoids, like that of desoxycorticosterone, was potentiated in rats by sodium chloride in the drinking water (199–201), by a low potassium diet (202), and by coadministration with desoxycorticosterone in doses which produced no effects alone (188). It is interesting that infarcts produced in dogs by ligating a branch of a coronary artery were made worse by the administration of desoxycorticosterone and improved over the controls by the administration of hydrocortisone (208). However, corticosteroid therapy of acute myocardial infarctions of the human has proven to be ineffective (209).

In 1957 Selye and Renaud (210) tested a new corticosteroid for its effectiveness in the production of cardiomyopathies. This compound, 2α-methyl-9α-chlorocortisol, when combined with the oral administration of sodium phosphate, was most effective in producing lesions in the rat heart. Since then a number of similar halogen-substituted steroids have been tested with a variety of other agents and treatments (118, 119, 210–228). Details of the speculations concerning the nature of the numerous interactions between corticosteroids, salts, stressors, and miscellaneous compounds can be found in books by Selye (229, 230). The mechanism of the toxicity has been the subject of considerable speculation and some disagreement. These lesions referred to as "electrolyte-steroid-cardiopathy with necrosis" (ESCN) by Selye's group were prevented by treatment with potassium (32). Their causation was said to be related to an undefined interaction between so-called "activating" anions, specifically phosphate, sulfate, and perchlorate, and certain halogenated corticosteroids. The answer to the question of mechanism begins with the clearly demonstrated activity of either mineralocorticoids or glucocorticoids in producing myocardial necrosis. Such activity has been shown to be intensified by the combination of glucocorticoid and mineralocorticoid activities whether as two separate compounds (14, 19, 53) or as a single highly active halogenated corticosteroid with both effects in a single molecule. In those few cases where an investigator has been unable to produce cardiac necrosis in the rat with desoxycorticosterone (231, 232), it might be concluded that doses, animals, or treatments were not optimal. In an attempt to resolve this seemingly confused picture, Nickerson and co-workers (84) studied the mechanisms of corticosteroid and the so-called "activating" anion. They determined that the "activating" anions were simply producing potassium-depletion through what they felt was catharsis, coupled with the potassium depleting effect of the halogenated steroid. The hypothesis of simple potassium depletion as the causative mechanism was later rejected by Prioreschi (231, 232) because he was unable to produce necrosis with desoxycorticosterone alone, because he seemingly protected the animals by the administration of chlorides other than potassium, and because not all animals with a low cardiac potassium developed necrosis. These apparent discrepancies in the low potassium hypothesis were later examined by Tucker and co-workers (233). They found that necrosis of the heart muscle was associated with a high metabolic alkalosis, an increase in intracellular sodium, and a decrease in skeletal muscle potassium. It was concluded that sodium phosphate as well as the other "activating" anions increased the rate of potassium excretion by their action on the kidney rather than by catharsis. Furthermore, the apparent protection by chlorides described by Prioreschi was interpreted as lack of potentiation rather than protection. The lack of a clear relationship between depletion of myocardial potassium and necrosis was found to result from the protective effect of potassium in skeletal muscle. Lack of a positive effect of desoxycorticosterone, in Prioreschi's studies, was related to the use of liberal amounts of potassium in the diet he fed his rats.

VASOCONSTRICTORS

Although the sympathomimetics include many agents with vasoconstrictor activity, they were treated separately because of their multiple actions and their over-all significance in terms of cardiomyopathies. As is the case with drugs classified as antihypertensives or vasodilators, the vasoconstrictors are assumed to produce myocardial injury through hemodynamic changes rather than direct myocardial toxicity.

The ergot alkaloids produce severe anginal symptoms in the presence of hyperthyroidism, syphilitic aortitis, deformities of the aortic valve, or stenosis of the coronary ostia (234, 235). Electrocardiographic changes, coronary thrombosis, and/or myocardial infarction have also been shown to follow therapy with ergot derivatives (236–238). The effect of the ergot alkaloids on the coronary vessels is seen in the electrocardiographic alterations during the ergonovine (ergometrine) stress test (239). Such ECG alterations occur when the drug is administered in the presence of pathologic changes of the coronary arteries (240, 241). In addition to being employed clinically, this test has been used to obtain evidence of restricted coronary flow in the living animal (242–244). The coronary constriction produced by

ergometrine in the rabbit receiving a hypercholesterolemic diet and chronic nicotine in the drinking water was sufficient to produce electrocardiographic alterations, thickening and fibrosis of the small branches of the coronaries, and myocardial necrosis (245, 246).

Vasopressin is another major vasoconstrictor drug shown to produce myocardial lesions. The earliest indication of its effects on the myocardium were reports by Scheps in 1934 (247, 248). He treated rabbits and guinea pigs with intramuscular injections of vasopressin and observed myocardial ischemia, hyperemia, edema, and necrosis. Others have repeated this observation using rabbits (249), dogs (250, 251), rats (252, 253), and cats (254), with effects ranging from hemorrhage to necrosis. Several cases of infarction and sudden death have been reported from the use of vasopressin in the human (255, 256). The marked reduction of coronary flow by vasopressin in normal, noninfarcted hearts (257) with no evidence of direct toxicity leaves ischemia as the probable mechanism. Vasoconstriction produced by posterior pituitary[2] has been combined with altered blood coagulability (thrombin administration) and/or coronary atherosclerosis (hypercholesterolemic diet) in rabbits (258). Infarction resulted from the combination of posterior pituitary and thrombin, while more severe necrosis was produced by the addition of hypercholesterolemia to the regimen.

VASODILATORS AND ANTIHYPERTENSIVES

Vasodilators or antihypertensives are not usually considered to be precipitating factors in myocardial degeneration, although they may induce ischemia through severe hypotension accompanied by prolonged tachycardia. A shortened diastolic interval coupled with diminished venous return in the presence of aortic stenosis or coronary sclerosis may be sufficient to produce localized ischemia to the point of necrosis. In the absence of evidence suggesting a direct toxic effect, one must assume a hemodynamic mechanism for such drugs.

Ganglionic blocking agents have been found to produce myocardial lesions when employed for the treatment of hypertension (259–266). Specific agents have been: tetraethylammonium chloride (259–261), hexamethonium chloride (264), pentamethonium bromide (263), pentolinium tartrate (262), and mecamylamine hydrochloride (266). In all cases the basis for the development of infarction appeared to be the administration of single or repeated hypotensive doses of the drug to arteriosclerotic patients. In one series, infarctions were produced in 7 hypertensive patients following the daily aministration of antihypertensive agents for periods of 4 days to 9 months (265). It was concluded that these drugs should not be used for elderly patients with systolic hypertension and especially not in the presence of angina pectoris. Other drugs reported to produce myocardial lesions when used for the treatment of hypertension include reserpine (267–269) and hydralazine (270, 271).

While the nitrites are used to treat the symptoms of angina pectoris, they have been reported to increase the incidence of infarction when administered chronically in large doses to patients with arteriosclerosis (272). Degenerative changes of the rat myocardium have been produced by the oral administration of erythritol tetranitrate (273).

THYROID HORMONE

While the term "thyroid hormone," is used throughout this section the actual substances are crude thyroid extract, thyroxin, or thyroid-stimulating hormone. In 1913 Farrant (274) reported that the administration of large doses of desiccated thyroid to the rat produced scattered areas of necrosis in the myocardium. Many others have since repeated his observations on experimental animals (103, 275–294) which have included cats (285, 288, 289, 293), rabbits (280–284, 286, 287, 290), guinea pigs (278), rats and pigeons (291, 292). Histologic changes in the various studies ranged from minor fatty degeneration to frank necrosis of the muscle fibers with exudative cellular infiltration. In some cases fibroblasts were described as replacing myocardial bundles. Not all investigators were able to demonstrate specific myocardial lesions in animals with experimental hyperthyroidism (295–298). Thyroid hormone alone is relatively ineffective in producing focal myocardial lesions in the cat, but when it is combined with otherwise nontoxic doses of digitalis, potentiation results (293).

Treatment with various stressors has failed to produce myocardial necrosis in rats pretreated with thyroid hormone (229). Although clinicians have reported histopathological changes in the hearts of patients with hyperthyroidism (299–305), and it is common to find swollen myocardial fibers in patients with hyperthyroidism, myocarditis or myocardial necrosis are said to be comparatively rare (306).

The mechanism by which thyroid hormone can produce lesions of the myocardium is not known.

[2] Trademarked as Pituitrin by Parke Davis and Co., Detroit, Mich.

It has been observed that, when administered to young growing rats, it produces an increase in the magnesium requirements accompanied by a decreased efficiency of oxidative-phosphorylation by the cardiac mitochondria (307). A similar impairment of oxidative phosphorylation by cardiac mitochondria is observed following magnesium deprivation (308).

CARDIAC GLYCOSIDES

The fact that the cardiac glycosides are capable of producing injury to the myocardium in addition to their positive inotropic action has been observed clinically and experimentally, yet this phenomenon has received relatively little attention. Perhaps the earliest report of this toxic effect was in the doctoral thesis of Lewitzky (309). In his studies with rabbits, dogs, and cats he observed that large doses of digitalis extract produced myocardial necrosis followed by inflammation. Since this study, other investigators and clinicians have confirmed and extended his data with various cardiac glycosides including: crude digitalis (310–318), convallaria (315), digitoxin (319–327), digitalin (319), gitalin (319, 321), lanatoside-C (328, 329), oleandrin (324, 326), ouabain (319), and strophanthin (330, 331).

Myocardial lesions have been reported following the administration of therapeutic (311, 317, 318) or toxic doses (310, 322) to humans. In one case death occurred from a combination of cortisone, corticotropin, antibiotics, meralluride, ammonium chloride, and digitalis (316). Most investigators studying the toxicity of the cardiac glycosides have employed the cat because of its sensitivity (312, 313, 315, 319–321, 323–328, 331, 332). In one comparative study, cats were found to develop focal myocardial necrosis from a single intravenous injection of digitoxin while dogs or rabbits required repeated injections (320). Other studies have confirmed the relative resistance of the dog (314, 328, 329). The rabbit when bled was found to be more susceptible to the cardiac glycosides (330). It is probable that the effect of bleeding acted as a stressor.

While the mechanism by which the cardiac glycosides produce lesions of the myocardium is not known, the evidence is in favor of potassium depletion. The positive correlation between depletion of myocardial potassium and digitalis toxicity is well documented (333–335). The problem is complicated by conjoint factors which increase the potassium loss. Congestive heart failure, the condition for which digitalis is usually employed, results in increased secretion of aldosterone with an accompanying increase in sodium retention and potassium excretion. Potent diuretics, used either for the treatment of congestive heart failure or hypertension, may aggravate myocardial toxicity through potassium depletion. The importance of interacting factors is demonstrated by the production of myocardial lesions with otherwise nontoxic doses of digitalis when administered with thyroid hormone (293).

EMETINE

The therapeutic value of emetine in the treatment of amebic dysentery is limited by the considerable toxicity of the drug. This toxicity has been demonstrated upon the heart, skeletal muscle, and intestine (336), although reports of polyneuritis and nervous involvement are not unusual (337). Evidence of its toxicity for the myocardium in humans treated for amebiasis has been frequently reported (338–348). In addition to the myocardial lesions resulting from emetine, alterations in the electrocardiogram (349), ventricular fibrillation (350), diminished systolic force (351), and tachycardia (352) have been observed following its therapeutic use.

A number of investigators have noted the production of fatty degeneration and necrosis of the myocardium following administration of emetine to rabbits (353–356), dogs (356), and pigeons (357). Its toxic effects for the myocardium have been said to be lessened by the administration of inositol or pyridoxine (358) and intensified by physical exercise (359, 360) or psychological stress (361).

A number of studies have been conducted to determine the biochemical mechanism by which emetine produces cardiomyopathies (361–369). It has been suggested that emetine may act to interfere with the enzyme system by which the heart converts glycogen to useful energy (370). A single dose of 10 to 20 mg./Kg. was found to cause a rapid fall of liver glycogen in the rat (362). In testing this theory Diamant (367) concluded that the synthesis, rather than the utilization, of glycogen was significantly depressed by emetine. He found that emetine depressed the activities of both aldolase and phosphorylase and suggested these effects as causes of the reduced glycogen synthesis. Emetine was shown to have no effect on the synthesis of cocarboxylase by the rat liver (366), and its effects on the heart were not blocked by the administration of nicotinamide adenine dinucleotide (368). The metabolism of vitamin A, riboflavin, nicotinic acid, or biotin were unaffected by the administration of emetine while smaller amounts of folic acid and thiamine were stored in the livers of pair-fed rats (364).

In studies with heart homogenate or mitochondrial preparations, emetine decreased the oxygen uptake in the presence of glucose, pyruvate, malate, fumarate, or without added substrates (365), and with butyrate or β-hydroxybutyrate (371). Oxygen uptake was augmented by succinate (365). Evidence was presented that the enhancement of succinate oxidation may have resulted from inhibition of malic dehydrogenase (369). As liver homogenates from emetine-poisoned rats did not demonstrate an impaired ability to oxidize any of the previously mentioned substrates (372), and as the liver accumulates a far higher concentration of emetine than does the heart (373), it was apparent that the toxicity to the heart was the result of a susceptibility of one or more still unidentified metabolic processes in this organ. The similarity of the effects of emetine to those of thyroxin on heart homogenates and to the toxicity of thyroxin for the myocardium has been noted (369).

METALLIC COMPOUNDS

Arsenic—Toxic interstitial myocarditis and related symptoms have been reported during the use of arsenicals in the treatment of syphilis (374, 375) and in acute or chronic arsenic poisoning (376–378).

Antimony—The usual cause of antimonial toxicity to the myocardium is its use in the treatment of schistosomiasis. Electrocardiographic abnormalities are common and morphologic alterations of the heart are frequently seen when sudden death ensues. These alterations are similar to the findings with arsenic poisoning. The myocardial toxicity of both the older and newer forms of antimonials has been the subject of several reports (379–381).

Other Metallic Compounds—Bismuth has been reported to produce a toxic myocarditis similar to that observed with arsenic or antimony (382, 383). Myocardial toxicity from the mercurials has produced sudden death from ventricular fibrillation or severe abnormalities of the electrocardiogram (384–388). Similar effects with morphologic changes of the myocardium have been demonstrated with animals (389–391).

While the mechanism by which the metallic compounds induce cardiopathies is not known, the protection against their over-all toxicity by dimercaprol suggests inhibition of sulfhydryl enzymes as a general mechanism (392).

ANTIMALARIALS

The earliest indication that the antimalarials may produce myocardial damage was in a report by Chopra and Wahed in 1934 (393). In treating malarial patients with a combination of pamaquine and quinacrine they observed evidence of myocardial injury, including tachycardia, palpitation, ECG changes, and signs of heart failure. It was apparent that the combination was considerably more toxic than either drug alone. It has since been found that quinacrine interferes with the metabolic degradation of the 8-aminoquinolines thus increasing their concentration in the plasma from five to tenfold (394). Quinine has been reported to produce myocardial damage when it was injected intravenously each day for the treatment of malaria (395).

Studies with rats have demonstrated a severe myocardial toxicity for the experimental antimalarial, plasmocid 8-(3-diethylaminopropylamino)-6-methoxyquinoline (117–119, 121, 396). Quinacrine has produced necrosis and fibrosis of the myocardium of rats, mice, or hamsters when administered as a single LD_{50} (397). Dogs, however, appeared to be refractory to this effect. The addition of small amounts of chloroquine to the diet of rats for periods up to 2 years resulted in fibrosis of the myocardium (398).

PSYCHOTHERAPEUTIC AGENTS

The different classes of psychotherapeutic agents are grouped for convenience of reference rather than to imply a common mechanism. Their potential myocardial toxicity was first reported following the intravenous administration of large doses of chlorpromazine to mental patients (399, 400). A deleterious cardiac action of promethazine was also suggested when it was employed for the production of "deep sleep" therapy for infarction (401). While promethazine, combined with chlorpromazine and meperidine, was said to be useful for suppressing the symptoms of myocardial infarction, heart damage was observed when it was used to treat patients in a state of severe collapse or older patients (402). Further indication of the phenothiazine's myocardial toxicity was suggested from the marked quinidine-like effect of thioridazine (403). In these cases the electrocardiographic changes resembled those of severe hypokalemia. With large doses, circulatory collapse and ventricular tachycardia had occurred, terminating in death. At necropsy, however, nonspecific changes were observed in the myocardium. In another instance, 30% of a group of patients under therapy with chlorpromazine or perphenazine had significant ECG abnormalities (404). About this time a number of unexpected deaths associated with chlorpromazine therapy were reported (405–407). In one 2,000-

bed neuropsychiatric hospital at least two cases of sudden, unexplained deaths had occurred each year since 1957 (408). A detailed histochemical analysis of the hearts from 12 such patients who had received phenothiazine therapy revealed lesions in the arterioles and myocardial muscle which were not present in a control group. Focal lesions of the myocardium, although less extensive, were observed in 70% of tranquilized patients dying from other causes. This effect of the phenothiazines was later demonstrated by the same authors using experimental animals subjected to chronic physical stress.

Evidence that imipramine may possess myocardial toxicity is seen in a report of infarction during its use for the treatment of depression (409) and evidence of cardiac complications during treatment with and poisoning by the drug (410).

Isoniazid (411) and iproniazid (412) have been reported to produce myocardial infarction in patients being treated for tuberculosis. Iproniazid has also been thought to damage the myocardium in patients to whom the drug was being administered for angina pectoris (413).

ALCOHOL

The toxicity of alcohol for the myocardium is infrequently noted, possibly because of the more obvious liver damage. Nevertheless, as early as 1873 an association was observed between alcohol and heart disease (414). These effects were described as..."a localized form of cirrhosis occurring in the myocardial wall and *trabeculae carneae* in the absence of impaired coronary circulation." The term "Munchen Bierherz" was introduced in 1884 to describe the cardiac dilatation and hypertrophy observed in Munich brewery workers who consumed excessive amounts of beer (415). This subject was recently revived following the deaths of 17 people in the U. S. and 20 in Canada from what authorities have called "Beer Drinkers Heart Disease" (416). In 1895 alcoholic myocarditis was observed in alcoholics with liver disease (417) and in 1902 the term "Alcoholic Heart Disease" was used to describe the general cardiac symptoms associated with chronic alcoholism (418). The similarity of alcoholic heart disease to beriberi was observed as early as 1906 (419). While later investigators also noted the similarity between these conditions (420), some reported that patients with alcoholic heart disease responded poorly to thiamine therapy (421). A number of investigators have documented the electrocardiographic abnormalities in chronic alcoholics and often noted that these alterations were reversible when alcohol was withheld for a sufficiently long period (422–424). Still others have observed low cardiac output, gallop rhythm, left ventricular failure, and a gradual refractoriness to thiamine therapy (425–427). Pathological changes ranging from microscopic areas of fibrosis to large confluent areas of fibrosis have been reported (428). A detailed study of 50 very heavy drinkers over a 10-year period revealed the usual functional changes of the heart with 10 deaths (429). At postmortem examination macroscopic fibrosis was found in the left ventricles with scattered areas of muscle degeneration and some fibrosis in all chambers. The lesions were said to resemble those produced by hypokalemia. It was suggested that they may have resulted from magnesium depletion, an effect known to occur with heavy drinking (430). The possibility that excessive alcohol consumption may have triggered an autoimmune reaction was also considered. In 10 patients examined for this purpose there were none of the usual reactions such as persistent fever, serositis, raised ESR, or arthropathy, but two of the 10 demonstrated anti-heart antibodies (429). Myocardial lesions have been reported to occur as a consequence of acute intoxication, although there was no evidence that chronic alcoholism was not a factor (431). An attempt has been made to correlate hemodynamic and biochemical changes in a group of hospitalized alcoholics (432). Hemodynamic changes were accompanied by the leakage of myocardial enzymes into the blood suggesting biochemical and physical alterations of the myocardium.

Electron microscope studies have demonstrated swelling of the mitochondria, a decrease in intramitochondrial enzymes, and deposition of lipid in myocardial cells from animals treated with alcohol (433). In chronic studies with alcoholic rats, impaired functioning of the citric acid cycle was observed with increased levels of pyruvate and lactate (434). Such changes were thought to be related to the myocardial lesions of chronic alcoholics (432). Dogs, to whom alcohol was administered for 12 weeks, demonstrated a marked and sustained increase in triglycerides, lipid phosphorus, and total cholesterol with a decrease in free fatty acids (435). The significance of these changes was related to the organ damage produced during chronic alcoholism. Recently, the question of whether chronic alcoholism produces myocardial damage through nutritional deficiencies was studied with pair-fed rats (436). Rats to whom alcohol was administered suffered from functional changes of the heart including arrhythmias following either epinephrine or mechanical

stress. These effects did not occur in the pair-fed animals, nor were they prevented by vitamin supplements. It was concluded that the myocardial toxicity of alcohol was not the result of nutritional deficiencies and it was speculated that alcohol may produce its effect through a reserpine-like action on the heart, an effect which has been previously reported (437, 438). The degeneration observed in the sympathetic neurons of chronic alcoholics (439) may also relate to catecholamine depletion.

DRUGS PRODUCING HYPERSENSITIVITY REACTIONS

It is not always clear whether a hypersensitivity reaction of the myocardium to drugs is the result of a direct injury to the myocardial cells or whether it is secondary to vasculitis. Interstitial and occasionally granulomatous myocarditis are the usual pathological lesions of the heart in these cases, although occasionally necrosis has resulted.

The sulfanamides are prone to produce such injury. The clinical administration of sulfanilamide was first demonstrated to produce myocarditis in 1939 (440). Since then this myocardial hypersensitivity has been reported again clinically (441–443) and been demonstrated using mice, rats, or rabbits (444, 445). The effect is not limited to sulfanilamide (440, 442, 444), but has been reported to occur with sulfapyridine (442, 444), sulfathiazole (441–445), sulfadiazine (441), and sulfasuxidine (442).

Myocarditis as a result of hypersensitivity to other drugs has been noted with chloramphenicol (446–449), chlortetracycline (450), streptomycin (451), carbutamide (452), and phenylbutazone (453). Penicillin sensitivity has been found to result in cardiomyopathies. Since 1950 a number of cases of minor myocardial reactions (454–460) and infarctions (461–466) have been reported.

Allergic myocardial reactions to vaccines, sera, and toxins have also been observed. The nature of the electrocardiographic changes produced by such agents was studied by Criep in 1931 (467). He postulated that the disturbances were the result of anoxia. Diphtheria (468–472) or typhoid (473) toxins were shown to produce fatty degeneration and necrosis of the myocardium in rabbits (469, 470, 473), guinea pigs (468, 470, 472, 473), rats (473), cats (471), or mice (473). Myocarditis and/or myocardial infarction have since been reported to result from the therapeutic administration of tetanus antitoxin (474, 475), rabies vaccine (476), and smallpox vaccine (477, 478).

ANDROGENS

A number of androgens were tested and found to be relatively nontoxic to the myocardium in rats (479) and guinea pigs (191) sensitized with monobasic sodium phosphate. When the rats were further sensitized by uninephrectomy and a high salt diet, or with other treatments, a greater degree of myocardial degeneration was produced (181, 480, 481). Adrenalectomy protected against such treatments, suggesting that at least part of the effect was related to the release of catecholamines and/or corticosteroids (482).

ANTICOAGULANTS

Anticoagulants continue to be a principal form of therapy for myocardial infarction, but there have been reports suggesting that they aggravate the condition (483, 484), retard healing of infarcts (485), and even produce fatal myocarditis due to a sensitivity reaction (486). Prolonged administration of bishydroxycoumarin in the diet of mice resulted in myocardial fibrosis, necrosis, and hemorrhage (487). These lesions were identical in appearance to those produced by the addition of sulfaguanidine to the diets of rats and were prevented by the administration of vitamin K.

HISTAMINE

While histamine is seldom used medicinally, its release from endogenous stores plays an important role in a number of pathological states. Following injury, locally released histamine is responsible for the initiation of an inflammatory response (488, 489). The administration of polymyxin B, a histamine-releaser, has been shown to produce severe myocardial necrosis in rats (490). A number of investigators have produced degenerative lesions in the hearts of experimental animals by the administration of histamine (94, 491–494). The pharmacodynamic and pathologic effects of histamine have been reviewed (495).

INSULIN

The administration of large doses of insulin to experimental animals has produced myocardial changes ranging from edema to disseminated necrotic patches (496–498). Other workers administering insulin for prolonged periods have been unable to demonstrate such lesions (499, 500). It has been suggested that the release of catecholamines and corticosteroids by insulin overdosage is the probable mechanism of toxicity (501). Insulin has been found to produce myocardial infarction during its routine use in the treatment of

diabetes (502–508) or when employed for shock therapy in schizophrenia (509, 510).

LOCAL ANESTHETICS

Large doses of local anesthetics have occasionally been observed to produce myocardial necrosis. The nature of this action has not been studied although, in most instances, it is probable that a marked fall in blood pressure was responsible. In one instance infarction followed procaine infiltration of the stellate ganglion (511). In other cases, injury was reported during the instillation of tetracaine into the urethra (512). Procaine–epinephrine has produced fatal infarction following its administration (513). The production of myocardial injury during spinal anesthesia has been reviewed by Gross *et al.* (514).

VITAMIN D

The administration of large doses of vitamin D has been shown to injure the myocardium of rachitic children (515) and of parathyroid patients (516). Myocardial calcium deposits were observed in patients using excessive amounts of vitamin D in conjunction with alkaline inorganic salts (517). Such effects have since been amply demonstrated in experimental animals (117–121, 183, 225, 518–523). The fact that such effects are difficult to produce except when vitamin D is combined with a potassium-depleting regimen strongly implicates low-potassium as the causative mechanism. In fact, a hypercalcemic nephropathy is produced by large doses of vitamin D, which in turn impair renal conservation of potassium (524).

Drug Transport Through Model Membranes and Its Correlation with Solubility Parameters

By SAID A. KHALIL* and ALFRED N. MARTIN†

The kinetics of drug transport through lipoidal barriers was studied using a series of nonpolar liquids as models of living membranes. The nonpolar liquids were selected to represent a range of different solubility parameters (Hildebrand δ values), which varied between 7.1 and 10.7. Carboxyl salicylic acid-^{14}C was used as the drug molecule, the solubility parameter of which was found to have a δ value of approximately 10.8. The rate of drug transfer was studied from layer *a*, an aqueous buffer solution of pH 2, representing the stomach, through layer *b*, a liquid lipoidal barrier representing the gastric mucosal barrier, to layer *c*, an aqueous solution buffered at pH 7.4, representing the blood serum. The rate constants for the drug transport were obtained using an analog computer. The distribution of the drug between the three layers can be represented by a mathematical expression from which drug concentrations in the layers at various times can be calculated. It was found that the closer the δ value of the drug molecule to that of the lipoidal barrier, the faster was the disappearance of the drug from layer *a* and the slower its appearance in layer *c*. The results provided an approach for estimating the desired chemical characteristics of drug molecules required for optimum membrane penetration.

THE PASSAGE of drug molecules across living membranes has been the subject of many studies. Mullins (2), in his review of the physical mechanisms involved in narcosis, postulated that the membrane acceptance of a narcotic molecule depends upon its having a cohesive energy density (Hildebrand solubility parameter) appropriate to that of the membrane, and that the membrane acceptance is related to the ideal partition coefficient of the narcotic drug. Brodie and his associates (3–10) reported that the absorption of drug molecules from the gastrointestinal tract depends on their ability to penetrate a lipoidal barrier, and that the transport of most drugs is accomplished by the passive diffusion of their unionized species. The importance of the physicochemical characteristics of drug molecules, their solubility as well as partition coefficients between aqueous media and lipoidal barriers, has received much attention since the start of this century (2, 9–20).

Hansch and his co-workers (21), employed a mathematical treatment to correlate the molecular structure of a series of chemically related compounds with biological activity. They considered the partition coefficient to be an important factor in the equation. Recently, Swintosky and his associates (22–24) reviewed the importance of partition coefficients in biological and pharmaceutical systems. They studied drug partitioning between aqueous solutions of different pH values representing the gastrointestinal contents, a nonpolar solvent representing the lipoidal barrier, and a buffer solution of pH 7.4, corresponding to the blood serum. They used a rocking Y-tube apparatus for their studies. The various possibilities of drug transfer between the three compartments were also reported. Schulman (25) had previously suggested a cell of different design for such studies, and Perrin (26) recently reported on the application of this apparatus for the study of drug absorption.

Factors such as pKa, pH (3–6), binding to plasma proteins (6, 27–32), and the existence of active transport mechanisms (33) have been investigated. No attempts, however, have reportedly been made to evaluate the characteristics of the different lipoidal barriers and to correlate the solubility properties of various drug molecules with the characteristics of lipoidal membranes. Since the early work of Meyer and Overton (11), the partition coefficient of drug molecules between water and immiscible nonpolar liquids has been determined. Yet, the selection of the specific nonpolar liquid in

such studies has not usually been made on a rational basis.

INTRODUCTION

In the present investigation, the Hildebrand solubility theory (1) is used to describe in a quantitative way a series of nonpolar liquids representing models of biological membranes. The values obtained can then be employed to correlate the structures and solubilities of drug molecules with ability to pass through different membranes. Work along similar lines has been reported by Mullins (2, 34) in his studies on narcosis and olfaction. Dikstein (35, 36) also used the solubility parameter as an index of drug action. It is proposed that Mullins' approach might serve as the primary step toward characterizing biological membranes relative to drug penetrability.

In vitro experiments were carried out to correlate the Hildebrand solubility parameters (δ values) of selected lipoidal barriers with the δ values of drug molecules passing through the barriers. This *in vitro* method was used to simulate *in vivo* transport of drugs through biological membranes. It was accomplished by the use of an apparatus essentially the same as that described by Doluisio and Swintosky (23), which consisted of a slow rocking bar to which a set of inverted Y-shaped tubes were fixed. The two arms of each Y-tube contained aqueous layers, and the two aqueous layers were separated by a nonpolar liquid that was immiscible with them. The liquid interface expanded and contracted with the rocking motion of the tubes, simulating movement of the gastrointestinal tract. A series of nonpolar liquids, having δ values which varied between 7.1 and 10.7, were employed. Carboxyl salicylic acid-^{14}C was used to represent the drug molecule, the δ value of which was determined using previously established techniques (37, 38). The rate of drug transfer, as well as equilibrium drug distribution in the different lipoidal barriers, was determined by measuring the radioactivity of the drug in samples of each of the three layers at various time intervals, using a liquid scintillation counter. Plots of the radioactivity *versus* time were made. The equilibrium concentrations in the three phases were read from the graphs, and the rate constants for the transfer of salicylic acid through the various lipoidal barriers were determined from the graphs using an analog computer.

The present kinetic method, developed by Doluisio and Swintosky (23) for determining the partitioning of drugs between various phases, is a more informative technique than usual partition coefficient measurements. Rate constants of both forward and reverse transfer, as well as partition coefficients, can be obtained by this method. Furthermore, a system consisting of two aqueous phases of definite pH and an intervening lipid phase more nearly simulates absorption conditions in some biological processes. Since absorption and drug action depend upon penetration of lipoidal barriers, this *in vitro* model appears to be suitable for studies on transport and action of drugs and has been adopted for the present study.

This report describes the rate of drug transfer through different lipoidal barriers having variable solubility parameters (δ values). An attempt was made to correlate the rate of drug transfer with the Hildebrand δ values of both the drug and the liquid lipoidal barrier, through which it passed. From the preliminary *in vitro* results, as well as those under investigation, it is hoped to correlate *in vitro* results with *in vivo* findings reported in the literature, using a specific drug molecule. By such a means, it should be possible to specify roughly the region of drug penetration and rate of transport. The site of absorption of the gastrointestinal tract and other biological barriers could then be assigned δ values, or similar parameters, which measure the polarity of the membranes.

The correlation of solubility properties of nonaqueous systems with a single parameter such as the δ value or the dielectric constant has been criticized, because it assumes the solvent phase to be a continuum; more emphasis should be placed on such factors as the solute–solvent–cosolvent interactions (39). Furthermore, biological membranes are complex structures, and it is not likely that a single parameter, adapted to express the polar nature of solvents, could be highly successful in characterizing a living membrane. The Hildebrand δ value is used here because it has a precise meaning and can be expressed in a quantitative manner. At a later point in this program, it is planned to introduce modified parameters or combinations of parameters to express in a more satisfactory way the polar character of complex living membranes.

THEORY AND CALCULATION

The system tested may be represented by the model:

$$A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} B \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} C \qquad \text{(Eq. 1)}$$

The kinetics of this system is expressed by the following equations:

$$V_a \frac{dA}{dt} = -V_a k_1 A + V_b k_{-1} B \qquad \text{(Eq. 2)}$$

$$V_b \frac{dB}{dt} = V_a k_1 A - V_b k_{-1} B - V_b k_2 B + V_c k_{-2} C \qquad \text{(Eq. 3)}$$

$$V_c \frac{dC}{dt} = V_b k_2 B - V_c k_{-2} C \qquad \text{(Eq. 4)}$$

Where V_a, V_b, V_c, are the volumes and A, B, C, are the concentrations of the drug at any instant in the three layers a, b, and c, respectively. The symbols k_1 and k_2 represent the apparent rate constants for forward drug transfer from a to b and from b to c; and k_{-1} and k_{-2} represent the apparent rate constants of the reverse drug transfer from b to a, and from c to b, respectively. A_0 is the initial concentration present in layer a at time t = 0, and:

$$A_0 = A + B + C \qquad \text{(Eq. 5)}$$

The volumes V_a, V_b, and V_c were in the ratios of 1:2:1. (See under *Experimental.*) In order to keep this ratio constant throughout the experiment, the sample volume withdrawn from layer b was double the volumes withdrawn from layers a

and c. The volume terms may therefore be neglected and Eqs. 2, 3, and 4 reduce to Eqs. 6, 7, and 8:

$$\frac{dA}{dt} = -k_1A + k_{-1}B \quad \text{(Eq. 6)}$$

$$\frac{dB}{dt} = k_1A - k_{-1}B - k_2B + k_{-2}C \quad \text{(Eq. 7)}$$

$$\frac{dC}{dt} = k_2B - k_{-2}C \quad \text{(Eq. 8)}$$

To calculate the true transfer rate constants, pH-partition effects must be taken into consideration by assuming that only the unionized portion of the drug molecule passes through the lipoidal membrane. The true rate constant k_1' is related to the apparent rate constant reported in this study, k_1, for the forward step from a to b of Eq. 1 by:

$$k_1' = \frac{k_1}{(1 - \alpha)} \quad \text{(Eq. 9)}$$

where α is the degree of ionization $[I/(U + I)]$ of the drug at the specified pH. The true rate constant may be defined (23) as:

$$k_1' = \frac{(U + I)}{U} k_1 \quad \text{(Eq. 10)}$$

where U and I are the unionized and ionized species of the drug molecule, respectively. In the present study, only the apparent rate constant is considered.

EXPERIMENTAL

Reagents—The solvents and their sources are given as follows: *n*-pentane, technical grade (b.p. 36.1°), *n*-hexane (b.p. 68.5–69°), and *n*-hexyl alcohol (b.p. 157–158°) from Eastman Organic Chemicals; *n*-octyl alcohol from Matheson Coleman & Bell (b.p. 193.5–195.1°); benzene from Baker & Adamson (b.p. 79.8–80.2°); toluene, Baker analyzed reagent (b.p. 110.1–110.7°); cyclohexane, Phillips (b.p. 80.5–82.0°). The reagents were redistilled, and the first and the last portions of the distillate were rejected. Distillation was continued until gas chromatography indicated that they were pure.

Karl Fischer reagent was obtained from Mallinckrodt Chemical Works; naphthalene, *p*-dioxane, and 2-ethoxyethanol were obtained from Eastman Organic Chemicals; 2,5-diphenyloxazole (PPO) and 1,4-bis-2-(4-methyl-5-phenyloxazolyl) benzene (dimethyl POPOP) were products of the Packard Instrument Co.

Carboxyl salicylic acid-^{14}C (17.5 μc./mg.) was synthesized in the laboratories of the Bionucleonics Department, Purdue University, Lafayette, Ind.[1] Its chemical purity was established by thin-layer chromatography. A sample of salicylic acid, Fischer certified reagent grade, which has been recrystallized from chloroform, was used as a reference standard. The radio-purity of carboxyl salicylic acid-^{14}C was determined by autoradiography.

Potassium chloride, monobasic sodium phosphate, sodium hydroxide, and hydrochloric acid were all of reagent grade.

Apparatus—The rocking device and Y-shaped tubes described by Doluisio and Swintosky (23) were used for the model membrane penetration experiment; a Beckman model 72 pH meter; Autoprep, model A 700 Aerograph; Wilkens-Anderson Lo-Temp constant-temperature bath; Packard Tri-Carb liquid scintillation spectrometer model 3003; and A. D. analog computer model 2-24 PB (Applied Dynamics, Inc.) were also employed in the study.

Procedure—Experiments were first conducted to determine the solubility of water (from the buffer solutions) in the nonpolar liquid phase. The drug, salicylic acid, was not added to the acid solution in these preliminary experiments. Inverted Y-shaped Pyrex glass cells were filled with the appropriate liquid phases. Into one arm was introduced 40.0 ml. of a KCl–HCl buffer solution of pH 2, and into the other arm 40.0 ml. of a phosphate buffer of pH 7.4. Then 80.0 ml. of a nonpolar liquid was carefully introduced into the cell over the two aqueous layers. A series of nonpolar liquids having different Hildebrand δ values (1) were used. These included *n*-pentane (δ = 7.1), *n*-hexane (δ = 7.3), cyclohexane (δ = 8.2), toluene (δ = 8.9), benzene (δ = 9.2), *n*-octyl alcohol (δ = 10.3), and *n*-hexyl alcohol (δ = 10.7). The rocking apparatus with its tubes was submerged in a thermostatically controlled water bath at 25 ± 0.1°. The apparatus was slowly rocked at a rate of one stroke per minute for a period of 24 hr. Then samples from the nonpolar liquids were taken and left in a separator for 24 hr. to allow any suspended water droplets to separate. The supernatant was analyzed for its water content using the Karl Fischer method.

The experiments were repeated substituting an aqueous pH 2 buffer solution of carboxyl salicylic acid-^{14}C (33.25×10^{-5} moles/L.) for the pH 2 buffer solution alone. The nonpolar liquids, *n*-octyl alcohol and *n*-hexyl alcohol, were presaturated with the aqueous buffer layers for 24 hr. as described above. The other solvents did not dissolve water sufficiently to require presaturation. On introducing the nonpolar liquid over the aqueous layers in each tube, care was taken to minimize any turbulence or mixing. The apparatus was rocked as described above, and samples were withdrawn from each of the three layers in each Y-tube at various intervals. Each sample was injected into a liquid scintillation spectrometer vial containing 15.0 ml. of liquid scintillator. The liquid scintillator consisted of 8.0% w/v naphthalene, 1.0% w/v of 2,5-diphenyloxazole (PPO), and 0.05% w/v of 1,4-bis-2-(4-methyl-5-phenyloxazolyl) benzene (dimethyl POPOP), in a mixture of toluene, *p*-dioxane, and 2-ethoxyethanol in the ratio of 1:3:3 parts by volume.

A blank for each experiment was carried out at the time, using the same procedure, but without the radioactive salicylic acid. The activity obtained from each sample of the blank experiment was considered as the background activity for its respective sample, and was subtracted from its activity when recording the results. The samples

[1] The authors wish to acknowledge the assistance of Dr. Wayne Kessler and Dr. A. Noujaim, Department of Bionucleonics, Purdue University, for their assistance in the radioactive analysis conducted in this study. Dr. A. M. Knevel, Department of Medicinal Chemistry, assisted in determining the identity and purity of the solvents.

TABLE I—APPARENT RATE CONSTANTS FOR THE TRANSFER OF SALICYLIC ACID THROUGH THE DIFFERENT LIPOIDAL BARRIERS

Nonpolar Liquid Used as Barrier	δ Value of Liquid Barrier	Adjusted δ Value of Barrier	∇[a]	Apparent Rate Constants (as Obtained from Analog Computer) × 10^4 sec.$^{-1}$ k_1	k_{-1}	k_2	k_{-2}
n-Pentane	7.1	7.1	3.7	0.024	0.003	0.650	0.003
n-Hexane	7.3	7.4	3.4	0.032	0.028	0.570	0.002
Cyclohexane	8.2	8.3	2.5	0.018	0.107	0.250	0.002
Toluene	8.9	8.9	1.9	0.126	0.008	0.335	0.000
Benzene	9.2	9.2	1.6	0.107	0.019	0.330	0.000
n-Octyl alcohol	10.3	10.8	0.0	0.230	0.003	0.019	0.000
n-Hexyl alcohol	10.7	11.4	0.6	0.452	0.005	0.042	0.008

[a] $\nabla = |\delta_D - \delta_B|$, where δ_D is the δ value of salicylic acid taken as 10.8, and δ_B is the δ value of the liquid lipoidal barrier.

were counted in a model 3003 Tri-Carb liquid scintillation spectrometer. Five 1-min. counts were taken and their average recorded.

An internal standard, carboxyl benzoic acid-^{14}C standard solution, was added to each sample and the sample was recounted so that the efficiency of the counting instrument, as well as the existence of any quenching effect due to the different samples in the liquid scintillator, could be determined.

The solubility parameter of the salicylic acid was determined using already established techniques (37, 38).

RESULTS AND DISCUSSION

From the Karl Fischer titration results, it was obvious that under the condition of the experiment the nonpolar layer became saturated with the aqueous layers, which resulted in a change in the δ values in some cases. From the estimation of water content, the δ values of the resulting nonpolar layers were calculated as described by Chertkoff and Martin (37). The results are summarized in Table I.

The water saturation effect was quite apparent in the case of *n*-octyl and *n*-hexyl alcohol resulting in an increase in their δ values of 0.5 and 0.7 unit, respectively. Because of this fact, it was important to presaturate these two liquids before the rate of drug transfer through them was determined. Presaturation was not required for the other liquids, as their water saturation capacity was very small, and their δ values were not changed significantly by the addition of water.

The solubility of the nonpolar phase in both aqueous layers no doubt affects the rate constant to a small extent. Only apparent rate constants are reported. It is more probable that this effect does not significantly alter the conclusion drawn from a consideration of the δ value of the lipoidal phase in relation to drug transport, which is the main concern.

The δ value of salicylic acid was found to be approximately 10.8. This value agrees with that given by Paruta *et al.* (40). They reported a dielectric constant requirement for salicylic acid of 15, possibly another of 25. The equation relating the dielectric constant ε and the delta value δ in pharmaceutical solvents, *i.e.*, alcohols, glycols, and water, reported also by Paruta *et al.* (41) is:

$$\delta = 0.22\,\epsilon + 7.5$$

The δ value for salicylic acid can thus be calculated:

$$\delta = 0.22 \times 15 + 7.5 = 10.8$$

Typical results obtained by determining the concentration of radioactive salicylic acid in the three different layers at various time intervals are shown in Figs. 1–4, where drug concentrations in each of the three layers as measured by radioactivity in c.p.m. *versus* time were plotted.

A consecutive first-order rate of transfer was expected from the results obtained. Curves were drawn to fit the experimental points using an *x–y* recorder attached to an analog computer. The analog computer was programmed to represent a reversible consecutive first-order transfer rate, as shown in Fig. 5. This model was quite suitable for the cases studied as shown by the fit of the computed curves to the experimental points. Apparent rate constants were obtained from the computer potentiometer settings for the best fitting curves, as shown in Table I.[2] From Table I, it is observed that a relation exists between the apparent rate of transfer of salicylic acid from a buffer solution of pH 2, layer *a* to the liquid lipoidal barrier, layer *b*. The results suggest that the closer the δ value of the liquid lipoidal barrier to the δ value of the drug molecule, the greater the rate of drug transfer or disappearance from layer *a*. This fact could also be shown if the logarithm of the concentration of salicylic acid in layer *a* was plotted *versus* time for all cases studied. Such curves for the different nonpolar liquids are found in Fig. 6. Straight lines (in most cases) with negative slopes were obtained. It was possible to relate the slopes of the linear portions of the lines to the δ values of the liquid lipoidal barriers used. The slopes increased as the δ values of the liquid lipoidal barriers increased.

Some of the results did not coincide exactly with those expected from the hypothesis connecting the slope or the apparent rate of transfer with the δ value of the nonpolar liquid layers, and these discrepancies are not easily accounted for. Cyclohexane has a δ value higher than *n*-pentane and *n*-hexane, and it should have produced a slope greater than the slopes for *n*-pentane and *n*-hexane. Yet it has the smallest slope of all tested nonpolar liquids. The reverse transfer rate constant of salicylic acid from *b* to *a* is significant in this case, namely 0.107 ×

[2] The dependability of the analog computer results as well as the *x–y* recorder were checked with an IBM 7094 digital computer. The rate constants calculated by use of the analog computer were fed to a digital computer to give the theoretically expected curves. The curves obtained by use of the digital computer fitted those produced on the *x–y* recorder by the analog computer. The digital program is not reported here, but may be obtained by contacting one of the authors.

10^{-3} sec.$^{-1}$. This finding has been reported previously in the literature (24). Similarly the rate of transfer of salicylic acid through benzene should be higher than through toluene, but the reverse was found. Again the reverse specific rate of transfer from *b* to *a* for benzene is higher than for toluene,

as shown in Table I. All other cases followed the expected correlation between the rate of drug transfer and the δ value of the lipoidal barrier through which the drug is transferred. It should be noted from Fig. 6 that the rate of transfer of salicylic acid through the rather polar liquids,

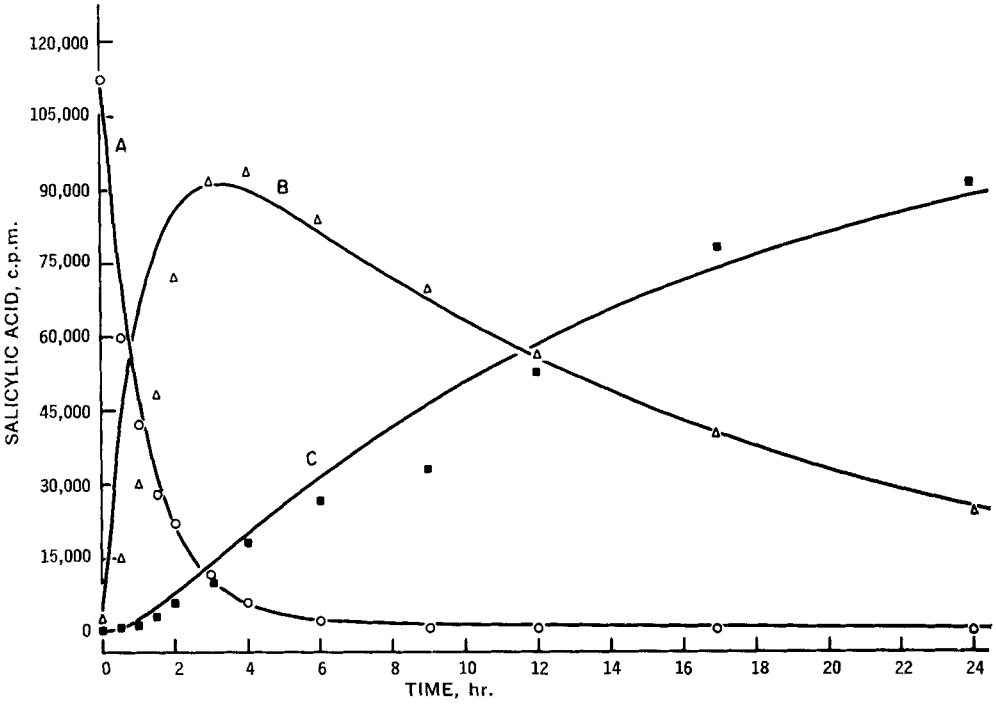

Fig. 3—The transfer of salicylic acid from an aqueous pH 2.0 buffer (layer a) *through a* n-*octyl alcohol barrier (layer* b) *to an aqueous pH 7.4 buffer (layer* c). *The points are experimental and the lines are theoretical. Key:* O, *pH 2.0 layer* a; Δ, n-*octyl alcohol layer* b; ■, *pH 7.4 layer* c.

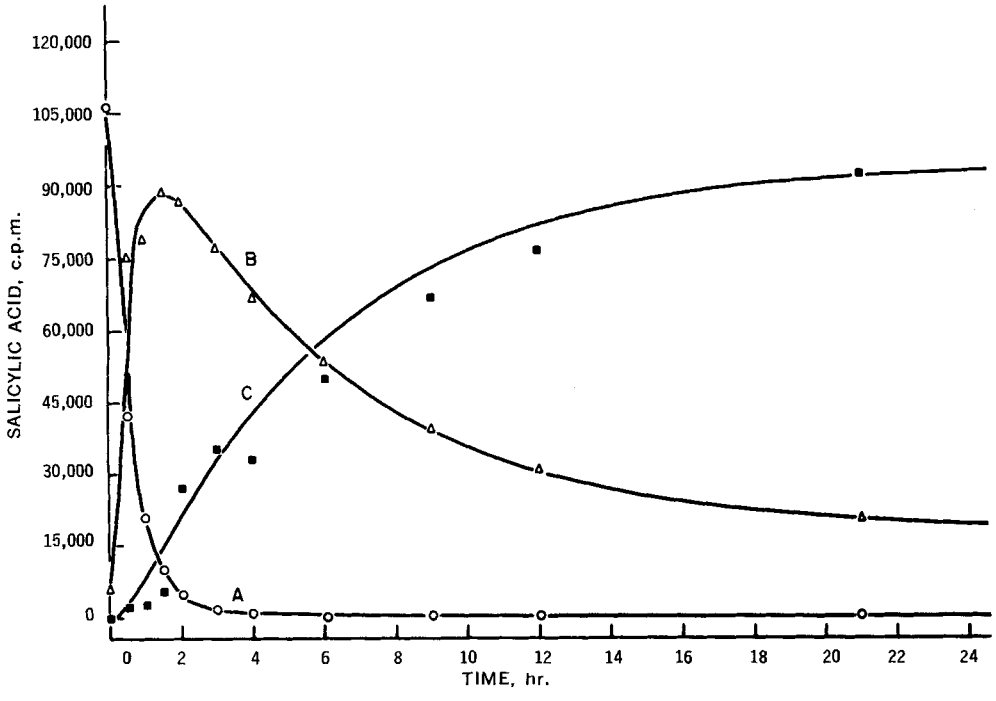

Fig. 4—The transfer of salicylic acid from an aqueous pH 2.0 buffer (layer a) *through a* n-*hexyl alcohol barrier (layer* b) *to an aqueous pH 7.4 buffer (layer* c). *The points are experimental and the lines are theoretical. Key:* O, *pH 2.0 layer* a; Δ, n-*hexyl alcohol layer* b; ■, *pH 7.4 layer* c.

n-octyl alcohol and *n*-hexyl alcohol, followed a first-order transfer in the first 3 to 4 hr., then began to disappear from *a* at a reduced rate, as can be seen by their curvilinear plots. This is probably due to the rapid onset of equilibrium between layers *a* and *b*. Such equilibrium requires longer periods of time to be reached in the relatively nonpolar barriers used.

In the case of *n*-octyl alcohol (Fig. 3) the analog computer curves representing layer *a* and *c* fitted the experimental data quite well, while in layer *b* the sample concentrations withdrawn in the early hours of the experiment were less than the expected theoretical concentrations. This is explained by the high rate of transfer from *a* to *b* with insufficient time for equilibration in layer *b*, and the concentration of the salicylic acid in the interface during the time that samples were taken from the bulk of the nonpolar layer. The same reasoning could explain the relatively lower concentration of salicylic acid in layer *c* as compared with the expected value when hexyl alcohol was used as the lipoidal barrier, as seen in Fig. 4. Doluisio and Swintosky (24) suggested that deviations in solvents, such as octyl alcohol, are possibly due to hydrogen bonding.

The second observation which can be made from Table I is that the apparent rate constant, k_2, of transfer of salicylic acid from the liquid lipoidal barrier, layer *b*, to layer *c*, decreased with the increase in the δ value of the liquid lipoidal barrier. The reverse rates of transfer k_{-1} and k_{-2} are considered to be small in most cases and their effects are negligible. Consequently, a plot of the forward rate constants, k_1 and k_2, can be made *versus* the δ value of the liquid lipoidal barrier, as shown in Fig. 7. Although the points do not lie well along the lines, it is observed that k_1 increases and k_2 declines with an increase in the δ values of the organic solvents. Theoretically, k_1 should reach a maximum and then fall off, whereas k_2 should reach a minimum and then rise. The expected maximum and minimum values should be reached at a δ value of about 10.8, the δ value of salicylic acid. Such a maximum or minimum could not be obtained experimentally in this work due to the failure to find a nonpolar liquid that was immiscible with water and also had a δ value higher than 10.7.

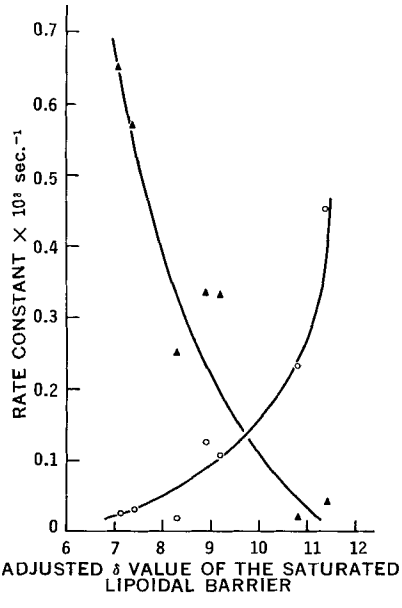

Fig. 7—Apparent rate constants for the transfer of salicylic acid from layer a *to layer* b, k_1 *and from layer* b *to layer* c, k_2, vs. *the adjusted* δ *values of the liquid lipoidal barrier layer* b. *Key:* ○, *rate of transfer from* a *to* b, k_1; ▲, *rate of transfer from* b *to* c, k_2.

If liquids could be found to provide a broader spectrum of δ values, and at the same time immiscible with the buffer solution, a maximum might be reached in the rate of drug transfer from *a* to *b* and a minimum from *b* to *c*. These points should then correspond to the δ value of the drug used.

In general, although only one compound, salicylic acid, was used as a solute in this work, the results suggested that the apparent rate constant, k_1, of drug disappearance from layer *a* to the liquid lipoidal barrier *b*, would increase with a decrease of the difference, ∇, in the δ values between the drug and the lipoidal barrier:

$$\nabla = |\delta_D - \delta_B|$$

where δ_D is the δ value of the drug molecule and δ_B is the δ value of the lipoidal barrier. The apparent rate constant, k_2, of drug release from the lipoidal layer to the aqueous layer *c* should decrease with the decrease in ∇.

The trend of ∇ values with k_1 and k_2 is observed in Table I. Thus, it might be said that as the δ value of the drug molecule approaches that of the lipoidal barrier, the rate of transfer of the drug to the lipoidal barrier increases and the rate of release of the drug from the lipoidal barrier decreases. The lipoidal barrier would tend to act as a storage compartment for the drug molecules with a prolonged release time. An optimum rate of passage of the drug from one aqueous compartment to another through a lipoidal barrier should occur when the δ value of the drug was somewhat different from that of the barrier. As seen in Fig. 7, the curves for k_1 and k_2 intersect at δ = 9.7. This should be the optimum δ value of the simulated membrane for the most rapid penetration of a drug with a δ value of 10.8. The principle might also be applied to the sustained release of drugs from tissue depots. Here one would desire a δ value of the drug relative to that of the tissue such that the drug penetrates rapidly into the tissue yet is released at a slow rate over a prolonged period of time.

The kinetics of the transfer of salicylic acid through the different lipoidal barriers studied can be an *in vitro* model for some of the theoretically possible kinetics cases suggested by Doluisio and Swintosky (24). From the values of the apparent rate constants found in Table I, as well as the concentration of drug at various times as seen in Figs. 1 through 4, the following cases are observed.

The transfer of the drug through *n*-pentane can be considered to represent kinetics of the type $a \rightarrow c$. This is possible because the concentration of the drug in layer *b* is relatively small and does not accumulate (see Fig. 1), and the reverse transfer rates, k_{-1} and k_{-2}, are also small and can be considered negligible (see Table I). Using cyclohexane as the lipoidal barrier, the process can be simulated by kinetics of the type $a \rightleftharpoons b \rightarrow c$. This is due to the relatively large rate of reverse transfer from *b* to *a*, and the relatively fast rate of forward drug transfer from *b* to *c*. Drug transfer through *n*-octyl alcohol can represent the kinetics of the type $a \rightarrow b \rightarrow c$. The drug builds up in layer *b*, and the reverse rate constants are very small and can be considered negligible. The results of the present study are summarized in Fig. 8, where the length of the arrows represent the relative rates of forward and reverse processes.

The concept of using δ values as one of the parameters that may explain the relative rates of drug transport across biological membranes and subsequent equilibrium concentrations can be applied to some of the experimental data reported by Brodie *et al.* (6). They reported that salicylic acid and barbital exist mainly in the stomach in their unionized form; yet the absorption of salicylic acid was quite high, while that of barbital was very poor. This fact can perhaps be explained by saying that the δ value of salicylic acid (δ = 10.8) is closer to the supposed δ value of the gastric lipoidal barrier (δ = 10) than that of barbital with a δ value of about 13.5. The δ values of salicylic acid and barbital were obtained by the method of Chertkoff and Martin (37), and the results are shown in Fig. 9.

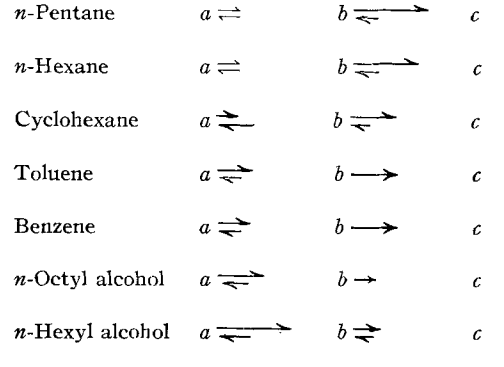

Fig. 8—Representation of the system A ⇌ B ⇌ C, *where the length of the line signifies the relative magnitudes of the rate constants.*

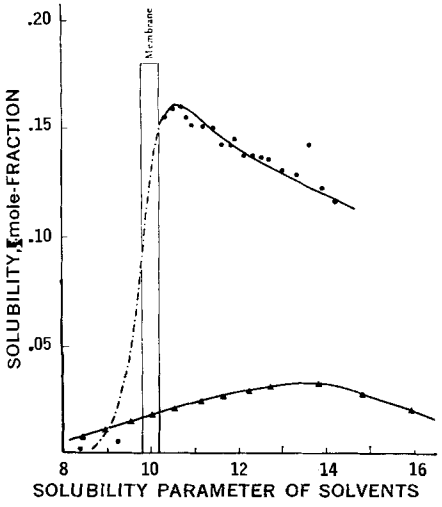

Fig. 9—Determination of the solubility parameter of salicylic acid and barbital at 25°. Key: ●, salicylic acid; ▲, barbital.

One observes from Fig. 9 that the suggested δ value for optimum penetration into the lipoidal membrane is about 10. Salicylic acid with a δ value of 10.8 being close to the δ value of the membrane will easily cross the lipoidal barrier. Barbital has a δ value of about 13.5,[8] well beyond the δ value of the membrane and would not be expected to show marked membrane penetrability.

SUMMARY AND CONCLUSIONS

The rate of transfer of carboxyl salicylic acid-^{14}C through different liquid lipoidal barriers was studied and the rate constants were determined using an analog computer. The liquid lipoidal barriers used represented a range of different solubility parameters expressed as Hildebrand δ values. A correlation between the δ value of the liquid lipoidal barrier, the δ value of the drug model, salicylic acid, and the rate of transfer of the drug through the lipoidal barrier has been presented. It is hypothesized that the smaller the difference between the δ value of a drug molecule that exhibits significant lipid solubility, and the δ value of the liquid lipoidal barrier, the faster would be the transfer across the barrier and into the lipoidal layer, and the slower the drug would be released from the lipoidal layer into the aqueous buffer phase. This suggests that a quantity ∇ could perhaps be used to express the optimum difference in δ values of the drug and membrane for transport and penetration by the drug. The results of the study seem to bear out this principle, but a number of drugs and liquids of varying δ values must be tested before the hypothesis can be accepted.

The δ value concept may also be valuable in relating partition coefficients to drug action. The proper choice of the nonpolar liquid in partition coefficient experiments may be arrived at through a knowledge of δ values, and the authors intend to present the results of a study dealing with this suggestion at a later time.

The goal is to be able to correlate *in vitro* with *in vivo* results and suggest molecular structures which can facilitate drug transfer across membranes, and drug release from tissue depots in the body. The region of absorption and drug release at the lipoidal barriers in the gastrointestinal tract and other membranes and tissues could be assigned δ values, or more acceptable polarity parameters, which would account for the complex nature of these biological structures.

[8] Barbital has no sharp maximum point of solubility in the solvents studied, and it is difficult to assign it a definite δ value. The solubility of barbital over the whole range of δ values from 7 to 16 is seen to be low and accordingly the drug is not expected to show marked solubility in the simulated membranes.

Effect of Deuterium Oxide on the Saprophytic Culture of *Claviceps* II

Alkaloid Production

By R. G. MRTEK*, H. L. CRESPI, M. I. BLAKE, and J. J. KATZ

The effect of growth conditions on alkaloid production by *Claviceps* in a deuterated environment was explored. Alkaloid formation was strongly inhibited in fully deuterated organisms. Consequently, a replacement culture technique was developed for the biosynthesis of highly deuterated alkaloids. Cultures grown in an ordinary hydrogen environment were transferred to a deuterated medium containing various substrates such as tryptophan, mevalonic acid, phenylalanine, succinic acid, and sugars, either as hydrogen or deuterium compounds. Multimilligram amounts of alkaloids were obtained from replacement cultures containing phenylalanine and deuterio-succinic acid as substrates. The alkaloid fraction, consisting of elymoclavine with minor amounts of agroclavine, was isolated by solvent extraction. The alkaloids were identified by thin-layer chromatography, and the incorporation of deuterated substrate into the alkaloids by the replacement culture technique was verified by NMR spectroscopy.

In the previous paper (1) of this series the nutritional factors involved in optimal growth of *Claviceps* (strain 47A-Tyler) in high concentrations of heavy water were investigated. The successful maintenance of a fully deuterated organism in saprophytic culture was achieved on a medium containing fully deuterated mixed monosaccharides (2%), deuterio-succinic acid (0.5%), and traces of vitamins in a low phosphate salt medium. However, in high concentrations of D_2O the formation of alkaloids was found to be strongly impaired. Consequently, a replacement culture technique was used to induce the elaboration of deuterated alkaloids from water-grown fungal tissue that was resuspended in a medium containing more than 98% D_2O.

EXPERIMENTAL

General Culturing Techniques—The organism used for all experiments in this investigation was a high alkaloid-yielding strain of *Claviceps purpurea*, strain 47A. Conditions for growth, culturing techniques, and adaptation studies in D_2O are described in the previous paper (1).

Replacement Culture Method—The mycelia of 1-L. sterile cultures were used as the "raw tissue" for preparative replacement cultures. This tissue was transferred aseptically from 3-L. conical growth flasks to 1-L. polypropylene bottles, which had been previously sealed with aluminum foil and then autoclaved. The bottles were then centrifuged for 15 min. at 1600 r.p.m. in an International centrifuge, size 2, model V. The supernatant nutrient was decanted and 600 ml. of sterile D_2O was added to the packed mycelia in each bottle. The contents were stirred thoroughly with a sterile glass rod and the bottles were again centrifuged. This process was repeated with 400 ml. of sterile D_2O. Then the mycelia were washed twice with 500-ml. portions of sterile 0.1 *M* phosphate buffer in D_2O, pD 7.1. Finally, 800 ml. of 0.1 *M* phosphate D_2O buffer solution plus any substrates, as indicated in the particular experiment, was added to each bottle. This constituted the replacement medium. The mycelia were dispersed in the medium and the contents were transferred to a clean sterilized 3-L. culture flask. The bottle was rinsed with 200 ml. of sterile replacement medium, and this solution was also added to the culture flask. A 5-ml. aliquot of the culture was withdrawn aseptically, centrifuged, and the supernatant solution analyzed for deuterium content. The culture flask was returned to the shaker for incubation. All manipulations of exposed cultures were performed in a bacteriological hood under sterile conditions.

In developing the optimum conditions for alkaloid production on a preparative scale and in evaluating the effect of substrates, preliminary replacement cultures were prepared using smaller volumes of medium. The tissue from 50 ml. of a dense aqueous fungal suspension was centrifuged, washed, and transferred to two replacement cultures of 50-ml. volume each in 125-ml. conical flasks, resulting in a twofold dilution of the semisolid fungal culture. All replacement culture flasks were incubated at 25° on a rotary shaker. Deuterium oxide and alkaloid analyses were performed periodically throughout the culturing period.

Addition of Substrates—A variety of metabolites was examined by the replacement culture technique. Phenylalanine and succinic acid were incorporated directly into the medium prior to autoclaving. Heat labile components, such as mevalonic acid and vitamin mixtures, were sterilized by filtration of a concentrate through a Millipore filter into the sterile medium.

Accepted for publication June 19, 1967.

Presented to the Pharmacognosy and Natural Products Section, A.PH.A. Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

Abstracted in part from a dissertation presented by R. G. Mrtek to the Graduate College, University of Illinois at the Medical Center, Chicago, in partial fulfillment of Doctor of Philosophy degree requirements.

This study was performed under the auspices of the U.S. Atomic Energy Commission, Washington, D.C.

* Present address: Department of Pharmacy, University of Illinois at the Medical Center, Chicago, IL 60612

Previous paper: Mrtek, R. G., Crespi, H. L., Blake, M. I., and Katz, J. J., *J. Pharm. Sci.*, **54**, 1450(1965).

Mevalonic acid was obtained from a commercial source[1] as a high purity dibenzylethylenediamine salt. The free acid was prepared by passing an aqueous solution of the salt through an ion-exchange resin column,[2] 1 × 5 cm. The free acid was eluted from the column with water until the pH was neutral, and the eluate was then concentrated to a small volume with a rotary evaporator. Ten milliliters of phosphate buffer was added, and the solution was then lyophilized. The solids were dissolved in 25 ml. of D_2O and the solution was lyophilized again. Finally, the solids were dissolved in 10 ml. of D_2O and the solution was added to the culture medium by filtration through a Millipore filter.

Tryptophan, which is relatively insoluble and heat labile, was incorporated directly into the replacement medium. The solution was then filtered through a Millipore filter. The filtrate was collected in a sterile 2-L. flask to which was attached a short length of cotton-plugged sterile pressure tubing.

All replacement cultures were prepared in duplicate and were incubated on a rotary shaker. Deuterium analyses of the nutrient were performed at the start of an experiment and periodically throughout the course of the study. Periodic alkaloid determinations were performed during the incubation period.

Alkaloid Analysis—Total alkaloids were determined by a modification of the method of Michelon and Kelleher (2). A sample of medium (5 to 10 ml.) was withdrawn aseptically and clarified by centrifugation. An aliquot of the supernatant solution containing between 5 and 50 mcg. of total alkaloid was transferred to a 25-ml. Squibb funnel. The solution was made basic with a few drops of ammonium hydroxide and extracted with two 7-ml. portions of chloroform. The chloroform extracts were placed in a separator containing 2.0 ml. of water. Exactly 2.0 ml. of 0.1% *p*-dimethylaminobenzaldehyde in 50% (v/v) H_2SO_4 was pipeted into the separator which was then stoppered and shaken vigorously for 1 min. The aqueous layer was transferred quantitatively to a 15-ml. centrifuge tube and was allowed to stand until 15 min. had elapsed from the time that the acidic reagent had been added to the separator. Then 0.10 ml. of a 0.1% aqueous sodium nitrite solution was added to the centrifuge tube. A blue color developed upon gentle agitation of the tube. The tube was centrifuged for 1 min. and the clear supernatant solution was transferred to a 1-cm. cell by a dropping pipet. Absorbance measurements were made at 585 mμ with a Cary-14 spectrophotometer. Total alkaloid calculated as elymoclavine was determined from a standard curve prepared with authentic elymoclavine.

Deuterium Analysis—The deuterium oxide content of the nutrient was determined by the infrared absorption method described by Crespi and Katz (3).

Isolation of Alkaloids—The mycelia in the replacement cultures were separated from the liquid by filtration through a coarse sintered-glass funnel and the filtrate was clarified by passage through a bed of diatomaceous earth.[3] After the volume was reduced to 300 ml. on a rotary evaporator at 30°, the solution was rendered basic with 25 ml. of ammonium hydroxide and extracted with 400 ml. of chloroform in a 1-L. separator. Three extractions with 200-ml. portions of chloroform were carried out and the combined chloroform extracts were concentrated to 200 ml. in a rotatory evaporator at 30°. The concentrate was washed three times with 50-ml. portions of 1 *N* ammonium hydroxide, and the ammoniacal washings were discarded after showing a negative alkaloid test with the modified Ehrlich's reagent. The chloroform solution was then extracted with 20-ml. portions of 2% tartaric acid solution until the extracting solution gave a negative alkaloid test.

The tartaric acid solution was cooled in an ice bath, adjusted to pH 8.5 with ammonium hydroxide, and extracted three times with 15-ml. portions of chloroform. The combined chloroform extracts were dried over anhydrous magnesium sulfate, concentrated to a small volume in a rotary evaporator at 25°, and transferred quantitatively to a tared glass tube sealed at one end. The solution then was evaporated to dryness at room temperature under a stream of nitrogen gas. Last traces of solvent were removed by evacuation in a vacuum line for 30 min., and the yield of alkaloid determined by weighing.

Thin-Layer Chromatography—Chromatographic analysis of alkaloid fractions was performed on Silica Gel G plates. Plates were spread to a uniform 250-μ layer with a Desaga variable thickness spreader, dried at room temperature overnight, and stored in a desiccator until used. Immediately before use, the plates were activated by heating for 20 min. at 110°. After the plates had cooled in a desiccator, spots containing 5 to 20 μl. of sample in chloroform were applied.

The chromatogram was developed in an oversaturated chamber containing ethyl acetate–acetone–diethylamine (10:10:2). The solvent front was marked, and the chromatogram was allowed to dry thoroughly at room temperature. The dried chromatogram was sprayed with von Urk's reagent prepared by dissolving 0.5 Gm. *p*-dimethylaminobenzaldehyde in a mixture of 50 ml. of 25% HCl and 50 ml. of 95% ethanol. After the chromatogram was sprayed, it was heated at 110° for 5 min. The plate was cooled and first sprayed lightly with a fresh solution of 0.05% $NaNO_2$ in 50% ethanol and then sprayed with a mixture of equal volumes of 95% ethanol and 25% HCl. The spots containing the indole alkaloids became intensely blue. R_f values were measured from densitometric scans prepared when the color of the spots was at maximum intensity.

RESULTS AND DISCUSSION

In cultures grown under fully deuterated conditions (1, 4) alkaloids were never detected in the medium in greater than trace amounts. Inocula size, aeration, light, and varying culture volumes had little, if any, effect in stimulating the production of alkaloids, even after incubation periods as long as 3 months. Fully deuterated cultures incubated in closed cabinets containing a D_2O saturated atmosphere were observed for periods up to 6

[1] Calbiochem, Los Angeles, Calif.

[3] Marketed as Celite by the Johns-Manville Corp., New York, N. Y.

months. Tissue growth appeared to cease after about 2 months. The deuterio-culture became pigmented, as in the case of ordinary cultures, but no alkaloids formed. Thin-layer chromatograms failed to reveal the presence of even trace amounts of alkaloids in any culture medium obtained from fully deuterated *Claviceps*.

Decantation of the medium from a deuterated culture, followed by replacement with fresh complete D_2O medium, caused additional tissue growth and elaboration of pigment, but no alkaloid synthesis. Essentially the same observations were made when the deuterated cultures were supplemented with added deuterio-monosaccharides and vitamins. Addition of (D_2O-exchanged) protio-phenylalanine or protio-tryptophan also failed to stimulate alkaloid production. Different stock slants of *Claviceps* were adapted to growth in D_2O, but the resultant cultures all failed to produce alkaloids. The protio-ancestor of each deuterium experiment was carried through successive H_2O transfers to test for strain regression. Such "control" protio-cultures were still capable of producing clavine alkaloids at the conclusion of the deuterium experiments.

Thus, the prospect of obtaining alkaloids from a culture of *Claviceps* grown under fully deuterated conditions is not good. The absence of alkaloids may be the result of (*a*) an incomplete medium, or (*b*) a primary repression of one or more enzymatic mechanisms involved in alkaloid synthesis. As for the first possibility, the development of a defined medium for any biologic clone is a highly empirical task. Apart from the obvious additions of selected substrates and variation in phosphate concentration which is known to have a strong effect on alkaloid production in water, there are no obvious nutritional factor or factors that may be invoked to allow *Claviceps* to produce clavine alkaloids. To locate the specific sites of the deuterium isotope effect in the biochemical mechanisms of the fungus requires a much more thorough understanding of individual enzyme systems responsible for alkaloid production than is now available for the organism under normal conditions.

Based on the experiments described above, a new set of experimental conditions was devised to study alkaloid production in *Claviceps* at high levels of D_2O. These experiments were designed to require the organism to utilize deuterium under physiologic conditions in which alkaloid synthesis is known to occur.

Replacement culture techniques have been employed by other investigators in studies involving the saprophytic culturing of strains of *Claviceps* in aqueous media. Thus, Brady and Tyler (5) investigated the effect of certain precursors on the production of clavine alkaloids, while Groger and Erge (6) reported the effects of mannitol solutions in supporting alkaloid production by the replacement technique. Abe *et al.* (7) used a surface replacement culture technique in their studies of alkaloid production. Suitable choice of replacement media allows alkaloid production to be studied under conditions independent of growth. Thus, replacement studies permit the separate analysis of the effects of deuterium isotope substitution on vegetative growth and on alkaloid production.

In these experiments the organism was allowed to mature on an aqueous medium containing 10% mannitol and 0.5% protio-succinic acid added to a stock solution of Tyler's salt mixture (8). The organism was then introduced into a D_2O medium containing only deuterium exchanged phosphate buffer salts and selected substrates. Growth was virtually stopped by selecting a buffer of high ionic strength and a pH far removed from the growth optimum. No trace elements or other substrates normally required in a complete growth medium were added. Under such conditions the clone may either undergo autolysis or it may supply its own respiratory requirements by whatever metabolic routes are still available to it. It is recourse to the latter alternative that usually results in the elaboration of metabolites which are the end products of normally nonobligatory pathways.

In preliminary studies performed on replacement cultures a number of compounds, singly and in combination, were tested for their ability to stimulate alkaloid production. Alanine, 5-fluorotryptophan, *p*-fluorophenylalanine, and anthranilic acid were not found to induce alkaloid synthesis. The amino acid fraction isolated from fully deuterated algae (9) likewise had no demonstrable effect on alkaloid production. Although fully deuterated aspartic acid, glutamic acid, alanine, and glycine are present in large amounts in this mixture, no alkaloids are formed. In accordance with conclusions arrived at by studies in H_2O medium, only phenylalanine and tryptophan of the amino acids tested are capable of serving as substrates for clavine alkaloid synthesis in D_2O replacement cultures.

Figure 1 demonstrates the effect of various substrates on alkaloid production in a replacement culture. These include 0.1% tryptophan, 0.2% mevalonic acid, 2.0% protio-glucose, and 2.0% deuterio-sugars (glucose–mannose, 1:1), obtained from fully deuterated algae (9). In most instances a vitamin mixture supplement was added (1). In the absence of additives no alkaloid production took place (curve F). Mevalonic acid alone was a poor substrate (curve E), but tryptophan alone did serve as an adequate substrate (curve D). However, in the presence of mevalonic acid and vitamins, alkaloid production increased somewhat (curve C). Maximum alkaloid production occurred when tryptophan, mevalonic acid, sugars, and vitamins were included in the medium. Protio and deuterio-sugars produced essentially the same effect as can be seen in curves A and B.

In another series of experiments (Fig. 2) protio-phenylalanine and protio-succinic acid were utilized as substrates in replacement cultures. Phenylalanine alone at a concentration of 0.5% was the most effective in stimulating alkaloid formation (curve E). When succinic acid was added, alkaloid production diminished (curve D). Severe inhibition resulted when the succinic acid concentration was increased tenfold and the phenylalanine concentration was reduced to one-fifth (curve C). After 20 days not even a trace of alkaloid was detected in the medium. The addition of protio-glucose suppressed alkaloid synthesis (curve A). This may be a result of the utilization of the substrates for growth rather than for alkaloid production. When all substrates were omitted the organism failed to produce alkaloids in any measurable quantity.

Multimilligram amounts of deuterated alkaloids

Key: A, *0.1% tryptophan, 0.2% mevalonic acid, 2.0% protio-glucose, and vitamins in trace amounts;* B, *tryptophan, mevalonic acid, deuterio-sugars, and vitamins;* C, *tryptophan, mevalonic acid, and vitamins;* D, *tryptophan;* E, *mevalonic acid;* F, *control.*

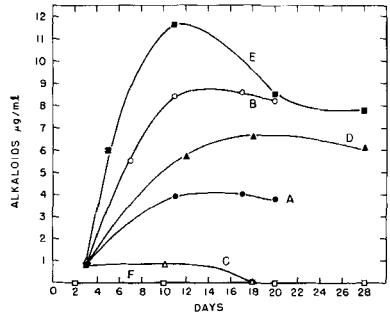

Fig. 2—Alkaloid production in D_2O replacement cultures in the presence of certain substrates. Key: A, *0.5% phenylalanine, 2.5% succinic acid, 2.0% protio-glucose;* B, *0.5% phenylalanine, 2.5% succinic acid;* C, *0.1% phenylalanine, 2.5% succinic acid;* D, *0.5% phenylalanine, 0.2% succinic acid;* E, *0.5% phenylalanine;* F, *control.*

were obtained from large-scale preparative replacement cultures in D_2O. For this purpose the replacement medium contained 0.5% protio-phenylalanine and 0.5% protio-succinic acid dissolved in 99% D_2O. The phenylalanine and succinic acid were exchanged[4] with D_2O prior to incorporation into the medium. In a second experiment protio-phenylalanine and succinic acid-d_6, both of which were exchanged with D_2O, were used as substrates in a D_2O medium. In the first culture, the only source of deuterium accessible to the organism was the solvent D_2O used in the medium. In the second culture the organism was required to utilize deuterium from both the solvent and the nonexchangeable positions of the deuterio-succinic acid. Table I gives the yield of deuterated alkaloids obtained from these cultures. A total of 24.8 mg. was obtained in the first experiment and 9.0 mg. in the second.

Thin-layer chromatography of the purified deuterated alkaloid fraction indicated that only elymoclavine was formed in the highly deuterated cultures. No agroclavine could be detected in the alkaloid fraction. With the chromatographic solvent system employed in this study protio-elymoclavine and protio-agroclavine had R_f values of 0.29 and 0.59, respectively. Deuterated elymoclavine had a distinctly lower R_f value of 0.27, as observed previously for other deuterated compounds (9).

[4] Deuterium atoms exchange only for the hydrogen of the carboxyl and amino groups.

TABLE I—YIELD OF DEUTERATED ALKALOIDS BY REPLACEMENT CULTURE METHOD

Substrate	D_2O Content,[a] %	Incubation Period, Days	Vol. at Harvest, ml.	Total Alkaloids, mg.
Protio-phenylalanine (0.5%) Protio-succinic acid (0.5%)	99.0	26	1900	24.8
Protio-phenylalanine (0.5%) Deuterio-succinate (0.5%)	98.8	24	1920	9.0

[a] Determined at harvest.

A complete nuclear magnetic resonance (NMR) analysis was carried out on authentic samples of protio-clavine alkaloids and on deuterated elymoclavine. Spectra were obtained with a Varian HA-100 spectrometer using alkaloid solutions which were 0.1 *M* in pyridine-d_5. From these data it was possible to deduce the H/D ratio at the various hydrogen positions in the molecule. The elymoclavine obtained from replacement cultures in 99% D_2O with added protio-succinate and protio-phenylalanine was highly deuterated at all positions. The hydrogens at positions 10 and 17 were completely replaced by deuterium and the hydrogens at positions 4, 5, 6 (CH_3—N), 7, and 9 contained from 68 to 86% deuterium. These data indicate extensive labilization of carbon-bound hydrogen during the biosynthesis of the alkaloid. In a similar replacement culture containing deuterio-succinate in place of protio-succinate (Table I) the over-all level of deuteration was not significantly different. The complete details and analysis of these experiments are to be published in a subsequent paper.

When deuterated tissue was used in a replacement culture experiment, no alkaloids were elaborated. In addition, when deuterated tissue was introduced into an H_2O replacement medium, no alkaloid synthesis occurred. The phenomenon of alkaloid production is probably nonessential and organisms which elaborate this class of compounds do so only under specific and often nonobligatory conditions.

It appears that a primary effect of deuterium in biological systems is the suppression of nonessential metabolism. The stress imposed on *Claviceps* by the introduction of large amounts of deuterium results in the utilization of available metabolites to maintain the nutrition of the isotopically altered fungus at the expense of alkaloid synthesis.

Establishment of Sink Conditions in Dissolution Rate Determinations

Theoretical Considerations and Application to Nondisintegrating Dosage Forms

By MILO GIBALDI and STUART FELDMAN

The importance of approximating perfect sink conditions for the determination of dissolution rates which may be correlated with *in vivo* results is pointed out. A theoretical treatment of zero and first-order dissolution under perfect sink and nonsink conditions is presented. It is shown that unless sink conditions are maintained, *in vitro* results will bear little relationship to *in vivo* observations. The use of an organic solvent phase which can function as a reservoir for dissolved drug and thereby maintain sink conditions in the aqueous dissolution fluid is demonstrated for a model nondisintegrating tablet exhibiting zero-order drug release. The use of an organic solvent reservoir for the determination of first-order dissolution rates is also discussed.

One of the most important as well as most difficult approaches in the biopharmaceutic evaluation of a drug is the quantitative correlation of absorption and *in vitro* dissolution kinetics. Levy *et al.* (1) have recently reported the development of a single *in vitro* dissolution rate test which correlates quantitatively with the gastrointestinal absorption, in man, of aspirin from three markedly different types of dosage forms. The basic method, however, is limited to the study of drugs which are relatively water soluble.

Dissolution rate-limited absorption implies that there is no build-up of drug concentration in the gastrointestinal fluids, *i.e.*, the fluids function as a perfect sink. Unless this condition is embodied in the design of the *in vitro* test (*i.e.*, drug concentration in the dissolution fluids does not exceed 10 to 20% of solubility), *in vitro* results will bear little relationship to *in vivo* observations (2).

As noted recently by Levy (2), those drugs which represent the greatest dissolution problem are also those which are least soluble and give the greatest difficulty with respect to maintenance of perfect sink conditions. Frequently, it is necessary to use exceedingly large volumes of solvent for this purpose and to adopt very sensitive analytical procedures. At times, it may be very difficult to follow the dissolution of more than a small fraction of the drug contained in the dosage form. Under these conditions one must assume a uniform pattern of release rate. Wood (3), however, has pointed out that in practice there are many cases in which one point in time or a rate constant does not characterize the dissolution process and a full dissolution curve (based on the total drug content of the dosage form) is required for *in vitro* to *in vivo* correlation.

A definite need exists for the development of methodology to maintain sink conditions during dissolution rate determinations of poorly soluble drugs. Levy (2) has suggested two possibilities: the use of an upper organic phase which can act as a reservoir for the dissolved drug or the addition of adsorbents to the aqueous medium. The ability of adsorbents to maintain "sink" conditions had been demonstrated previously by Wurster and Polli (4). Both approaches involve the same principle, *i.e.*, removal of dissolved drug from the dissolution medium and prevention of accumulation. The removal of drug from the dissolution fluid is analogous to removal of drug from the gastrointestinal fluids by the absorption process in dissolution rate-limited absorption.

The present report concerns the theory and application of the use of an upper organic solvent

phase for the maintenance of perfect sink conditions during dissolution rate determinations of nondisintegrating solids in aqueous systems.

EXPERIMENTAL

Model Dosage Form—Nondisintegrating flat-faced tablets of pure drug were prepared by compressing 300 mg. of benzoic acid or 600 mg. of salicylic acid by means of a Carver model B hydraulic press equipped with a 0.5-in. diameter punch and die. The compression pressure was 10,000 p.s.i.

Dissolution Assembly—The assembly consisted of a 500-ml. three-neck round-bottom flask immersed in a constant-temperature bath adjusted to 37° ± 0.1°. A 3-in. Teflon stirring blade and shaft attached to a stirring motor was inserted in the center neck. The motor was controlled by a Servodyne constant torque unit which also served to provide a direct read-out of speed of rotation.

Dissolution Procedure in 0.1 N HCl—One hundred and fifty milliliters of 0.1 *N* HCl was placed in the flask and permitted to equilibrate to 37°. The stirring blade was immersed in the dissolution medium to a depth of 20 mm. and accurately centered by means of a guide. The stirrer was rotated at a speed of 25, 50, or 100 r.p.m. and the benzoic acid or salicylic acid tablet was placed in the medium by dropping it through the side neck, along the side of the flask. The tablet remained at the bottom of the flask throughout each determination.

One-milliliter samples of the solution were taken at appropriate intervals, diluted, and assayed spectrophotometrically using a Beckman model DB-G spectrophotometer. A volume of 0.1 *N* HCl (maintained at 37°) equal to the sample volume was added immediately after each sampling. Absorbances were measured at 226 and 302 mμ for benzoic acid and salicylic acid, respectively. By appropriate calculations (5), the total amount of drug in solution as a function of time was determined.

The dissolution of benzoic acid was followed under conditions approximating a perfect sink, *i.e.*, benzoic acid concentration in the dissolution fluid never exceeded 12% of solubility. The dissolution of salicylic acid was followed well beyond sink conditions. At the end of the determination the salicylic acid concentration in the dissolution medium approximated 80% of solubility.

Dissolution Procedure in 0.1 N HCl with Upper Organic Solvent Phase—After addition of the 150 ml. of 0.1 *N* HCl and positioning of the stirrer, the tablet was dropped into the aqueous phase but remained unstirred while 150 ml. of organic solvent was slowly added to the flask. Stirring was initiated after addition of the organic solvent. Dissolution of benzoic acid was studied in 0.1 *N* HCl layered with a 1:1 mixture of cyclohexane and 1-octanol, while dissolution of salicylic acid was studied in 0.1 *N* HCl layered with a 1:1 mixture of cyclohexane and 2-octanol.

The selection of the upper organic solvent phase is dictated solely by a consideration of the partition coefficient of the drug between the aqueous dissolution medium and the organic sink. The total dose of drug to be studied must represent less than 20% of its solubility in the selected volume of organic solvent.

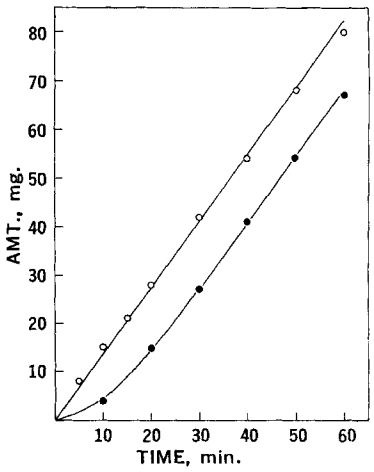

Fig. 1—Rate of appearance of benzoic acid from constant surface tablets in 0.1 N *HCl* (○) *and in cyclohexane–1-octanol layer above a 0.1* N *HCl phase* (●).

At various intervals after initiation of stirring, 1-ml. samples of the organic phase were taken, diluted with methanol, and assayed spectrophotometrically. The volume of the organic phase was maintained constant by replenishing with solvent after each sampling. By appropriate calculations, the total amount of drug appearing in the organic solvent phase as a function of time was determined.

Determination of Rate of Partitioning—The rate of partitioning of benzoic acid from water to 1:1 cyclohexane–1-octanol was determined in the dissolution assembly at 37° and 25 r.p.m. At time zero the aqueous phase contained 0.3 mg./ml. benzoic acid in 0.1 *N* HCl. The organic solvent phase was sampled at various intervals after addition and the quantity of benzoic acid present at each interval was determined.

RESULTS AND DISCUSSION

The dissolution of benzoic acid in 0.1 *N* HCl followed apparent zero-order kinetics over the time period studied. The appearance of benzoic acid as a function of time at 50 r.p.m. is illustrated in Fig. 1. The apparent zero-order dissolution rate constants determined at 25, 50, and 100 r.p.m. are listed in Table I. A plot of log dissolution rate *versus* log stirring rate is shown in Fig. 2. According to the equations developed by Cooper and Kingery (6), which relate the diffusion controlled dissolution rate from the surface of a rotating disk to the velocity of rotation (stirring rate), a plot of the logarithm of dissolution rate (expressed here in mg./min./total surface area) *versus* the logarithm of stirring rate (expressed in r.p.m.) should yield a straight line with a slope of 0.5. As indicated in Fig. 2, the slope of the line fitted to the benzoic acid data (0.494) is quite close to the theoretical value. Thus, the described relationship between dissolution rate and stirring rate holds for the methodology used in the present study.

The rate of appearance of benzoic acid in the cyclohexane–octanol phase during the dissolution process also followed zero-order kinetics, after an initial lag period. A representative plot is included.

TABLE I—KINETIC DATA FOR THE DISSOLUTION OF BENZOIC ACID FROM CONSTANT SURFACE TABLETS IN 0.1 *N* HCl LAYERED WITH CYCLOHEXANE–1-OCTANOL

in Fig. 1. The zero-order rate constants for appearance of drug in the organic phase at the various stirring speeds studied are listed in Table I. There is excellent agreement between the zero-order dissolution rate constants and the zero-order appearance rate constants at both 50 and 100 r.p.m. At 25 r.p.m. the rate of appearance of drug in the organic phase adhered to zero-order kinetics but the rate constant was somewhat lower than the dissolution rate constant found in 0.1 *N* HCl at 25 r.p.m. The reason for this phenomenon appears to be related to the effective stirring rate, *i.e.*, although the paddle rotated at 25 r.p.m., the flow of aqueous fluids about the tablet was dampened by the physical presence of the organic layer. An estimate of the effective stirring rate in the two-phase system at a paddle speed of 25 r.p.m. was obtained by extrapolating the data shown in Fig. 2 (assuming that appearance rate corresponded to dissolution rate). The experimental appearance rate was found to correspond to an effective stirring rate of 20 r.p.m. The dampening effect appeared to be totally absent at 50 and 100 r.p.m.

The rate of appearance of drug in the organic phase may be related to the dissolution rate in the aqueous phase by means of the following kinetic model:

$$A \xrightarrow{k_0} B \xrightarrow{k_p} C \qquad \text{(Eq. 1)}$$

where A is the amount of drug in the tablet, B is the amount of drug in the aqueous phase, C is amount of drug in the organic layer, k_0 is the zero-order dissolution rate constant, and k_p is the first-order rate constant for partitioning of drug from the aqueous phase to the organic solvent phase. The rates of change of B and C may be expressed by the following differential equations:

$$dB/dt = k_0 - k_pB \qquad \text{(Eq. 2)}$$

and

$$dC/dt = k_pB \qquad \text{(Eq. 3)}$$

Integrating Eqs. 2 and 3 yields, respectively:

$$B = \frac{k_0}{k_p}(1 - e^{-k_pt}) \qquad \text{(Eq. 4)}$$

and

$$C = k_0t - \frac{k_0}{k_p}(1 - e^{-k_pt}) \qquad \text{(Eq. 5)}$$

At some finite time t, $e^{-k_pt} \rightarrow 0$ and Eqs. 4 and 5 reduce to Eqs. 6 and 7:

$$B = \frac{k_0}{k_p} = \text{constant} \qquad \text{(Eq. 6)}$$

and

$$C = k_0t - \frac{k_0}{k_p} \qquad \text{(Eq. 7)}$$

The more rapid the rate of partitioning, the shorter the time period required for the attainment of true steady-state kinetics, *i.e.*, B = constant, $dB/dt = 0$. After attainment of steady-state, a plot of C *versus* time should yield a straight line with a slope of k_0.

The experimental data permitted calculation of k_p by means of Eq. 7 and B at the steady state by means of Eq. 6. These calculated values are listed in Table I. The k_p value of 0.071 calculated from the data at 25 r.p.m. was in agreement with the experimentally determined value of 0.067.

The data in Table I indicate a positive correlation between k_p and stirring rate. The reason for this relationship is that the k_p values are actually a product of the first-order rate constant for diffusion across the interface and the interfacial area between the water and solvent phases. As stirring rate is increased, the turbulence at the interface increases causing a degree of mixing and "emulsification" in the interfacial region. This increase in the "thickness" of the interface results in a marked increase in the mean interfacial area. It is likely that the increased interfacial area is primarily responsible for the increased values of k_p.

The steady-state values listed in the table represent only 0.8 to 1.8% of the solubility of benzoic acid in 0.1 *N* HCl. This is an excellent indication of the efficiency of the organic solvent in maintaining near-perfect sink conditions in the aqueous phase.

The salicylic acid studies were designed to

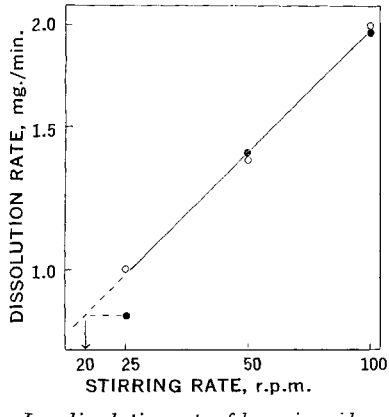

Fig. 2—Log dissolution rate of benzoic acid versus *log stirring rate. Dissolution rate determined in 0.1* N *HCl* (○) *and in 0.1* N *HCl layered with cyclohexane–1-octanol* (●).

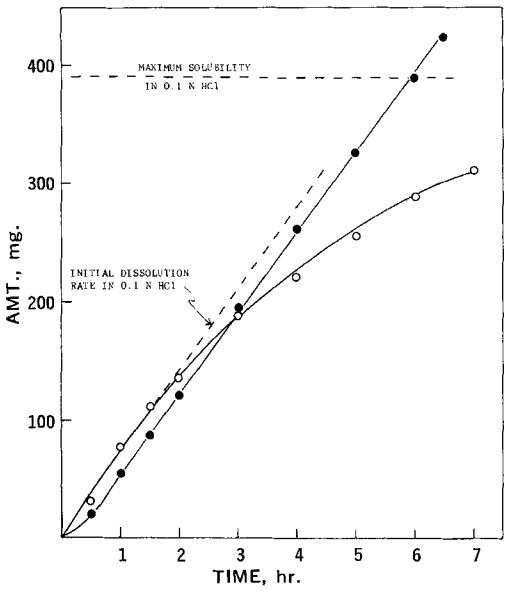

Fig. 3—Rate of appearance of salicylic acid from constant surface tablets in 0.1 N HCl (○) under nonsink conditions and in cyclohexane–2-octanol layer above a 0.1 N HCl phase (●) where perfect sink conditions are approximated. The broken horizontal line indicates the total solubility of drug in 150 ml. of 0.1 N HCl.

illustrate the different dissolution kinetics which result from lack of sink conditions and to demonstrate the resolution of these differences by means of an organic solvent reservoir. The model dosage form of salicylic acid was anticipated to retain a constant surface area during the release of a significant amount of drug. Hence, the gastric absorption of a large percentage of a dose of salicylate from this constant surface dosage form would be expected to follow zero-order kinetics. For any meaningful *in vivo–in vitro* correlation the dissolution rate method should at least demonstrate the same order of kinetics as the absorption process. The data in Fig. 3 show that this is clearly not the case when dissolution is followed under nonsink conditions.

The appearance of salicylic acid in 0.1 *N* HCl at 50 r.p.m. followed apparent zero-order kinetics up to about 25% of solubility. When the salicylate levels exceeded 30% of solubility, marked deviations from zero-order kinetics were noted and in fact, dissolution appeared to be first order. The apparent zero-order rate constant calculable from the initial dissolution data was 1.15 mg./min./total surface area.

When the dissolution of salicylic acid was followed in 0.1 *N* HCl layered with an organic solvent reservoir a totally different kinetic picture emerged. (See Fig. 3.) After an initial lag phase (required to establish steady state conditions), the rate of appearance of drug in the cyclohexane–octanol phase followed apparent zero-order kinetics. By means of the organic reservoir it was possible to demonstrate that the release rate from the model dosage form of a quantity of drug *in excess* of its total solubility in 0.1 *N* HCl adhered to apparent zero-order kinetics. In the absence of the reservoir it appeared that the release rate of a quantity of drug equal to only 25% of its solubility followed zero-order kinetics.

The zero-order rate constant for appearance of salicylic acid in the organic phase after attainment of steady state, *i.e.*, the apparent zero-order dissolution rate constant, was calculated to be 1.14 mg./min. This value is in agreement with the apparent initial zero-order rate constant of 1.15 mg./min. determined under nonsink conditions. The amount of drug in the aqueous phase after attainment of steady state was calculated by means of Eqs. 6 and 7 and found to be 17.1 mg. Thus, the maximum accumulation of drug in the aqueous phase in the presence of the organic reservoir represented less than 5% of solubility.

The reason for the different dissolution kinetics under nonsink conditions is readily explained by the Noyes-Whitney equation (7). The following example is illustrative. The dissolution of a quantity of drug A_0, in a dosage form designed to provide zero-order release, is followed in a quantity of solvent which is just sufficient to dissolve the total amount of drug in the dosage form, *i.e.*, $X_s = A_0$, where X_s is the total solubility of the drug in the given volume of solvent. Under these conditions, the rate of loss of drug from the dosage form may be expressed as:

$$-dA/dt = k(X_s - X) \qquad \text{(Eq. 8)}$$

where X is the amount of drug in solution at time t. Assuming dissolution rate-limited absorption *in vivo*, or sink conditions *in vitro*, Eq. 8 reduces to a zero-order equation, *i.e.*,

$$-dA/dt = k\,(X_s) = \text{constant} \qquad \text{(Eq. 9)}$$

and

$$A = A_0 - (k \cdot X_s)t \qquad \text{(Eq. 10)}$$

However, under the nonsink conditions in this particular example, Eq. 8 may be expressed as:

$$-dA/dt = k[A_0 - (A_0 - A)] \qquad \text{(Eq. 11)}$$

or

$$-dA/dt = kA \qquad \text{(Eq. 12)}$$

and

$$A = A_0 e^{-kt} \qquad \text{(Eq. 13)}$$

Therefore, a drug which may be absorbed, or dissolve, under sink conditions in a zero-order fashion may demonstrate first-order dissolution kinetics under nonsink conditions.

APPLICATION TO FIRST-ORDER DISSOLUTION

A drug which dissolves from a given dosage form in an apparent first-order fashion (1, 2) will also show marked differences in *in vitro* dissolution kinetics depending on the conditions employed for dissolution rate determination. Using an example similar to the one cited above, one may illustrate these phenomena. The dissolution of a quantity of drug A_0 contained in a dosage form from which first-order release occurs is followed in a quantity of solvent which is just sufficient to dissolve the total amount of drug, *i.e.*, $X_s = A_0$, where X_s is the total solubility of the drug in the given volume of solvent.

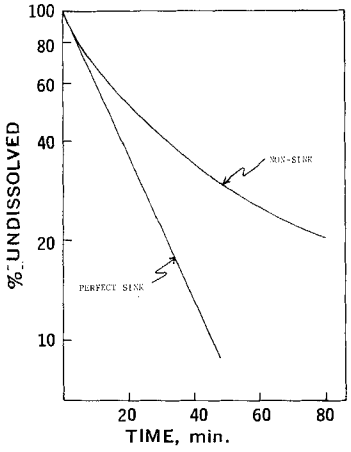

Fig. 4—Plot of per cent drug undissolved from hypothetic dosage form releasing drug in a first-order fashion under perfect sink and nonsink conditions.

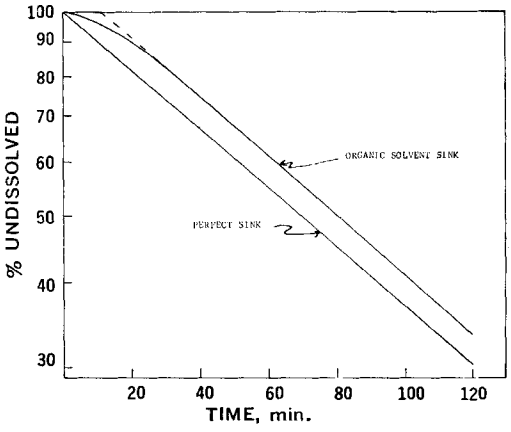

Fig. 5—Plot of per cent drug undissolved from hypothetic dosage form releasing drug in a first-order fashion under perfect sink conditions and under conditions where a perfect sink is approximated by the presence of an organic solvent reservoir.

Under these conditions the rate of loss of drug from the dosage form may be expressed as:[1]

$$-dA/dt = k(X_s - X)A \qquad \text{(Eq. 14)}$$

where X is the amount of drug in solution at time t. Assuming dissolution rate-limited absorption *in vivo* or sink conditions *in vitro*, Eq. 8 reduces to a first-order equation, *i.e.*,

$$-dA/dt = (k\,X_s)A = k'A \qquad \text{(Eq. 15)}$$

and

$$A = A_0 e^{-k't} \qquad \text{(Eq. 16)}$$

However, under the nonsink conditions cited in this example, Eq. 14 may be expressed as:

$$-dA/dt = k[A_0 - (A_0 - A)]A$$

or

$$-dA/dt = kA^2 \qquad \text{(Eq. 17)}$$

Therefore,

$$A = \frac{A_0}{1 + (kA_0)t} = \frac{A_0}{1 + k't} \qquad \text{(Eq. 18)}$$

which represents an integrated form of a *second-order* rate equation.

Figure 4 is a hypothetic plot of first-order loss of drug from a dosage form under perfect sink and nonsink conditions. The marked difference in results clearly reinforces the hypothesis that unless sink conditions are maintained in dissolution rate determinations, *in vitro* results may bear little relationship to *in vivo* observations. The difference between the two plots diminishes as $A_0/X_s \to 0$.

An organic solvent reservoir which functions to maintain approximate sink conditions is also applicable to the determination of first-order dissolution rates. The rate of appearance of drug in the organic phase may be related to the first-order dissolution rate in the aqueous phase by means of the following kinetic model:

$$A \xrightarrow{k'} B \xrightarrow{k_p} C \qquad \text{(Eq. 19)}$$

which is analogous to the model presented in Eq. 1 for zero-order dissolution. If the choice of organic solvent and other experimental conditions are such that $k_p/k' \geqslant 10$, then within a short period of time after initiation of dissolution the appearance of drug in the organic solvent phase may be approximated by the following equation:

$$\ln (A_0 - C) \cong \ln A_0 - k't = \ln A \qquad \text{(Eq. 20)}$$

A hypothetic plot of per cent drug undissolved from a dosage form releasing drug in a first-order fashion (calculated by determining the amount of drug in an organic solvent reservoir phase and subtracting this value from A_0) is illustrated in Fig. 5. This curve is shown in contrast to a curve for the same dissolution process occurring under theoretically perfect sink conditions. The hypothetic conditions were selected such that $k' = 0.01$ min.$^{-1}$ and $k_p = 0.1$ min.$^{-1}$. After an initial lag phase, the curve determined with the use of an organic solvent reservoir parallels exactly the theoretic line. The larger the value of k'/k_p, the shorter will be the lag time before Eq. 20 becomes valid.

Present studies in these laboratories are concerned with the development of methodology for the determination of dissolution rates of poorly water-soluble drugs from disintegrating tablets and capsule dosage forms by means of an organic solvent reservoir for maintenance of sink conditions.

[1] Equation 14 represents a modification of the Noyes-Whitney equation. Since dissolution is apparent first order, it follows that $S \cong k'A$ where S is the surface area.

Deaggregation Behavior of a Relatively Insoluble Substituted Benzoic Acid and Its Sodium Salt

By ARMANDO J. AGUIAR, JOYCE E. ZELMER, and ARLYN W. KINKEL

The deaggregation rates of a relatively insoluble benzoic acid derivative and its soluble sodium salt were studied. Based on the postulate that the deaggregation rate follows a first-order process, equations were developed to measure the rates quantitatively. A spectrophotometric procedure, which is simple and convenient for use routinely, is described. The surface area of the aggregates at the final state was estimated from a correlation between the absorbance measurements and the surface area determined with a Coulter counter. It was seen that encapsulating or tableting these compounds decreased the deaggregation rates. The addition of a nonionic polyol surfactant or the sodium salt of polymerized alkyl naphthalene sulfonic acid enhanced the rates. A relationship between the deaggregation rate and rate of solution of the acid in simulated intestinal fluid T.S. (U.S.P. XVI) is demonstrated. The biopharmaceutical significance of the deaggregation rate is discussed.

THE IMPORTANCE of particle size reduction of relatively insoluble drugs to enhance their gastric absorption has been emphasized during the past decade (1–4). The emphasis is based on the premise that the smaller the size, the faster the dissolution rate of the drug due to the increased surface area presented to the dissolving medium. This premise holds as long as the effective species undergoing dissolution are the primary particles. However, when dealing with insoluble drugs which are also difficult to wet and disperse, the effective species are generally not the primary particles but more often their aggregates.

The situation is further aggravated when these drugs are encapsulated or tableted. Very often the aggregates formed during the preparation of the dosage forms are difficult to disperse. The deaggregation or dispersion rate can, in these instances, be the rate-limiting step in the absorption sequence particularly in the initial phases.

The importance of deaggregation or dispersion in pharmaceutical systems has been recognized for a number of years (5) and recently re-emphasized (6–10). However, there has not been a systematic study carried out to evaluate the rate of deaggregation in pharmaceutical systems, except for two recent studies carried out by Lemberger and Mourad (11, 12). Their studies have dealt with the influence of a number of variables on the deaggregation behavior of oil and water emulsions.

A limited number of deaggregation studies were carried out in nonpharmaceutical systems. These have dealt with rates of systems at equilibrium. For instance, Hiemenz and Vold (13) studied the rates of flocculation and deflocculation of carbon black in hydrocarbon liquids, and Reich and Vold (14) of carbon black and ferric oxide in water. Gillespie (15) determined the rate constants of aggregation and deaggregation of monodisperse latexes in water. Parenthetically, there is also an extensive literature (13) on both the theoretical and experimental aspects of the associated phenomena of aggregation.

The present study was carried out to study quantitatively the deaggregation rates of a relatively insoluble benzoic acid derivative and its sodium salt from different dosage forms. Equations were developed based on the postulate that the deaggregation rate followed a first-order process. The effects of a wetting agent and a dispersant on the rate were evaluated. A correlation between the rates of solution and deaggregation was established.

THEORETICAL CONSIDERATIONS

Smoluchowski (16) showed that deaggregation follows a first-order process. If, therefore, for a particular system there are a number of large aggregates Na, broken down to a number b, of small aggregates N, the following mechanism can be written to describe this occurrence:[1]

$$Na \xrightarrow{k} bN$$

k is described as an apparent rate constant for the deaggregation process. The rate of disappearance of Na with time (t) is then:

$$\frac{dNa}{dt} = -kNa \qquad \text{(Eq. 1)}$$

The following conditions can also be set: at $t = 0$, $Na = Na^0$, $N = 0$; at $t = t$, $Na = Na$, $N = N$; at $t = \infty$, $Na = 0$, $N = Ns$; where Na^0 is the concentration of large aggregates at zero time and Ns is the concentration of small aggregates at the final state.

[1] The reaction is considered irreversible since under the experimental conditions employed in this study, the reverse reaction is negligible.

The authors thank Dr. J. C. Samyn for the Coulter counter measurements, Mr. H. R. Sotherland for preparing the tablets, and Dr. L. M. Wheeler for his interest and encouragement.

Integrating Eq. 1 using the limits $t = 0$ and $t = t$, one obtains:

$$\ln \frac{Na}{Na^0} = -kt \qquad \text{(Eq. 2)}$$

Since the number of small aggregates Ns at the final state is proportional to Na^0, one can set $Ns = bNa^0$. Then:

$$bNa = Ns - N \text{ or } Na = \frac{Ns - N}{b}$$

Equation 2 can now be written in terms of Ns and N:

$$\ln \frac{Na^0}{Na} = \ln \frac{Ns}{Ns - N} = kt \qquad \text{(Eq. 3)}$$

or

$$2.303 \log \frac{Ns}{Ns - N} = kt \qquad \text{(Eq. 4)}$$

The applicability of Eq. 4 in this study is based on the hypothesis that the only species present in the system at any time are the large aggregates Na and/or small aggregates N. This implies that the large aggregates Na are broken down into the small aggregates without going through intermediate stages, or if these are formed, they are extremely short-lived. Experimental verification of the hypothesis was obtained by microscopic examination of samples removed at various times during the runs. To prevent shearing the aggregates during examination, the samples were removed with an inverted pipet and a drop was placed gently on a slide and viewed microscopically without a cover slip.

The number of aggregates N present in the system at any time can be evaluated from the time dependence of any property which is directly proportional to N. In this study, absorbance was used since it could be conveniently determined without disturbing the system during the measurements.

Writing Eq. 4 in terms of absorbance A and rearranging, one has:

$$\log \frac{As}{As - At} = \frac{k}{2.303} t \qquad \text{(Eq. 5)}$$

where As is the absorbance at the final state and At is the absorbance at time t.

If the deaggregation process follows Eq. 5, a plot of $\log As/As - At$ *versus* t should be linear and the rate constant k can be calculated by multiplying the slope of the resulting line by 2.303.

Vold (13), who used absorbance measurements in his studies of deaggregation rates of carbon black, has shown that although aggregates in many suspensions are of irregular shape, they are still likely to be spherically symmetrical if they are built up at random.

It is also apparent that absorbance can be used only if A^0 (absorbance at time zero) is much smaller than As (absorbance at the final condition). Furthermore, the absorbance should be a linear function of the concentration of aggregates present in the system. These two conditions were met in this study. The absorbance at time zero was negligible and the linear relationship between the absorbance and concentration was checked by measuring the absorbance of the aggregates (at the final state) over a hundredfold dilution. Measurements were carried out with a Coleman junior spectrophotometer and repeated with a Beckman DU spectrophotometer. Beer's law was obeyed in each case.

From the absorbance measurements, neither the absolute size of the aggregates nor their concentration in the system can be determined. These measurements are simply an indirect estimate of the size and number of aggregates present, *i.e.*, the total surface area presented by the aggregates to the light beam. However, one may reasonably assume that if the volume of the dispersing liquid, concentration of the drug used, and primary particle size are fixed, the higher the turbidity (*i.e.*, higher the absorbance), the greater is the number of aggregates present in the system. Material balance would then require that the greater the number of aggregates present, the smaller would be their size.

The surface area of the aggregates present at the final condition was obtained from Coulter counter measurements. A correlation between the surface area of the aggregates at the final state and absorbance was established. This was done by taking samples of the aggregates having different absorbance values at the final state and measuring their surface area, using a Coulter counter. A working curve was then prepared by plotting the absorbance *versus* the surface area in cm.^{2}/Gm. The surface area of the aggregates at the final state for other runs was estimated from this curve. The Coulter counter measurements were carried out by diluting a volume of the "slurry" in normal saline solution.

Admittedly, some change could occur during the Coulter counter measurements. Nevertheless, it was felt that the data would be of sufficient value to estimate the relative aggregate sizes.

EXPERIMENTAL

Materials—The benzoic acid derivative used in the studies was prepared by a special procedure to obtain the drug in a small but uniform particle size powder. The drug was further classified by passing through a No. 100 mesh screen (U.S. Standard) and collecting on a No. 120 mesh screen.

Capsules, tablets, and a suspension were prepared from the screened powder. The screened powder was hand filled into No. 1 and No. 00 hard gelatin capsules at a concentration of 250 mg. per capsule. The powder was also preblended with 0.5% of a nonionic polyol surfactant[2] and with 0.5% of the sodium salt of polymerized alkyl naphthalene sulfonic acid,[3] respectively, and made into capsules in a similar manner.

Compressed tablets were made containing 250 mg. of the acid, a disintegrant, a binder, and a filler. Another lot of tablets was prepared containing in addition 1.25 mg. of the polyol surfactant.

The suspension contained 250 mg. of the acid in 5 ml., a water-soluble gum, a preservative, a buffer, and a protective colloid.

The sodium salt was also sieved in the same manner as the acid and hand filled in a No. 1 capsule. A second lot of capsules was prepared containing in addition 0.5% of the polyol surfactant. Each capsule contained 275 mg. of the sodium salt, equivalent to 250 mg. of the acid.

[2] Marketed as Pluronic F-68 by the Wyandotte Chemical Corp., Wyandotte, Mich.

[3] Marketed as Daxad No. 11, Dewey and Almy Chemical Division, W. R. Grace Co., Cambridge, Mass.

The deaggregation studies were carried out in simulated gastric and intestinal fluid T.S. (U.S.P. XVI) without the enzymes. The enzymes were excluded as their turbidity interfered with the absorbance measurements. To compensate for the loss of wetting which the enzymes normally provide, 500 mg. of the polyol surfactant was added to 500 ml. of the test solution.

In carrying out the deaggregation studies with the tablets, it was necessary to add an amylolytic and a cellulolytic[4] enzyme to hydrolyze and solubilize the disintegrant and filler present in the tablet. Ten milligrams of each enzyme was dissolved in the 500 ml. of simulated intestinal fluid T.S., and the solution was filtered prior to use. In this way the turbidity caused by the filler and disintegrant was considerably minimized. It was not possible to determine the deaggregation rates of the tablets in the simulated gastric fluid T.S. since the amylolytic and cellulolytic enzymes have little activity at the low pH of the fluid.

Methodology—Five hundred milliliters of simulated intestinal or gastric fluid T.S. was added to an 800-ml. beaker placed in a constant-temperature bath set at 37° ± 0.5°. The solution was stirred at 70 r.p.m. and allowed to come to temperature. The design of the all glass stirrer used was such that it provided random agitation throughout the depth of the liquid, without creating a vortex. For all the studies, except those with the capsules, an empty capsule was dissolved in the test medium to provide a uniform background for the spectrophotometric measurements.

To study the deaggregation rate of the (loose) powders, 250 mg. of the acid (or 275 mg. of sodium salt) was sprinkled lightly on the surface of the agitated liquid. A stopwatch was started and readings were taken at appropriate intervals of time. Similarly, 5 ml. of the suspension containing 250 mg. of the acid was pipeted directly into 495 ml. of the agitated liquid. The capsules containing the drugs were added directly to the 500 ml. of simulated gastric fluid T.S. The stopwatch was started as soon as the gelatin dissolved and first traces of the drug appeared in the liquid, generally in about 2 min.

The gelatin shell composing the capsule was found to dissolve very slowly in the simulated intestinal fluid T.S. To minimize the difference in the time necessary to dissolve the capsule shell in the two fluids, a slightly different approach was used when studying the deaggregation rates of the capsules in the intestinal fluid. In this case, the capsule was first treated with 50 ml. of simulated gastric fluid T.S. (maintained at 37°) in a 100-ml. graduate. The graduate was gently rocked manually every 10 sec. At the end of 2 min., the contents of the graduate were emptied into 450 ml. of stirred simulated intestinal fluid T.S. also maintained at 37° ± 0.5°. This treatment of the capsule with the simulated gastric fluid T.S. effectively dissolved most of the gelatin leaving a very thin film. The remaining gelatin dissolved within a few minutes after the addition to the simulated intestinal fluid T.S. To neutralize the excess acid and maintain the pH of the simulated intestinal fluid T.S. at pH 7.5, 1.55 ml. of 2 *N* sodium hydroxide was added to it prior to adding the contents of the graduate. The treatment effectively cancelled any difference in the time necessary to dissolve the gelatin shell in the simulated gastric or intestinal fluid T.S.; the lag time in the two media could then be equated more easily.

Spectrophotometric Measurements—The per cent transmission (from which absorbance was calculated) was measured using a Coleman junior spectrophotometer. The wavelength used was 650 mμ. A Manostat Varistaltic pump[5] circulated the fluid *via* a 3 mm. diameter Tygon tubing from the beaker through a flow-through cell located in the spectrophotometer. The diameter of the tubing and the pumping rate provided a continuous flow of the liquid from the beaker through the cell and back, without shear. Thus, measurements could be carried out directly without disturbing the system or necessitating pipeting samples, a procedure which was found to introduce considerable errors.

The force necessary to deaggregate the drugs was provided by the shearing action of the stirred liquid. In each instance, the stirring was continued until the absorbance measured was constant, indicating that the final state had been reached.

Dissolution Studies—Part of the same lot of the acid used in the deaggregation studies was used in the dissolution studies. A 250-mg. quantity of the drug as a loose powder was added rapidly to 500 ml. of simulated intestinal fluid T.S. containing 500 mg. of the polyol surfactant instead of pancreatin. The solution was maintained at 37° ± 0.5° and stirred at 70 r.p.m. with the same glass stirrer described previously. After the addition of the powder, 4-ml. samples were withdrawn from the system at measured time intervals. The sample was filtered through Millipore filters (pore sizes 0.45 μ), using a Swinney syringe adapter. The concentration of the drug in solution was measured spectrophotometrically in the ultraviolet region at 335 mμ after appropriate dilution with the solvent. All spectrophotometric measurements were made with a Beckman DU spectrophotometer. When the solubility and dissolution rates were measured with the drug in the capsules, these were pretreated as described with 50 ml. of simulated gastric fluid T.S. to dissolve the gelatin prior to its addition to the simulated intestinal fluid T.S. The polyol surfactant at the concentration added facilitated the wetting of the powders, without affecting appreciably the solubility of the drug in the medium.

RESULTS AND DISCUSSION

The deaggregation profiles of the acid added to the simulated gastric fluid T.S. as a powder, suspension, and in two capsule sizes, are shown in Fig. 1. The profiles of these dosage forms and also of the tablet in the simulated intestinal fluid T.S. are shown in Fig. 2. These plots of logarithm of per cent transmission *versus* time provide a convenient comparison of the rates. They also compare the relative surface area of the aggregates present at the steady-state condition. The data presented in Figs. 1 and 2 indicate that there is no significant measurable difference in the deaggregation rates in the simulated gastric or intestinal fluid T.S. under the experimental condition used in these studies.

[4] Marketed as Mylase 100 and Cellase 1000, respectively, by the Wallerstein Co., Staten Island, N. Y.

[5] Manostat Corp., New York, N.Y.

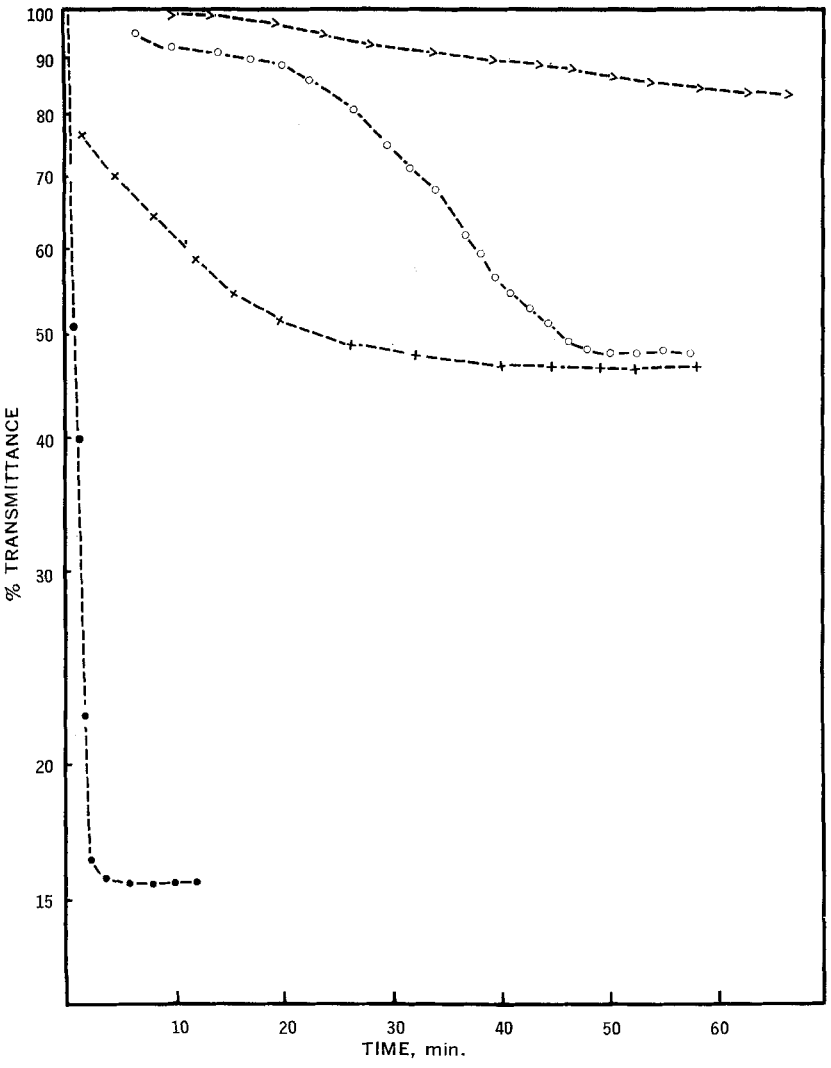

Fig. 1—Plot of per cent transmittance vs. time for the dosage forms studied showing relative rates of deaggregation in simulated gastric fluid T.S. Key: ●, suspension; ×, loose powder; ○, No. 00 capsule; >, No. 1 capsule.

The similarity of the plots also stresses the reproducibility of the experimental method used.

It is readily apparent from these plots that the suspension has the fastest rate in both media, and the aggregates formed have the largest surface area, and therefore the smallest aggregate size at the steady state. This is not surprising since the drug is deaggregated intentionally by homogenization during the manufacture of the suspension. The aggregates which form in the suspension on storage are generally readily redispersed in the test media.

The deaggregation rate of the acid in a No. 1 capsule is the slowest in both the simulated gastric and intestinal fluid T.S. and requires approximately 3 hr. to reach the steady-state condition. The surface area of the aggregates at this condition was similar to that shown for the loose powder. When the acid was packed in a No. 00 capsule, the rate was much faster. Although the steady state was reached sooner, the surface area of the aggregates was again the same as that of the loose powder.

The tablet showed a considerably faster initial rate than the capsules tested in the simulated intestinal fluid T.S.; however, the surface area of the aggregates at the steady state was much smaller. The presence of the disintegrants appeared to aid in breaking up the tablet readily, apparently exposing the granules; however, further deaggregation seemed to be difficult, probably due to the strong cohesive bonds formed between the primary particles during the granulation and compression processes.

The data shown in Figs. 1 and 2 are replotted in accordance with Eq. 5 in Figs. 3 and 4. The deaggregation rates of the acid added to the simulated gastric and intestinal fluid T.S. as a loose powder and as a suspension follow closely a first-order process. The apparent rate constant k, for the deaggregation in simulated gastric fluid T.S., calculated from the slope of each of these lines is given in Table I. The apparent rate constants for the deaggregation in simulated intestinal fluid T.S. are given in Table II.

The deaggregation process for the drug in the capsules, in both the simulated gastric and intestinal fluid T.S., shown in Fig. 4, seems to be more complicated. The curves for the capsules emerge from the abscissa with a very small slope which continues

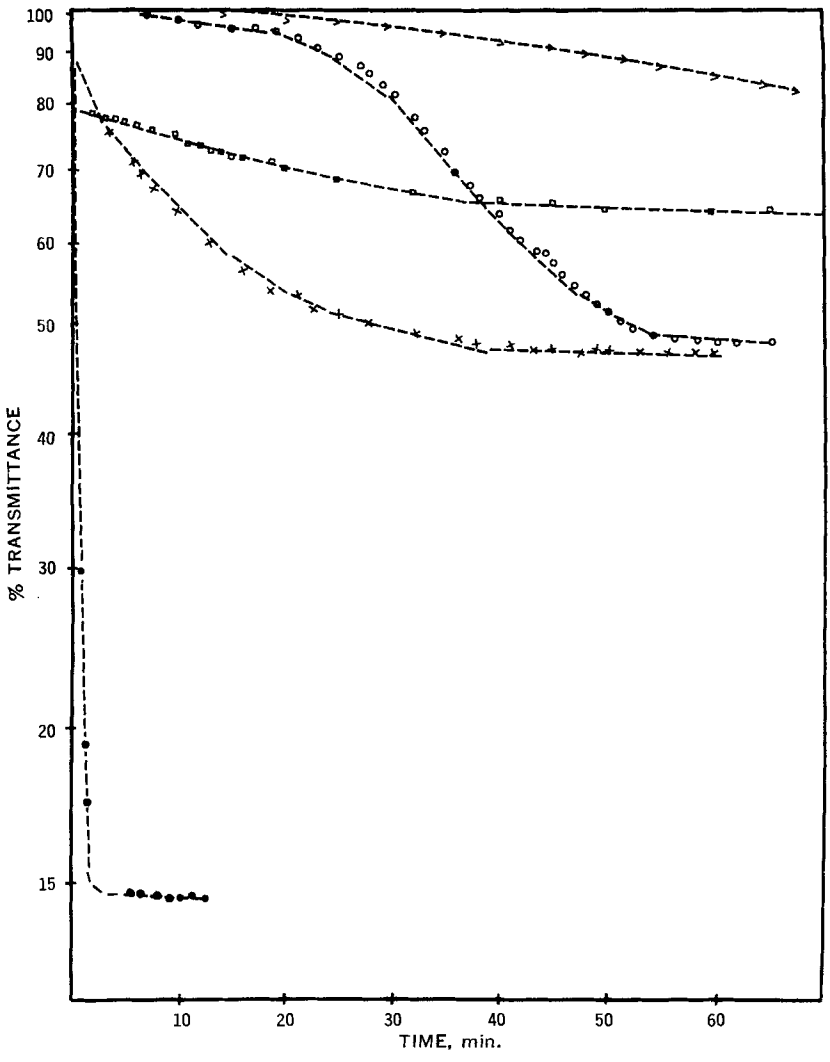

Fig. 2—Plot of per cent transmittance vs. *time for the dosage forms studied, showing relative rates of deaggregation in simulated intestinal fluid T.S. Key:* ●, *suspension;* ×, *loose powder;* □, *tablet;* >, *No. 1 capsule;* O, *No. 00 capsule.*

over a period of time; the curve then gradually bends upward and continues as a long straight line. There is, therefore, a lag time before the rate follows a first-order process. This lag time was apparently a function of the degree of compactness of the powder since it was longer for the smaller capsule. The rate was also approximately three times faster for the No. 00 than for the No. 1 capsule.

The observed deaggregation rate of the tablet in the simulated intestinal fluid T.S., shown in Fig. 4, was also complicated and indeterminate initially apparently due to the turbidity caused by the disintegrant and filler as they were released in the medium. However, after they were broken down and solubilized by the enzymes, the rate followed a first-order process fairly closely.

The apparent rate constant k, time necessary to reach the final state, and the estimated surface area at this state determined from Coulter counter measurements in the simulated gastric fluid T.S. are given in Table I and in the simulated intestinfluid T.S. are given in Table II.

The effects of compacting the powder in the capsules are evident from Table I. For example, the estimated surface areas for the aggregates of the acid at the final state are very close for the loose powder and two capsule sizes. However, the rate of deaggregation of the drug in the larger capsule was approximately two times faster than that in the smaller one. Similarly, the time to reach the final state was also faster for the drug in the No. 00 capsule.

The data in Table II for the deaggregation measurements in simulated intestinal fluid T.S. also emphasize the same aspects. They also show that while the deaggregation rate for the tablet was relatively fast compared to the smaller capsule, and the final state was reached in only 50 min. *versus* 180 min. for the capsule, the estimated surface area of the aggregates at the final state was considerably smaller than that obtained with the other dosage forms in the same medium.

It is difficult to assess *a priori* which of these would govern the rate of absorption. However, one can assume that in the initial phases the deaggregation rate, lag time, and time to reach the final state would be more important than the final surface area of the aggregates, for the simple reason that

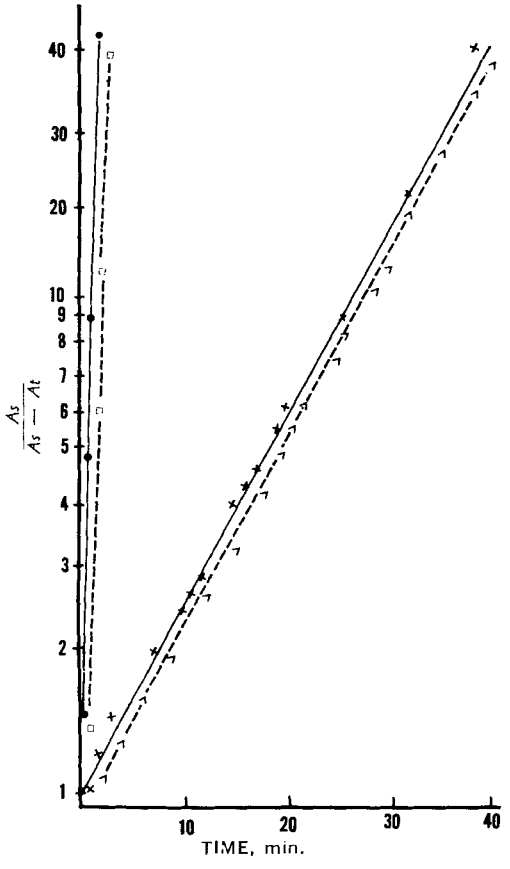

Fig. 3—Plot showing deaggregation rates of the acid as a loose powder and in suspension in simulated gastric fluid T.S. and intestinal fluid T.S. Key: ●, suspension in simulated intestinal fluid T.S.; □, suspension in simulated gastric fluid T.S.; ×, loose powder in simulated intestinal fluid T.S.; >, loose powder in simulated gastric fluid T.S.

they make the drug available earlier for dissolution in the gastrointestinal fluids at the absorption sites. The surface area would become more important after the initial exposed drug is dissolved and the rate of solution becomes dependent only on the area. Ideally, the fastest dissolution and absorption would occur in a preparation which is deaggregated rapidly, and in which the surface area of the aggregates at the final state is large. The drug in a suspension has these characteristics and would

TABLE I—COMPARISON OF THE DATA FOR DEAGGREGATION OF THE ACID IN SIMULATED GASTRIC FLUID T.S.

therefore be absorbed more rapidly, since the drug is exposed to the dissolving medium at the site of absorption rapidly and the dissolution rate would be fast because of the large surface area present.

The effect on the deaggregation rate of adding 0.5% of the polyol surfactant to the acid powder is shown in Fig. 5. The presence of the surfactant slowed the initial rate, possibly due to the tackiness it induced in the powder; however, the rate was increased perceptibly in the later stages. The exact mechanism by which the surfactant increased the rate was not clear and is under investigation at the present time. It could be due simply to the enhanced wetting of the powder by the liquid or coating of the surface of the particles, preventing their adhesion.

It is also seen from Fig. 5 that the sulfonate salt at the same concentration also increased the deaggregation rate of the powder in the simulated intestinal fluid T.S. The sodium salt of polymerized alkyl naphthalene sulfonic acid cannot be classified as a true wetting agent (17) since it does not reduce the interfacial tension between the powder and the

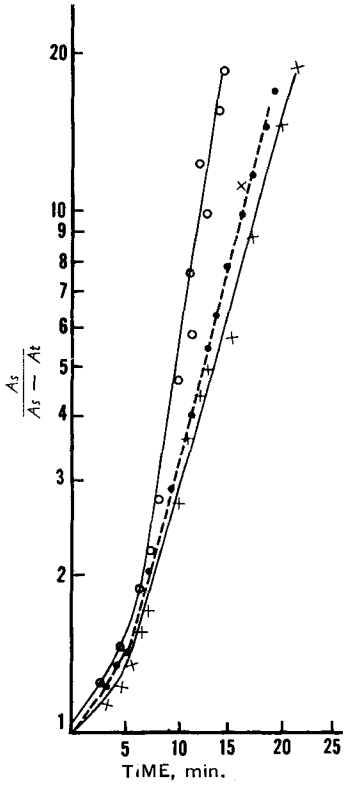

Fig. 5—Plot showing the effect of 0.5% nonionic polyol surfactant on the deaggregation rates of the acid as a loose powder in simulated gastric fluid T.S. and intestinal fluid T.S., and the effect of 0.5% sodium salt of polymerized alkyl naphthalene sulfonic acid on the rate of powder in simulated intestinal fluid T.S. Key: ●, loose powder with 0.5% polyol surfactant in simulated gastric fluid T.S.; ×, loose powder with 0.5% polyol surfactant in simulated intestinal fluid T.S.; ○, loose powder with 0.5% sulfonic acid salt in simulated intestinal fluid T.S.

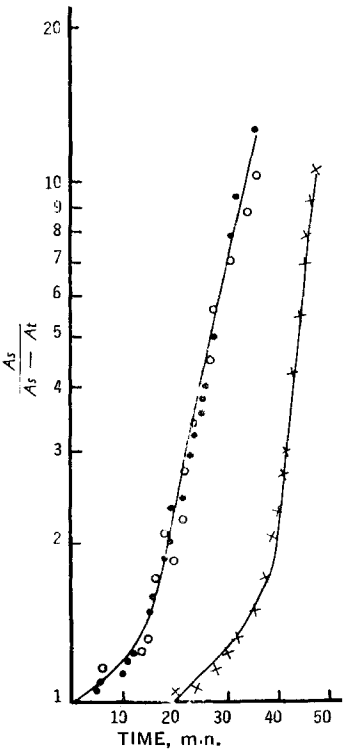

Fig. 6—Plot showing the effect of 0.5% sulfonic acid salt and polyol surfactant on the deaggregation rate of the acid in No. 1 capsule. TABLE III—EFFECT OF 0.5% OF THE POLYOL SURFACTANT AND OF THE SULFONATE SALT ON THE DEAGGREGATION OF THE ACID IN SIMULATED GASTRIC FLUID T.S. AND INTESTINAL FLUID T.S.

Dosage Form	Lag Time, min	k, min.$^{-1}$	Time to Reach Final State, min.	Estimated Surface Area of the Aggregates at the Final State, cm.^{2}/Gm.
Powder + 0.5% polyol surfactant (gastric and intestinal T.S.)	4	2.76	23	15,000
Powder + 0.5% sulfonate salt (intestinal T.S.)	4	2.92	20	26,000
No. 1 capsule + 0.5% polyol surfactant (gastric and intestinal T.S.)	12	1.01	40	13,000
No. 1 capsule + 0.5% sulfonate salt (intestinal T.S.)	37	2.3	52	24,000

liquid. Its action is not completely understood, but it seems (17) that it induces like charges on the individual particles so that they repel each other, thus preventing strong interparticulate bonds being formed.

The addition of 0.5% of the polyol surfactant and of the sulfonate salt to the acid in the capsule also has a significant effect on the deaggregation rate. The data are shown in Fig. 6. It is evident that the polyol surfactant effectively decreases the lag time, probably due to its wetting properties and also increases the deaggregation rate. The sulfonate salt also increases the deaggregation rate; however, its effect on the lag time is not so great as that of the surfactant. The surface area of the aggregates for the drug containing 0.5% sulfonate salt in No. 1 capsule was also larger than that for the polyol surfactant at the same concentration. The data are summarized in Table III.

Deaggregation Rates of the Sodium Salt—Only simulated gastric fluid T.S. was used to evaluate the deaggregation characteristics of the sodium salt since it is soluble in the simulated intestinal fluid T.S. It should be pointed out that the deaggregation rates measured are actually those of the nascent acid, since the sodium salt is rapidly converted to the acid when it is exposed to the simulated gastric fluid T.S.

The results of determinations with the sodium salt in the simulated gastric fluid T.S. are plotted in accordance with Eq. 5 in Fig. 7. It is seen that the loose powder again showed the fastest rate. By encapsulating the drug in a No. 1 capsule, the rate was considerably slowed. It was observed during the determinations that after the removal of the gelatin shell from the capsule, the salt exposed to the simulated gastric fluid T.S. was converted to the acid. The action of simulated gastric fluid T.S. on the exposed salt formed an acid mantle around the unconverted sodium salt, maintaining the shape of the capsule and preventing the liquid from reaching the inner core. It is also obvious from Fig. 7 that the addition of the polyol surfactant had a limited effect on the rate when the salt was encapsulated. It should be pointed out that of all the determinations, the deaggregation rate of the sodium salt with the polyol surfactant in the No. 1 capsule was the least reproducible. The reason is probably that a nonuniform acid mantle forms on repeated runs when the gelatin is removed, exposing uneven pockets of the surfactant at the surface.

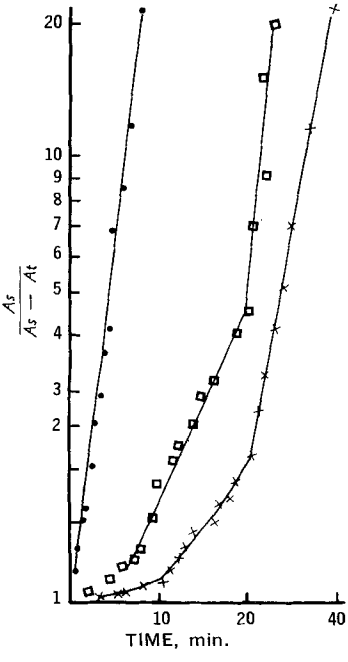

Fig. 7—Plot showing the deaggregation rate of the sodium salt in simulated gastric fluid T.S. as a loose powder, in No. 1 capsule, and in No. 1 capsule with 0.5% polyol surfactant. Key: ●, loose powder; □, No. 1 capsule with 0.5% polyol surfactant; ×, No. 1 capsule.

TABLE IV—COMPARISON OF THE RATE CONSTANT, LAG TIME, AND TIME TO REACH STEADY STATE FOR THE SODIUM SALT IN SIMULATED GASTRIC FLUID T.S.

Dosage Form	Lag Time, min.	k, min.$^{-1}$	Time to Reach Final State, min.
Powder	...	9.21	9
No. 1 capsule	18	6.12	30
No. 1 capsule + 0.5% polyol surfactant	≈15	8.0	24

The rate constant, calculated from the slope of these lines, lag time, and time to reach the steady state are summarized in Table IV. The data presented in Table IV stress the influence which the surfactant had on the deaggregation rate, time to reach the final state, and lag time when the salt was encapsulated.

DISSOLUTION STUDIES

The results of rate of solution studies carried out with the acid as a loose powder and in different dosage forms are shown in Fig. 8. It is obvious that the drug in suspension has the fastest dissolution rate and reaches the plateau level in approximately 8 min. On the other hand, the acid in a No. 1 capsule shows the slowest rate. These results appear to correlate with the deaggregation rates, which is to be expected, as it is well established that the dissolution rate is dependent on the surface area exposed to the dissolving media. Since the suspension deaggregates very rapidly, the surface area presented is much greater than that of the capsules or other dosage forms studied.

The dissolution behavior of the acid in a tablet also reflects its deaggregation pattern. The tablets broke up readily in the medium exposing some of the drug to the dissolving medium. This gave a comparatively fast dissolution rate in the initial phases. However, as the exposed drug dissolved, the rate of solution at the later time became solely dependent on the surface area of the large aggregates present, and the dissolution rate was considerably slowed.

The effect on the dissolution rate of adding 0.5% polyol surfactant to the acid powder, tablet, and No. 1 capsule is demonstrated in Fig. 9. It is apparent that the presence of polyol surfactant increased significantly the dissolution rate of the acid as a loose powder and in the No. 1 capsule. The increase in the dissolution rate of the powder and capsule can again be attributed to the faster

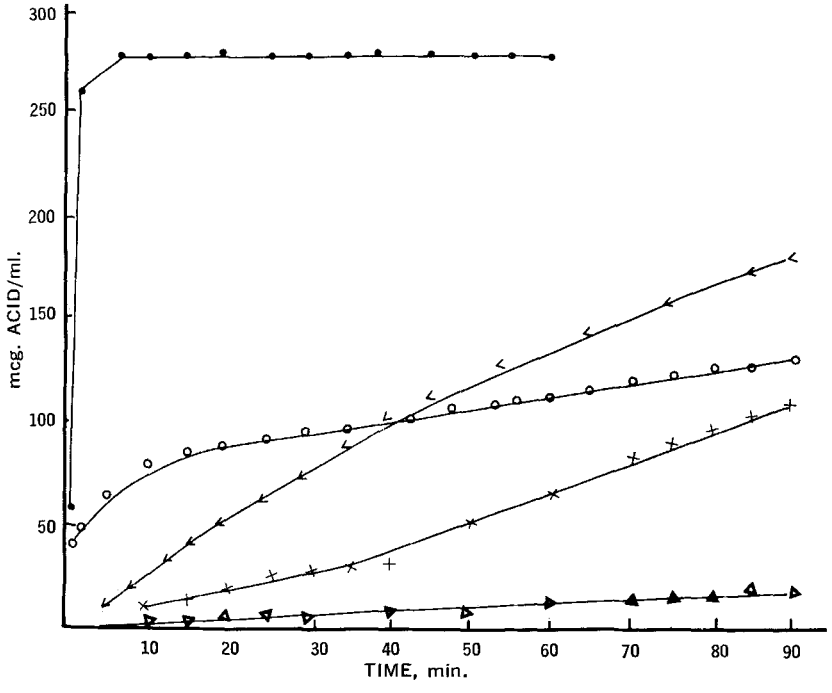

Fig. 8—Plot showing the dissolution rates of various dosage forms of the acid. Dissolution rate measured in simulated intestinal fluid T.S. Key: ●, suspension; O, tablet; <, loose powder; ×, No. 00 capsule; ▶, No. 1 capsule.

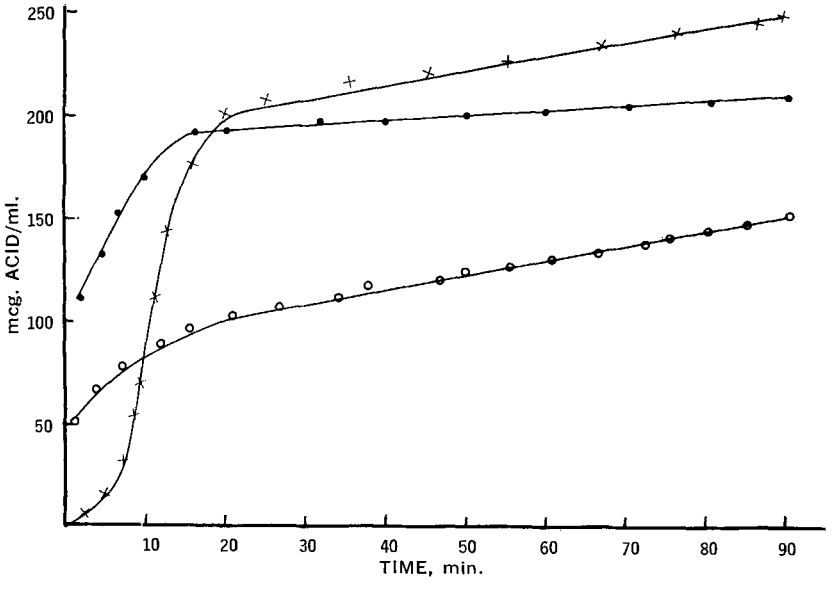

Fig. 9—Plot showing the effect of 0.5% polyol surfactant on the dissolution rates of the acid as a tablet, in a No. 1 capsule, and as a loose powder. Dissolution rates measured in simulated intestinal fluid T.S. Key: O, tablet with 0.5% polyol surfactant; ×, loose powder with 0.5% polyol surfactant; ●, No. 1 capsule with 0.5% polyol surfactant.

deaggregation rates induced by the surfactant in these dosage forms. The effect of tackiness, due to the surfactant, in the initial phases of the dissolution of the powder was also evident.

The effect of the surfactant on the deaggregation rate of the tablet was small, and this was reflected in the small increase in the rate of solution. Possibly higher concentrations of the surfactant are necessary to break up and disperse the aggregates.

BIOPHARMACEUTICAL IMPLICATIONS

The study emphasizes the importance of deaggregation rates. If the absorption is dependent on the dissolution rates, which in turn are dependent on the rates of deaggregation, the study would predict that the highest and earliest blood levels would be obtained with the suspension followed in order by the sodium salt, the acid as a loose powder, in the No. 00 capsule, in the tablet, and last the No. 1 capsule. It is probable that the addition of a surfactant to the acid to increase the deaggregation rate would also increase the absorption rate.

The absorption profiles in man of the acid and sodium salt are currently being investigated in these laboratories. Preliminary results of these investigations support the findings of these studies, and will be published elsewhere.

Recently Wagner and his co-workers (10) studied the effect of dosage form on serum levels of indoxole. They found that the drug administered as a suspension produced a greater serum level response than did the hard gelatin capsules, although both were prepared from the same lot of drug with identical small particle size. They state that the most likely explanation is that the indoxole particles were less agglomerated when administered in suspension form than when given in capsules, and the surface area of indoxole presented for dissolution in the gastrointestinal fluids at the absorption sites must have been greater with the suspension.

In a recent publication, Higuchi *et al.* (6) cited various other examples where the deaggregation rates were the controlling factors in absorption.

It would appear that in dealing with insoluble drugs which are difficult to wet and disperse, the rate of deaggregation from different dosage forms should be routinely determined, just as the rate of solution, particle size, and polymorphic forms are investigated.

Mechanistic Toxicology of Triethyl Citrate in Mouse Fibroblast Cells by Liquid Scintillation Techniques

By MARILYN GOLAZ, W. L. GUESS, and JOHN AUTIAN*

Mouse fibroblast cells, strain L-929, in static tube culture were exposed to 6, 9, and 12 mmole doses of triethyl citrate (TEC) for periods up to 78 hr. At 1.5, 48, and 78 hr. after TEC exposure, the cells were pulsed with ^{14}C-labeled purine and pyrimidine metabolic precursors in an attempt to differentiate the site of purine–pyrimidine metabolism interference. U.V. spectrophotometric analyses were run concurrently with liquid scintillation analyses. The mechanism of inhibition appeared to be initial mitochondrial involvement, with secondary DNA repression.

SINCE ALL pharmacology and toxicology begins ultimately at the cellular level, it seems only logical to elucidate mechanisms involving basic biochemical pathways by way of cellular techniques, and project or apply these findings to the whole organ or body. The advantages of cell culture in a variety of applications are many. Highly specialized cells, differentiating cells, or abnormal cells may be used so that drug effects may be seen under widely varying circumstances. Another convenience is that quantitative evaluation of activity is possible, whereas pharmacodynamic quantitization in the intact animal is often impossible due to the nature of the compound or of the system. Using cell culture techniques, one can test solids, liquids, and gases, and evaluate changes both to the cells and to the growth medium (1–3).

Recently in this laboratory, Rosenbluth *et al.* (2), found that triethyl citrate (TEC), a commonly used plasticizer for polyvinyl chloride resin, was a growth inhibitor to mouse fibroblast cells, strain L-929, in static tube culture at 35° at several dose levels. Through a series of simple experiments, he was able to eliminate chelation of calcium ions as the mechanism of triethyl citrate toxicity. By correlating parachor and other physiochemical values assigned to triethyl citrate, it was postulated that TEC is probably a physically toxic compound. Triethyl citrate is relatively lipid soluble. soluble in water only to the extent of 6.25% w/v, it would be classified according to Ferguson (4) on the basis of its thermodynamic activity as a physical toxicant as opposed to a chemically specific toxicant. Thermodynamic activity is an expression of threshold activity concentration relative to its solubility in water. Because of its lipid solubility and molecular volume, triethyl citrate should have a certain affinity for proteins, nucleic acids, lipoproteins, enzymes, and other macromolecules normally found within the cell and in the cell membranes.

From the previous studies, it was known that triethyl citrate in some way interfered with purine and pyrimidine metabolism to the extent that cell growth was inhibited relative to the dose. The interference need not be a direct effect on mitotic cells, since purines and pyrimidines are indispensable in energy metabolism and cytoplasmic synthetic activities as well as chromosomal replication.

In the above-mentioned study, the method of analysis did not differentiate the site of interference, but merely represented total activity. Since it is widely accepted that thymidine and uridine are precursors of the nucleic acids, DNA and RNA (5), respectively, their uptake could easily be adapted to the original method of McIntire and Smith (6). If adenine, a constituent of the mitochondrial enzymes, adenosine triphosphate (ATP), and the nucleic acids were assayed simultaneously within the same cell population, a more complete profile of purine and pyrimidine metabolism could be easily obtained.

Consequently, it was decided to follow purine and pyrimidine utilization with ^{14}C-labeled precursors and liquid scintillation techniques in an attempt to explain the mechanism of triethyl citrate toxicity. The liquid scintillation study was designed to analyze the parameters of exposure time to TEC, concentration effects, and precursor utilization within each time period and concentration.

MATERIALS AND METHODS

Cell Culture—Mouse fibroblast cells, strain L-929[1] were maintained in static culture in 120 ml. prescription bottles or in Blake culture bottles at 35° in a 5% carbon dioxide atmosphere. Eagle's basal medium 1X (1) supplemented with 1% L-glutamine,[1] 4% calf serum, and 0.5% streptomycin sulfate (Pfizer) per milliliter was used routinely. At regular intervals, the cells were subcultured with the aid of a 0.05% trypsin solution.

Static Tube Culture—The mouse fibroblast cells used in the study were placed in Eagle's basal medium (BME 1X) with 10% calf serum and 1% L-glutamine. Cell population was determined by hemocytometer count and volume adjustments made to provide 3.0×10^5 cells per 1.5 ml. The cells were delivered into sterile disposable culture tubes by a Cornwall automatic pipet. An additional 1.0 ml. of medium (BME 1X) was added to control tubes for assay at 48 and 78 hr. To the test sample tubes was added 1.0 ml. of triethyl citrate[2] at the desired concentrations dissolved in BME 1X. The tubes were covered with sterile aluminum or plastic closures, placed upright in racks in the incubator, and withdrawn at the specified time intervals for pulse-labeling and assay procedures. All tubes were left in the incubator for 1.5 hr. prior to initial assay to allow for resumption of normal cellular activities which are disturbed during the subculture and inoculation techniques.

The tubes to be used in liquid scintillation studies were pulsed by the addition of 1.0 ml. of ^{14}C-purine and pyrimidine precursors[3] dissolved in sterile deionized water to give an activity of 0.15 μc./ml. One milliliter of Eagle's basal medium 2X (7) was added to ensure tonicity of the radioisotope solution. The tubes were then incubated for 1 hr., at the end of which time they were assayed for total purine–pyrimidine content (2).

Assay Procedure for Absorbance Readings—Tubes for initial assay were centrifuged at 2000 r.p.m. for 15 min. No others were centrifuged unless the cells appeared to be loose or had the tendency to be washed from the test tube walls. The supernatant medium was decanted, and the cells were washed twice with 2.5-ml. portions of phosphate buffered saline solution (PBS 1X) (2), to remove color interference. Cells were then covered with 5.0 ml. of 0.3 N H_2SO_4 in 20% NaCl. The closures were replaced and the tubes placed in a sterilizer, covered, and maintained at 100° for 30 min. The tubes were quickly removed to a 4° refrigerator for 20 min. At the end of this period, all tubes were centrifuged at 2000 r.p.m. for 15 min. The resulting supernatant solution was drawn off with a bulb-tipped capillary pipet and read in a quartz cell against the acid-salt blank in a Beckman DB spectrophotometer at 268 mμ (3).

Assay Procedure for Liquid Scintillation—The supernatant medium was decanted after the 1-hr. incubation period, and the cells were washed twice with 2.5-ml. portions of PBS 1X to remove all unbound, extracellular, radioactive material. Centrifugation was carried out only when cells appeared loose from the test tube walls. The cells were then covered with 0.5 ml. of 0.25% trypsin[4] to remove the monolayer from the glass. After trypsinization, the cells were covered with 1.0 ml. of 0.3 N H_2SO_4. Tubes were recapped and boiled at 100° for 30 min., then quick-cooled in a 4° refrigerator for 20 min. After centrifuging at 2000 r.p.m. for 15 min., the supernatant solution was decanted into 15 ml. of the liquid scintillation solvent mixture. A 1.0-ml. quantity of 0.3 N sulfuric

acid wash was added to the scintillation cocktail to make a total of 17.5 ml. The scintillation cocktail, a modified Bray's solution (8), was composed of dioxane–ethylene glycol monomethyl ether–xylene[5] (12:2:1) with an additional 4.2% of a premix solution (50 Gm. PPO and 0.625 Gm. POPOP/L. of toluene).[6] Each Wheaton snapcap potassium-free counting vial was appropriately labeled, placed in the refrigerated detection chamber, and allowed to cool to −7.0° before counting. Control vials contained 15.0 ml. of scintillation solvent, 0.5 ml. of 0.25% trypsin solution, 1.0 ml. of 0.6 *N* H_2SO_4, and 1.0 ml. of radioisotope with an activity of 0.15 μc./ml.

Counting Technique—Counting was performed with a Nuclear-Chicago, series 720, liquid scintillation spectrometer. The channels ratio method (9) was used to correct for quenching with an efficiency of 49%.

RESULTS

All data were compiled by summing the means of four replicate experiments and obtaining the ratios of treated to control cells. Variance analysis was used to determine statistical significance within the parameters of time, concentration, and precursor utilization. Unless otherwise mentioned, all changes referred to as significant were at the 95% confidence level or greater.

Liquid scintillation data showed that within all concentrations of TEC used, adenine utilization was decreased significantly (C.L. >90%) at the initial time period, with respect to controls, and to the other precursors. At a TEC dose level of 6 mmoles, however, adenine uptake was apparently resumed after 48 hr. (Fig. 1.) At a dose level of 9 mmoles, adenine uptake was decreased at 1.5 hr. and at 48 hr., but had resumed normal utilization at 78 hr. (Fig. 2). At a dose level of 12 mmoles, adenine uptake was more significantly reduced than at other dose levels and continued to decrease throughout the 78-hr. period. (Fig. 3.)

Thymidine incorporation was not significantly affected by a dose of 6 mmoles over a time period of 78 hr. However, at 9 mmoles, it decreased significantly at 48 hr. and began an upward trend again at 78 hr. The same pattern was true of the 12-mmoles TEC dose, except that decreased uptake was more pronounced at all time periods.

At a TEC dose level of 6 mmoles, uridine incorporation was decreased only with respect to controls, and by 78 hr. had exceeded control uptake. It was more significantly decreased at the 9-mmole dose level at 1.5 hr., but again resumed uptake by 48 hr. and exceeded that of controls at 78 hr. There was little difference between 9 and 12 mmole TEC dose effects on uridine uptake at all time periods.

Adenine uptake levels remained significantly lower than thymidine and uridine in all TEC dose levels. Uridine uptake increased significantly over adenine and thymidine at 48 to 78 hr., but only at the 9 and 12 mmoles TEC dose levels.

From the standpoint of time of exposure of the cells to TEC, the initial assay revealed a more significant decrease in uridine and adenine utilization than in thymidine, regardless of dose. Adenine

uptake was most depressed at the 12 mmole TEC level at 48 hr., while thymidine did not vary appreciably among 9 and 12 mmole TEC doses during this time period. At all time periods, uridine uptake was significantly higher at 9 and 12 mmole dose levels than at a 6-mmole dose with respect to other precursors. Of all three precursors, adenine incorporation into the cell was lowered to the greatest extent at all dose levels. The decreased adenine uptake continued with time only at 12 mmoles, while at the other dose levels, it recovered and approached normal values by 78 hr. Thymidine remained relatively unchanged with respect to TEC dose level except at 48 hr. where a significant decrease in uptake was observed. Uridine uptake increased with both time and dose, and was therefore not inhibited in its incorporation into the cell by TEC.

Spectrophotometric data yielded results similar to those obtained in previous studies (Fig. 4). Liquid scintillation data were compared to spectrophotometric data to ascertain what fractions each of the labeled purines and pyrimidines occupied in the total cell extract. It should be realized at this point that the cell extracts for both spectrophotometry and liquid scintillation contained total purines and pyrimidines, but that the extract for liquid scintillation "read out" only the ^{14}C-labeled purines and pyrimidines. The differences between readings on the two instruments can be accounted for by guanine and cytosine, the base pairs found in both RNA and DNA, as well as other areas of intermediary metabolism.

Ratios of uptake percentages taken from counts per minute and absorbance (CPM/*A*) showed the rel-

ative quantities of each precursor in the total purine and pyrimidine content. These ratios are higher than true values because labeled guanine and cytosine were not introduced into the system in this study.

Assuming there is no significant change between initial absorbance values and those at 1.5 hr., the zero-time value was derived by taking the ratio of the individual precursor in question to total precursors as expressed by counts per minute under each of the three initial assay conditions and obtaining an average value. Since there is no real number, *per se*, for initial assay by absorbance, the absorbance values were representative of 100% growth.

At all dose levels, adenine had an approximate CPM/*A* ratio of 0.24 initially, 0.63 at 48 hr., and 1.45 at 78 hr. Thymidine had a CPM/*A* ratio of about 0.66 initially, 0.51 at 48 hr., and 0.91 at 78 hr. Uridine gave a ratio of about 0.13 initially, 0.82 at 48 hr., and 1.25 at 78 hr. There occurs, then, the general tendency for uridine/adenine and adenine/thymidine ratios to increase significantly with time. These data essentially substantiated the liquid scintillation data, indicating a major, over-all increase in uridine content when compared to the other purines and pyrimidines. (Table I.)

In general then, only the 9 and 12-mmole dose levels of TEC showed significant effects on cellular utilization of the test precursors except at initial assay. At both the 9 and 12-mmole dose levels, however, adenine was apparently inhibited preferentially and did not recover to normal values.

Uridine	0.13	0.82	1.25

DISCUSSION

The immediate and sustained adenine decrease was one of the most noticeable effects of treatment of mouse fibroblasts by triethyl citrate. With this in mind, one should first look into the possibility of mitochondrial involvement since generation of adenosine triphosphate (ATP) occurs within this particular organelle. The energy processes involving mitochondria are electron transport, oxidative phosphorylation, and the citric acid cycle. The substrates oxygen, adenosine diphosphate, and inorganic phosphate enter the mitochondria and leave as carbon dioxide, water, and ATP. ATP is a high energy phosphate-ester moiety which mediates reactions such as cleavage of molecules, synthesis and coupling of molecules, transfer of materials across cell membranes, protein synthesis, enzyme synthesis, lipid metabolism, and nucleic acid metabolism. Without ATP, there would occur an increase in entropy and an alteration in balance of endergonic biological processes (10).

Adenine is also involved in the coenzymes participating in the electron transport system within the mitochondria, and in acetyl coenzyme A, which mediates glucose, and fatty acid metabolism. Blockage of either the electron transport system or proper metabolism of coenzyme A would favor inhibition of ATP production, accumulation of polysaccharides and lipids, and decreases in synthetic processes such as DNA and RNA polymerization.

It is of interest that uridine uptake increased while there was a concurrent decrease in adenine utilization and a relative decrease in thymidine uptake. The fact that thymidine decreased proportional to the increase in uridine, but tended to remain fairly constant within a 78-hr. period indicated that there was little or no chromosomal replication and cell duplication (11, 12, 15, 17). This could in part account for the observed inhibitory effect on cellular growth by TEC. It is, however, still possible for RNA to be synthesized as evidenced by the now common knowledge that RNA synthesis continues in the G_2 phase after DNA synthesis has stopped (14) and that "heterochromatin" of a nongenetic nature is apparently the source of a large amount of RNA which functions in the metabolism of the cell (12, 13). As long as there is DNA template available, RNA, and particularly messenger RNA, will be synthesized. It is quite possible, then, that as long as sufficient precursors, primers, and ATP are available, RNA synthesis will continue (14, 16). However, it seemed that in this study, the amount of uridine accounted for by liquid scintillation far exceeded that of adenine, and was so disproportionate that

synthesis of RNA after 48 hr. would be impossible. This is only reasonable since adenine not only is a major constituent of RNA, but is necessary in the form of ATP for the polymerization of RNA. By referring to Figs. 2 and 3, it can be seen that uridine appeared to be involved in a cyclic relationship with thymidine. Initially, at a TEC dose level of 12 mmoles, thymidine was not depressed significantly, indicating that some DNA synthesis was still occurring. At 48 hr., the decreased thymidine uptake could be representative of the RNA depression which resulted from 1.5-hr. exposure to TEC. If there is an insufficient quantity of RNA for synthesis of proteins and enzymes, a secondary depression in DNA will ensue, and it appears quite likely that this is happening at 48 and 78 hr. with triethyl citrate (18). The uridine increase at 48 and 78 hr. could then be explained by the presence of pre-existing DNA which functions only as a template.

It is also possible, but highly unlikely, that uridine was being aminated *via* a small proportion of available ATP and glutamine to form cytidine; in this way, the same level of radioactivity would be maintained and the amount of adenine consumed would probably be less than half of that required to phosphorylate and polymerize new ribonucleic acid.

There is yet another possibility that triethyl citrate might serve as a substrate to enzymes mediating citrate transformations into and out of the citric acid cycle (19). This possibility is feasible only if the ethyl groups of TEC do not sterically hinder "active sites" of the enzymes. If such were the case, however, inhibition of ATP would occur.

After reviewing individual possibilities, there still remains the question of TEC exerting its effects by multiphasic involvement. This would include accumulation of TEC in membranes of a lipoprotein nature, including those of the mitochondria, or clathrate formation with macromolecules in a nonspecific manner (22). Such a mechanism would make nucleic acids, enzymes, and other proteins virtually unavailable for cellular metabolism (23). Since there is a rapid labeling, degeneration, and turnover of soluble RNA normally occurring with the cell (20), it is more plausible that the increased uridine count is actually the result of pooled degradation products caught in the cytoplasmic gel which forms at the higher dose levels studied in this paper (21).

CONCLUSION

At the TEC dose levels reported in this paper, it might be concluded that the action of triethyl citrate is fairly specific. Its apparent initial site of action is in the mitochondria which generate energy necessary for other cellular processes to occur. Secondary cyclic functions are then noticeably altered at 48 and 78 hr., especially at 9 and 12 mmole dose levels. The DNA content of the cell does not increase sufficiently to support duplication, but does serve as a template for some further RNA synthesis at the expense of adenine before the 48-hr. assay. Finally, that RNA which was built up between initial assay and 48 hr. is probably degraded, pooled, and kept within the cell membranes by gelation (21), accounting for the resulting uridine levels as revealed by the liquid scintillation techniques. Other sites of action are possible but were not investigated in this study.

Polymeric Pharmaceutical Coating Materials II

In Vivo Evaluation as Enteric Coatings

By LEWIS C. LAPPAS and WAYNE MCKEEHAN

A series of polymeric films exhibited a gradient in dissolution pH within the pH range of the gastrointestinal tract. The *in vivo* release properties of these films were evaluated clinically as enteric coated tablets using acetylsalicylic acid as the marker. The absorption and excretion of these tablets were studied through plasma salicylate and urinary salicylurate measurements in normal, fasting subjects. A direct relationship was observed between the polymer dissolution pH and the onset and induction times of these enteric tablets in the plasma and urine, respectively. No significant difference in absorption rates existed between the stomach for the control and the upper intestine for two of the enteric products. A further increase in the dissolution pH of the polymers released the drug in the lower intestine effecting a progressive decrease in the absorption rate and total absorption. Variation in the upper intestine was significantly less than in the lower intestine.

THE INCREASING emphasis on the clinical efficacy of drug formulations has greatly stimulated the study of those physical and chemical properties which contribute directly to the release and subsequent absorption of orally administered pharmaceuticals. Many drugs are absorbed at various rates throughout the gastrointestinal tract due to their degree of dissociation and solubility (1). The pH gradient of the gastrointestinal tract may then be utilized to control and study the release and ultimate absorption of a drug in specific areas of the intestine. This factor is significant for those medicinals which are absorbed primarily in the intestine from enteric and sustained-release dosage forms. A series of films, half esters of poly(vinyl methyl ether maleate), was prepared to dissolve at various pH values within the pH range of the intestine (2). Earlier reports described the *in vivo* utility of some of these materials as enteric and sustained-release coatings (3–5).

The drug, acetylsalicylic acid, has been studied extensively relative to the effect of the gastrointestinal pH gradient on its rate of absorption. Proven analytical procedures are available for its detection as free salicylate in the blood plasma and as conjugated metabolites in the urine. In view of these considerations, this drug is suitable for use as a marker in this study.

Rapidly disintegrating tablet cores of acetylsalicylic acid were coated with the various films to produce a gradient in their disintegration pH. The effect of these products on the intestinal absorption was measured clinically in normal, fasting subjects through plasma salicylate and urinary salicylurate measurements.

Received April 14, 1967, from the Pharmaceutical Research Department, Lilly Research Laboratories, Eli Lilly and Co., Indianapolis, IN 46206

Accepted for publication June 19, 1967.

Presented to the Basic Pharmaceutics Section, A.PH.A. Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

Previous paper: Lappas, L. C., and McKeehan, W., *J. Pharm. Sci.*, **54**, 176(1965).

The authors express their appreciation to Dr. M. E. Amundson, Mr. W. M. Seidler, and Miss M. M. Webster, Eli Lilly and Co., for their assistance in this work.

EXPERIMENTAL

Physiological Aspects—The essentially unionized form of acetylsalicylic acid and its hydrolysis product, salicylic acid, are passively and preferentially absorbed throughout the entire gastrointestinal tract (6). The pKa of acetylsalicylic acid is 3.49, and the pH of the gastrointestinal tract will determine its degree of dissociation at various absorption sites. Its rate of absorption is highest in the stomach (6, 7), decreases progressively in the intestine (8), and becomes minimal in the colon (9). At the fasting gastric pH range of 1.2–3.5, the ionic state of acetylsalicylic acid is highly favorable for absorption (10); the extent of its absorption is limited by the low solubility in this pH range and the emptying time of the stomach. The pH of the intestine varies from 4 to 7.5, increasing from the proximal to the distal end (11); therefore, the degree of unionized molecule is reduced to approximately 1%. The increased dissolution rate and greater mucosal surface in the upper intestine could effect an equivalent or more rapid absorption from this area than from the stomach (12–14). It is apparent that salicylic acid (pKa 3.0) might produce a similar absorption pattern in the gastrointestinal tract. Eriksen *et al.* demonstrated a similarity of absorption for salicylate in the stomach and 2–3 ft. past the pylorus (15). These investigators noted the rate and efficiency of absorption in the cecum were less than in the stomach and small intestine.

The absorption of acetylsalicylic acid from solid dosage forms is limited and controlled by the dissolution rate of the drug in the gastrointestinal fluids (16). Enteric coatings are designed to transfer the dosage form intact through the gastric fluid and render the drug available for dissolution in the intestinal fluid. Assuming the dissolution properties of a pharmaceutical dosage form are reproducible, it is evident that gastric emptying

time can become a source of significant variation in the intestinal absorption for enteric products. Those factors contributing greatly to this variation are the presence or absence of food (17) and position of the body during sleep (18). Another source of variation in intestinal absorption is the transit or resident time of the dosage form as it traverses the intestine. In general, transit time is minimal proximally and gradually increases distally. These potential variables make it essential to assess the dissolution rates of both the enteric coating and the drug from the solid dosage form.

Plasma and urinary salicylate measurements have been used frequently to study the relative absorption rates of various orally administered dosage forms. The majority of the plasma salicylate is present as protein bound salicylate or free salicylate ion in solution (19). Metabolism of acetylsalicylic acid occurs in the tissues, and elimination as conjugated salicylates is effected readily at 90% yield. Salicyluric acid is the chief metabolite excreted in a normal acid urine, and its rate of formation may become the limiting step in the excretion process. This metabolic lag is seen in the differences between peak times of the plasma and urinary salicylate levels indicating the metabolic rate is slower than the absorption rate from the gastrointestinal tract.

Cummings and Martin studied the kinetics of acetylsalicylic acid metabolism relative to dosage and noted the urinary excretion rates between doses of 325 mg. and 650 mg. were decreased with the higher dose (20). This change in half-life was attributed to the attainment of a saturation excretion level which was related to plasma concentration. Other investigators have studied the half-life of salicylate in the blood and observed a range from 4.7 to 19 hr. depending on the plasma concentration (21–23).

Preparation of Enteric Polymers—A series of half esters of the copolymer poly(vinyl methyl ether/maleic anhydride) (PVM/MA) was prepared, and the dissolution pH of these films was determined according to the procedures described by Lappas and McKeehan (2).[1] The dissolution pH of each enteric film, determined after 24 hr. at 25°, is listed in Table I.

Preparation of Tablet Core—A circular, biconvex tablet was formulated from a starch base and contained 0.325 Gm. of acetylsalicylic acid by the U.S.P. method of analysis (24). The disintegration property of this tablet was designed to rupture and disperse completely in 1–2 min. at pH 1.2, 6.0, and 7.5 using the U.S.P. disintegration apparatus, without disks, at 37° (25). The test fluids of designated pH were prepared by mixing solutions of enzymeless, U.S.P. simulated gastric and intestinal fluids (26). In order to promote the adhesion of these enteric polymers to this tablet, two types of subcoatings were used. In the film coating process, methylcellulose 10 cps. (Dow Chemical Co.) was applied at 3 mg./tablet, with a DeVilbiss sprayer, from a solution of equal volumes of methanol and methylene chloride. In the alternate process, approximately 15 mg./tablet of a powder subcoat was applied by ladling syrup on the tablets to produce tackiness and then dusting to dryness with talc–acacia (88:12). The disintegration times of these subcoated cores were the same as that of the uncoated tablet core.

TABLE I—DISSOLUTION pH OF ENTERIC FILM COATINGS

Half Ester of PVM/MA	Dissolution pH[a]
Ethyl	4.25
Isopropyl	5.25
n-Butyl	5.75
Cyclopentyl	6.25

[a] pH of complete solubility; the film is intact at 0.25 pH unit below this pH.

Preparation of Enteric Coated Tablets—The polymeric film coatings were applied to the subcoated tablets in batch sizes of 3000 in a conventional 16-in. diameter tablet coating pan. Solutions of 4% w/v polymer in a mixture of acetone–isopropanol (85:15) were applied from a DeVilbiss sprayer. The final weight of coating per tablet was determined as the amount required to withstand the disintegration test for 1 hr. in enzymeless gastric fluid without physical change. The maximum amount of acetylsalicylic acid extracted from any tablet under these conditions was 4.8 mg. The disintegration pH of the tablet was defined as a function of pH and time required to dissolve the enteric film coat and disperse the tablet contents. The apparatus and method of preparation for the pH-adjusted test solutions were described previously for the uncoated tablet core. The pH at which the tablet remained intact for a minimum period of 1 hr. demonstrated the small range in pH between solubility and insolubility. The presence of enzymes in the test solutions did not alter the disintegration times of the enteric tablets. The disintegration properties of the various enteric coated tablets are summarized in Table II. The rate of disintegration at pH 7.5 increased in direct relationship from a mean of 6 min. for the 1/2 ethyl PVM/MA coated tablet to 12 min. for the 1/2 cyclopentyl PVM/MA coated tablet. At the lower pH's, the differences in disintegration time between the various enteric tablets are more clearly defined than at pH 7.5.

Clinical Procedure—A total of 12 healthy male subjects, who were known to be absorbers of acetylsalicylic acid, were used throughout the study; however, not all members of this panel participated in all of the experiments. The subjects were selected at random for testing the various enteric coated tablets as follows: five subjects in a cross-over study with the uncoated control, the 1/2 ethyl PVM/MA and the 1/2 isopropyl PVM/MA; eight subjects were used to study the 1/2 *n*-butyl PVM/MA; and six subjects constituted the group for the 1/2 cyclopentyl PVM/MA. A total of 0.650 Gm. of acetylsalicylic acid, two tablets, was administered to overnight fasting subjects with 200 ml. of water. A light breakfast was permitted 1 hr. after the administration of this dose. Although liquids were taken freely after 1 hr., 100 ml. of water was administered after each urine void. Preliminary evaluation of these materials determined the optimal time for the withdrawal of blood and the collection of urine samples. Urinalysis was continued for 48 hr., the time of complete excretion for all products tested.

[1] Polymer-grade used was Gantrez AN 139 for PVM/MA which is available from General Aniline and Film Corp.

TABLE II—DISINTEGRATION PROPERTIES OF ENTERIC COATED TABLETS OF ACETYLSALICYLIC ACID 0.325 Gm.

Enteric Coating	Subcoat	Enteric Coat, mg./Tablet	Disintegration pH[a]	Disintegration min.	Insolubility pH[b]
1/2 Ethyl PVM/MA	Methyl-cellulose	28	5.75	25	5.0
1/2 Isopropyl PVM/MA	Methyl-cellulose	20	6.0	38	5.5
1/2 *n*-Butyl PVM/MA	Powder	16	6.2	38	6.0
1/2 Cyclopentyl PVM/MA	Powder	10	6.75	15	6.5

[a] pH of solutions was monitored constantly. [b] Tablet was physically unaltered for at least 1 hr.

Analytical Procedures—A modification of the procedure reported by Schachter and Manis was used to determine the plasma salicylate fluorimetrically (19). Freshly drawn blood samples were mixed with heparin, and the plasma was separated by centrifugation. An aliquot of this sample was acidified and extracted with chloroform to remove the free salicylate. This solution was alkalinized with sodium hydroxide and activated at a wavelength of 314 mμ. Its fluorescence was measured at an emission wavelength of 410 mμ using an Aminco-Bowman spectrophotofluorometer.

Generally, about 75% of the dose of acetylsalicylic acid is excreted as the metabolite, salicyluric acid; 10% is found as the free salicylate. In order to economize time and effort, the metabolite salicyluric acid was measured to evaluate the comparative absorption and total excretion of acetylsalicylic acid from the various preparations. Individual urine samples were pooled and collected at 4, 8, 12, 18, 24, 32, and 48 hr. These samples were refrigerated prior to analysis for pH and salicyluric acid content. Although the pH of the urine samples varied for the individuals, the range of pH 5.0 to 6.8 was considered normal for acid urine. The method of analysis for salicyluric acid was essentially that described by Schachter and Manis (14). An aliquot of the urine sample was acidified with hydrochloric acid and extracted with ether. This layer was subsequently extracted with sodium hydroxide solution, and its fluorescence was measured at an emission wavelength of 410 mμ after activation at 335 mμ.

RESULTS AND DISCUSSION

This investigation was undertaken to demonstrate the *in vivo* release properties of a series of polymeric

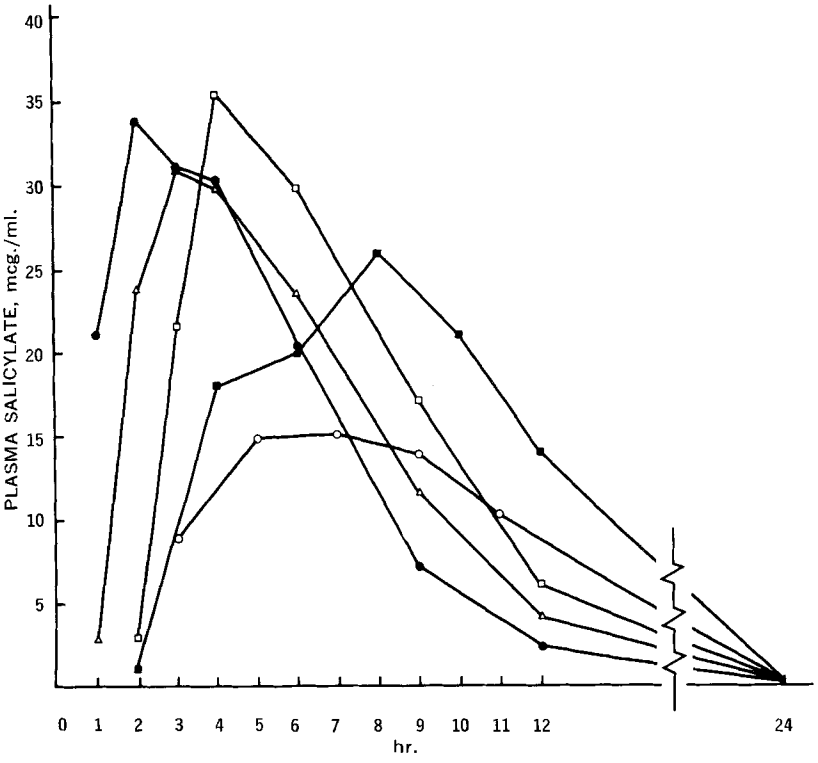

Fig. 1—Plasma salicylate concentration vs. *time: effect of polymer dissolution pH gradient. ASA blood levels; single dose, 650 mg. (two tablets). Key:* ●, *control uncoated;* △, *1/2 ethyl PVM/MA;* □, *1/2 isopropyl PVM/MA;* ■, *1/2* n-*butyl PVM/MA;* ○, *1/2 cyclopentyl PVM/MA.*

films having a dissolution pH gradient within the pH range of the intestinal tract. These films, applied over a rapidly disintegrating core of acetylsalicylic acid, exert a direct control over the release, dissolution, and subsequent absorption of this active ingredient. The significant physiological variables affecting its absorption are the pH of the intestine, the gastric emptying time of the stomach, and the transit time of the drug in the intestine. In consideration of these factors, the absorption aspects are revealed for areas of the intestine rather than exact locations.

The absorption-excretion data are expressed as average plasma salicylate and urinary salicylate levels as a function of time. These measurements illustrate the relative differences in the absorption of acetylsalicylic acid as it is presented to various pH values along the gastrointestinal tract. The frequency of the urine collection is a factor which limits the use of these data for quantitative kinetic study of the absorption-distribution-excretion properties of this drug.

The plasma salicylate levels plotted in Fig. 1 reveal similar peak levels for the control, the 1/2 ethyl PVM/MA and 1/2 isopropyl PVM/MA coated tablets at 2, 3, and 4 hr., respectively. The absorption slopes are steep and similar for the three products indicating equivalent absorption rates in the stomach for the control and two locations in the upper part of the small intestine for the enteric tablets. This observation is in accord with that of other investigators (6–14) and may be explained by the increased solubility of the drug in an area of vast intestinal mucosal surface which equalizes the optimal ionic conditions for absorption of this drug in the stomach. The 1/2 *n*-butyl PVM/MA coated tablet effected a decrease in the absorption slope and peak level; a salicylic acid concentration of 26 mcg./ml. was attained in 8 hr. Similarly, the 1/2 cyclopentyl PVM/MA coated product plateaued at 5–9 hr. reaching its peak salicylate value of 15.1 mcg./ml. after 7 hr. This gradient in the absorption rates of acetylsalicylic acid is attributed to the decreased efficiency in absorption from the lower parts of the intestine.

In Fig. 2, the average cumulative urinary excretion is expressed as mg. of salicylic acid and as the per cent released relative to the uncoated control. These data indicate the onset of absorption was progressively delayed with an increase in the disintegration pH of the enteric coated tablets. The cumulative excretions of the control, the 1/2 ethyl PVM/MA, and the 1/2 isopropyl PVM/MA coated tablets were equivalent after 12 hr. This level of

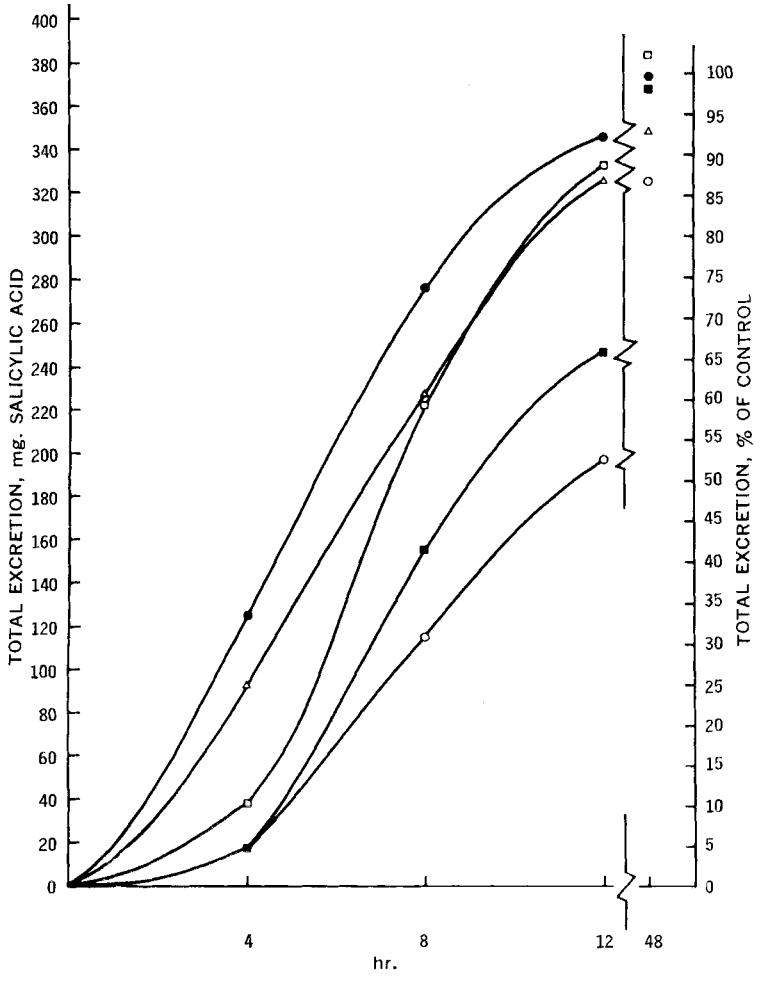

Fig. 2—Total urinary salicylate excretion vs. *time: effect of polymer dissolution pH gradient. ASA urinary excretion; single dose, 650 mg. (two tablets). Key:* ●, *control uncoated;* △, *1/2 ethyl PVM/MA;* □, *1/2 isopropyl PVM/MA;* ■, *1/2* n-*butyl PVM/MA;* ○, *1/2 cyclopentyl PVM/MA.*

excretion was approached by the 1/2 *n*-butyl PVM/MA and the 1/2 cyclopentyl PVM/MA coated tablets in 18 and 24 hr., respectively. The excretion study was conducted through 48 hr. indicating complete availability for all enteric tablets except for the 1/2 cyclopentyl PVM/MA coated tablet which was 87% available. The deposition of an enteric tablet at a lower absorption site than the latter tablet would be expected to result in slower and less complete absorption with a lower plasma peak and lower degree of availability.

The variation of the tested products was considered by examination of the distribution of peak times for individuals. This parameter is a reflection of the combined variables of gastric emptying time, pH, and intestinal transit time. The distribution patterns for the control, the 1/2 ethyl PVM/MA, and the 1/2 isopropyl PVM/MA coated tablets were equivalent. The 1/2 *n*-butyl PVM/MA coated tablet indicated increased variation, and the 1/2 cyclopentyl PVM/MA coated tablet exhibited the greatest variation. In these fasting ambulatory subjects the absorption reproducibility of the enteric tablets was greatly dependent upon the absorption site of the intestine, *i.e.*, the upper part of the intestine exhibited significantly less variation in absorption than the lower part of the intestine.

These data reveal that the gradation in coating dissolution pH is significant in permitting some control over the absorption of acetylsalicylic acid. Many other drugs are absorbed at various rates throughout the intestinal tract. Therefore, each drug should be considered an individual problem in formulating enteric-release products to effect optimal absorption.

Hydrolysis of Solubilized Aspirin

By A. G. MITCHELL* and J. F. BROADHEAD

The hydrolysis of aspirin in buffered solutions of the nonionic surfactant, cetomacrogol, has been studied at 37° over the pH range 1 through 7. Cetomacrogol reduces the hydrolysis rate of unionized aspirin but not that of ionized aspirin. The reaction occurs mainly in the aqueous phase but at low pH the contribution of a hydrogen ion catalyzed reaction within the micelles becomes significant. A kinetic expression has been derived to account for reaction both in the aqueous phase and in the micelles.

THE HYDROLYSIS of aspirin in aqueous solution has been investigated extensively by Edwards (1, 2) and Garrett (3, 4). They determined overall first-order rate constants as a function of pH and proposed various reaction mechanisms.

The effect of anionic, cationic, and nonionic surfactants on the stability of solubilized aspirin has been studied by Nogami *et al.* (5). It was shown that each surfactant suppressed the hydrolysis of unionized aspirin, while the hydrolysis of the anionic form of aspirin was suppressed only by cationic surfactants.

In this work, a detailed study has been made of the stability of aspirin at 37° in several concentrations of the nonionic surfactant, cetomacrogol, over the pH range 1 through 7. A kinetic expression has been derived to account for the hydrolysis of the solubilized drug.

EXPERIMENTAL

Reagents and Solutions—Aspirin was recrystallized from acetone, m.p. 134–136°. Salicylic acid was recrystallized from alcohol and then water,

m.p. 159–161°. Cetomacrogol 1000 B.P.C.[1] has the general formula $CH_3 \cdot (CH_2)_m [O \cdot CH_2 \cdot CH_2]_n \cdot OH$, where m may be 15 or 17 and n may be 19 to 23. The molecular weight was taken as 1300. Solutions of cetomacrogol were passed through a column of mixed bed ion-exchange resins to remove alkaline impurities (6). Using a Zeiss laboratory interferometer the refractive index of the effluent was measured as an instrument scale reading and the concentration of cetomacrogol determined from a standard curve of instrument scale reading *versus* molar concentration.

Cetomacrogol solutions were buffered as follows: pH 1.0–2.2 HCl–KCl buffer (7), pH 2.2–2.9 glycine–HCl buffer (7), pH 2.9–4.6 acetate buffer (8), and pH 6.8–7.1 phthalate buffer (8). Ferric chloride reagent (1% $FeCl_3 \cdot 6H_2O$ in 0.05 N HCl). All solutions were made using freshly boiled and cooled glass-distilled water.

Apparatus—Beckman research pH meter (relative precision ± 0.001 under optimum conditions). The glass-saturated calomel electrode system was standardized, using 0.05 M potassium hydrogen phthalate, and the electrode response was checked on this buffer after each reading. The pH/E.M.F. relationship of the electrode was checked periodically using 0.05 M sodium borate. pH measurements were made at 37 ± 0.1° in a constant-temperature jacketed beaker.

Colorimetric analyses were made using a Unicam SP 1300 colorimeter and an Ilford No. 624 bright spectrum green filter (495–575 mμ).

Analytical Method—Solutions were analyzed for salicylic acid, using the blue color developed on reaction with ferric chloride (9).

Solubility of Aspirin—Excess aspirin was equilibrated with aqueous buffer or buffered cetomacrogol solutions by rotation in sealed cylinders in a water bath thermostatically controlled at 37 ± 0.1°. After filtration through a jacketed filter-funnel, aliquots of filtrate were assayed for salicylic acid present due to hydrolysis. Further samples were made alkaline with 0.5 N KOH, heated on a steam bath for 60 min., reacidified with 0.5 N HCl, and assayed for total salicylic acid. The solubility of aspirin was calculated from the difference between the amount of salicylic acid present initially and the amount found after complete hydrolysis.

Kinetic Procedure—An accurately weighed amount of aspirin was dissolved in aqueous buffer or buffered cetomacrogol solution maintained at 37 ± 0.1° in a thermostatically controlled water bath. Duplicate samples were withdrawn at zero time and then at suitable time intervals. One sample was assayed immediately for salicylic acid and the other for salicylic acid after complete hydrolysis. The concentration of aspirin remaining at each sampling time was calculated.

Density Measurements—A pycnometer of approximately 10-ml. capacity was used to measure the density of the cetomacrogol solutions at 37° (10). Each density was the mean of at least two determinations.

RESULTS AND DISCUSSION

Hydrolysis—The hydrolysis of aspirin proceeds as a first-order reaction both in aqueous buffer and in buffered cetomacrogol solutions (Fig. 1). Reaction rate constants were determined over the pH range 1 through 7 and the pH profiles in various surfactant concentrations are shown in Fig. 2. (Table I.) At the pH of maximum stability, pH 2.27, where aspirin exists largely in the unionized form, the half-life increases with cetomacrogol concentration and in 0.07 M cetomacrogol is approximately twice that in aqueous buffer. In the plateau region where aspirin is largely ionized, the rate of hyrolysis is independent of cetomacrogol concentration.

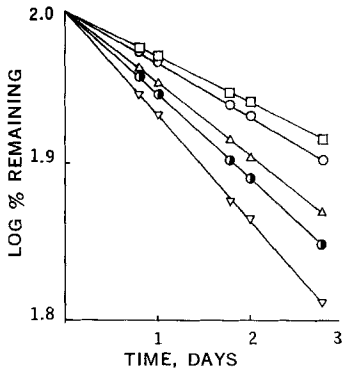

Fig. 1—First-order plots for the hydrolysis of aspirin solubilized in cetomacrogol solutions at 37°, pH 2.27. Key: cetomacrogol, moles L.$^{-1}$—▽, 0.00; ◑, 0.01; △, 0.02; ○, 0.05; □, 0.07.

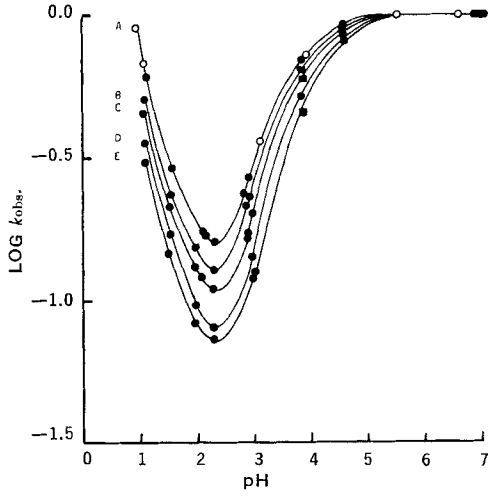

Fig. 2—Variation of observed first-order rate constant with pH for hydrolysis of aspirin solubilized in cetomacrogol solutions at 37°. Key: cetomacrogol, moles L.$^{-1}$—A, 0.00; B, 0.01; C, 0.02; D, 0.05; E, 0.07; ●, present study; ■, calculated; ○, Nogami (5).

On the two-phase model of micelle formation, solute will partition between the aqueous phase and the micellar phase. Using the two-phase model for a first-order process in surfactant solution, Yamada and Yamamoto (11) derived Eq. 1:[2]

$$k_{obs.} = \frac{1 - v}{Kv + (1 - v)} k_w \qquad \text{(Eq. 1)}$$

where $k_{obs.}$ is the observed rate constant in surfactant solutions at a given pH, k_w is the rate constant in aqueous solution at the same pH, K is the apparent partition coefficient for the distribution of solute between the micelles and aqueous phase, v is the volume fraction of micellar phase, and $1-v$ is the volume fraction of aqueous phase.

To test the applicability of Eq. 1 to the hydrolysis of aspirin in surfactant solutions, it was first necessary to estimate v and K.

Partial Molar Volume—The partial molar volume of cetomacrogol at 37° calculated from the density measurements shown in Fig. 3 was 1170 ml. mole^{-1}. Florence (12) has reported a value of 1099 ml. mole^{-1} at 30°. The partial molar volume was used to calculate v at each cetomacrogol concentration. The CMC of cetomacrogol is sufficiently low (13) for the concentration of monomeric surfactant to be neglected at the cetomacrogol concentrations under consideration.

Apparent Distribution Coefficient—The pH-dependent apparent distribution coefficient, K, is given by:

$$K = \frac{D_m}{v} \cdot \frac{(1 - v)}{D_w} \qquad \text{(Eq. 2)}$$

where D_m is the amount of solute in the micellar phase and D_w is the amount of solute in the aqueous phase. The total amount of solute, D, is given by:

$$D = D_w + D_m \qquad \text{(Eq. 3)}$$

In a given volume of a saturated solution the total amount of solute is equal to the solubility, C_s, and Eq. 3 becomes:

$$C_s = D_w + D_m \qquad \text{(Eq. 4)}$$

D_w was calculated from:

$$D_w = C_{sw}(1 - v) \qquad \text{(Eq. 5)}$$

where C_{sw}, the total solubility of aspirin in aqueous solution, is given by Eq. 6 (14):

$$C_{sw} = C'_{sw}\,[1 + \text{antilog (pH–pKa)}] \qquad \text{(Eq. 6)}$$

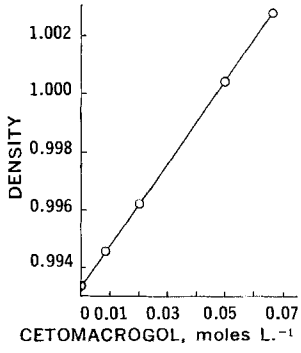

Fig. 3—Densities of cetomacrogol solutions at 37°.

[a] *K* calculated from the mean value of *Dm* at each cetomacrogol concentration.

C'_{sw}, the aqueous solubility of unionized aspirin at 37°, is 5.46 Gm. L.$^{-1}$, and the pKa for aspirin calculated by the solubility method (14) is 3.5 ± 0.03.

The solubility of aspirin at various pH values is shown as a function of cetomacrogol concentration in Fig. 4. The amount of aspirin in the micelles, D_m, at each cetomacrogol concentration is constant and from Eqs. 4 and 5 is given by:

$$D_m = C_s - C_{sw}(1 - v) \qquad \text{(Eq. 7)}$$

Table II shows some of the values for D_w, D_m, and K.

Agreement between the theoretical solubility curves shown in Fig. 4 (calculated from solubilities measured at pH 1.11 and Eqs. 4–7) and solubility values determined experimentally over the pH range where direct estimations were possible confirms the validity of this approach. Apparent distribution coefficients at any required pH can be determined from the plot of *K versus* $1/1 + k_a/[H^+]$, shown in Fig. 5.

Kinetics—One of the assumptions implicit in Eq. 1 is that only drug in the aqueous phase undergoes hydrolysis. It has been shown recently (15) that this assumption is valid for the hydrolysis of chlorobutol in nonionic surfactants at pH 8.7 and pH 9.2. If Eq. 1 is applicable to the hydrolysis of aspirin in cetomacrogol solutions, then a plot of the observed rate constant, $k_{obs.}$, for each pH against $(1-v)/Kv+(1-v)$ should be a line of slope k_w passing through the origin. Figure 6 shows that the equation holds at pH 2.95 and above, but at lower pH values the lines intercept the ordinate above the origin. The occurrence of an intercept indicates that at pH < 2.95 a reaction additional to that in the aqueous phase is making a significant contribution toward the over-all reaction.

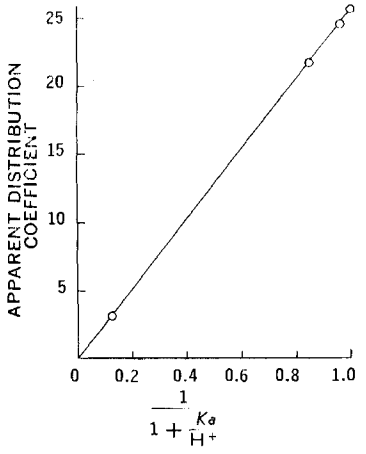

Fig. 5—Apparent distribution coefficients for the partition of aspirin between the micelles and aqueous phase of cetomacrogol solutions at 37°, plotted as a function of the ionization constant and hydrogen ion concentration.

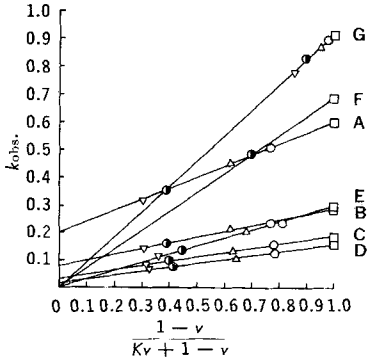

Fig. 6—Plot of observed rate constant against $(1 - v)/Kv + (1 - v)$ *in accordance with Eq. 1. Key: cetomacrogol, moles L.*$^{-1}$*— □, 0.00; ○, 0.01; Δ, 0.02; ◑, 0.05; ▽, 0.07; A, pH 1.11; B, pH 1.55; C, pH 1.95; D, pH 2.27; E, pH 2.95; F, pH 3.84; G, pH 4.60*

When the term $(1-v)/Kv + (1-v) = 0$, the volume of the micellar phase, v, is equal to 1. Hence the additional reaction must be taking place in the micellar phase and has a rate constant, k_m, equal to the intercept. It is apparent from Fig. 7 that k_m is directly proportional to the hydrogen-ion concentration which suggests that the reaction is due to hydrogen-ion attack on unionized aspirin within the micelles. To account for the reaction in the micelles, Eq. 8[3] was derived in a manner similar to the derivation of Eq. 1.

$$k'_m = \frac{Kv}{Kv + (1 - v)} \cdot k_m \qquad \text{(Eq. 8)}$$

where k'_m is the contribution of the micellar rate constant to the observed rate constant in the solubilized system. If k'_w is the corresponding contribution of the aqueous rate constant then the over-all rate constant is given by:

$$k_{obs.} = k'_m + k'_w \qquad \text{(Eq. 9)}$$

Equation 1 can now be rewritten to account for the micellar reaction:

$$k'_w = \frac{1 - v}{Kv + (1 - v)} \cdot k_w \qquad \text{(Eq. 10)}$$

where from Eqs. 9 and 8:

[3] See the *Appendix*.

$$k'_w = k_{obs.} - k'_m = k_{obs.} - \frac{Kv}{Kv + (1 - v)} \cdot k_m$$

At pH > 2.95, the reaction within the micelles is negligible and $k'_w = k_{obs.}$. Hence at any pH, a plot of k'_w, the contribution of the aqueous rate constant to the observed rate constant, *versus* the term $(1 - v)/Kv + (1 - v)$ should be a straight line

[a] Different strength glycine–HCl buffer, all other ionic strengths adjusted with KCl.

of slope k_w, which passes through the origin. Such a plot is shown in Fig. 8. Equation 10 therefore separates the contributions of the aqueous and micellar rate constants toward the observed rate constant and is essentially the same as an equation derived by Winters and Grunwald (16) for the reaction of methyl bromide with cyanide ions in anionic and cationic surfactants.

Both Eqs. 1 and 10 are derived on the assumption that the distribution of aspirin between the micelles and aqueous phase obeys the simple partition law. This appears to be true for some solutes, but for others Mitchell and Brown (17) have shown that the distribution coefficient depends on the degree of saturation of the system with solute. In the present work direct estimation of the apparent distribution coefficient was difficult because of the unstable nature of aspirin. The apparent distribution coefficients therefore were calculated using solubility data and Eqs. 2–7. This procedure is open to criticism since the method is limited to measurements at saturation below which it cannot be assumed that the calculated distribution coefficients will be valid. If, however, the apparent distribution coefficient varies with the degree of saturation of the system with aspirin, then $k_{obs.}$ should also vary. Results in Table III show that, at each pH for a given cetomacrogol concentration, values of $k_{obs.}$ are independent of aspirin concentration. It is reasonable to conclude therefore that the apparent distribution coefficients are independent of aspirin and cetomacrogol concentrations. Table III also includes values of $k_{obs.}$ determined at the same pH but different ionic strengths to show that the reaction is independent of ionic strength.

APPENDIX

Derivation of Eq. 1—Let C = initial reactant concentration (moles L.$^{-1}$ total system), C_w = initial reactant concentration in the aqueous phase (moles L.$^{-1}$ aqueous phase), and x = concentration reacting in time t (moles L.$^{-1}$ total system). Then, on the assumption that hydrolysis in a solubilized system takes place only in the aqueous phase, the concentration of reactant remaining after time t, is $C_w(C - x)/C$ moles L.$^{-1}$ aqueous phase or $C_w(1 - v)(C - x)/C$ moles L.$^{-1}$ total system. The differential rate equation for the concentration change with respect to the total system is:

$$\frac{dx}{dt} = k_w C_w (1 - v) \frac{(C - x)}{C} \qquad \text{(Eq. 11)}$$

which on integration and rearrangement gives:

$$k_w = \frac{C}{C_w(1 - v)} \frac{1}{t} \ln \frac{C}{C - x} \qquad \text{(Eq. 12)}$$

From Eq. 2, the distribution coefficient:

$$K = \frac{C - C_w(1 - v)}{C_w v} \qquad \text{(Eq. 13)}$$

which on rearrangement becomes:

$$\frac{C}{C_w} = Kv + (1 - v) \qquad \text{(Eq. 14)}$$

Substitution into Eq. 12 gives:

$$k_w = \frac{Kv + (1 - v)}{1 - v} \cdot \frac{1}{t} \ln \frac{C}{C - x} \quad \text{(Eq. 15)}$$

where $1/t \ln C/(C - x)$ is the observed rate constant $k_{obs.}$, assuming that hydrolysis takes place only in the aqueous phase. Substitution of $k_{obs.}$ into Eq. 15 and rearrangement leads to Eq. 1:

$$k_{obs.} = \frac{1 - v}{Kv + (1 - v)} k_w \quad \text{(Eq. 1)}$$

Derivation of Eq. 8—On the assumption that decomposition in solubilized systems takes place only in the micelles, the differential rate equation is given by:

$$\frac{dx}{dt} = k_m C_m v \frac{(C - x)}{C} \quad \text{(Eq. 16)}$$

where C_m is the intiial reactant concentration in the micelles (moles L.$^{-1}$ micellar phase). Integration and rearrangement gives:

$$k_m = \frac{C}{C_m v} \frac{1}{t} \ln \frac{C}{C - x} \quad \text{(Eq. 17)}$$

From Eq. 2, the distribution coefficient:

$$K = \frac{C_m (1 - v)}{C - C_m v} \quad \text{(Eq. 18)}$$

which on rearrangement becomes:

$$\frac{C}{C_m} = \frac{K_v + (1 - v)}{K} \quad \text{(Eq. 19)}$$

Substitution into Eq. 17 gives:

$$k_m = \frac{Kv + (1 - v)}{Kv} \frac{1}{t} \ln \frac{C}{C - x} \quad \text{(Eq. 20)}$$

where the term $1/t \ln C/(C - x)$ is the observed rate constant, assuming that hydrolysis takes place only in the micelles. In a system where reaction takes place in both micelles and aqueous phase this term is equal to k'_m, the contribution of the micellar rate constant to $k_{obs.}$, where $k_{obs.}$ is now the over-all observed rate constant defined in Eq. 9. Substitution of k'_m into Eq. 20 and rearrangement leads to Eq. 8:

$$k'_m = \frac{Kv}{Kv + (1 - v)} \cdot k_m \quad \text{(Eq. 8)}$$

Ultrastructural Hepatotoxicity Induced by an Organotin Ester

By DAVID CALLEY, W. L. GUESS, and J. AUTIAN*

Adult mice and rats were intubated with daily one-fourth LD_{50} amounts of the organotin dibutyltin diacetate. Histopathology by light microscopy, and cellular ultrastructural changes by electron microscopy to hepatic tissue was determined at 24-hr. intervals to elucidate the mode of hepatotoxic action of the compound. It was found that early mitochondrial damage with cristae swelling and subsequent hydropic degeneration occurred. Swelling of granular and agranular endoplasmic reticulum followed soon after mitochondrial changes were seen, and progressed to hydropic vesicular formation. There was a progressive congestion of bile canaliculi due to cellular and microvilli swelling. The proposed mechanism of action of the organotin was dithiol inhibition of ATP production in the mitochondria, with consequent interference of ATP-dependent membrane activity in other parts of the cell. Rats maintained greater cellular integrity possibly due to early inhibition of phagocytosis or phagolysosomal activity.

A SERIES OF organotin esters has previously been studied in this laboratory for their toxic effects to biological systems *in vivo* and *in vitro*. It was found that certain of these compounds even in low concentrations, and particularly those possessing the acetate ester moiety, were highly toxic. In investigations by Guess *et al.* (1) and Calley *et al.* (2), these compounds have been shown to rapidly cause death of cell cultures *in vitro;* have an initial CNS depressant effect when administered orally or parenterally to rabbits, rats, or mice; are highly irritating to dermal, muscle, and ocular issue; and bring about hepatic disturbances resulting in biliary obstruction, jaundice, and liver necrosis in mice, and altered liver function in rats and rabbits.

No study reported to date has discussed the mechanism of toxicity to liver tissue by organotin at the subcellular level. According to Rees (3), exogenous toxic agents may cause biochemical changes in liver tissue which lead either to fat accumulation or to necrosis with resultant autolysis. One of these mechanisms of toxic action may be evidenced without the other, or both may occur simultaneously. A reduction or blockage of protein synthesis is the key event in fat accumulation (4–8). The changes in protein synthesis are detectable at a time when intracellular fat accumulations become visible by light microscopy. Harris, Robinson, and Seakins (4–6) have proposed that lack of protein, normally constituting part of the lipoprotein molecule, causes the formation and deposition of triglycerides intracellularly. According to Rees and Shotlander (7, 8), this process is coincidental with a fall in serum lipoprotein levels.

It is generally agreed that intracellular changes which lead to tissue necrosis involve at least two events. These are cell permeability changes and mitochondrial injury. In addition, lysosomal damage may sometimes occur. The latter is thought by de Duve and co-workers (9) to be a terminal stage of liver cell injury and may be the event precipitating necrosis. Disagreement on this point is based upon the late occurrence of above normal amounts of unbound serum lysosomal enzymes, signifying lysosomal damage. Investigations by Slater, Greenbaum, and Wang (10) at this level of liver cell injury have shown a preponderance of unbound enzymes only after necrosis has occurred. Mitochondrial injury is also thought to be a relatively late event in hepatic poisoning, although preceding lysosomal damage. The manner in which mitochondrial change occurs is uncertain, but according to Rees *et al.* (11) may be secondary to other changes. Rees (3) suggests that the initial point of attack of all liver poisons is the endoplasmic reticulum and that this sets into motion a series of events leading to necrosis or fatty degeneration, depending upon whether smooth or rough endoplasmic reticulum is affected, *i.e.*, whether cell permeability and ionic changes occur, or alternatively, protein synthesis is inhibited.

Status of knowledge concerning organotin toxicity through 1958 has been well documented in a monograph by Barnes and Stoner (12). Inhibition of oxidative phosphorylation has been demonstrated by Sone (13) in triethyltin poisoning. Tetraethyltin was found by Cremer (14) to be converted in small amounts to triethyltin, primarily by liver cells, when administered intraven-

ously in rats. Barnes and McGee (15) found that dibutyltin salts produced lesions of the bile duct in rats and mice, and was found in highest concentration in liver and kidney tissue and was excreted unchanged in bile. They also found that species difference was noted as to bile duct damage, with rabbits, guinea pigs, and cats showing no effect, rats and mice showing lesions.

A serious lack of knowledge exists as to the mechanisms involved in toxicity induced to cellular material by the organotin esters. Changes which may be brought about to the cytoplasmic and nuclear membranes, to cell organelles such as mitochondria, lysosomes, Golgi apparatus, chromosomes, endoplasmic reticulum, *etc.*, and how these changes are related to enzyme levels and normal body function is virtually unknown. The electron microscope is, of course, the most useful tool in determining structural changes at the subcellular level. It was decided that a study combining the capabilities of this instrument with customary light microscope pathological determinations of liver tissue from dosed animals would be a rational approach to delineate some of the more subtle aspects of toxicity.

MATERIALS AND METHODS

Young adult female Holtzman rats, weighing between 275 and 300 Gm., were intubated daily with one-fourth the LD_{50} concentration of dibutyltin diacetate (LD_{50} 109 mg./Kg.). Cottonseed oil was employed as the vehicle and control. One rat was sacrificed at each 24-hr. interval, with the dosage and sacrifice schedule covering a 10-day period. A similar schedule was followed in which young adult female, Swiss-Webster white mice weighing between 17 and 20 Gm. were dosed and sacrificed daily. Liver tissue from both rats and mice was taken immediately upon sacrifice and prepared for histological examination by light microscopy and for ultrastructural interpretation by electron microscopy.

Liver tissue selected for light microscopy was fixed in 10% phosphate buffered formalin, paraffin embedded, and the mounted sections were hematoxylin-eosin stained for examination.

A cross-section of tissue from the center portion of the left lobule of the liver was prepared for electron microscopy. Liver slices approximately 2 mm. in thickness were placed in 2.5% gluteraldehyde buffered with 0.2 *M* collidine. All tissue was placed in preservative within 1 min. after sacrifice to prevent autolysis. After 10 days, the tissue was removed from the buffered gluteraldehyde, cut into 2 mm. by 2 mm. cubes, washed twice for 30 min. in collidine buffer, and post-fixed for 1.5 hr. in cold (4°) 1% osmium tetroxide buffered with collidine. After removal from the osmium fixative, the tissues were dehydrated in a graded series of ethanol solutions, with final dehydration of the tissue in acetone. The material was then embedded in a resin[1] and sectioned on a Porter-Blum Servall MT 1 microtome fitted with a diamond knife. Sections were post-stained with 0.5% uranyl acetate and lead citrate, examined, and photographed on an RCA model 3G electron microscope. Negative prints were taken at ×8,330 magnification and developed to obtain ×21,000 photomicrographs. In the liver tissue, parenchymal, Kupffer, and endothelial lining cells, as well as bile ductules were observed for ultrastructural changes from normal condition represented by the control tissues. Comparisons were made of the size, configuration, spatial relationship, and relative numbers of all cell organelles, including mitochondria, rough and smooth endoplasmic reticulum, lysosomes, phagosomes, Golgi bodies, lipid droplets, or other storage particles. In addition, changes in nuclear size, shape, content, and nuclear and cytoplasmic membranes were also observed.

Data from all procedures were analyzed and compared to determine whether changes had been induced in rats or mice as the result of oral administration of the organotin.

RESULTS

Histopathological Determination by Light Microscopy

After about a 2 to 3-day lag period in the development of visible liver damage, both mice and rats began to exhibit progressive liver involvement that reached a peak of pathological change on the sixth and seventh days of the 24-hr. repeating dosage schedule (Fig. 1). In the rat the severity lessened after this critical point, whereas in the mouse the degree of histopathology continued to be manifest.

At the peak of hepatocellular response in the mouse on the seventh through ninth doses, loss of hepatic architecture was severe, often involving the histologic organization of the entire lobule. Cells showed a spectrum of responses including cloudy swelling, opacification, cytoplasmic granulation, some fatty degeneration and infiltration, hyaline change, rupture of cell wall, cellular debris, changes in nuclear size, nuclear dust, and chromatin condensation. Vascular channels lost their continuity, protein was precipitated, and necrosis was common. No repair processes were evident, and the injury to these liver cells was deemed irreversible.

In the rat all changes which were seen in mice were visible except those which might be considered irreversible and lethal to the hepatic cell. There was

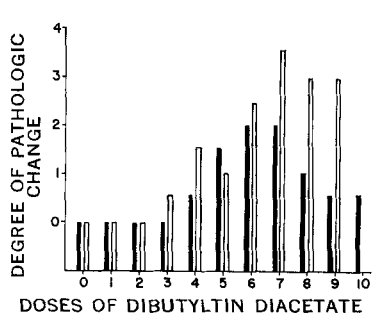

Fig. 1—Histopathological response to daily intubation with one-fourth LD_{50} concentration of dibutyltin diacetate in mice and rats. Degree of pathologic change was rated as: 0, normal; 1, minimal; 2, moderate; 3, moderately severe; 4, severe. Key: ■, rat; □, mouse.

minimal necrosis, rupture of cell walls, profound nuclear change, or vascular discontinuity even at the height of liver damage on the sixth and seventh day of dosing. In other words, the injury to the rat cells was not so extensive, and rats exhibited a terminal recovery pattern.

Ultrastructural Histopathology

Mitochondria—Normal mouse liver mitochondrial profiles (Fig. 2) exhibit a dense, nonvacuolated matrix with a few electron dense narrow lines representing the cristae, the structure bounded by a double membrane. Both mouse and rat hepatic parenchyma cells underwent vacuolar degeneration of the mitochondria as a direct consequence of poisoning with dibutyltin diacetate. These changes were visible 24 hr. after the first dose and were progressive in nature. Mice were more drastically affected than rats.

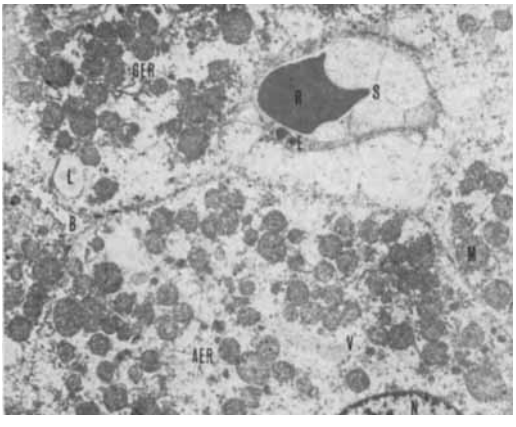

Fig. 2—Micrograph of control mouse hepatic cells showing normal parenchyma cell and organelle architecture. Key: AER, *agranular endoplasmic reticulum;* B, *bile canaliculus;* E, *endothelial lining cell;* GER, *granular endoplasmic reticulum;* L, *lysosome;* M, *mitochondria;* N, *nucleus;* R, *red blood cell;* S, *sinusoid;* V, *Golgi vesicle.*

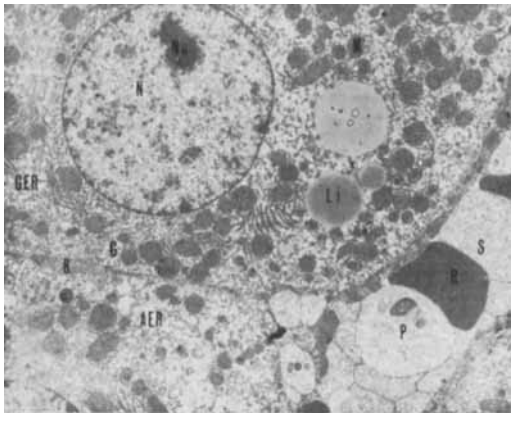

Fig. 3—Micrograph of mouse hepatic cells following the third successive dose of dibutyltin diacetate showing accumulation of lipid (Li), *condensation of chromatin in nucleolus* (Nu) *inside the nucleus, extrusion of phagolysosomes* (P) *into sinusoid* (S). *Several mitochondria* (M) *contain swollen cristae membranes. Lumen of bile canaliculi* (B) *is reduced and contains swollen microvilli. Also appearing unchanged are granular* (GER) *and agranular* (AER) *endoplasmic reticulum, a Golgi complex* (G), *red blood cell* (R), *and sinusoid* (S).

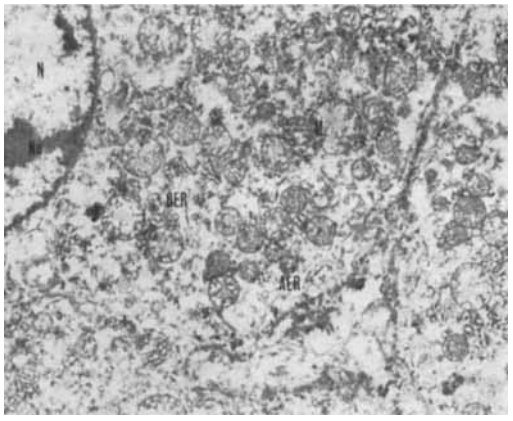

Fig. 4—Micrograph at higher magnification of mouse hepatic parenchyma cell following the sixth successive dose of dibutyltin diacetate showing hydropic degeneration and the formation of myelin figures in mitochondria (M), *swelling and vacuolization of granular* (GER), *and agranular* (AER) *endoplasmic reticulum.*

Initially, the cristae in a few mitochondria of both species became slightly distended (Fig. 3). After six successive doses, the mouse showed a pattern as illustrated in Fig. 4, in which the cristae were swollen and disrupted, the matrix of the mitochondria became less dense, and membranous whorls developed inside. It is obvious at this point that the mitochondrial damage was extensive and probably irreversible. With this degree of organelle injury, it is doubtful that a functional unit existed. Rat mitochondria did not degenerate to the extent described for mice, although they did develop numerous swollen cristae. A recovery pattern in rats was observed to take place beginning with dose seven. Here the cristae began to return to a more normal condition, although swelling of cristae, sometimes developing small vacuoles, could still be seen in some cells. Many cristae appeared normal, indicating a good recovery pattern or lack of original injury by the organotin.

Granular Endoplasmic Reticulum (GER)—In normal parenchyma cells, the double layered membranes of this organelle are often found in close proximity to mitochondria (Fig. 2). Their planar surfaces are covered with small electron dense particles called ribosomes. The cisternae between the membranes have a narrow, undulating appearance. Very little if any change in this pattern was seen after initial organotin dosing (Fig. 3). After repeated doses of organotin, both mice and rat GER showed a progressive swelling but with no noticeable loss of ribosomes. It can be seen in Fig. 4 that after six successive doses in mice, no normal GER can be found. Most cisternae have undergone gross swelling or enlargement and much GER appears to have dispersed as small vesicles, ribosomes intact, into the cytoplasm. Rats showed a similar pattern but to a lesser degree. Considerably greater amounts of GER either remained intact or were more rapidly regenerated in the rat cells (Fig. 5).

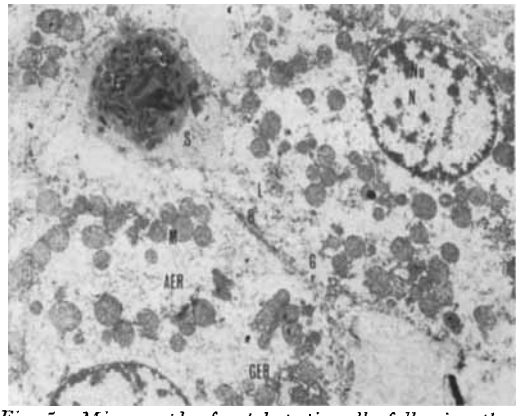

Fig. 5—Micrograph of rat hepatic cells following the tenth successive dose of dibutyltin diacetate in which organelles have been preserved or regenerated, in contrast to the condition found in the mouse at this dose interval. Agranular (AER) *and granular* (GER) *endoplasmic reticulum have near normal structure, bile canaliculus* (B) *remains obstructed, eosinophils* (Eo) *are present in sinusoid* (S), *Golgi* (G) *and lysosome* (L) *activity is present, mitochondria* (M) *appear normal except for a few vacuolated forms, chromatin in nucleolus* (Nu) *remains condensed.*

Agranular Endoplasmic Reticulum (AER)—In normal hepatic cells the AER were visualized as minute channels, often appearing in cross section as tiny vesicles (Fig. 2). These were most often irregularly dispersed in areas within the cell which were lacking in other structures, and having a somewhat transparent cytoplasmic matrix. The complexity of these structures greatly increased after the first three doses in both species, depicted in the mouse in Fig. 3. Further dosing led to irregular dispersion of these tubules, with some disruption into discrete vesicles appearing. Random invasion by cellular components of the areas formerly occupied only by the AER was evident (Fig. 4) creating a disorganized assemblage of vesicles from both AER and GER plus abnormal mitochondria and other vacuolar material. This pattern was seen in certain hepatic cells of both species, although much more prevalent in the mouse. Many of the rat cells appeared to regain or retain much of the original internal architecture (Fig. 5) and the AER was again found in normal amounts and sites inside the cells.

Bile Canaliculi—The normal condition of this structure in both rats and mice, as shown in Fig. 2, was an uncongested lumen into which projected a few small microvilli. Membranous whorls or myelin figures were commonly found unattached in the lumen, which was otherwise free of particles. In both study species, beginning with the second dose of organotin, these bile capillaries were rapidly closed (Fig. 3) so that after the third dose, no lumen was visible. The closing was attributed to two primary factors, one of these being the swelling of the parenchyma cell. The microvilli also appeared to have become swollen, further contributing to the congestion. No relief from this pattern was noted through the dose series in either mice or rats.

Lysosomes—Normal lysosomal activity involves discharge of contents from this aging organelle into the bile canaliculi as depicted in Fig. 2. After dosing with organotin, the bile capillaries became swollen and obstructed and lysosomes were seen to empty into the sinusoid instead, as shown in Fig. 3. As dosing frequency increased beyond the sixth in the series, an inhibitory effect was seen on parenchyma cell lysosomal activity, especially in mice. This lack of lysosomal activity was associated in both species with extreme disorganization and random dispersion of numerous vesicles and particles inside many cells (Fig. 4). In mouse cells, lysosomal activity was never reactivated to any appreciable extent. In rat cells, however, there was an apparent regeneration of lysosomal activity as shown in Fig. 5, even though the structures seen were much smaller and less numerous than in controls. Phagocytic activity, often associated with lysosome activity, was initially stimulated by dosing in mice but appeared to be inhibited in rats. This could have accounted in part for the damage seen in mouse cells as compared to rats.

Golgi Complex—The Golgi complex in normal cells is seen to arise from normal AER and is easily recognized by its structure (Fig. 2). Since the Golgi complex may be one of the sources for lysosomal production, it would be expected that damage to the AER would damage the Golgi and hence the lysosomal enzyme production. It was apparent that lysosomal activity showed a decrease at about the same time as the disappearance of the Golgi was noted. After the sixth dose of organotin in mice, the Golgi were not seen (Fig. 4) but are readily distinguishable in rat cells even after dose ten (Fig. 5).

Nucleus—The primary effect of organotin on the nucleus was a condensation of the nucleolus in both species to create a more dense often somewhat reticulated pattern shown in Fig. 3. This effect was noted after dose three and remained unchanged throughout the remainder of the series in mice and rats. Another effect was the accumulation of lipid and other small droplets in the nucleus seen during the later phases of dosing, primarily in mice.

Lipid Droplets—A noticeable increase in the number of lipid droplets began to be apparent from the first dose of organotin and were evident through the third dose (Fig. 3) in mice. These droplets were seen only rarely thereafter, indicating little or no fat accumulation in the cell or, alternatively, an increased mobilization from the cell, which was doubtful. In rats, small amounts of lipid were found after dose four and little or none at successive doses. This observation confirms the general observation that rat cells are still functioning.

Kupffer and Endothelial Lining Cells—Endothelial lining cells of both species showed increased thickness and granularity after dosing. Excessive swelling in some cells developed later, with sparse matrix containing small amounts of tiny vesicles. Kupffer cells increased in matrix density and showed greater numbers of dark staining granules in the cytoplasm.

DISCUSSION

The earliest noted ultrastructural change attributable to the dibutyltin diacetate dosing schedule was in the parenchymal cell mitochondria of both rats and mice. In this organelle, the cristae membranes responded initially by swelling and this became more

pronounced through time as doses of the organotin were repeated daily. This mitochondrial reaction was much more advanced in mice at any given dose than in the corresponding rat hepatic cells. As dosing continued in the mouse, the swollen cristae developed into the formation of large vacuoles and finally into a complete disorganization of the mitochondrial structures. At the latter stages of dosing, myelin figures were noted in grossly distorted mitochondria.

The observed fact that the mitochondria were the earlier organelles to be visually injured by the organotin appears to be in some disagreement with the views proposed by Rees (3). According to the scheme which he proposed, the granular endoplasmic reticulum is the first subcellular organelle to be injured by a liver poison. This injury to the GER would result in cellular permeability changes and ionic imbalance, resulting in a later mitochondrial injury.

Based on the over-all morphological changes in the mitochondria as observed in this study, one could propose that the first alteration of consequence would be the failure of the mitochondria to produce adequate ATP for the cell to maintain normal energy requiring functions. It is known that the cristae of the mitochondria are involved with electron transport enzymes and are more susceptible to swelling than the outer limiting membrane (16). Christie and Judah (17) concluded from their studies on vacuoles of mitochondrial origin obtained from poisoned hepatic cells that such poisons could induce hydropic changes to mitochondria and this in turn interferred with the tricarboxylic acid cycle at the citrate and maleate level, thus preventing final metabolism of pyruvate and acetate necessary for eventual ATP formation. The possible mechanism of interference with the tricarboxylic acid cycle has been proposed by Peters (18) and Williams (19) as interfering with the activity of α-keto acid oxidases. A molecule of the divalent toxic substance, in this case, dibutyltin diacetate, will combine with two SH groups in the enzyme, which is thereby inhibited. The enzymes inhibited by this mechanism would be pyruvic and α-keto glutaric dehydrogenases, enzymes which are essential for the formation of ATP *via* these cycles. Robinson (20) found that 2,4-dinitrophenol, which makes energy released by oxidation unavailable for ATP formation, causes tissues to take up water, implying that energy is normally expended by cells to prevent hydropic degeneration. Price *et al.* (21) found that isolated liver mitochondria maintained normal water content when incubated under conditions favorable to oxidative phosphorylation. Other investigators (22–24) have also found that failure of ATP synthesis appears to be a critical factor in determining whether cell degeneration will proceed to autolysis. Mouse liver mitochondria showed a progressive degeneration and this was reflected in areas of eventual liver necrosis in these animals, but was not as extensively shown in rats. However, as pointed out previously, the rat mitochondria were never injured to the same extent as the mouse tissue, thereby explaining the apparent partial cellular recovery in rats.

It can be postulated, then, that early mitochondrial injury in mouse and rat hepatic parenchyma cell poisoning is probably one of the underlying causes for toxic manifestations to other cellular organelles having a dependency on ATP for normal function.

Under the conditions of this study the granular or rough endoplasmic reticulum (GER) was the second cell organelle to manifest degenerative change. A progressive hydropic change with gross swelling and vacuolization of the cisternae of this structure is considered to be a contributing factor to the cloudy swelling as seen through the light microscope. Confirming studies by Molbert (25) and Oberling (26) also have shown that vacuolization of the endoplasmic reticulum and dilation of its cisternae were contributing factors to hydropic degeneration and cloudy swelling. It was apparent from the series of micrographs of normal cells that a very close spatial relationship existed in these cells between mitochondria and the GER. There is, no doubt, a direct functional dependency. The GER, for example, depends upon material elaborated by the mitochondria for membrane transport. In pathological cells, particularly those showing greatest degenerative change, the close relationship between these two organelles was lost. In the rat, the ability to maintain to a greater degree the integrity of both structures in certain areas of the cell was evident. It is probable that in such cases the GER maintains its membrane activity by ATP supply from mitochondria, and in the absence of this supply, cannot adjust to ionic and/or water imbalance. When the latter exists, swelling of the cisternae develops.

Porter and Bruni (27) postulate that the agranular or smooth endoplasmic reticulum (AER) portion of the vacuolar system is formed from the terminals of the GER and has a function in carbohydrate metabolism. In addition Essner and Novikoff (28) proposed that secretory and hydrolytic Golgi complexes were formed from the AER. Shnikta (29) indicated that microbodies may also arise from the AER, but in a different manner than do the secretory or hydrolytic bodies. As a result of the administration of the organotin compound, there was an obvious disruption of the AER as well as the GER, followed by a disappearance of the above-mentioned elaborated structures. If these structures are no longer elaborated by the AER, there would follow a cessation of various enzyme formation and activity, an accumulation of precursors and raw materials usually subject to metabolism by enzyme action.

Of particular importance, perhaps, was the loss of ysosomal action which maintains intracellular digestion and either recycles or extrudes from the cell the breakdown products. According to de Duve and Wattiaux (30), lysosomes are almost always involved in the response of the cell to challenging agents and by failing to perform their lytic actions adequately or performing them in injurious fashion may contribute to the cell pathology. Their malfunction may be due to uptake of inhibitors by a derangement of enzyme biosynthesis, or as Triederici and Pirani (31) suggest, by the production of abnormal proteins of low molecular weight which contribute to edema of the cell. It is not thought, however, that compressive or congestive lysosomal damage was a major factor in poisoning by dibutylin diacetate in rats, although in mice there was an obvious initial lysosomal or phagolysosome stimulation which declined with successive dosing.

One of the prime responses of the hepatic cells of both mice and rats was the rapid congestion of the bile capillaries upon dosing with the test compound.

This feature was not observed after the first dose, but some congestion was observed after the second dose, and almost complete reduction of the lumen of the canal was observed after the third repeated dose. This injury was of great significance to the welfare of the hepatic cells, since it obstructs a primary route of discharge of unwanted waste products, causing them to pile up inside the cell or, when possible, to be discharged into the sinusoid or extracellular spaces. In rats, lysosomal enzymes are all present in the bile, according to de Duve and Wattiaux (30), at a concentration indicating a daily unloading of about 5% of the total hepatic lysosomes. Confer and Stenger (32) and Bruni and Porter (33) suggest that the peribiliary location of many liver lysosomes and the presence of amembranous dense bodies and myelin figures in the lumen of bile capillaries suggest elimination by exocytosis into this structure. This suggests that the bile may be the major pathway for unloading lysosomes or their contents by hepatic parenchyma cells. The release of lysosomal enzymes into body fluids or into extracellular fluids has been observed by several researchers (34–37) to be associated with pathological phenomena. This congestion then left the parenchyma cell without a normal route of elimination of these cellular waste products, possibly resulting in an intracellular accumulation and subsequent necrosis.

SUMMARY AND CONCLUSIONS

Dibutyltin diacetate was administered daily in one-fourth LD_{50} doses for a period of 10 days. Ultrastructural damage to liver parenchyma cells after each 24 hr. of dosing was evaluated by the electron microscope and by the light microscope. Chronologically, the order of injury to the subcellular organelles and structures were as follows.

1. Mitochondrial damage with early cristae swelling followed by vacuolization and hydropic swelling.

2. Swelling and vacuolization of the granular endoplasmic reticulum.

3. Progressive congestion of the bile canaliculi due to cellular and microvilli swelling.

4. Formation of a dense population of small vacuoles resulting from the disruption of the rough and smooth endoplasmic reticulum.

It is felt then that the initial and progressive mitochondrial lesions interfered with normal biochemical and synthetic activity through a reduction and/or blockage of ATP production by dithiol inhibition. As a consequence, other cell functions involving active transport across membranes as well as certain synthetic and metabolic functions were inhibited. The net result of these inhibitory processes was cell necrosis in both mice and rats, although moderated in the latter. The ability of the rat hepatic cells to maintain better internal organization throughout the dosage schedule seemed to be related in part to an early cessation of phagocytosis or phagolysosomal activity, thus preventing intake of lethal (cellular) doses of the organotin by these routes.

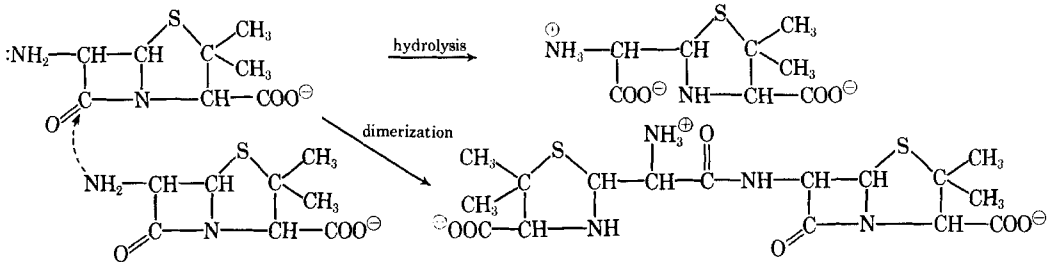
Degradation Kinetics of 6-Aminopenicillanic Acid

By DAVID W. DENNEN

The degradation of 6-aminopenicillanic acid (6APA), as measured by the loss of the β-lactam ring, followed pseudo first-order kinetics with initial concentrations of 0.05–0.92 *M* and in the pH and temperature range of 5.8–6.6 and 35–90°, respectively. Higher orders of degradation rates were approached with increasing pH while the maximum stability of the molecule at all temperatures examined was at approximately pH 8.0. Polymeric materials, measured by ultraviolet absorbance, were formed under all conditions examined.

THE FINDING that solutions of 6APA yielded increasing antibiotic activity to *Staphylococcus aureus* with time was observed in these laboratories (1), and it was suggested that a 6APA dimer was being formed in solution, presumably through nucleophilic attack of the amino group of one molecule to the β-lactam of another to form a penicillin (2). (Scheme I.)



Scheme I

Confirmatory studies remained unpublished when this mechanism was postulated by Grant *et al.*, who isolated a number of antimicrobially inactive polyamides with 7–8 residues from concentrated solutions of 6APA (3). In addition, a material termed factor 1 has subsequently been obtained with antimicrobial activity against *Bacillus subtilis* from 6APA preparations (4). The factor was apparently not an impurity carried with 6APA during purification and appeared to be an antimicrobial condensation product of this molecule containing at least one intact β-lactam ring.

Studies concerned with isolation and subsequent acylation of 6APA for the synthesis of semisynthetic penicillins required an examination of the stability of this molecule. This paper describes the stability of 6APA in terms of its rate of degradation as a function of temperature and pH.

Received May 24, 1967, from the Antibiotic Development Department, Eli Lilly and Co., Indianapolis, IN 46206
Accepted for publication July 5, 1967.

EXPERIMENTAL

Preparation of 6APA—Penicillin nucleus was prepared by the cleavage of the side chain of phenoxymethylpenicillin by amidase (5). The 6APA was then precipitated quickly as the zwitterion at pH 4.7. Repeated solution in base and titration with acid to the isoelectric point produced the product which crystallized as hexagonal plates. The percentage composition of the product was measured as theoretical, m.p. 208–210°, and the pK's 5.5, 4.05 in DMF.

Preparation of Penicic Acid (Open Lactam 6APA)—Penicillinase A (Riker Laboratories) at a concentration of 200,000 units in 5 ml. was suspended within a dialysis tubing in a solution of 6APA (1 mg./ml.) for 24 hr. at 25°. After the 6APA solution gave a negative hydroxamate test, the material was lyophilized. The percentage composition of penicic acid was measured as theoretical and the molecule had pK's 4.7 and 7.8 in water. In 66% acetonitrile, the compound had an R_f of 0.54 and formed a blue color with ninhydrin.

Measurement of β-Lactam Content—Measurement of β-lactam content was performed according to the procedure of Ford (6) by reacting intact β-lactam with neutral hydroxylamine to give the hydroxamate, followed by color development with ferric chloride.

Preparation of 6APA Dimer—6APA solutions (20%) were allowed to stand at room temperature for 1 week, after which they were passed through a G-10 Sephadex column as described in Fig. 6. Hydroxamate positive material eluting between 22–27 ml. was collected and lyophilized. Infrared measurements (Beckman IR-7) revealed the appearance of mono-substituted amide at 6.0 and 6.6 μ and the loss of β-lactam at 5.6–5.7 μ. Titration of the material gave a molecular weight of 430. The

bulk of the sample moved 5.85 cm. toward the anode during paper strip electrophoresis (pyridine–acetate buffer; pH 4.3, 17 v./cm., 4 hr., 25°) and coincided with the value reported elsewhere for antimicrobially active material derived from 6APA (4). Degradation of the sample at pH 5.8, 75°, yielded an ultraviolet absorbing chromophore with a maximum at 304 mμ.

Degradation of 6APA—6APA was weighed and diluted to volume with preheated buffer of the desired pH. The buffers used were acetate, phosphate, and tris(hydroxymethyl)aminomethane in their respective ranges. The concentration of buffer was systematically twice the molar concentration of the initial concentration (C_0) of 6APA used. The constancy of pH was checked periodically throughout the time studies. No attempt was made otherwise to control the ionic strength to constancy. The buffered 6APA solution was then incubated at constant temperature under nitrogen in order to eliminate access of CO_2 and the possible formation of 8-hydroxypenillic acid (7). Aliquots were taken periodically for various assays described above. Cooling or diluting the aliquots were shown substantially to stop the reaction.

RESULTS

The loss of β-lactam content in 6APA solutions (0.05–0.92 *M*) followed first-order kinetics in the pH range 5.8–6.6 and shifted to second-order rates at pH 7.5–8.0 and above. In Fig. 1, the degradation of β-lactam is plotted in a fashion that designates a second-order reaction as a linear curve, while those data deviating from linearity obey the first-order rate law. Since below pH 7.5, the degradation of 6APA could be described by first-order kinetics at an initial concentration of 0.184 *M*, suggesting simple β-lactam hydrolysis, it was desirable to see if increased initial concentrations of 6APA would lead to second-order rates concomitant with bimolecular polymerization. However, as illustrated in Fig. 2, the first-order rate law was obeyed in increasing initial 6APA concentrations to 0.92 *M*.

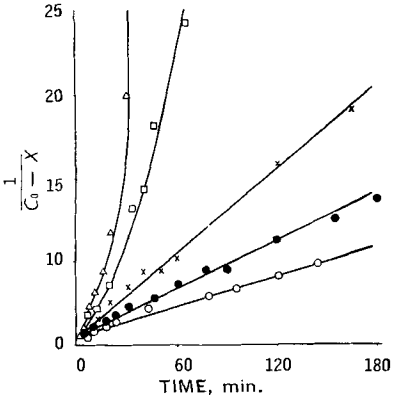

Fig. 1—Rate of β-lactam disappearance at constant initial concentration of 6APA, as a function of pH. First-order curves: pH 5.80 (△), pH 6.60 (□), second-order curves: pH 8.50 (×), pH 8.0 (●), and pH 7.50 (○). $C_0 - x$ is the amount of intact β-lactam 6APA. Initial concentrations of 6APA were 0.184 M and the degradation was measured at 90°.

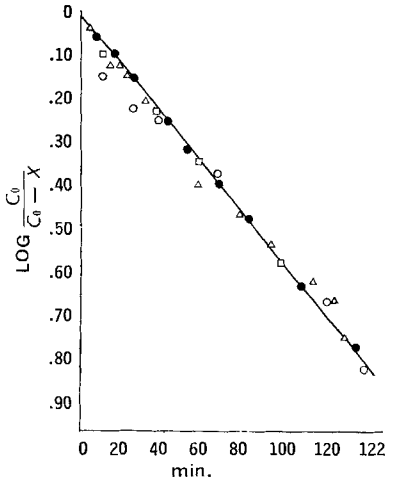

Fig. 2—Rate of β-lactam disappearance with increasing initial concentrations of 6APA. 6APA solutions incubated at pH 6.30, 80°. Initial concentrations: 0.13 M (○), 0.365 M (□), 0.42 M (●), 0.92 M (△). C_0 is the initial concentration of 6APA, and $C_0 - x$ is the amount of intact β-lactam.

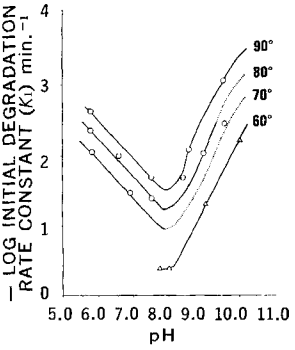

Fig. 3—Initial rate of β-lactam loss in 6APA solutions. Initial rate constants determined in 6-APA solutions by the rate of hydroxamate disappearance (○) and by titration in a pH-stat (△).

An examination of 6APA degradation at various pH's and temperatures revealed maximum stability of this molecule at approximately pH 8.0, well above the pKa (5.5) of its free amino group. In Fig. 3, the stability of 6APA β-lactam is depicted in relation to the initial rates of degradation. The data presented were obtained by two methods: disappearance of the 6APA reactivity to hydroxamate, and electrometric titration of the proton liberated by the opened β-lactam. It is important to note that in the degradation reaction below pH 8.0, the free amino group shifts from pKa 5.5 to that characteristic of an α-amino group and no base is consumed in the pH-stat titration.

The initial rates of degradation of β-lactam at an initial concentration of 0.184 *M* are plotted according to the method of Arrhenius in Fig. 4 as a function of temperature. The activation energy (E_a) for the degradation was calculated to be 17 Kcal./mole, comparing with the inactivation of phenethicillin (8), for example, at 17.6 Kcal./mole and benzylpenicillin (9) at 20 Kcal./mole. The activation energy associated with these latter penicillins can be essentially attributed to the formation of penicilloates (10) (β-lactam hydrolysis) at those pH's examined. The energy associated with 6APA

degradation, however, must take into account that activation energy pre-empting any polymerization that occurred simultaneously with β-lactam hydrolysis. Since second-order kinetics were visualized only in alkaline solutions, the distinct possibility was presented that penicic acid, formed initially from 6APA, could in turn prime the polymerization of 6APA. Below pH 7.5 it could not participate as a nucleophile, and 6APA would degrade simply through β-lactam hydrolysis as observed kinetically. The consequence of such a polymerization mechanism, however, would preclude the retention of an intact β-lactam in the dimer or polymer formed to account for the observed increase in antimicrobial activity.

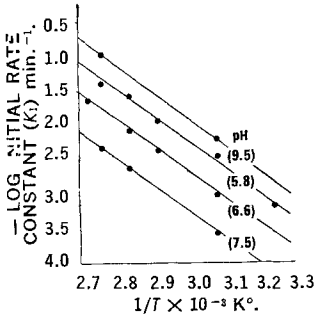

Fig. 4—Effect of temperature on the initial rate loss of β-lactam as a function of pH. Rate constants determined with 0.184 M solutions of 6-APA.

Since solutions of 6APA are not routinely allowed to remain at pH's much above neutrality, it was of importance to examine the character of the degradation product at pH's below 7.0 rather than in alkaline solution in order to determine whether polymerization was occurring at a rate proportional to the first rather than second order of the remaining 6APA concentration.

To measure polymerization, advantage was taken of an ultraviolet absorbing material that appeared during the progress of 6APA degradation. The ultraviolet spectra of this material shown in Fig. 5, had a maxima at 304 mμ while penicic acid, when similarly degraded from nearly the same initial concentration, had very little absorbance at this wavelength.

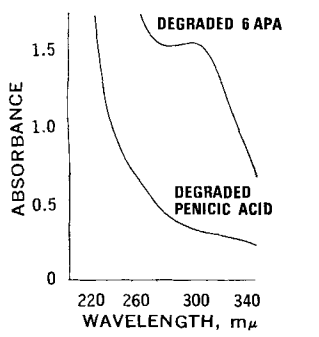

Fig. 5—Ultra violet spectra of degraded 6APA and penicic acid. Initial 6APA concentration, 2.5%; initial penicic acid concentration, 2.0%. Degradation for 2.5 hr., 75°. Degradation mixtures diluted 1:-12.5 for assay.

A degradation mixture of 6APA containing this chromophoric material was passed through a G-10 Sephadex column, and as shown in Fig. 6, it is clear that this material represented a molecular size greater than 6APA. Species were present in the effluent which coincided in position to phenoxymethylpenicillin and benzylpenicillin while the leading edge of the effluent yielded materials of greater molecular size than the penicillins. Any condensation that could occur with 6APA or penicic acid to form diketopiperazines did not seem to involve an increase in the absorbance at 304 mμ. The 304 mμ chromophore thus appeared to represent subsequent rearrangement of 6APA to penaldehyde and/or azlactone-type compounds following the acylation of one molecule by another.

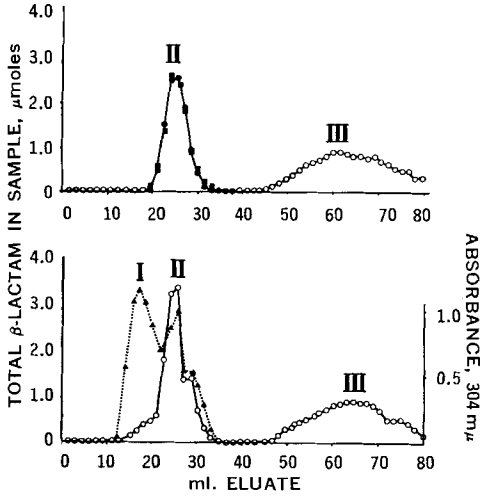

Fig. 6—Separation of penicillins, 6APA, and 6APA degradation mixture by gel-filtration. Top: 14.9 μmoles penicillin and 11.50 μmoles 6APA applied to column, phenoxymethylpenicillin (■), benzylpenicillin (●), 6APA (○). Recovery of total β-lactam, 88%. Bottom: the starting material was 6APA which was degraded and then applied to the column. Intact β-lactam of 6APA and polymeric material (○), 304 mμ absorbing material (▲). Sephadex G-10 column 1 × 39 cm. with 39 cm. head of buffer for elution. Peaks I, II, and III represent polymeric material, penicillin, or 6APA dimer and 6APA, respectively.

In Fig. 7, the formation of the 304 mμ absorbing material is shown in degradation mixtures of 6APA at an initial concentration of 0.184 *M* as a function of temperature at pH 6.30. It is apparent that a constant amount of polymeric material, represented by ultraviolet absorbance, was formed at this initial concentration. The addition of varying amounts of penicic acid to 6APA failed to increase the 304 mμ absorbance yield, and thus it appeared that the former was not necessary to prime the polymerization. It is also interesting to note that the total polymeric material produced from increasing initial concentrations of 6APA did not increase as the square of the concentration, but rather was directly proportional to the initial concentration of 6APA as shown in Fig. 8. Furthermore, the formation of polymeric materials adjudged from the 304 mμ absorbance in 6APA degradation reactions at pH 6.3 was confirmed at pH 5.8 and 6.0 as well, indicating that polymerization occurred as a parallel reaction to 6APA hydrolysis.

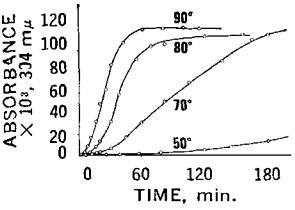

Fig. 7—Formation of 304 mμ absorbing material from degraded 6APA solutions. Initial 6APA concentration, 0.184 M, pH 6.30.

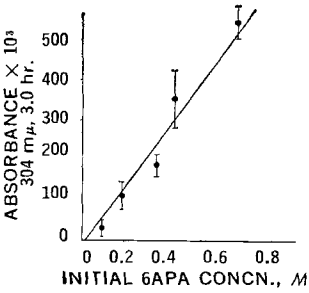

Fig. 8—Maximum level of 304 mμ absorbance as a function of the initial 6APA concentration. 6-APA degraded at pH 6.30, 80°.

DISCUSSION

The rates of β-lactam hydrolysis and dimerization of 6APA are both proportional to the first order of the intact β-lactam content in solutions below pH 7.5. This is not a surprising result since no direct measure of 6APA monomeric concentration is obtained by the assay of intact β-lactam in a system undergoing hydrolysis and polymerization. The dimerization or further polymerization of 6APA involving a β-lactam acylation by another 6APA molecule always leaves one β-lactam intact per two molecules of 6APA. The rate of dimerization would thus be proportional to the square of the 6APA concentration, whereas it would be directly proportional to the first-order loss of β-lactam.

Since the activation energy (E_a) for the hydrolysis of other penicillins is similar to that measured in the degradation of 6APA, it is reasonable to conclude that both β-lactam hydrolysis and intermolecular acylation occur with equal ease. This is one suggested explanation for the proportionately direct increase in the amount of polymer formed as a function of the initial 6APA concentration. Otherwise, one might expect that the rate of dimerization, which is proportional to the square of the initial concentration of 6APA, would be reflected by a proportionate increase in the polymer yield.

In alkaline solution, second-order kinetics of β-lactam loss are apparent from the data, and in these instances the β-lactam content can be visualized to closely approach the actual remaining concentration of 6APA. The increased lability of an acylated β-lactam over that of 6APA affects the apparent loss of two β-lactams per dimer rather than one.

Cytotoxicity of Rubber Closures in Tissue Culture Systems

By P. J. VASINGTON, H. D. PIERSMA, J. J. CORBETT, and J. L. BITTLE

Rubber closures used in the pharmaceutical industry were tested for cytotoxicity in primary cultures of chick embryo cells and in cultures of cells passaged from human malignant tissue. Assay was by three methods: direct contact, growth-extract, and maintenance-extract. In the first, rubber samples were placed in direct contact with cell monolayers. In the growth-extract system, a sample was incubated in growth medium, and the resultant extract was placed in a cell suspension. In the maintenance-extract method, following incubation of a sample in maintenance medium, the extract was overlayed on a cell monolayer. Tissue culture provided a more sensitive test of toxicity in comparison with the generally accepted implantation of rubber in the paravertebral muscles of rabbits.

TESTING THE toxicity of rubber closures for pharmaceutical applications has been primarily physicochemical. To date, there is no acceptable biological assay system, although the rabbit implantation method of Brewer and Bryant (1) for screening plastics has gained considerable favor.

The need for a rapid, economical, and reproducible *in vitro* test has led to the investigation of

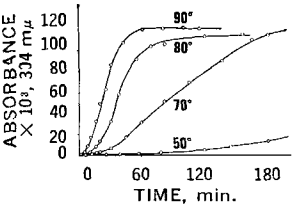

Fig. 7—Formation of 304 mμ absorbing material from degraded 6APA solutions. Initial 6APA concentration, 0.184 M, pH 6.30.

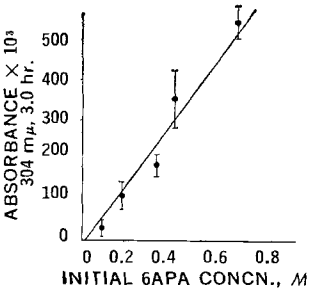

Fig. 8—Maximum level of 304 mμ absorbance as a function of the initial 6APA concentration. 6-APA degraded at pH 6.30, 80°.

DISCUSSION

The rates of β-lactam hydrolysis and dimerization of 6APA are both proportional to the first order of the intact β-lactam content in solutions below pH 7.5. This is not a surprising result since no direct measure of 6APA monomeric concentration is obtained by the assay of intact β-lactam in a system undergoing hydrolysis and polymerization. The dimerization or further polymerization of 6APA involving a β-lactam acylation by another 6APA molecule always leaves one β-lactam intact per two molecules of 6APA. The rate of dimerization would thus be proportional to the square of the 6APA concentration, whereas it would be directly proportional to the first-order loss of β-lactam.

Since the activation energy (E_a) for the hydrolysis of other penicillins is similar to that measured in the degradation of 6APA, it is reasonable to conclude that both β-lactam hydrolysis and intermolecular acylation occur with equal ease. This is one suggested explanation for the proportionately direct increase in the amount of polymer formed as a function of the initial 6APA concentration. Otherwise, one might expect that the rate of dimerization, which is proportional to the square of the initial concentration of 6APA, would be reflected by a proportionate increase in the polymer yield.

In alkaline solution, second-order kinetics of β-lactam loss are apparent from the data, and in these instances the β-lactam content can be visualized to closely approach the actual remaining concentration of 6APA. The increased lability of an acylated β-lactam over that of 6APA affects the apparent loss of two β-lactams per dimer rather than one.

the use of tissue culture systems. The cytotoxicity of some rubber closures used to stopper cell culture tubes and bottles of synthetic medium became quite obvious to early investigators. Parker *et al.* (2) found a number of rubber closures to be toxic to cell cultures. Cruickshank *et al.* (3) employed tissue explants of chick embryo and guinea pig skin to test the toxicity of rubbers and plastics used in transfusion-giving sets. They concluded that tissue culture explants might prove valuable as a screening method to select suitable materials for clinical trials. The method involved peripheral fibroblastic outgrowths away from the area of toxic samples.

Rosenbluth *et al.* (4) reported the similar use of fibroblastic-like "L" cells for testing the toxicity of plastic materials employed in medical practice. They compared their results with those obtained in rabbit implantation and found the cell culture system to be more sensitive. They placed a sample in direct contact with the cell monolayer. Zones of degeneration developed when samples were toxic.

This report compares the use of primary and continuous cell cultures for evaluating the toxicity of rubber closures using three methods of assay in tissue culture. These are defined as: (*a*) direct contact with the cell monolayer, (*b*) maintenance medium-extract overlay on the cell monolayer, and (*c*) growth medium-extract in a cell suspension. The rubber closures tested were received in the laboratory for routine use. They were composed of natural rubber or synthetic butyl rubber and ranged in size from 13 mm. to 30 mm. in diameter.

EXPERIMENTAL

Direct Contact Method—Primary cell monolayers were prepared as follows. Nine-day-old chicken embryos were decapitated, minced, washed with phosphate buffered saline (PBS, pH 7.4), and the cells dissociated with 0.25% trypsin. Approximately 2×10^6 cells were inoculated into 60-mm. tissue culture plates[1] containing 5 ml. of Eagle's basal medium (BME) supplemented with 10% bovine serum. The plates were incubated at 37° in a humidified CO_2 incubator which maintained a pH of 7.0–7.4. When the cell monolayer was confluent, usually 2–3 days, the medium was evacuated and a rubber sample placed carefully at the center of the monolayer. Growth medium (BME + 10% fetal bovine serum) was added and the plate incubated as above. The rubber samples were tested as received unless the geometry of the closure necessitated cutting them. They were washed in pyrogen-free distilled water prior to testing. Samples were cut to approximately 5 mm.[3] and the cut surface exposed to the cell monolayer. Plates were observed daily for 3 days for evidence of cellular degeneration. When the sample was toxic, macroscopic observation revealed clear zones surrounding the sample, because of degradation of the cell monolayer (Figs. 1 and 2). Microscopic observation was made with a low power objective (10×). A sample was considered to be toxic when cells appeared granular, rounded, and detached from the surface of the culture plate.

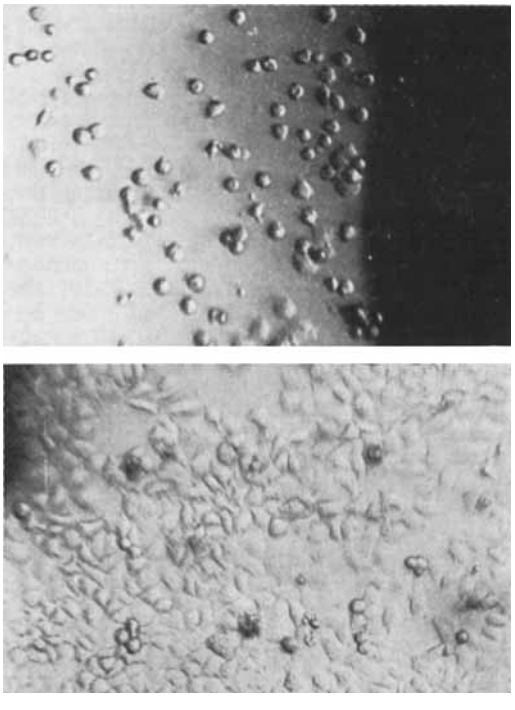

Fig. 2—Microscopic view of areas adjacent to rubber sample shown in Fig. 1. Key: top, toxic sample (shadow) showing degenerative cells; bottom, nontoxic sample (shadow) showing a healthy confluent epithelial cell monolayer. Cells are HEp-2 cultures. 100× magnification.

[1] Falcon Plastics, B-D Laboratories.

Human epidermoid carcinoma cell cultures (HEp-2), originally derived from a carcinoma of the larynx by Toolan (5) in 1955, were grown in 60 cm.^{2} milk dilution bottles (MDB). The cells had undergone an unknown number of passages before receipt. The cells were grown as monolayers by transferring them twice weekly using 0.25% trypsin in phosphate buffered saline (PBS, pH 7.4) to detach the cells from the glass. This was accomplished by removing the maintenance medium from MDB and adding 20 ml. of the trypsin solution to bathe the cell sheet. Following incubation at room temperature for 1 min., the trypsin was removed and the cultures incubated at 37° for 15 min. Sufficient growth medium (BME plus 10% fetal bovine serum) was added to give a cell suspension which was subdivided into MDB or 25 cm.^{2} Falcon plastic flasks at a split ratio of 1 to 6. The concentration of fetal bovine serum was dropped to 2% for maintenance. When the cell sheet became confluent, the tests were performed in the same manner as described for primary cultures except as noted.

Maintenance-Extract Method—Primary and continuous cell cultures were prepared as described above. When the cell monolayer was confluent, the growth medium was removed and replaced with a maintenance medium to which a sample extract had been added. The extract was prepared by suspending a rubber sample, as received, into 2 ml. of maintenance medium and incubating the suspension at room temperature for 24 hr. The medium was aseptically drawn off and added to sufficient maintenance medium diluent to give a final extract concentration of 25%. The cell cultures were incubated at 37° and examined daily for 3 days under low power magnification (10×). Cellular granulation, rounding, and detachment from the surface of the container were indicative of a toxic response.

Growth Medium-Extract Method—The sample extract was prepared as described above except that growth medium was used in place of maintenance medium. Cell suspensions of chick embryo and HEp-2 cultures were prepared by detaching the cells from MDB or plastic flasks with 0.25% trypsin as previously described. The cells were suspended in the growth medium-extract mixture to give a planting concentration of 1.6×10^5 cells per ml. for chick embryos and 75×10^3 cells per ml. for HEp-2 cultures. The resulting cell suspensions were inoculated into plastic plates, incubated at 37°, and observed daily for 3 days. Absence of cell growth and attachment indicated a toxic response.

Rabbit Implantation—Intramuscular implantation of rubber samples was performed and evaluated by the method described in the USP XVII or in the NF XII for plastics.

Samples used for rabbit implantation were prepared by cutting strips from the top of the rubber closure with a razor blade to a size approximating $1 \times 1 \times 10$ mm. This method resulted in smooth cut surfaces on all sides of the sample.

RESULTS AND DISCUSSION

A comparison between HEp-2 and primary chicken cell cultures was made using the direct contact method to determine the effect of subcultivation on the sensitivity of the cell cultures to toxic samples. Differences were noted by measuring the approximate diameter of the zones of degeneration surrounding the samples as shown in Figs. 1 and 2. Variation in cell sensitivity occurred in both types of cell culture. However, it was interesting to note (Figs. 3 and 4) that the degree of sensitivity of the sample and positive control varied in the same direction with HEp-2 cells as the substrate, whereas there was random variation in primary cell cultures. This may be attributed to the uniformity of epithelial-like cell populations from continuous culture, even though sensitivity changes with different passage levels. In contrast, primary cell cultures are generally disorganized and contain cells of many types. The degree of cytotoxicity in primary cultures may be dependent on the differing distribution and concentration of cell types with each culture preparation.

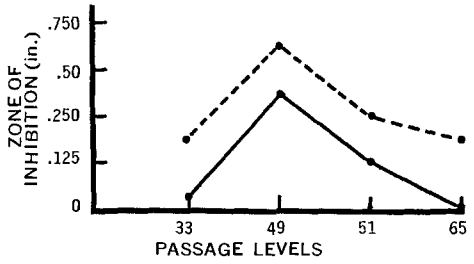

Fig. 3—Effect of passage levels of continuous (HEp-2) cell cultures on rubber closures. Key: - - - -, positive control; ——, sample 2342-2.

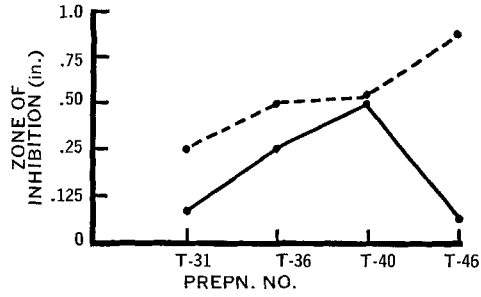

Fig. 4—Effect of different preparations of primary chick embryo (ChE) cell cultures on rubber closures. Key: - - - -, positive control; ——, sample 2342-2.

This study suggested that HEp-2 cells provided more reproducible results than did primary chicken cell cultures, although primary cells appeared more sensitive than HEp-2 cells as judged by the generally larger zones of degeneration.

Table I summarizes the results of an experiment designed to compare the three tissue culture assay systems in the more sensitive primary chicken cells. Sample 7 was completely nontoxic in all three systems, and sample 5 was toxic, and only slightly, by the direct contact method. The growth-extract system was the least sensitive, with little inhibition of cell proliferation by samples that were toxic in the direct contact and maintenance-extract tests. It may be significant that in the last two methods samples are introduced into established cell monolayers. Since the degree of sensitivity

between the direct contact and maintenance-extract methods did not vary markedly, the former was chosen because of its simplicity for a comparison of toxicity determinations in tissue culture and by rabbit implantation.

TABLE I—COMPARISON OF THREE TISSUE CULTURE METHODS IN EVALUATING TOXICITY OF RUBBER SAMPLES

Sample	Contact (Zone in.)	Extract: Growth (Confluency %)	Extract: Maintenance (Confluency %)
1	.25	95	10
2	.25	80	10
3	.125	80	25
4	.25	70	40
5	.0625	100	100
6	.25	95	75
7	Nontoxic	100	100
8	.50	95	10
9	.50	90	5
10	.25	90	40
Normal control	...	100	100
Neg. control	Nontoxic	100	100
Pos. control	.25	10	25

Table II shows results of implants in rabbits and direct contact in both HEp-2 and chick embryo cell cultures. The findings in the two types of cell cultures correlate well, although the primary cells were significantly more sensitive. The first five samples varied in toxicity between the two preparations, while samples *6*, *7*, and *8* were unquestionably toxic in both. The tissue culture system compared favorably with intramuscular implantation and appeared to be more sensitive, since *2A* and *4*, negative by implantation, were positive in both culture systems. It is also interesting to note that the nonchlorinated segment of sample *2* (*2A*) and the chlorinated (*2B*) were both toxic for tissue culture, but only the chlorinated sample was positive in rabbits.

TABLE II—COMPARISON OF RABBIT IMPLANT AND TISSUE CULTURE TESTING OF RUBBER CLOSURES

Sample	Rabbit Implant	Direct Contact: HEp-2	Direct Contact: ChE
1	+	3/3[a](1-ST)[b]	3/3
2A	−	3/3(1-ST)	4/4(1-ST)
2B (chlorinated)	+	3/3(1-ST)	3/3
3	Questionable	1/3(ST)	3/3
4	−	3/4(ST)	4/4(1-ST)
5	+	4/4(3-ST)	4/4(1-ST)
6	+	4/4	4/4
7	+	4/4	3/3
8	+	3/3	3/3
9	Questionable	0/1	0/1
Neg. control	− (Sometimes reactive)	0/7	0/4
Pos. control	+	5/5	4/4

[a] Denotes number of times the sample was toxic over the number of tests performed. [b] Slightly toxic.

Another study was designed to determine the effect of autoclave sterilization on rubber closures. Eight samples shown to be toxic by the direct contact method were compared in the growth-extract system. The results (Table III) showed two samples, *N* and *O*, to be negative when autoclaved and allowed to stand 1 hr. prior to assay. There was good correlation between the direct contact method and the growth-extract method for samples which were not autoclaved, except for sample *K*.

TABLE III—EFFECT OF AUTOCLAVE STERILIZATION ON CYTOTOXICITY IN HEp-2 CELL CULTURES

Sample	Direct Contact	Autoclave Sterilized Growth-Extract	Growth-Extract
H	Very toxic	No cell attachment	No cell attachment
I	Nontoxic	75% confluent	65% confluent
J	Very toxic	No cell attachment	No cell attachment
K	Sl. toxic	30–35% confluency	40% confluent
L	Nontoxic	75% confluent	65% confluent
M	Sl. toxic	60% confluent	70% confluent
N	Toxic	75% confluent	30–35% confluency
O	Sl. toxic	75% confluent	55% confluent
Neg. control	Nontoxic	75% confluent	75% confluent

The results of this investigation suggest that tissue culture may be useful as a biological assay to screen rubber closures prior to use in the manufacture of parenteral drug products. The two methods of assay involving established cell monolayers were in general agreement with each other but not with the growth-extract method. The direct contact method appears to be the most useful because of the ease of performance and evaluation. Although it would be difficult to equate cytotoxicity with reactions in man, such a screening mechanism could reasonably be assumed to reduce the risk of potential danger in man.

Pilot studies on a number of plastics using the same methods described for rubber closures compare favorably with the results of Rosenbluth *et al.* cited earlier in this report (4).

Methods for the Qualitative and Quantitative Analysis of Some Hydroxystilbenes

By JOSEPH E. SINSHEIMER and ROBERT VICTOR SMITH*

Paper, thin-layer, and gas chromatographic systems for the separation of 2-hydroxy-, 4-hydroxy-, 4,4′-dihydroxy-, and 4-hydroxy-3-methoxystilbene have been developed. Quantitative analysis of 4-hydroxy- and 4,4′-dihydroxystilbene *via* spectrofluorimetry on thin-layer plates is described along with an assay of these compounds as their trimethylsilyl ethers using vapor phase chromatography (VPC) with flame ionization detection. The use of electron capture detection in the quantitative VPC analysis of three derivatives of 4-hydroxy- and 4,4′-dihydroxystilbene has been investigated. A colorimetric assay, based on the reduction of blue tetrazolium, has been devised for 4,4′-dihydroxystilbene.

INVESTIGATIONS in these laboratories of the metabolism of certain stilbenes require assay procedures for 2-hydroxy-, 4-hydroxy-, 4,4′-dihydroxy-, and 4-hydroxy-3-methoxystilbene. Qualitative and quantitative literature analyses of these compounds are lacking and thus the purpose of this investigation was to devise such methods.

Paper chromatography of hydroxystilbenes indigenous to plants is well described in the literature (1) and served as a reference point for the development of paper and thin-layer systems in the present investigation. The recent commercial availability of fluorescent thin-layer scanners made a study of the quantitative evaluation of fluorescent hydroxystilbenes directly from thin-layer plates of interest.

Langer *et al.* (2) have successfully gas chromatographed simple monobenzenoid phenols as their trimethylsilyl (TMS) ethers. Formation of these derivatives from hexamethyldisilazane (HMDS) and trimethylchlorosilane (TMCS) in pyridine has been reported to take place rapidly and nearly quantitatively at room temperature (3). An application of these techniques to the hydroxystilbenes was proposed. Of further interest was an evaluation of the sensitivity and utility of electron capture detection of these compounds for quantitative analysis. Chloromethyldimethylsilyl (CMDMS) ethers (4), with their added aliphatic chlorine, were expected to be of particular usefulness in the electron capture procedure.

The reduction of blue tetrazolium by compounds embodying the hydroquinone or quinone nucleus has been shown to be analytically useful (5). However, the analysis of hydroquinone vinylogs by this reaction has not been reported. Since 4,4′-dihydroxystilbene represents a hydroquinone vinylog, its reactivity with blue tetrazolium was also of interest.

EXPERIMENTAL

Reference Compounds

Commercially obtained *trans*-stilbene (Eastman Chemicals), 4-hydroxy-, and 4,4′-dihydroxystilbene (K & K Laboratories) were recrystallized prior to use. 2-Hydroxystilbene was prepared according to Singh, Chand, and Chojer (6), m.p. 143–145°.[1] [Lit. 147° (7).]

4-Hydroxy-3-methoxystilbene—A modified procedure of Dey and Row (8) was used for the preparation of this compound. A mixture of 1.52 Gm. of 4-hydroxy-3-methoxybenzaldehyde, 1.36 Gm. of phenylacetic acid, and 0.5 ml. of piperidine was refluxed for 4 hr., then poured over ice. The precipitate formed was recrystallized from ethanol–water to give 1.45 Gm. of a brown solid which was chromatographed over silica gel (75 Gm., 100 mesh) (Mallinckrodt) with benzene–methanol (96:4) to give 773 mg. of a pink crystalline solid. This solid was recrystallized from cyclohexane to give 707 mg. (31.2%) of white leaflets, m.p. 132.5–133.5°. [Lit. m.p. 134° (8).]

4-Acetoxystilbene—A mixture of 1.96 Gm. of 4-hydroxystilbene, 7 ml. of acetic anhydride, and 27 mg. of *p*-toluenesulfonic acid was refluxed for 2 hr., then poured over ice. Recovery of this precipitate by ether extraction and recrystallization from ethanol–water gave 1.91 Gm. (80.2%) of white needles, m.p. 151–152°. [Lit. m.p. 152° (9).]

4,4′-Diacetoxystilbene—A mixture of 531 mg. of 4,4′-dihydroxystilbene, 4 ml. of acetic anhydride, and 16 mg. of *p*-toluenesulfonic acid monohydrate was refluxed for 1.5 hr., then poured over ice. The precipitate formed, was recrystallized from chloroform–methanol to give 636 mg. (85.8%) of white plates, m.p. 218–219°. [Lit. m.p. 213° (10).]

4-Methoxystilbene—The procedure of Hewitt, Lewcock, and Pope (11) was used as the basis for the synthesis of this compound. To a stirred solution of 500 mg. of 4-hydroxystilbene in 30 ml. of methanol and 50 ml. of 30% potassium hydroxide, 20 ml. of dimethyl sulfate was added dropwise

TABLE I—PAPER CHROMATOGRAPHY

Hydroxystilbene	Rf in Solvent Systems[a] 1	2	3	Detection: Diazotized Sulfanilic Acid[b]	Gibb's Reagent[c]	Fluorescence[d]
2-Hydroxy-	0.90	0.91	0.88	Orange	Blue	Bright blue
4-Hydroxy-	0.85	0.89	0.84	Yellow	Yellow-gray	Pale blue
4,4′-Dihydroxy-	0.65	0.64	0.69	Yellow	Grey	Bright blue
4-Hydroxy-3-methoxy-	0.80	0.92	0.79	Red-orange	Yellow-gray	Blue

[a] Solvent systems used were: *1*, *n*-butanol–14% ammonium hydroxide (1:1) (top layer); *2*, *n*-butanol–benzene–acetic acid–water (0.5:2:2:1) (top layer); *3*, isopropanol–28% ammonium hydroxide–water (8:1:1). [b] Chromatogram sprayed with 0.5% sulfanilic acid–0.5% sodium nitrite (1:1), then oversprayed with 10% sodium carbonate. [c] Spraying with 0.1% ethanolic *N*-2,6-trichloro-*p*-benzoquinoneimine, followed by saturated sodium bicarbonate solution. [d] Excitation at 320–400 mμ with chromatographic viewer.

TABLE II—THIN-LAYER CHROMATOGRAPHY

Hydroxystilbene	Rf in Solvent Systems[a] 1	2	3	4	5	6
2-Hydroxy-	0.27	0.59	0.14	0.52	0.76	0.90
4-Hydroxy	0.13	0.52	0.05	0.47	0.71	0.85
4,4′-Dihydroxy-	0.00	0.18	0.00	0.21	0.58	0.76
4-Hydroxy-3-methoxy-	0.34	0.67	0.27	0.49	0.76	0.82

[a] Solvent systems employed were: *1*, benzene; *2*, benzene–methanol (92:8); *3*, cyclohexane–chloroform (1:1); *4*, cyclohexane–*p*-dioxane (2:1); *5*, benzene–*p*-dioxane–acetic acid (90:25:4); *6*, benzene–isopropanol–28% ammonium hydroxide (5:4:1). Detection reagents, methods, and color reactions are the same as indicated in Table I.

during a period of 50 min. Following an additional 30 min. of stirring, the reaction mixture was exhaustively extracted with methylene chloride. The methylene chloride layer was washed with water and saturated NaCl, dried over anhydrous sodium sulfate, and passed over 20 Gm. of alumina (Woelm, grade 1, neutral). Reduction to dryness *in vacuo* and recrystallization from ethanol–water gave 348 mg. (65.0%) of white leaflets, m.p. 137–138.5°. [Lit. m.p. 135–136° (9).]

Analytical Procedures

Paper Chromatography—Whatman No. 1 was used throughout for ascending development of 15–16 cm. Table I lists the solvent systems used.

Thin-Layer Chromatography—Silica Gel G plates (20 × 20 cm.) were prepared from a slurry containing 3 Gm. of Silica Gel G[2] and 7 ml. of water per plate. After air drying, plates were activated at 105° for 1 hr. Developing distance employed was 10 cm. using the solvent systems listed in Table II.

TLC Fluorimetry—Activated Silica Gel G plates were scored into 0.5-cm. channels, spotted (each concentration in triplicate) with 2.0–12.0 mcg. of 4-hydroxystilbene or 0.25–1.50 mcg. of 4,4′-dihydroxystilbene and developed (10 cm.) in benzene–isopropyl alcohol–28% ammonium hydroxide (5:4:1). The developed plates were overlayed with a clean glass plate after air drying and scanned with an Aminco-Bowman thin film scanner (No. 4-8221A) connected to an Aminco-Bowman spectrofluorometer (SPF 4-8202) and a 100-mv. Beckman recorder (93500). Measurement of 4-hydroxystilbene was performed under the following conditions: λ excitation, 370 mμ; λ emission, 425 mμ; sensitivity, 23; meter multiplication, 0.01; scanner motor, 1 r.p.m.; recorder speed, 60 in./hr. 4,4′-Dihydroxystilbene was measured under the same conditions used for 4-hydroxystilbene except that the λ emission was set at 435 mμ.

Gas Chromatography—Columns were packed according to Maunder *et al.* (12), with 3% SE-52 on Chromosorb W (60/80 mesh-HMDS treated). Qualitative VPC (Figs. 3 and 4) was performed with an F & M model 700 gas chromatograph equipped with dual flame ionization detectors, using the following conditions: columns, 4 ft. × 1/8 in. copper; injection port temperature, 270° ± 5°; column temperature, 174° (TMS ethers, Fig. 3), 220° (CMDMS ethers, Fig. 4); detector temperature, 261° ± 1°; carrier gas flow, 60 ml./min., helium (40 p.s.i.); hydrogen flow, 50 ml./min. (16 p.s.i.); air flow, 380 ml./min. (16 p.s.i.); attenuation, 5; range, 10^2. Quantitative VPC of 4-hydroxy- and 4,4′-dihydroxystilbene as their TMS ethers was conducted with an F & M model 300 gas chromatograph equipped with a model 1609 flame ionization detector, under the following conditions: column, 2 ft. × 1/4 in. copper; injection port temperature, 261° ± 2°; column temperature, 174°; detector temperature, 271° ± 2°; helium rotometer setting 9.0 (flow about 60 ml./min.) (30 p.s.i.); hydrogen rotometer setting, 7.0 (24 p.s.i.); air rotometer setting, 9.0 (20 p.s.i.); attenuation, 8; range, 10^2.

Trimethylsilyl (TMS) Ethers—Hydroxystilbenes (1–20 mg. each), dissolved in 0.7 ml. of dry pyridine (over potassium hydroxide pellets), were reacted with 0.2 ml. of hexamethyldisilazane (HMDS) and 0.1 ml. of trimethylchlorosilane (TMCS) for 10–15 min. at room temperature. With flame ionization detection, reaction mixtures were injected directly, while with electron capture detection, they were first diluted twentyfold with high purity *n*-hexane[3] prior to injection.[4]

Chloromethyldimethylsilyl (CMDMS) Ethers—CMDMS ethers were prepared as the TMS ethers only using di(chloromethyl)tetramethyldisilazane (CMTMDS) (0.2 ml.) and chloromethyldimethylchlorosilane (CMDMS)[3] (0.1 ml.) as silating reagents. Injections of these derivatives were made as indicated for the TMS ethers.

[2] Warner-Chilcott Laboratories, Richmond, Calif.

[3] Burdick and Jackson Laboratories, Inc., Muskegon, Mich.

[4] Hamilton 1 and 10-μl. syringes used throughout.

Blue Tetrazolium Reduction—Reagents were prepared as described previously (5). To 0.1612 mg. of 4,4′-dihydroxystilbene in 10 ml. of absolute alcohol was added 2 ml. of tetramethylammonium hydroxide and 2 ml. of blue tetrazolium reagent. Absorbance readings at 530 mμ were obtained at room temperature (23° ± 1°) against an identically prepared blank with a Zeiss PMQ II spectrophotometer. A solution prepared with 0.2728 mg. of 4-hydroxystilbene was reacted and measured similarly.

RESULTS AND DISCUSSION

Paper and Thin-Layer Chromatography—Tables I and II summarize conditions and results of the paper and thin-layer chromatographic separation and detection of 2-hydroxy-, 4-hydroxy-, 4,4′-dihydroxy-, and 4-hydroxy-3-methoxystilbene.

The mobilities of the hydroxystilbenes in the paper chromatographic systems, where partition phenomena prevail, are readily explicable on the basis of the number of polar functions present. However, in thin-layer systems *1* through *4* (Table II), where adsorption effects predominate, the mobilities of 2-hydroxy- and 4-hydroxy-3-methoxystilbene are greater than might be predicted. In the former compound, this could result from steric hindrance of the approach of the phenolic group to the silica gel surface (13). While for 4-hydroxy-3-methoxystilbene, intramolecular hydrogen bonding would explain its high R_f values relative to that of 4-hydroxystilbene (14).

TLC Fluorimetry—The use of fluorescent scanning of thin-layer plates with system *6* for the analysis of 4-hydroxy- and 4,4′-dihydroxystilbene was investigated. In the apparatus employed, plates are scanned perpendicular to the solvent front with an activation wavelength slit limited to 0.5 cm. in length. Thus, while diffusion of spots toward the solvent front is related to the width of the recorded peaks, lateral diffusion beyond 0.5 cm. is not recorded. It was found necessary to limit such lateral diffusion by scoring the thin-layer plate into 0.5-cm. columns.

Figures 1 and 2 show the relationship of peak area to concentration obtained for 4-hydroxy- and 4,4′-dihydroxystilbene. Both curves reveal a restricted but usable linear range, limited at high concentrations by quenching effects (15).

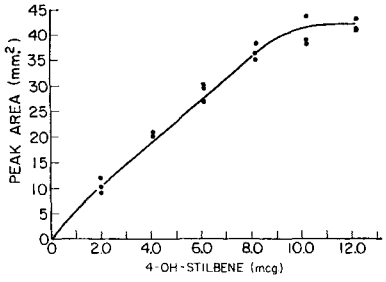

Fig. 1—TLC fluorimetry of 4-hydroxystilbene.

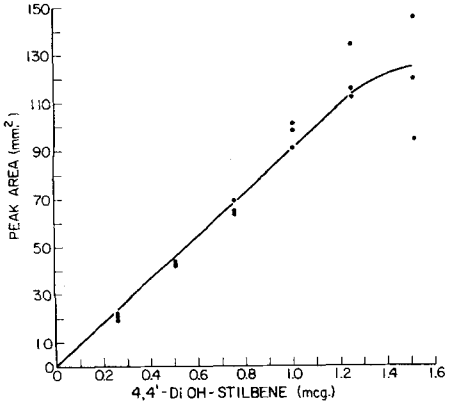

Fig. 2—TLC fluorimetry of 4,4′-dihydroxystilbene.

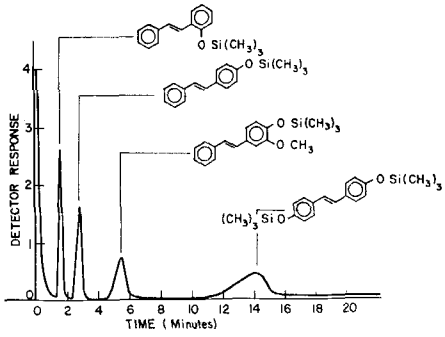

Fig. 3—Gas chromatographic separation of 2-hydroxy-, 4-hydroxy-, 4-hydroxy-3-methoxy-, and 4,4′-dihydroxystilbene as their TMS ethers.

Gas Chromatography—The TMS ethers of 2-hydroxy-, 4-hydroxy-, 4,4′-dihydroxy-, and 4-hydroxy-3-methoxystilbene were prepared and separated by VPC as shown in Fig. 3. The chloromethyldimethylsilyl (CMDMS) ethers of these compounds also showed suitable development and resolution when subjected to gas chromatographic analysis (Fig. 4).

The utility of the TMS ethers in the quantitative analysis of 4-hydroxy- and 4,4′-dihydroxystilbene was studied. Based on the characteristics of their peaks (*e.g.*, Fig. 3) assessment to three significant places was achieved by using peak height and peak area measurements for 4-hydroxy- and 4,4′-dihydroxystilbene, respectively.[5] Linearity was exhibited in the range of 1 to 8 mcg. for 4-hydroxystilbene and 2 to 14 mcg. for 4,4′-dihydroxystilbene.[6]

Though the use of flame ionization detection was found suitable for the quantitative analysis of the TMS ethers of 4-hydroxy- and 4,4′-dihydroxystilbene, it was felt that an increase in sensitivity might be realized by employing electron capture detection for these or other volatile derivatives.

Studies concerning electron capture detection in the vapor phase chromatography of certain aromatic

[5] Peak height calculations were made according to the base line technique of Gaul (16) while peak area approximations (b 1/2 × h) were performed as indicated by Kaiser (17).

[6] Plots of peak height or peak area *versus* amount of hydroxystilbene did not pass through the origin. Wotiz and Clark (18) note that this may be due to loss on the column or irreversible adsorption of a constant amount of derivative during development.

hydrocarbons, has shown *trans*-stilbene to possess four times the electron affinity of chlorobenzene (19). The effect of substitution, specifically of oxygenated functions, on this affinity, however, has not been reported.

Table III lists the detection sensitivity relative to *trans*-stilbene and the limit of detection of three derivatives of 4-hydroxy- and 4,4′-dihydroxystilbene. The detection limit is calculated as that amount of compound giving a peak height of two times the noise level, the latter taken as 2 mm.

Relative sensitivities were calculated from a comparison of peak areas derived from 10^{-9} moles of *trans*-stilbene and each stilbene derivative. For

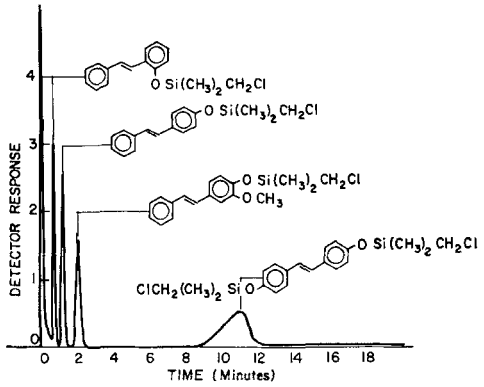

Fig. 4—Gas chromatographic separation of 2-hydroxy-, 4-hydroxy-, 4-hydroxy-3-methoxy-, and 4,4′-dihydroxystilbene as their CMDMS ethers.

this comparison, both compounds were chromatographed under identical conditions. When column temperatures above 200° were required for the development of a given compound (*Footnotes d, e*, Table III), direct comparison to *trans*-stilbene was not possible. At these temperatures, *trans*-stilbene elicits a peak which is not readily measurable due to its proximity to the solvent peak. Thus, in these cases, the compound was compared to a derivative which had previously been related to *trans*-stilbene.

Since *trans*-stilbene captures electrons by a process involving the propagation of a molecular ion (20, 21), a derivative of it, possessing an electron donating substituent might be expected to show a decrease in electron affinity. This effect is noted as a sensitivity decrease for 4-methoxystilbene (Table III).

The increase in sensitivity of the acetates of *trans*-stilbene is interesting since simple esters usually show little affinity for electrons (22). However, the increase in sensitivity of the TMS ethers of 4-hydroxy and 4,4′-dihydroxystilbene is explicable on the basis of increased electron affinity due to the considerable π character of the silicon-oxygen bond (21).

The significant increase in sensitivity of the CMDMS ethers, due to the ready dissociation of aliphatic halides in the electron capture detector (23), provides an extremely sensitive mode of analysis for these compounds and should have general applicability with analogous compounds.

Blue Tetrazolium Reduction—The oxidation of 4,4′-dihydroxystilbene by blue tetrazolium was established and the analytical applications of this reaction were studied. Since tetrazolium salts have been employed as detection reagents on paper

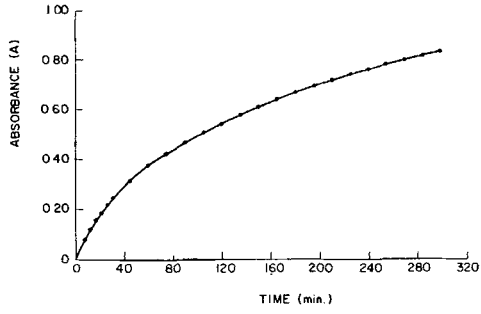

Fig. 5—Reduction of blue tetrazolium by 4,4′-dihydroxystilbene (5.4×10^{-5} M in reaction solution).

[a] An F & M model 700 gas chromatograph, fitted with a 4 ft. × 1/8 in. column (copper) packed as indicated under *Experimental* and equipped with a model 700A-3 electron capture detector (tritium), was used throughout with the following constant conditions: injection port temperature, 225° ± 5°; detector temperature, 215° ± 3°; carrier gas, argon–methane (95:5) (50 p.s.i.); purge, 10 ml./min.; pulse, 15. Varied conditions: *A*, carrier gas flow, 60 ml./min.; column temperature, 183° ± 1°; range 10^2; attenuation, 2; *B*, carrier gas flow, 60 ml./min.; column temperature, 217° ± 1°; range, 10^2; attenuation, 2; *C*, carrier gas flow, 60 ml./min.; column temperature, 183° ± 1°; range, 1; attenuation, 5; *D*, carrier gas flow, 90 ml./min.; column temperature, 216° ± 1°; range, 1; attenuation, 2. [b] Relative to solvent front. [c] Calculated from the average area of three runs. The magnitude of response (peak area) of all compounds studied was found to be inversely proportional to the column temperature emphasizing the need for strict adherence to conditions during quantitative studies. [d] Compared to 4-acetoxystilbene under conditions *B*. [e] Compared to 4-chloromethyldimethylsiloxystilbene under conditions *D*.

chromatograms (24), similar procedures were applied for the detection of 4,4′-dihydroxystilbene. However, the slow rate of the tetrazolium–dihydroxystilbene reaction caused this procedure to be unsuccessful.

A measure of the formazan produced with time, when blue tetrazolium was reacted with 4,4′-dihydroxystilbene (5.4×10^{-5} *M*), is shown in Fig. 5. Similar measurement of a solution containing 4-hydroxystilbene (1×10^{-4} *M*) and blue tetrazolium showed no absorbance attributable to formazan production, over a period of 3 hr. Furthermore, spectrophotometric measurement of solutions containing varying amounts of 4,4′-dihydroxystilbene after 60 min. reaction with blue tetrazolium, showed a good correlation between absorbance and concentration. Thus, the feasibility of assaying 4,4′-dihydroxystilbene in the presence of 4-hydroxystilbene was established.

SUMMARY AND CONCLUSIONS

Paper, thin-layer, and gas chromatographic methods have been presented for the qualitative analysis of 2-hydroxy-, 4-hydroxy-, 4,4′-dihydroxy-, and 4-hydroxy-3-methoxystilbene.

A sensitive and rapid method for the analysis of 4-hydroxy- and 4,4′-dihydroxystilbene has been devised, based on fluorescent scanning of thin-layer plates. Gas chromatographic analysis of these compounds as their trimethylsilyl ethers has also been shown to be a reliable quantitative procedure.

Vapor phase chromatography, coupled with electron capture detection has been shown to be a highly sensitive tool for the analysis of certain derivatives of 4-hydroxy- and 4,4′-dihydroxystilbene.

The analysis of 4,4′-dihydroxystilbene, even in the presence of 4-hydroxystilbene, is possible through the use of blue tetrazolium.

Comparative Study in Man of the Absorption and Excretion of Amobarbital-^{14}C from Sustained-Release and Nonsustained-Release Dosage Forms

By EARL ROSEN*, ANDREW POLK*, SPENCER M. FREE*, PHILIP J. TANNENBAUM†, and ARCHER P. CROSLEY, JR.†

Amobarbital was tagged with a radioactive carbon atom and incorporated into sustained-release and nonsustained-release dosage forms to obtain comparative absorption and excretion data. Radioactivity levels in plasma and urine showed that the sustained-release formulation released about one-third of its amobarbital promptly and the remaining portion gradually, whereas the nonsustained-release dosage form showed a steady decrease in plasma concentration after 1 hr. and a higher urinary excretion rate during the first 12-hr. period. These performance characteristics indicate that a moderately short-acting drug, such as amobarbital, can be pharmaceutically modified so as to be a candidate for use with longer-acting drugs, such as trifluoperazine, in a single dose unit.

TESTS IN ANIMALS showed that a combination of amobarbital and trifluoperazine has a broader spectrum of activity than the individual drugs, but combining them in a single dose unit posed a pharmaceutical problem because amobarbital is a moderately short-acting drug (1) while trifluoperazine is long acting. Incorporating the amobarbital component into a sustained-release formulation would solve the problem if a formulation could be prepared that would release amobarbital promptly and gradually over an extended period. This report describes the specific sustained-release dosage form and how it was evaluated in man.

EXPERIMENTAL

Preparation of Dosage Forms—Based on the results of preliminary clinical studies, a combination of 30 mg. of amobarbital and 2 mg. of trifluoperazine was chosen for testing. However, conventional bioanalytic techniques to measure levels of amobarbital and its metabolites in blood and urine are not sufficiently sensitive to accurately measure drug concentration from a 30-mg. dose, so it was necessary to label the amobarbital with a radioactive carbon atom. The utility of this technique for evaluating pelleted sustained-release preparations has been reported previously (2–4).

Based on human safety considerations, an upper limit of 50 μc. of ^{14}C was selected for the 30-mg. amobarbital dose. To obviate the problems involved in uniformly mixing labeled and unlabeled drug, the 5-ethyl-5-isoamyl barbituric acid-2^{14}C was synthesized with a specific activity of 1.57 μc./mg.

The dosage forms for this study were prepared by a method similar to that reported previously (2, 4). One kilogram of nonsustained-release amobarbital pellets was prepared in a 12-in. stainless steel coating pan located in a disposable glove-box inside a walk-in fume hood fitted with special filters. A portion (150 Gm.) of these nonsustained-release pellets was set aside and the remaining pellets were coated with a wax-fat coating.

Six separate groups of sustained-release pellets with approximately 6, 7, 8, 9, 10, and 11% wax-fat (WF) coating were prepared to insure a sufficient spread in patterns to facilitate blending for the *in vitro* release pattern selected on the basis of controlled clinical studies. This desired *in vitro* pattern was 35, 60, 75, and not less than 80% released at the 0.5, 2, 4.5, and 7-hr. intervals, respectively.

The *in vitro* release patterns of the six experimental groups are shown in Table I; they were determined by the method of Souder and Ellenbogen (5). In these groups, it was found that the blend consisting of 35% nonsustained-release pellets, 10% WF-1, 20% WF-2, 15% WF-3, 10% WF-4, and 10% WF-5 gave a calculated pattern of 35, 56, 77, and 86% released at the desired time intervals.

The *in vitro* patterns of this blend assayed before and after it was encapsulated with 2 mg. of nonsustained-release trifluoperazine are shown in Table II. These data indicated that the *in vitro*

Received April 14, 1967, from the * Research and Development Division, Smith Kline & French Laboratories, Philadelphia, PA 19101, and the † Section of Clinical Pharmacology, Research Institute and Department of Medicine, Presbyterian-University of Pennsylvania Medical Center, Philadelphia, PA 19104

Accepted for publication June 22, 1967.

Presented to the Industrial Pharmaceutical Technology Section, A.PH.A. Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

TABLE II—BLEND AND CAPSULE *In Vitro* RELEASE PATTERNS (AMOBARBITAL-^{14}C)

Material	% *In Vitro* Release at Time Interval 0.5 hr.	2 hr.	4.5 hr.	7 hr.
Blend	34	54	80	86
Sustained-release amobarbital-^{14}C, trifluoperazine capsule	34	53	77	83

release pattern of the experimental capsule closely approximated the desired pattern.

The nonsustained-release pellets of labeled amobarbital, previously set aside, were encapsulated with 2 mg. of nonsustained-release trifluoperazine.

In Vivo Protocol—Two dosage regimens, *A* and *B*, were compared in 10 normal subjects, using a cross-over design: (*A*) sustained-release amobarbital-^{14}C, 30 mg., nonsustained-release trifluoperazine, 2 mg., given at 0 hr.; (*B*) nonsustained-release amobarbital-^{14}C, 30 mg., nonsustained-release trifluoperazine, 2 mg., given at 0 hr.

These regimens were tested to determine whether the sustained-release amobarbital formulation provided a prompt initial dose, whether the remaining portion of amobarbital was delivered gradually, and whether there was any significant reduction in the total amount of amobarbital made available from the sustained-release formulation.

Prior to the tests, the subjects were examined and found to be in good health. All underwent studies to rule out impairment of renal, hepatic, and hematopoietic function. The subjects were then divided into two groups of five and each group was studied on alternate weeks over a 4-week period. The order in which the test formulations were given was alternated within each group.

Each morning of the study, the subjects reported in a fasting state and were given a test dose with fruit juice. They received no food or drink for 90 min.; then they resumed their normal diets. For the first 12 hr., this consisted of a free selection of hospital cafeteria food.

Plasma and Urine Sampling—A blood specimen was taken from each subject before drug administration and at hourly intervals after it for a total of 12 hr., by means of an indwelling anticoagulated venous needle system (4). The plasma was separated and immediately frozen until assayed.

Complete urine specimens were collected for 96 hr. after drug administration. The collection intervals were 0–3, 3–6, 6–9, 9–12, 12–24, 24–48, 48–72, and 72-96 hr. Urine specimens were also frozen until assayed.

It was also decided to determine the pH of all urine specimens passed in the first 12 hr. of each segment of this cross-over study. The authors did not intend to try to establish a relationship between urinary pH and drug excretion (6, 7). An increase in the excretion of a weak acid like amobarbital (pKa 7.96), or its principal metabolite hydroxyamobarbital, could be expected only in an alkaline urine and Elliot *et al.* (8) have found that only 1% of urine specimens have a pH of 7.2 or more. Rather, the authors wanted to determine whether pH profiles would be similar on two separate occasions. Information of this sort is not presently available and would be useful in the design of dosage form performance studies involving drugs which *are* influenced by urinary pH fluctuations.

Analysis of the Specimens—Plasma and urine samples were assayed for radioactivity using a method previously used to assay dextroamphetamine-^{14}C (4). The pH of the urine specimens was determined immediately after voiding, using a Beckman model G glass electrode pH meter.

RESULTS AND DISCUSSION

Plasma Data—These data, as shown in Fig. 1, are reported as micrograms of amobarbital per ml. of plasma, but include radioactivity that originated from the metabolites as well as from the parent compound. A comparison of the two regimens at the first hour after administration shows that the plasma level of radioactivity resulting from the sustained-release formulation was 36% of the amount resulting from the nonsustained-release formulation. This value for the sustained-release formulation agrees closely with the *in vitro* release value of 34% at 0.5 hr.

The plasma levels of radioactivity following the administration of the nonsustained-release regimen were consistently and significantly higher ($P < 0.01$) than the levels of the sustained-release regimen. And there was a statistically significant difference ($P < 0.01$) in the patterns: the nonsustained-release regimen showed a steady decrease in plasma

S.D.	0.738	0.860	0.843	0.595	0.465	0.428	0.705	0.665

concentration after 1 hr.; in contrast, the sustained-release regimen showed a slowly rising pattern after 1 hr. All these data indicated that the sustained-release formulation made approximately one-third of its amobarbital content available for absorption promptly and that it delivered the remaining portion gradually.

Urine Data—The radioactivity excretion rates for the two regimens were computed by dividing the per cent of radioactivity excreted per collection-interval by the number of hours in the interval. Each value was then plotted at the midpoint of the collection interval, as shown in Fig. 2.

An analysis of the plots for the two regimens showed a statistically significant difference ($P < 0.01$). Furthermore, the data showed that less amobarbital was excreted from the sustained-release regimen than from the nonsustained-release regimen during the first 24-hr. period. But the reverse was true thereafter; more amobarbital was excreted from the sustained-release regimen. These findings are consistent with the plasma findings and give further proof that the sustained-release amobarbital formulation makes its drug gradually available for absorption.

The cumulative urinary recovery data, reported in Table III as the per cent of administered dose in each collection interval, are essentially identical for the two regimens over a 96-hr. period and indicate that amobarbital in the sustained-release formulation was as available for absorption as amobarbital in the nonsustained-release dose.

Urinary pH Data—The 0–12 hr. urinary pH profiles for each of the 10 subjects during the two test periods are reported in Table IV. The profiles were very similar and, as could be expected, showed a peak in the 3–6-hr. interval consistent with the afternoon postprandial tide and range reported by Elliot *et al.* (8). But the most interesting finding was the similarity in the averages of the profile values: the figures for the two test periods varied by less than 0.2 pH units.

SUMMARY

This study in man was undertaken to determine the performance characteristics of a sustained-release amobarbital formulation. To obtain comparative absorption and excretion data, amobarbital was tagged with a radioactive carbon atom and incorporated into sustained-release and nonsustained-release dosage forms. Data from plasma and urine studies showed that the sustained-release formulation made about one-third of its amobarbital content promptly available for absorption and that the remaining portion was absorbed gradually. This was in contrast to the nonsustained-release dosage form, which showed a steady decrease in plasma concentration after 1 hr. and had a higher urinary excretion rate during the first 12-hr. period. Furthermore, there was no reduction in drug availability from the sustained-release formulation: the cumulative urinary recovery of radioactivity from both dosage forms after 96 hr. was about 75%. These data indicate that it is possible to combine this sustained-release amobarbital formulation in a single dose unit with a long-acting drug like trifluoperazine.

During this study, urinary pH data were also recorded which showed that 0–12-hr. urinary profiles taken on two separate occasions were very similar and that profile averages varied by less than 0.2 pH units.

Diffusion, Permeation, and Solubility of Selected Agents In and Through Polyethylene

By M. A. GONZALES, J. NEMATOLLAHI, W. L. GUESS, and J. AUTIAN*

Even though polyethylene containers have and are being used with more frequency to package drug products, diagnostic agents, biological products, and cosmetic preparations, little emphasis apparently has been placed on the possible interactions between solute molecules in the product and the polyethylene. This report presents a study on the diffusion, permeation, and solubility of six compounds (acetophenone, benzaldehyde, benzoic acid, benzyl alcohol, 4-methylacetophenone, and 4-methylbenzaldehyde) in and through polyethylene. Results reveal that benzyl alcohol and benzoic acid had the lowest permeation (P) and diffusion (D) values as compared to the other compounds in the series. This was ascribed to the intermolecular hydrogen bonding potential of benzyl alcohol and benzoic acid; thus the formation of dimer or trimer whose permeation through the polymer is assumed to be restricted. In the case of 4-methylbenzaldehyde and 4-methylacetophenone, the D values obtained were similar to those of the parent compounds (benzaldehyde and acetophenone). Higher P values for the 4-methyl derivatives of benzaldehyde and acetophenone were related to the higher solubility of the molecules in the plastic.

THE PACKAGING of drugs, biological products, diagnostic aids, and cosmetic products in polymeric materials has increased greatly in the past decade. A number of advantages of plastics over the conventional glass, paper, and metals have helped to accelerate the adoption of plastic packaging systems to a host of old and new products entering the medical and para-medical fields. As might be expected with the introduction of new materials for a specific application, certain problems have arisen or may arise which justify research into drug–plastic interactions (1–4).

Presently the most commonly used polymeric material for containers is polyethylene. It has been found to be a good moisture-vapor barrier for aqueous products as well as a good barrier for a number of organic solvents. Pinsky (5) has studied the permeation rates of several classes of organic liquids through polyethylene and has found the rate was lowest with the highly polar substances, increasing in the following order of chemical structures: alcohol, acids, nitro derivatives, aldehydes and ketones, esters, ethers, hydrocarbons, and halogenated hydrocarbons. Salame and Pinsky have been able to develop an arithmetical method for predicting the permeability of liquids through polyethylene (6). They refer to their method as the "Permachor" method. It is interesting to note, however, that only a few reports are available on the barrier properties of polyethylene in contact with aqueous solutions of specific compounds. It should be apparent that any loss of an ingredient in a drug or similar type of product stored in a polyethylene container would decrease the effectiveness of the drug product leading to possible serious consequences to the patient and the manufacturer of the product.

To develop a body of knowledge on the barrier properties of polyethylene which may be of value to the pharmaceutical or cosmetic scientist, a study was undertaken to determine the diffusion, permeation, and solubility of some commonly found pharmaceutical compounds, namely, benzyl alcohol, benzoic acid, and benzaldehyde. Also included in the study were acetophenone, 4-methylbenzaldehyde, and 4-methylacetophenone which are structurally related to benzoic acid and benzaldehyde. Study of the latter compounds was designed to provide contrasting information on the effect of certain substituents on the rate of diffusion and permeation of the parent compounds.

EXPERIMENTAL

Materials and Supplies—Polyethylene film, 3 mil thickness (Gulf Oil Corp., Chemicals Department, Orange, Tex.); acetophenone, certified reagent grade (Fisher Scientific Co., Fairlawn, N. J.); benzaldehyde, Eastman grade (J. T. Baker Chemical Co., Phillipsburg, N. J.); benzyl alcohol, Eastman grade (Eastman Organic Chemicals, Rochester, N. Y.); 4-methylacetophenone, Eastman grade (Eastman Organic Chemicals, Rochester, N. Y.); 4-methylbenzaldehyde, Eastman grade (Eastman Organic Chemicals, Rochester, N. Y.).

Properties of Polyethylene Film—The density of the film as determined by the use of a density gradient column at 25° was found to be 0.9246 Gm./ml. This value indicates that the film falls in the category of a low density polyethylene. Weight average

Received March 20, 1967, from the Drug-Plastic Research and Toxicology Laboratories, College of Pharmacy, University of Texas, Austin, TX 78756

Accepted for publication July 5, 1967.

This investigation was supported in part by contract PH43-64-557 from the Division of Biologic Standards, National Institutes of Health, Bethesda, Md., and from a graduate fellowship from Abbott Laboratories, North Chicago, Ill.

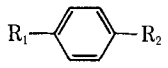
TABLE I—MOLECULAR STRUCTURES OF COMPOUNDS INVESTIGATED OF THE GENERAL FORMULA



Compd.	R_1	R_2	Mol. Wt.	Dipole[a] Moment	Solubilities[b] in Water, % w/v
Benzyl alcohol	$-CH_2OH$	$-H$	108.13	1.68	4.0
Benzoic acid	$-\overset{O}{\overset{\|}{C}}-OH$	$-H$	122.12	1.00	0.34
Benzaldehyde	$-\overset{O}{\overset{\|}{C}}-H$	$-H$	106.12	2.77	0.33
Acetophenone	$-\overset{O}{\overset{\|}{C}}-CH_3$	$-H$	120.14	2.77	0.30
4-Methylbenzaldehyde	$-\overset{O}{\overset{\|}{C}}-H$	$-CH_3$	120.14	3.30	0.10
4-Methylacetophenone	$-\overset{O}{\overset{\|}{C}}-CH_3$	$-CH_3$	134.17	3.20	0.10

[a] Values are in Debye units. These values were determined in benzene at 25° as reported in Wesson, L. G., "Tables of Electric Dipole Moments," The Technology Press, Massachusetts Institute of Technology, Cambridge, Mass., 1948. [b] The solubilities in water at approximately 25° are taken from "The Merck Index of Chemicals and Drugs," Merck and Co., Inc., Rahway, N. J., 1960, for benzyl alcohol, benzoic acid, and benzaldehyde. The solubilities for the other compounds were determined experimentally by the authors.

molecular weight was equal to 83,430 while the number average molecular weight was 15,820.[1] The polyethylene had an average of 19.3 methyl groups per 1,000 monomeric units (methylene groups) indicating a high degree of branching and a terminal vinylidene content equal to 0.37 per 1,000 methylene units.[1]

Permeation Experiments—The compounds studied in this report with some of their physical constants are listed in Table I. Aqueous solutions of each of these compounds were prepared at a specific original concentration as shown in Table II. Each agent was studied at four different temperatures (40°, 50°, 60°, and 70° ± 0.02°). The permeation experiment was conducted in a cell consisting of two chambers separated by the polyethylene film[2] secured in place by a clamp (Fig. 1) following the general procedure of Rodell (7). In the left chamber was placed 500 ml. of the solution under study and in the right, 500 ml. of distilled water. The solution and water were heated to a temperature slightly higher than the temperature of the water bath prior to adding them to the permeation cell. The cell was then placed into a constant-temperature water bath adjusted to the desired temperature. At various time periods aliquots from the right chamber were withdrawn and the quantity of the compound was determined spectrophotometrically at the wavelength of maximum absorbance. (See Table II.) From the data a figure was prepared plotting the quantity of the compound passing through the film against time. Each of the compounds was studied in this manner at various temperatures.

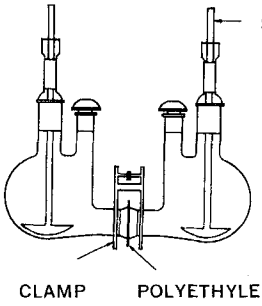


Fig. 1—Diagram of permeation cell.

TABLE II—ORIGINAL CONCENTRATIONS OF SOLUTIONS AND WAVELENGTHS OF MAXIMUM ABSORBANCE

Compd.	% Concn., Wt./Vol.	Wavelength Max. Abs., mμ	Diluting Solvent
Benzyl alcohol	1.0	258	Distilled water
Benzoic acid	0.3	230	0.1 *N* HCl
Benzaldehyde	0.3	250	Distilled water
Acetophenone	0.3	245	Distilled water
4-Methylbenzaldehyde	0.1	260	Distilled water
4-Methylacetophenone	0.1	257	Distilled water

Representative plots are shown for only two of the compounds (benzyl alcohol and benzaldehyde) in Figs. 2 and 3.

Extrapolation of lines in the various plots to the time axis permitted the calculation of the apparent diffusion coefficient (D) using the Barrer relationship (8):

[1] Statistics on molecular weights, branching, and olefinic bonds were generously furnished by Mr. T. O. J. Kresser, Plastics Laboratory, Gulf Oil Corp., Chemicals Department, Orange, Tex.

[2] Surface area exposed to solution was 22.07 cm.².

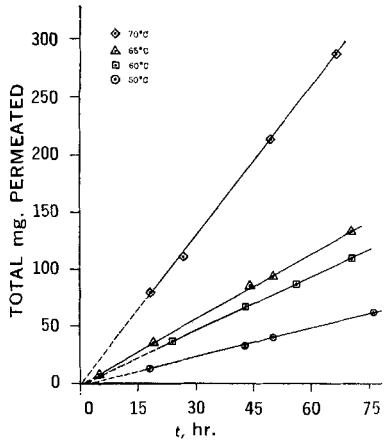

Fig. 2—Permeation plot of benzyl alcohol (1.0%) through polyethylene at several temperatures.

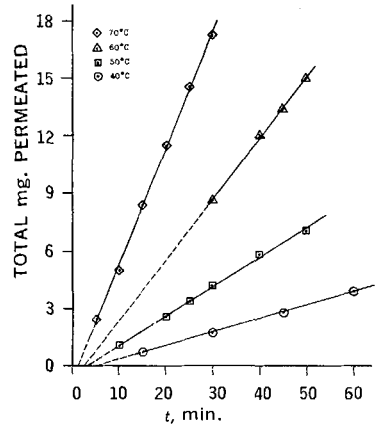

Fig. 3—Permeation plot of benzaldehyde (0.3%) through polyethylene at several temperatures.

$$D = L^2/6\tau \qquad \text{(Eq. 1)}$$

where L is the thickness of the film and τ is the time lag obtained from the extrapolated line.

The D values for each of the agents at the specific temperature of the experiment are listed in Table III. The same table also includes the activation energy (ΔE_D) of diffusion calculated by the use of the Arrhenius expression:

$$\log D = \log D_0 - \Delta E_D/2.303\ RT \qquad \text{(Eq. 2)}$$

The plots of log D *versus* $1/T$ for the solutes under study gave linear relationship, thus permitting the evaluation of ΔE_D from the slopes.

Permeability constants (P) were evaluated for each of the compounds for a given temperature using the expression:

$$P = c/t \cdot LV/CA \qquad \text{(Eq. 3)}$$

where c/t is the slope of the linear portion of the permeation plot (Figs. 2, 3), L is the thickness of the film, V the total volume of solution, C the original concentration, and A the surface area of the film exposed to the solution. The P values are listed in Table IV, which also includes the activation energies of permeation, evaluated in a manner similar to that described for the activation energy of diffusion.

Solubility coefficients (S) for each of the compounds were calculated by the relation of $P = SD$, and these values are listed in Table V. Heats of solution (ΔH), calculated by the use of the Arrhenius relationship are also included in Table V.

RESULTS AND DISCUSSION

Initial permeation studies were directed to compare the barrier properties of polyethylene toward benzyl alcohol, benzoic acid, and benzaldehyde. As are depicted in Tables III and IV, considerable difference is noted between the aldehyde and either the alcohol or the acid. At 50° benzaldehyde has an apparent diffusion coefficient of 542.0×10^{-10} cm.^{2}/sec., while for benzoic acid and benzyl alcohol the D values are 14.6×10^{-10} cm.^{2}/sec. and 11.6×10^{-10} cm.^{2}/sec., respectively. Comparison of the permeability constants (Table IV) for the three compounds indicates that benzaldehyde possesses a higher permeation rate than benzoic acid or benzyl alcohol and although the difference is not so large as with the diffusion coefficients, it is still significant.

Since the benzaldehyde gave much higher values for D and P than demonstrated for either the benzyl alcohol or benzoic acid, similar studies on three structurally related compounds (acetophenone, 4-methylbenzaldehyde, and 4-methylacetophenone) were undertaken.

Diffusion Coefficients and Activation Energies of Diffusion—As has been indicated above, the diffusion coefficient for benzaldehyde at any temperature was found to be greater than either the benzyl alcohol or the benzoic acid. These latter two compounds have nearly similar D values as may be noted in Table III. The similar apparent diffusion coefficients suggest a similar molecular volume. All other factors being equal, the diffusion coefficient is strongly dependent on the molecular volume of a

Table III—Diffusion Coefficients and Activation Energies of Selected Compounds in Polyethylene

[a] The solubility coefficients are unitless, since they express the ratio of the amount of solute in a volume of plastic over the amount of solute in a volume of solution at equilibrium (mg./ml. per mg./ml.). [b] S at 65° was 6.48.

diffusate molecule, D decreasing with an increase in molecular volume. One may cite as an example the diffusion coefficient of helium at 30° in a low density polyethylene reported in the literature as 81.5×10^{-7} cm.^{2}/sec., while that for oxygen under similar conditions is 6.05×10^{-7} cm.^{2}/sec. (9).

Since the diffusion coefficients for benzyl alcohol and benzoic acid were similar, there is a possibility that the diffusing species of these two compounds had a similar molecular volume. It is known that both benzoic acid and benzyl alcohol are capable of forming dimers by hydrogen and hydrophobic bonding, and it could be that the dimerization gives rise to large diffusate molecules (10–13). The larger diffusion coefficients for benzaldehyde were probably due to smaller diffusing species than those for benzyl alcohol and benzoic acid, since benzaldehyde does not possess a hydrogen capable of hydrogen bonding.

Further support for the existence of larger diffusate molecules with benzyl alcohol and benzoic acid is found in the activation energies for diffusion (Table III). The relatively high activation energies for benzyl alcohol, 12.6 Kcal./mole, and benzoic acid, 15.0 Kcal./mole, as compared to that of benzaldehyde, 8.16 Kcal./mole, may be interpreted as resulting from the high energy required to make a hole in the polymer matrix large enough to allow diffusion of the large dimerized molecules. According to Barrer and other investigators (14, 15) the activation energy for diffusion is strongly influenced by the size of the diffusate molecule and increases with an increase in molecular size. Since benzyl alcohol and benzoic acid require more energy to diffuse in polyethylene than does benzaldehyde, it should follow that benzyl alcohol and benzoic acid possess larger diffusing species than benzaldehyde.

The ability of carboxylic acids to form dimers in aqueous solutions by intermolecular hydrogen bonding and by hydrophobic interactions has been documented in the literature (10–12). Indirect proof for dimerization of benzyl alcohol has come through several sources. Scheraga *et al.* has shown that alcohols interact with each other through hydrophobic bond formation in model systems (13). Infrared spectra of various concentrations of benzyl alcohol in carbon tetrachloride reveal that the O–H stretching frequency band shifts to lower frequency as a function of concentration. The high boiling point of benzyl alcohol (205.2°), as compared to the lower boiling point of ethylbenzene (136.2°), a molecule having the same molecular weight as benzyl alcohol, is ascribed to the hydrogen bonding capacity of the former.

In the case of acetophenone, 4-methylbenzaldehyde, and 4-methylacetophenone the diffusion coefficients observed were very similar to those of benzaldehyde at 50°. Acetophenone had a D value of 592.0×10^{-10} cm.^{2}/sec., while 4-methylbenzaldehyde and 4-methylacetophenone had values of 403.0×10^{-10} cm.^{2}/sec. and 502.0×10^{-10} cm.^{2}/sec., respectively. Lack of intermolecular hydrogen bonding in this series of compounds would seem to be responsible for the almost identical D values. As with benzaldehyde, these compounds do not form dimers and are very slightly soluble in water (solubilities listed in Table I). The similarity of the diffusion coefficients and activation energies of diffusion of benzaldehyde and its methyl analogs, as listed in Table III, also indicates that the addition of a methyl group does not increase the molecular size enough to alter the diffusivity of these compounds significantly.

Permeability Constants and Activation Energies of Permeability—The permeability constants calculated for benzyl alcohol, benzoic acid, benzaldehyde, and acetophenone were found to have a similar relationship to that existing between the values for the diffusion coefficients of these compounds. The permeability constants for benzyl alcohol and benzoic acid at 50° were 0.771×10^{-8} and $1.00 \times$

10^{-8}, respectively. The values for benzaldehyde and acetophenone were 27.7×10^{-8} and 30.4×10^{-8}. Thus, the trend was generally an increase in the permeation of the compounds in the same order as the diffusion. The permeability constants, however, for the methyl substituted derivative of the latter two compounds were found to be twice as large as those for the parent compounds. The P value at 50° for 4-methylbenzaldehyde was 55.3×10^{-8} while the same constant for 4-methylacetophenone was 62.3×10^{-8}. No such relationship was observed with the diffusion coefficients. The D values for the *p*-methyl analogs were essentially the same as those of the parent compounds.

Except for benzyl alcohol, the values obtained for the activation energies of permeability for all the compounds were in the range of 17 Kcal./mole. Benzyl alcohol had the lowest activation energy, 11.5 Kcal./mole (Table IV). To explore the differences in the permeability, it was necessary to consider the solubility coefficients and the heats of solution of the permeating agents in polyethylene.

Solubility Coefficients and Heats of Solution—In this study the solubility coefficients (S) were found to be approximately the same for benzyl alcohol, benzoic acid, benzaldehyde, and acetophenone (Table V). With benzyl alcohol, however, the S values decreased with an increase in the temperature of the experiment, while the opposite occurred with the other compounds. By definition, the solubility coefficient is a ratio of the concentration of solute in a unit weight or volume of plastic to the concentration of the solute in a unit weight or volume of solution. The solubility coefficient, thus, can be visualized as a distribution ratio, which makes it possible to interpret the solubility data with facility.

Upon increasing the temperature of benzyl alcohol solution, dimerization decreases due to a disruption of intermolecular hydrogen bonding. The relatively high capacity of benzyl alcohol to form hydrogen bonds with water molecules renders it less soluble in polyethylene, thus resulting in a decrease of the S values. An Arrhenius plot of the values of the log of S *versus* $1/T$ gives a positive slope which yields a negative heat of solution. This may be interpreted as meaning that the exothermic heat resulting from the binding of benzyl alcohol molecules to the polymer chain segments predominates over the endothermic heat of mixing, and the resulting heat of solution is negative (-1.01 Kcal./mole).

All the other compounds studied had positive heats of solution, which would imply that the endothermic heat of mixing was predominant. It could follow that the increase in the solubility coefficients noted for benzoic acid, benzaldehyde, and acetophenone was due primarily to an increase in the mobility of the polymer chains which allowed a faster increase in the solubility of the solute in the polymer than in the solution. In the case of benzoic acid, however, the increase in temperature will result in the cleavage of intermolecular hydrogen bonds, as is true in the case of benzyl alcohol—differing in that benzoic acid molecule possesses two sites for the formation of intermolecular hydrogen bonds. The increase in monomer fraction will result in an increase in the solubility of benzoic acid in water. However, due to the relatively high polar character of benzoic acid molecule the increase in its solubility coefficient is not so rapid as that for benzaldehyde or acetophenone.

In the case of 4-methylbenzaldehyde and 4-methylacetophenone, the solubility coefficients were found to be twice as high as those of the parent compounds. At 50° 4-methylbenzaldehyde had an S value of 13.72 and 4-methylacetophenone had a similar value of 12.41. The same constants for benzaldehyde and acetophenone were 5.11 and 5.13, respectively. These high solubility coefficients could be ascribed to a decrease in the dielectric constant due to the presence of the methyl substituent.

After reviewing the solubility data, it is possible to explain the apparent anomalous results obtained for the permeability constants and activation energies of permeability. The high solubility coefficients for 4-methylacetophenone accounted for the high permeability constants obtained for these compounds. Since their diffusion coefficients were generally the same as those of their parent compounds, it follows from the relationship $P = DS$ that the permeability constants will vary according to the variation in the solubility coefficients. The solubility coefficients of 4-methylbenzaldehyde and 4-methylacetophenone are twice as large as those of benzaldehyde and acetophenone; thus, the permeability values as well would be expected to rise by twofold.

To propose a rationale for the resultant activation energies of permeability, it is necessary to recall that the activation energy for permeability is a measure of the energy required to allow the net transfer of a mole of solute through the amorphous regions of a plastic. This energy will then be the sum of the activation energy for diffusion and the heat of solution. Since benzyl alcohol had a negative heat of solution, the energy to accomplish the permeation of benzyl alcohol molecules through the polyethylene chains was less than the energy for diffusion. Benzyl alcohol also had the lowest activation energy of permeability.

Although a reasonable hypothesis has been presented in an attempt to explain the data, there are still several complications that should be emphasized. One of these is that the concentrations used in these studies were not always the same and although the constants derived mathematically are concentration independent, the possibility that the differences in concentration may contribute to some unexpected experimental results should not be overlooked. Finally, it should be remembered that with the type of polyethylene used in this experiment the degree of crystallization will decrease with an increase in temperature. In fact, studies above temperatures higher than 70° gave anomalous results which may have been due to the changes in crystallinity. This facet must, however, be investigated more thoroughly before the exact effects of changes of crystallinity on sorption can be presented.

SUMMARY

A series of structurally related aromatic compounds was employed for the evaluation of their permeation through a polyethylene film. Six compounds were used in the study: benzyl alcohol, benzoic acid, benzaldehyde, acetophenone, 4-methylbenzaldehyde, and 4-methylacetophenone.

Results of the experiments revealed that benzyl

alcohol and benzoic acid had the lowest P and D values as compared with the other compounds in the series. This was ascribed to intermolecular hydrogen bonding potential of benzyl alcohol and benzoic acid which produce dimers or trimers whose penetration into the polymer is not favorable.

In the case of 4-methylbenzaldehyde and 4-methylacetophenone, the D values obtained were similar to those of the parent compounds, benzaldehyde and acetophenone. The P and S values, however, were found to be larger. The difference in the P and S values was attributed to the effect of the methyl substituents which gave rise to higher solubility in the plastic.

Quantitative studies as reported here and similar studies with other compounds should be of value to those who may desire to package drugs, cosmetics, or other products in polyethylene.

Crystal and Molecular Structure of 5-[1-(2′-Deoxy-α-D-ribofuranosyl)uracilyl] Disulfide

By ELI SHEFTER, MICHAEL P. KOTICK, and THOMAS J. BARDOS

The molecular structure of 5-[1-(2′-deoxy-α-D-ribofuranosyl)uracilyl] disulfide (I) has been determined by X-ray crystallographic analysis. The molecule crystallizes in the orthorhombic space group $P2_12_12_1$, with the following cell dimensions: a = 9.492 Å., b = 14.061 Å., c = 16.328 Å. The valence state about the S-S linkage appears to be markedly different from that observed in other disulfide structures. The torsional angle about this bond is 49° and the S-S bond length was found to be 2.108 Å. The configurations of both the uracil and the deoxyribosyl residues are different in the two nucleoside units of the molecule. The crystal is bound together by hydrogen bonds.

A STRUCTURAL ANALOG of thymidine, 5-mercapto-2′-deoxyuridine (MUDR), has been recently synthesized (1), and found to be a potent inhibitor in several bacterial systems. This compound and some of its congeners are of potential chemotherapeutic interest because of their ability to inhibit the biosynthesis of DNA (2, 3). Both the α and β anomers of MUDR exhibited rapid autoxidation in aqueous solutions to the corresponding disulfides (4). These disulfides have interesting biochemical and physicochemical properties. They are capable of being reduced nonenzymatically at a virtually instantaneous rate by stoichiometric amounts of thiols (2, 5), and their high optical activities showed temperature dependence (6).

In an effort to gain further insight into the various properties that could be pertinent as to the mode of action on a molecular level of MUDR and its congeners, X-ray structural studies have been initiated on several of these compounds. This report concerns itself with the crystallographic structure of the first of these compounds to be completed, the disulfide of the α-anomer, 5-[1-(2′-deoxy-α-D-ribofuranosyl)uracilyl] disulfide (I). This compound has additional interest as it appears to be the first α-nucleoside whose crystal structure has been elucidated.

EXPERIMENTAL

The compound crystallizes from water as slightly yellow prisms belonging to space group $P2_12_12_1$, with the following crystallographic data:

$a = 9.492 \pm 0.003$ Å.
$b = 14.061 \pm 0.002$ Å.
$c = 16.328 \pm 0.003$ Å.
ρ(meas.) = 1.577 Gm./cm.^{3}
ρ(calcd.) = 1.579 Gm./cm.^{3}
$Z = 4$

alcohol and benzoic acid had the lowest P and D values as compared with the other compounds in the series. This was ascribed to intermolecular hydrogen bonding potential of benzyl alcohol and benzoic acid which produce dimers or trimers whose penetration into the polymer is not favorable.

In the case of 4-methylbenzaldehyde and 4-methylacetophenone, the D values obtained were similar to those of the parent compounds, benzaldehyde and acetophenone. The P and S values, however, were found to be larger. The difference in the P and S values was attributed to the effect of the methyl substituents which gave rise to higher solubility in the plastic.

Quantitative studies as reported here and similar studies with other compounds should be of value to those who may desire to package drugs, cosmetics, or other products in polyethylene.

Crystal and Molecular Structure of 5-[1-(2′-Deoxy-α-D-ribofuranosyl)uracilyl] Disulfide

By ELI SHEFTER, MICHAEL P. KOTICK, and THOMAS J. BARDOS

The molecular structure of 5-[1-(2′-deoxy-α-D-ribofuranosyl)uracilyl] disulfide (I) has been determined by X-ray crystallographic analysis. The molecule crystallizes in the orthorhombic space group $P2_12_12_1$, with the following cell dimensions: a = 9.492 Å., b = 14.061 Å., c = 16.328 Å. The valence state about the S-S linkage appears to be markedly different from that observed in other disulfide structures. The torsional angle about this bond is 49° and the S-S bond length was found to be 2.108 Å. The configurations of both the uracil and the deoxyribosyl residues are different in the two nucleoside units of the molecule. The crystal is bound together by hydrogen bonds.

A STRUCTURAL ANALOG of thymidine, 5-mercapto-2′-deoxyuridine (MUDR), has been recently synthesized (1), and found to be a potent inhibitor in several bacterial systems. This compound and some of its congeners are of potential chemotherapeutic interest because of their ability to inhibit the biosynthesis of DNA (2, 3). Both the α and β anomers of MUDR exhibited rapid autoxidation in aqueous solutions to the corresponding disulfides (4). These disulfides have interesting biochemical and physicochemical properties. They are capable of being reduced nonenzymatically at a virtually instantaneous rate by stoichiometric amounts of thiols (2, 5), and their high optical activities showed temperature dependence (6).

In an effort to gain further insight into the various properties that could be pertinent as to the mode of action on a molecular level of MUDR and its congeners, X-ray structural studies have been initiated on several of these compounds. This report concerns itself with the crystallographic structure of the first of these compounds to be completed, the disulfide of the α-anomer, 5-[1-(2′-deoxy-α-D-ribofuranosyl)uracilyl] disulfide (I). This compound has additional interest as it appears to be the first α-nucleoside whose crystal structure has been elucidated.

The density was measured by means of flotation in a mixture of chloroform and dibromoethane. The unit cell dimensions were obtained by least squares refinement of 30 general reflections measured on a General Electric XRD-6 diffractometer, using Cu Kα radiation.

The intensity data were collected by the stationary counter-stationary crystal technique using balanced filters and Cu Kα radiation. The crystal utilized for the data collection was mounted with a parallel to the ϕ axis of the goniostat and its dimensions were 0.66 mm. along a, 0.16 mm. along b, and 0.38 mm. along c. In the 2 θ range between 0° and 142°, 2328 reflections of a total possible number of 2408, had intensities significantly greater than their background counts. The intensities of the various reflections were corrected for Lorentz and polarization factors in the usual manner. A correction for absorption as a function of the angle ϕ was measured for various h.0.0. reflections. The average transmission factor obtained was then used to correct the intensities for anisotropy of absorption.

Structure Determination—The positions of the two sulfurs were easily obtained from a Patterson synthesis. A Fourier synthesis calculated using the phases of the sulfur atoms uncovered all but 8 of the nonhydrogen atoms. From successive difference syntheses the positions of these eight atoms were found. The refinement was then continued by block diagonal least squares, using a modified version of the Trueblood, Sparks, and Gantzel program (ACA No. 317), which minimizes the function $\Sigma w||Fo| - |Fc||^2$. The initial isotropic refinement was carried out with the weight equal to $1/f_{(n)}$, where $f_{(n)}$ is the scattering curve for nitrogen. After anisotropic temperature factors were introduced, a difference Fourier showed positive electron density (ranged between 0.2 to 0.4 e/Å.^{3}) in the regions where the hydrogen atoms were expected to be found. In the final least squares refinement the hydrogen atoms were included with isotropic temperature factors, and the weighting scheme utilized was $1/\sigma(F^2)$, where the standard deviations of the structure factors were calculated in the manner described by Evans (7). The final R value (usual discrepancy index) was 0.054 for the observed reflections, and 0.062 for all the reflections, where the unobserved data were given an intensity equal to half the minimum observable value. Throughout the refinement the unobserved data were given zero weight.

The atomic form factors used in all the above computations were those given by Cromer and Waber (8), except for the hydrogens. McWeeny's (9) scattering curve for the hydrogen atom was utilized. The sulfur atoms were corrected for anomalous scattering using both the real and complex terms (10).

Results and Discussion—The final atomic positions and thermal parameters for the molecule together with their respective estimated standard deviations (ESD) are shown in Tables I, II, and III. The ESD's were calculated from the inverted matrix of the normal least squares equations. The intramolecular bond lengths and angles are shown in Figs. 1 and 2. The atomic names shown in these figures will be used throughout the text. The average standard deviation in bond length is 0.008 Å. for the nonhydrogen atoms, with the exception of the disulfide bond which is 0.003 Å. The intramolecular angles between the various nonhydrogen bonds have an average error of 0.4°. The ESD's for the bonds and angles involving the hydrogens average around 0.1 Å. and 3°, respectively. These angles are not shown in Fig. 2, and only those relevant to the discussion of the molecule will be given.

In discussing the crystal structure, the various portions of the molecule shall be considered individually and then the packing of the molecule will be discussed.

Disulfide Linkage—The various structural features of some of the more accurately determined disulfides are compared to the present structure in Table IV. There is a striking difference between the various values listed for I and the other compounds.

The torsional angle, ϕss, defined as the projected angle of the two C—S bonds down the S—S bond (see Fig. 3), is much smaller in I than in any of the open chain disulfides. It is also much larger than the angle found in the cyclic disulfide structures. The angle in the open-linked disulfides is believed to be determined primarily by the repulsion of the electrons in the p orbitals of the sulfur atoms. This results in an energy minimum at 90°. Abrahams, in a review (18) of disulfide bonding, found that open disulfide structures have values distributed within the vicinity of 90°. This is seen to be true for the open-chain disulfides listed with the exception of I. The values for the constrained disulfides are

very much lower. Recently an analysis of these cyclic compounds has been presented by Hordvik (19), and as it is felt to be nonrelevant to the bonding in I, these structures will not be discussed.

The electronic structure about the disulfide linkage of I also appears to be quite different from the other compounds listed in this table. A large degree of double bond character appears to exist in the C—S bond of I, as evidenced by the significantly shorter lengths for these bonds. This could increase the electron density in the d orbitals of the sulfurs and thereby cause an overlap of the

[a] φss assumed to be 90°.

3 *d* electrons, which in turn may result in repulsion between the sulfurs, and subsequent lowering of the torsional angle. The greater S—S bond length in this structure, as compared to other disulfides, is in agreement with this postulation. The valence state of the C—S bonds appears to be influenced by the uracil moieties. The C5—C6 bonds in the two pyrimidines are substantially longer than the average value observed for this bond in a number of pyrimidine nucleosides and nucleotides (average 1.33 ± 0.01 Å.).

Uracil Moieties—Within experimental error, the bond lengths and angles of the two rings are quite similar. The most striking difference between the two residues exists between the planarity of the pyrimidine rings. The least squares planes calculated through the six ring atoms of the two bases are shown in Table V. The atoms comprising ring 1 are coplanar within their standard deviations, whereas those comprising ring 2 are significantly nonplanar. Pyrimidine ring 2 is puckered substantially about N3-C4-C5, with N3 and C5 being displaced on the opposite side of the plane to C4. Puckering has been observed in a number of pyrimidine nucleosides (20), and is possibly the result of the valence state of the nitrogen involved being intermediate between sp^2 and sp^3 hybridization. The puckering in this ring may also reflect the close proximity of portions of the two pyrimidine rings to each other, as a result of the disulfide conformation. The distance between 2C5 and 1C5 is 3.2 Å., less than the sum of the van der Waals radii of the two atoms, 3.4 Å. In the puckered uracil residue, both C1′ and O4 are displaced from the pyrimidine plane to a much greater extent than in ring 1.

The C4—O4 carbonyl groups have a significantly longer bond length than the C2—O2 groups. The greater degree of polarization in the 4 position of uracil derivatives has been discussed with respect to their hydrogen bonding (21). It can be pointed out that both O4 atoms are participating in hydrogen bonds, while only one O2 is involved in such a bond.

With the exception of the C4—C5 bonds of the two uracil moieties, the bond distances and angles are similar to those found in other pyrimidine containing nucleosides and nucleotides.

Deoxyribose Moieties—It is well established from structural data that the furanose ring in nucleosides

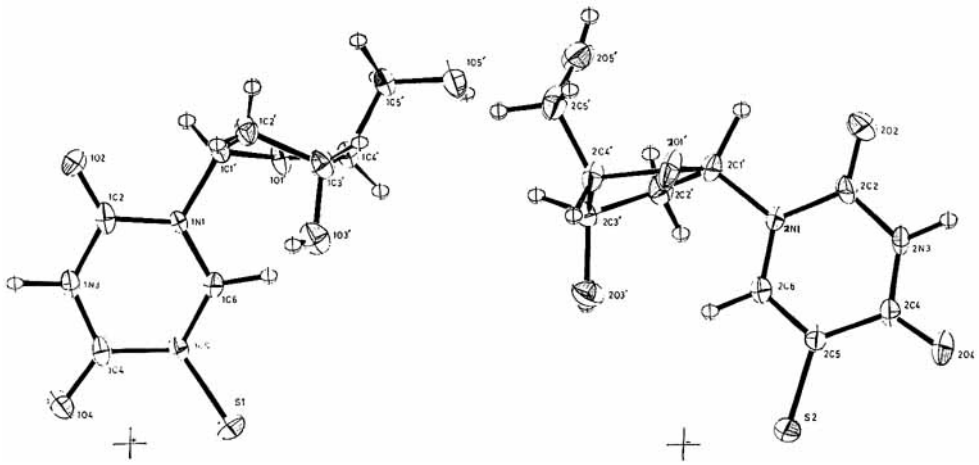

Fig. 3—The two nucleosidic portions of the molecule as viewed down the S1 → S2 bond. In order to visualize the complete molecule the + sign should be overlayed on the − sign. The thermal ellipsoids of the nonhydrogen atoms are shown. (Reduced to about $^1/_3$.)

TABLE V—LEAST SQUARES PLANES CALCULATED IN THE MANNER OF SCHOMAKER *et al.*[a]

Atoms Comprising the Plane	Displacements, Å.	Displacements of Other Atoms, Å.	
Uracil 1			
1N1	0.003	$1O_4$	0.056
1C2	0.001	$1O_2$	−0.006
1N3	−0.007	S(1)	0.045
1C4	0.008	$1C_1'$	0.068
1C5	−0.004	H1	−0.015
1C6	−0.001	H2	0.045
Uracil 2			
2N1	0.010	$2O_4$	0.124
2C2	−0.001	$2O_2$	−0.005
2N3	−0.023	$2C_1$	0.210
2C4	0.036	S(2)	−0.056
2C5	−0.028	H_{12}	−0.163
2C6	0.006	H_{13}	0.001

[a] Schomaker, V., Waser, J., Marsh, R. E., and Bergman, G., *Acta Cryst.*, **12**, 600(1959).

is puckered and not planar. The common puckering found in β-nucleosides usually involves the C2′ and C3′ atoms (22). In sugar 1, one of the modes of puckering observed in β-nucleosides is found, with C2′ and C3′ displaced on opposite sides of the plane through C1′, O1′, and C4′. The puckering in sugar 2 is quite different from that found in other furanose structures (23). Its distortion involves the displacement of C3′ and C4′ from the plane of the other 3 atoms. This is evident from Figs. 3 and 4.

One of the best ways to describe the puckering of furanose structures is in terms of a twist angle about each ring bond (23, 24). This conformational angle for a given bond, *e.g.*, φ C2′ → C3′, is the projected angle between the C1′—C2′ bond and the C3′—C4′, in that order, measured clockwise. The twist angles for the sugars are given in Table VI. The smaller the absolute value of the twist angle, the greater is the displacement of the atom opposite the bond concerned.

The conformation about the exocyclic C4′—C5′ is of interest, as it may be important in considering the hindered rotation about the disulfide bond. This can be seen in Fig. 4, which indicates that these exocyclic atoms may come in close contact upon rotation about the S—S bond. The conformation about this bond can be designated by the projected angles made by C5′—O5′ with C4—O1′ and C4′—C3′ (25). These angles are listed in Table VI, as φOO and φOC, the former of these refers to the angle between C5′—O5′ and C4′—O1′. A value near 60° is considered to be *gauche* and a value near 180°, *trans*. Sugar 1 has *tg* conformation about this bond, while sugar 2 has the *gg* conformation (the first letter refers to φOO and the second to φOC). These conformations would possibly afford a minimum amount of contact between these exocyclic atoms if the nucleoside residues are rotated about the disulfide bond.

The C—C bonds average 1.530 Å. and 1.536 Å.

TABLE VI—CONFORMATION ANGLES

	Residue 1	Residue 2
φ C1′ → C2′	−27° 36′	−7° 58′
φ C2′ → C3′	−34° 19′	21° 0′
φ C3′ → C4′	30° 2′	−27° 39′
φ C4′ → O1′	−13° 39′	23° 32′
φ O1′ → C1′	−8° 44′	9° 51′
φ OC	70° 2′	49° 27′
φ OO	174° 9′	68° 16′
φ CN	−30°	−72°

		103′.....H2-1C6	106°

[a] The value in parentheses following the donor atom name denotes its equivalent position in fractional coordinates, as follows: (1) $0.5 - x, -y, 0.5 + z$, (2) $1 - x, y - 0.5, 0.5 - z$, (3) $x - 0.5, -(y + 0.5), -z$, (4) $0.5 - x, -y, z - 0.5$, (5) $1.5 - x, -y, 0.5 + z$.

for sugars 1 and 2, respectively. These values do not deviate significantly from the bond length between two tetrahedral carbon atoms, 1.533 ± 0.003 Å. (26). The exocyclic C4′—C5′ in both sugars is substantially shorter than this distance, and as suggested by Sundaralingham and Jensen (27) for other nucleoside structures, that this effect may be due to the distortion of the C4′ atom from a tetrahedral conformation (see angles in Fig. 2). In other nucleoside structures, it has been observed that the C—O bond lengths can deviate substantially from the commonly accepted value for a C—O single bond, 1.425 ± 0.007 Å. (28). There are a number of significantly longer and shorter C—O bonds in the two sugars. The C—O bonds in furanose ring 1 show a commonly occurring deviation that is found in a number of nucleosides (22), that is the C1′—O1′ is significantly shorter than O1′—C4′. In sugar 2 this effect does not manifest itself to as great an extent, which may be a direct indication that this phenomenon is dependent on the conformation of the sugars.

Hydrogen Atoms and Bonding—The intramolecular bond lengths and angles (latter not shown) involving the hydrogen atoms agree fairly well with those found in other crystal structures. The O—H bond lengths are the only ones that deviate considerably from the commonly found values of 1.06 Å. for this bond. From various considerations (*i.e.*, C—O—H angles and hydrogen bond angles), it appears that only H7 has been positioned erroneously.

Table VII contains a list of all the hydrogen bonding contacts found in this structure. From a consideration of the distances and angles of various short intermolecular contacts, it appears that 103′ is forming a hydrogen bond with a 203′ atom. This would require that the 103′ hydrogen (H7) be placed at the cross in Fig. 5, rather than the position given for this atom. Though difference syntheses did not show any electron density at the likely position, this may be a reflection of the difficulty in obtaining accurate hydrogen positions in such a complex molecule. With H7 relocated, the hydrogen bonding scheme as shown in Fig. 5 is a very plausible one, *i.e.*, all angles and distances are reasonable. The molecules are held together in the lattice framework by these intermolecular hydrogen bonds.

Aside from the usual hydrogen bonding interactions, there also appears to be short C6—H . . . O3′ intramolecular contacts. The H13 . . . 203′ and H2 . . . 103′ distances are 2.37 Å. and 2.42 Å., respectively. These are shorter than the normal van der Waals contacts between an oxygen and hydrogen. The sum of the van der Waals radii of hydrogen and oxygen is 2.60 Å. The existence of such interactions has been presented by Sutor (29), and the C6 hydrogen in other pyrimidine nucleosides has been found to form such interactions (25). These C—H . . . O close contacts may be a determining factor for the conformations about the glycosidic C1′—N1′ bonds. The torsional angles (30), ϕCN, *i.e.*, the dihedral angle between the trace of the plane of the base with the C1′—O1′ bond, are given in Table VII for each of these bonds. The short C—H . . . O contacts are represented in Fig. 5 by dotted lines.

Thermal Parameters—In Figs. 3 and 4 the magnitudes and directions of the thermal motion for the various atoms are shown. The thermal ellipsoids were drawn using a Cal. Comp. plotter with a program written by Johnson (31).

The isotropic temperature factors for the hydrogens are quite low. This behavior has been found in a large number of other organic structures, where the scattering factor curve used for hydrogen was that of the free atom (32).

CONCLUSION

In conclusion it is worthwhile to compare the

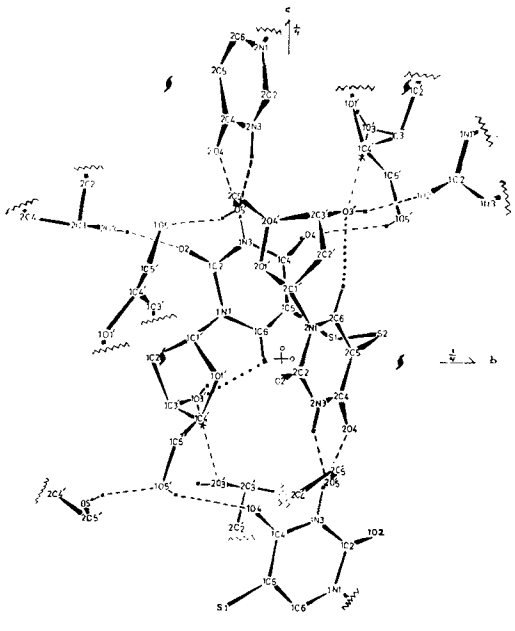

Fig. 5—Projection of molecule along the a *axis. Key: – – –, postulated hydrogen bonding scheme; . . . , short CH . . . O intramolecular contacts. (Reduced to about* 1/3.)

above structural observations with some of the properties found for this compound.

(*a*) The high optical rotation and its temperature dependence might find its explanation in that the electronic state about the disulfide linkage and the conformation of the sugar moieties may hinder free rotation of the two nucleoside residues about the S—S bond.

(*b*) The facile reducibility of the disulfide linkage for this compound appears to be attributable to the valence state of the disulfide bond.

Essential Oils and Their Constituents XXXIV

Isolation of Khusenic Acid and Isokhusenic Acid from Oil of Vetiver and Some Observations Concerning Their Structures

By ISHWAR C. NIGAM and HISASHI KOMAE

Khusenic acid and isokhusenic acid, two new tricyclic sesquiterpene acids, were isolated from oil of vetiver (*Vetiveria zizanioides*, Linn). The physicochemical properties of the acids and their methyl esters were determined. Infrared, NMR, and mass spectral data as well as the results of dehydrogenation suggest that the two acids differ in the location of the double bond. Khusenic acid and methyl khusenate possess a terminal methylene group which rearranges in the presence of mineral acid to a tetrasubstituted double bond leading to the formation of isokhusenic acid and methyl isokhusenate, respectively. Dehydrogenation of the acids as well as their esters failed to yield any aromatic products, the main reaction being decarboxylation of the compounds to a C_{14} hydrocarbon.

OIL OF VETIVER, an important essential oil used by the perfume and cosmetic industries, is obtained by steam distillation of the roots of *Vetiveria zizanioides* (*Gramineae*). Chemical examination of the oil has been carried out by many investigators for almost a century. Most of this work concerned its ketone, alcohol, and hydrocarbon fractions. The acids present in the oil have so far received only limited attention (1–4). The present report describes the isolation and characterization of the major acidic constituent as well as of a closely related isomer.

It is suggested that the major acidic constituent be named khusenic acid (3) rather than vetivenic acid (5) as the latter nomenclature may erroneously imply structural relationship with vetivane. The isomeric compound will accordingly be named isokhusenic acid.

Previous paper: *Perfumery Essent. Oil Rec.*, **56**, 783(1965).
The authors are grateful to Dr. Leo Levi for his interest in these investigations, to Dr. G. A. Neville and Dr. J. L. Holmes for the measurement of NMR spectra and mass spectra, respectively, and to Mrs. C. Radecka for her collaboration in some of the experiments. Special thanks are due to Dr. E. E. Langanau, Fritzsche Brothers, Inc., New York, N.Y., and Dr. Fausto Carreira, Ministerio da Economia, Lisbon, Portugal, who generously supplied samples of genuine reunion and angola vetiver oils, respectively, for this study.

Angola oil (acid value: 29.1) gave a higher recovery of acids than reunion oil (acid value: 6.3), and was, therefore, used in the present investigations. Since gas chromatographic analysis of carboxylic acids is best carried out on the esters, the acids were isolated as methyl esters using Amberlite IRA-400 ion-exchange resin (6). This method was superior to that involving extraction with $NaHCO_3$, hydrolysis of the salt with HCl, and subsequent methylation, as it yielded the esters directly in a higher yield and the isolated fraction was lighter in color.

The gas chromatograms of the ester fractions obtained by either method exhibited essentially the same peaks but the relative proportions of the constituents appearing at 16.2 min. and 13.1 min. were reversed. It appeared that isolation of the acids by the $NaHCO_3$ method, particularly regeneration of the acids from the sodium salts by treatment with hydrochloric acid, brought about isomerization of the main component, khusenic acid to isokhusenic acid. This was confirmed by treating methyl khusenate with aqueous methanolic HCl, which yielded methyl isokhusenate as the major product of reaction (see Fig. 1 and Table I).

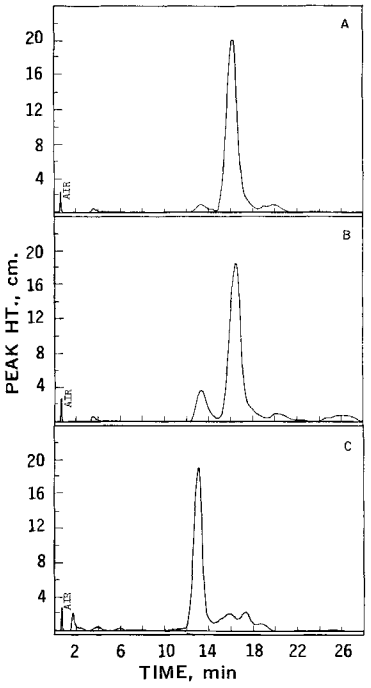

Fig. 1—Gas chromatograms of methyl esters of free acids present in oil of vetiver: A, resin treatment and methylation at room temperature; B, resin treatment and methylation under reflux; C, isomerization of A with HCl. Column: Reoplex 400, operated at 220°. Carrier gas: helium, 75 ml./min.

Analytical samples of methyl khusenate and methyl isokhusenate were obtained by preparative gas chromatography of the crude ester fraction and its isomerization product, respectively. Elemental analysis of methyl isokhusenate and molecular weights of both esters determined by mass spectrometry agreed with the molecular formula $C_{16}H_{24}O_2$. Hence, the corresponding acids are $C_{15}H_{22}O_2$.

Saponification of methyl isokhusenate yielded isokhusenic acid, which on purification *via* its cyclohexylamine salt (m.p. 131–133°) was obtained as a crystalline solid (m.p. 80–81°). For the preparation of pure khusenic acid, the crude acid obtained *via* $NaHCO_3$ extraction was converted into the cyclohexylamine salt (m.p. 146–148°), and the derivative decomposed with dilute hydrochloric acid. The acid so obtained was a liquid. Gas chromatographic analysis (Reoplex 400 column) showed it to be a mixture of two substances, which were isolated by preparative gas chromatography. The faster eluting one was a solid (m.p. 80–81°), the other a liquid. On the basis of infrared and NMR spectral data, the compounds were identified as isokhusenic acid and khusenic acid, respectively.

Hydrogenation of methyl khusenate and methyl isokhusenate confirmed the presence of one double bond in each molecule and hence the tricyclic character of the esters as well as the corresponding acids (2–4). The nature of unsaturation in both compounds was revealed by infrared and NMR spectral analysis as well as ozonolysis.

TABLE I—GAS CHROMATOGRAPHIC ANALYSIS OF METHYL ESTERS OF FREE ACIDS ISOLATED BY DIFFERENT METHODS

No.	Origin of Oil	Method of Obtaining Esters	—% of Main Components[a]— Methyl Khusenate	Methyl Isokhusenate
1	Reunion	$NaHCO_3$ treatment and methylation of the regenerated acid	13	60
2	Reunion	Resin treatment and methylation at room temperature	66	11
3	Angola	Same as in 2	88	5
4	Angola	Resin treatment and methylation under reflux	69	14
5	Angola	Sample from 3 isomerized with HCl	14	73

[a] The balance of 100% represents unidentified minor constituents.

The infrared spectra of the two acids and their esters are shown in Fig. 2. Khusenic acid exhibited infrared absorption bands at 3080, 1635, and 888 cm.$^{-1}$, characteristic of an unsymmetrical disubstituted double bond (>C=CH_2) (7). The corresponding peaks in the spectrum of methyl khusenate appeared at 3085, 1637, and 890 cm.$^{-1}$. The infrared spectra of isokhusenic acid and its methyl ester lacked characteristic olefinic absorption bands, thereby indicating the tetrasubstituted nature of the double bond in both these compounds.

The NMR spectra of the two acids and their methyl esters supported the infrared assignments and in addition suggested the presence of two more methyl groups in these compounds. Thus khusenic acid and methyl khusenate showed peaks for the >C=CH_2 group at 4.75 and 4.61 δ and at 4.77 and 4.63 δ, respectively. Isokhusenic acid and methyl isokhusenate did not give any signal attributable to an olefinic proton. These compounds, on the other hand, exhibited peaks at 1.47 and 1.46 δ, respectively, which could be assigned to a CH_3 group attached to an olefinic carbon atom. In addition, all four compounds gave peaks indicative of the presence of two paraffinic methyl groups. For isokhusenic acid and its ester, these groups possessed identical chemical shifts and generated a single peak. The positions and assignments of characteristic peaks observed in the NMR spectra of these compounds are summarized in Table II.

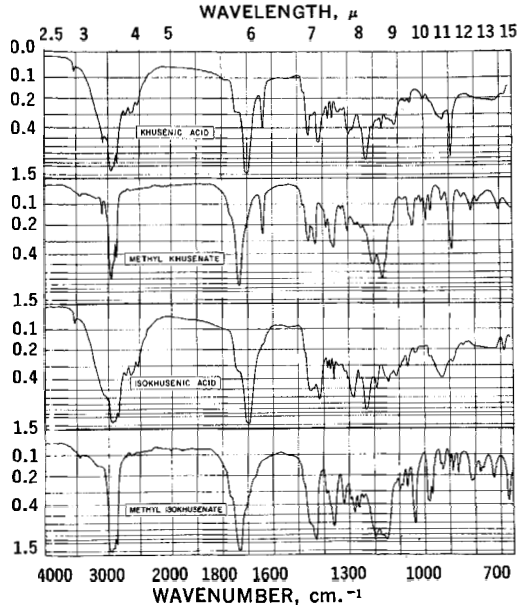

Fig. 2—Infrared spectra of khusenic acid, isokhusenic acid, and their methyl esters. The ordinate is labeled absorbance.

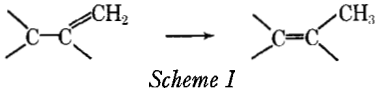
On ozonolysis methyl khusenate lost one carbon atom and yielded a monoketo ester ($C_{15}H_{22}O_3$). The infrared spectrum of the product exhibited carbonyl bands at 1708 and 1728 cm.$^{-1}$ for the keto group and the ester group, respectively. The observation confirmed the presence of an exocyclic double bond in methyl khusenate and hence, in the corresponding acid.

On the basis of the above data it would appear that the acid-catalyzed isomerization of khusenic acid and its methyl ester involves the rearrangement of the unsaturated linkage shown in Scheme I. Close resemblance between the



Scheme I

infrared spectra of the two acids and their methyl esters in the fingerprint region and the generation of peaks at the same positions in their mass spectra (Fig. 3) suggests that the isomerization involves only the double bond and does not affect any other part of the molecule. This deduction was further supported by the results of dehydrogenation experiments, in which the acid as well as their esters yielded the same major reaction product.

In none of these experiments was any aromatic or azulenic compound obtained. A hydrocarbon ($C_{14}H_{22}$) was always the main reaction product. The infrared spectrum of this hydrocarbon did not exhibit any absorption characteristic of aromatic or olefinic groups. The NMR spectrum indicated the presence of three methyl groups, one of them attached to an olefinic carbon atom

TABLE II—NMR SPECTRAL DATA FOR KHUSENIC ACID, ISOKHUSENIC ACID, AND THEIR DERIVATIVES

Compd.	Positions (δ) of Characteristic Peaks and Assignments

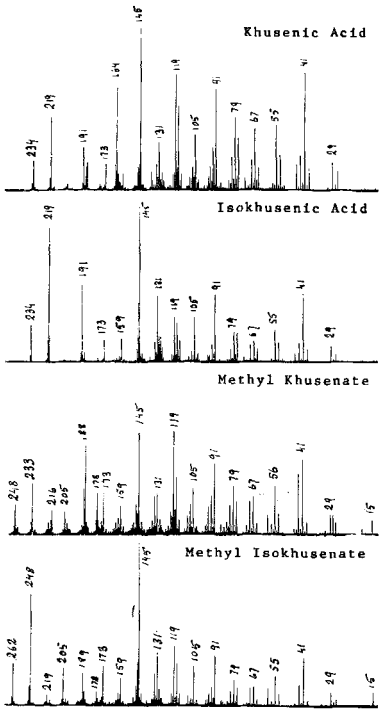

Fig. 3—Mass spectra of khusenic acid, isokhusenic acid, and their methyl esters.

(see Table II). These data suggested that in the case of isokhusenic acid and its methyl ester the reaction involved primarily loss of the carboxyl or the ester group, respectively. In the case of khusenic acid and its methyl ester it involved, in addition, rearrangement of the olefinic methylene group to a tetrasubstituted double bond, a reaction analogous to the isomerization of these compounds observed under the influence of acid.

The experimental data presented describe, for the first time, standardized procedures for the preparation of khusenic acid, isokhusenic acid, and their methyl esters, and yield some preliminary information regarding the structures of these substances. Isokhusenic acid and its methyl ester are crystalline solids and can, therefore, be readily characterized. They may also serve for the identification of khusenic acid and its methyl ester from which the former may be easily prepared *via* isomerization. The spectral and gas chromatographic data should prove of value as additional criteria of identity. Although both acids yield solid cyclohexylamine salts, these compounds were not found to be sufficiently stable for use as characteristic derivatives.

EXPERIMENTAL

All melting points and boiling points are uncorrected. Microanalyses were carried out gas chromatographically employing an F&M, C, H, and N analyzer model 185. Infrared spectra were recorded on a Perkin-Elmer model 221 spectrophotometer and NMR spectra measured in $CDCl_3$ solution employing TMS as internal reference using a Varian A-60A spectrometer equipped with a Varian C-1024 time averaging computer (CAT). Mass spectra were obtained with a Hitachi-Perkin-Elmer RMU-6D spectrometer. Measurements of optical rotations were carried out in $CHCl_3$ solution using a Rudolph model 200 photoelectric polarimeter. Gas chromatographic analyses were carried out on two instruments: (*a*) Burrell Kromo-Tog K-2 equipped with a 20% Reoplex 400 column prepared as previously described, the carrier gas being helium (75 ml./min.) (8); (*b*) aerograph Hi-Fi 600-C equipped with a stainless steel column (outside diameter $^1/_8$ in., length 5 ft.) containing 3% silicone rubber SE-30 on silanized 60 to 80 mesh Chromosorb W prepared according to the method of Horning *et al.* (9, 10), the carrier gas being nitrogen (16 ml./min.).

Isolation of Acids from Reunion Vetiver Oil by Extraction with $NaHCO_3$—The oil (175 Gm.) was dissolved in hexane (350 ml.) and shaken with five 175-ml. portions of 10% $NaHCO_3$ solution. The aqueous extract was washed with water (100 ml.), acidified with 1 *N* HCl solution, and the liberated acid was extracted with five 200-ml. portions of ether. The ether extract was washed with water, dried over anhydrous Na_2SO_4, and evaporated. Yield of crude acids: 1.86 Gm. (1.1%).

Preparation of Methyl Esters—A portion of the crude acids (840 mg.) was dissolved in the methylating reagent (20 ml.) prepared by adding acetyl chloride dropwise to ten times its volume of cold absolute methanol. The mixture was left overnight, then diluted with water (80 ml.), and extracted five times with 20-ml. portions of ether. The ether extract was freed from HCl by repeated washings with water, dried over anhydrous Na_2SO_4, and evaporated. Yield of methyl esters: 572 mg. (68.1%).

Isolation of Free Acids as Methyl Esters from Reunion Vetiver Oil by Treatment with Ion-Exchange Resin—Oil of vetiver (2 Gm.) was dissolved in hexane (25 ml.), and the mixture was stirred for 5 min. with Amberlite IRA-400 (10 Gm.) converted into the OH form by pretreatment with alkali. Following decantation the resin was washed with 25-ml. portions of hexane until evaporation of the washings did not yield an oily residue. The oil-free resin was allowed to react with the above described methylating reagent (25 ml.) for 30 min. with frequent shakings. The supernatant liquid was decanted and the resin washed twice with 10 ml. of the methylating reagent. The supernatant liquid and the washings were combined, and the methyl esters were isolated from the reaction mixture in accordance with the procedure described. Yield of esters: 118 mg. (5.9%).

Isolation of Free Acids as Methyl Esters from Angola Vetiver Oil by Treatment with Ion-Exchange Resin—A sample of the oil (5.05 Gm.), was allowed to react with Amberlite IRA-400 resin (40 Gm.), as described above. The acid-bearing resin was divided in two equal parts. One part was methylated (50 ml. reagent) for 30 min. as previously described and the other part was refluxed with the same volume of reagent for the same length of time. The

methyl esters were recovered from each reaction mixture as described before. Yields of the ester fractions: obtained at room temperature, 661 mg. (26.2%); under reflux, 581 mg. (23.0%).

Acid-Catalyzed Isomerization of Esters Obtained by Resin Treatment—A sample of the ester (104 mg.) obtained from Angola oil by methylation at room temperature was dissolved in a mixture of methanol (9 ml.) and concentrated HCl (1 ml.), and refluxed for 2 hr. Following conventional processing the reaction mixture gave the isomerized product, yield: 101 mg. (97.1%).

Gas Chromatography of Ester Fractions—The esters obtained in accordance with the procedures described above were gas chromatographed on Reoplex 400 and SE-30 columns, operated at 220° and 180°, respectively. All samples exhibited two main peaks corresponding to methyl khusenate and methyl isokhusenate. The relative retention times of the two constituents on the Reoplex 400 column (reference standard: 1,2-dimethylnaphthalene) were 1.59 and 1.31, and on the SE-30 column (reference standard: phenanthrene) 0.85 and 0.77, respectively. The relative proportions of methyl khusenate and methyl isokhusenate in the different samples are recorded in Table I.

Preparation and Properties of Methyl Khusenate and Methyl Isokhusenate—The crude ester fractions were subjected to fractional distillation under reduced pressure—methyl khusenate fraction, yield 87%, purity by GLC 92%; methyl isokhusenate fraction, yield 90%, purity by GLC 95%. Methyl isokhusenate was further purified by recrystallization from ethanol, and an analytical sample of methyl khusenate was obtained by preparative gas chromatography on the Reoplex 400 column. The properties of the two esters are described below.

Methyl Khusenate—$b_{0.7}$ 130°; $[\alpha]_D$ +43.5° (c 3.54); n_D^{26} 1.5058; mol. wt. (mass spectrum) 248.

Anal.—Calcd. for $C_{16}H_{24}O_2$: C, 77.37; H, 9.74. Found: C, 77.60; H, 9.79.

Infrared absorption bands (liquid film) at 3085, 1730, 1637, 1457, 1430, 1385, 1365, 1351, 1303, 1200, 1165, 1045, 991, 973, 930, 890, 850, 815, 790, and 707 cm.$^{-1}$; NMR peaks at 4.63, 4.77, 3.67, 1.08, and 1.05 δ.

Methyl Isokhusenate—Melting point 51°; $b_{0.6}$ 125°; $[\alpha]_D$ +46.8° (c 1.64); mol. wt. (mass spectrum) 248.

Anal.—Calcd. for $C_{16}H_{24}O_2$: C, 77.37; H, 9.74. Found: C, 77.60; H, 9.66.

Infrared absorption bands (melt film) at 1732, 1452, 1432, 1387, 1360, 1320, 1293, 1278, 1261, 1243, 1199, 1190, 1168, 1153, 1098, 1087, 1069, 1040, 981, 968, 937, 929, 902, 888, 867, 815, 780, 770, and 728 cm.$^{-1}$; NMR peaks at 3.64, 1.46, and 1.00 δ.

Preparation of Isokhusenic Acid from Methyl Isokhusenate—Methyl isokhusenate (203.9 mg.) was refluxed with 1 *N* methanolic KOH (5 ml.) for 3 hr. The reaction mixture was acidified (pH 3) with 1 *N* HCl and extracted with three 20-ml. portions of ether. The ether extract on conventional processing yielded crude isokhusenic acid (160.4 mg.). Reaction of the crude acid with cyclohexylamine (0.2 ml.) in acetone (2 ml.) yielded the cyclohexylamine salt recrystallized from the same solvent (m.p. 131–133°). Isokhusenic acid was regenerated from the salt by treatment with 1 *N* HCl (2 ml.). The liberated acid was extracted with ether (3 × 2 ml.); the extract was washed with water, dried over Na_2SO_4, and evaporated. The residue, on recrystallization from aqueous ethanol, yielded pure isokhusenic acid (26.4 mg.), m.p. 80–81°; $[\alpha]_D$ +27.9° (c 2.78).

Anal.—Calcd. for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46. Found: C, 77.32; H, 9.61.

Infrared absorption bands (CCl_4 solution) at 3520, 3000–2400 (broad band), 1700, 1453, 1418, 1384, 1372, 1359, 1281, 1231, 1191, 1144, 1068, and 938–928 cm.$^{-1}$; NMR peaks at 1.47 and 1.00 δ.

Isolation of Khusenic and Isokhusenic Acids from Crude Acid Fraction—The dark viscous acid fraction (1.0 Gm.) obtained from Reunion vetiver oil following treatment with $NaHCO_3$ was allowed to react with cyclohexylamine (1.0 ml.) in acetone solution (5 ml.). The cyclohexylamine salt separated as a solid which was recrystallized from acetone (m.p. 146–148°). On treatment with 1 *N* HCl (3 ml.) it yielded an oil (650 mg.), which by gas chromatographic analysis was found to be composed of khusenic acid (52%) and isokhusenic acid (48%) (retention times: 55.0 min. and 44.5 min., respectively; column: Reoplex 400; temperature 220°). Each of the two acids were collected separately by gas chromatography. The I.R. spectrum and melting point of isokhusenic acid were identical with those of the sample prepared from methyl isokhusenate. Khusenic acid had the following properties: $b_{0.5}$ 158°; $[\alpha]_D$ +17.2 (c 4.39); n_D^{26} 1.5198.

Anal.—Calcd. for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46. Found: C, 77.34; H, 9.55.

Infrared absorption bands (CCl_4 solution) at 3520, 3080, 1700, 1635, 1457, 1415, 1378, 1362, 1335, 1297, 1225, 1165, 1114, 943–928, and 888 cm.$^{-1}$; NMR peaks at 4.75, 4.61, 1.09, and 1.03 δ.

Hydrogenation of the Methyl Esters—Methyl khusenate and methyl isokhusenate were hydrogenated in glacial acetic acid solutions employing Adam's platinum oxide catalyst. The volume of hydrogen absorbed by 105 mg. of methyl khusenate at 27° and 754 mm. pressure was 13 ml. (1.2 moles of H_2 per mole of ester). Hydrogen uptake by 100 mg. of methyl isokhusenate under the same conditions was 10 ml. (1.0 mole).

Attempted Dehydrogenation of Methyl Khusenate and Methyl Isokhusenate—Each of the esters was mixed with twice its weight of selenium and refluxed at 300 ± 10° in an atmosphere of nitrogen. The resultant products were extracted with hexane and chromatographed as described below.

Products from Methyl Khusenate—The reaction mixture (reaction time: 4 hr.) from methyl khusenate (100 mg.) was chromatographed on grade I alumina (5.5 Gm.). The following fractions were obtained: hexane (8 ml.), 13.1 mg.; hexane (24 ml.), 3.8 mg.; hexane (96 ml.), 1.9 mg.; benzene (32 ml.), 13.4 mg.

Products from Methyl Isokhusenate—Reaction of this ester (70 mg.) was allowed to proceed for 9 hr. The products were chromatographed on grade I alumina (5 Gm.) and three fractions were collected: hexane (8 ml.), 2.7 mg.; hexane (64 mg.), 0.3 mg.; hexane–benzene (4:1, 72 ml.), 4.4 mg.

Attempted Dehydrogenation of Crude Acid Mixture—*Employing Selenium*—The crude acid (356 mg.) was allowed to react with selenium for 14 hr. under experimental conditions described above for esters. The acidic constituents present in the reac-

tion mixture were separated as methyl esters employing Amberlite IRA-400. Yields of the neutral and acidic fractions (isolated as methyl esters) were 197 mg. and 22.1 mg., respectively. The neutral fraction was purified by chromatography on grade I alumina (5 Gm.) when a colorless hydrocarbon fraction (72 mg.) was obtained.

Employing Metal Catalysts—The experiment was repeated with the crude acid (250 mg.), employing 5% Pt on alumina (50 mg.) as the dehydrogenating agent. Analogous processing of the reaction mixture yielded a neutral oil (148 mg.) and methyl esters (41 mg.). Chromatography of the neutral fraction on alumina gave hydrocarbons (58 mg.). I.R. and U.V. analyses showed the hydrocarbon fraction did not undergo any chemical change on further refluxing with 5% Pd-on-carbon (31 mg.) for 2 hr. at 320–350°.

Characterization of the Hydrocarbon Fractions Obtained by Dehydrogenation Experiments—Similar hydrocarbon fractions (I.R. spectroscopy and gas chromatography) were obtained in each of the dehydrogenation experiments. The main constituent (79%) of the hydrocarbon fraction obtained by Se-dehydrogenation of the acids was isolated by gas chromatography on a Reoplex 400 column. It possessed the following characteristics: relative retention times on Reoplex 400 (column temperature, 200°) and SE-30 (column temperature, 185°): 0.49 and 1.76, respectively (reference standard: naphthalene; retention times: 6.70 min. and 1.65 min., respectively). NMR peaks at 1.47, 1.02, and 0.98 δ. Mol. wt. (mass spectrum) 190.

Ozonolysis of Methyl Khusenate—Methyl khusenate (1.00 Gm.) was dissolved in ethyl acetate (5 ml.), cooled to 0°, and ozonized using a Gallenkamp ozone apparatus GE-150. The ozonide was decomposed with hydrogen in the presence of Pd-C and the product treated with Amberlite IRA-400 (5 Gm.) in accordance with the procedure described above. The neutral fraction (918 mg.) obtained was purified by chromatography on grade III alumina (50 Gm.) using hexane–benzene mixture (1:1) as solvent and recrystallized from ethanol. Yield: 52% (by GLC), m.p. 102–103°.

Anal.—Calcd. for $C_{15}H_{22}O_3$: C, 71.95; H, 8.86. Found: C, 71.97; H, 8.87.

Infrared absorption bands (CCl_4 solution) at 1728, 1708, 1458, 1430, 1388, 1356, 1300, 1195, 1164, and 1042 cm.$^{-1}$.

New Electromechanical Method for the Assay of Heparin *In Vitro*

By WILLIAM F. SEIP, THEODORE R. CARSKI, and DAVID N. KRAMER

A rapid, simple, and accurate *in vitro* assay for heparin employing a diatomaceous silicate modified plasma and a precision coagulation timer is reported. The method reveals standard deviations of ±2.5 sec. from the average clotting times with a coefficient of variation of about 2 per cent. Sodium heparin U.S.P., heparin reference standard lot H, and the second international standard for heparin have been successfully assayed by this method. The assays have also revealed the stability of sodium heparin to autoclaving and high energy electron irradiation.

WALTON *et al.* (1) have recently reviewed current methods of heparin assay. One of the most commonly employed methods is that of Reinert and Winterstein (2) which is the basis for the U.S.P. heparin assay procedure. A second method is that of Adams (3) which is prescribed by the British Pharmacopoeia. There exist numerous other methods which are essentially modi-

fications of the original Howell procedure (4) upon which the various current heparin activity units are based.

Elliott (5) reported the use of a coagelometer in the determination of heparin concentration. A linear relationship was observed at heparin concentrations of 0 to 2.0 mcg./ml. of whole blood with coagulation times varying from 12 to 30 min. The coagelometer employed, based on a photoelectric readout of the coagulation, was complex and no details were given as to the reproducibility and reliability of the method employed. No data were presented on the assay of heparin employing plasma.

The accepted procedures employed in the assay of heparin are generally time-consuming (a few hours to several days) and subjective to a large extent. It was considered desirable to simplify the assay procedure and to obtain a more precise end point determination by detecting clotting times by the use of the Fibrometer[1] precision coagulation timer. Recently Barnett and Pinto (6) and Fletcher *et al.* (7) presented data describing the performance of the instrument in the determination of coagulation times.

Attempts to employ the standard U.S.P. heparin assay procedure using the precision coagulation timer were unsuccessful in our hands.

The use of a diatomaceous silicate[2] in the partial thromboplastin time assay by Struver and Bittner (8) prompted an investigation of the effect of this "activating" agent on plasma clotting times. As a result, the necessary conditions for a simple and reliable assay for heparin activity were obtained by modification of the U.S.P. assay procedure by the addition of the diatomaceous silicate. This report summarizes the new *in vitro* assay procedure, its assets, and limitations.

EXPERIMENTAL

Apparatus—The precision coagulation timer and standard accessory equipment were employed. The automatic pipet was set to deliver 0.1 ml. The thermal Prep-Block precision heating unit was used to provide a constant supply of disposable plastic Fibrotube[1] cups preheated to 37 ± 0.5°.

Freezing point depression readings were obtained on 0.9% sodium chloride solution using a Beckman molecular weight apparatus to assure isotonicity.

Chemicals and Reagents—Dry sodium heparin preparations were obtained from three sources; these preparations were stored at −20° in their original containers over desiccant; the units/mg. are their assigned potencies.

(*a*) Second international standard for heparin, described by Bangham and Mussett (9), from the National Institute for Medical Research, Mill Hill, England: 130 units/mg.

(*b*) U.S.P. sodium heparin reference standard; lot H, U.S.P., New York, N.Y.: 2.8 units/mg.

(*c*) Sodium heparin; Pharmaceutical Division, Wilson Laboratories, Chicago, Ill: 143 units/mg.

A stock diatomaceous silicate reagent was made by suspending 1.5% of the diatomaceous silicate (w/v) in 0.025 *M* calcium chloride in distilled water and stored at room temperature.

Citrated plasma was obtained by bleeding healthy sheep as directed under *assay* in the U.S.P. monograph entitled "Sodium Heparin" (10). Various plasma lots, from individual sheep, were obtained in approximately 100-ml. volumes and stored in the frozen state at −20°. The 100-ml. volumes of plasma were subsequently thawed, thoroughly mixed, subdivided into 10-ml. portions in screw-capped borosilicate vials, and stored at −20°.

Assay Solution Preparations—A fresh heparin sample (tablet or powder) was used for each assay. Dry heparin was weighed and appropriate dilutions made in 0.9% sodium chloride for stock concentrations as follows: 0.33, 0.36, 0.39, 0.42, 0.45, and 0.48 units/ml., according to labeled potency. The heparin assay solutions were maintained at room temperature during the assay period.

A 10-ml. portion of frozen plasma was thawed, mixed, brought to 37°, and decanted into 10-ml. borosilicate glass-stoppered volumetric flasks, then placed for use in an ice bath at 0°. A freshly thawed 10-ml. portion of plasma was prepared daily for each assay. One 10-ml. portion is more than sufficient to complete an assay as presented in Table III.

The diatomaceous silicate reagent was maintained at 37° ± 0.5° in a water bath.

Clotting Time Assay—The control clotting time (CCT) of citrated sheep plasma was determined by delivering 0.1 ml. of 0.9% sodium chloride into each of three or four disposable plastic cups which were then equilibrated at 37° for 3 min. or longer. One-tenth milliliter of plasma was then added to the first plastic cup placed in the center well of the coagulation timer. Precisely at the end of 30 sec., 0.1 ml. of the diatomaceous silicate reagent, preheated to 37° ± 0.5° and well mixed by a magnetic stirring bar, was delivered, with moderate force, into the 0.9% sodium chloride–plasma mixture and the timer started automatically.

When the coagulation timer digital read-out mechanism stopped, the probe assembly was immediately removed, the probes rinsed with fresh 0.9% sodium chloride, brushed gently with a soft-bristle toothbrush, rinsed once again, and blotted dry. The clotting time, in seconds, was recorded. The digital timer was reset to zero and the probe assembly reinserted into the instrument and the next determination immediately made using the second plastic cup containing 0.1 ml. of 0.9% sodium chloride. The procedure was repeated again until three or four determinations were obtained. Each determination required approximately 4 min. to complete.

For the assay of heparin standards and unknowns 0.1-ml. volumes of the various heparin concentrations were substituted for the 0.9% sodium chloride solution.

Plasma control clotting times (CCT) were determined before and after heparin assay. Times were averaged and subtracted from the clotting times (HCT) obtained from the heparin determinations.

RESULTS

At a constant calcium chloride concentration (0.025 *M*), as seen in Fig. 1, a concentration of 1.5% (w/v) of the diatomaceous silicate was found suitable for the determinations since the least variation of plasma clotting times was observed at this value.

It was apparent that the average CCT was dependent upon the plasma lot employed, as shown in Table I. In practice it was found that the CCT was constant to within ± 5 sec. of the average during the assay period. Qualitative observation on plasma stored in the frozen state for a period of 1 year did not reveal apparent changes in clotting time. For example, lot No. 1 plasma assayed initially gave an average CCT value of 123.6 ± 8 sec. for 15 assays; 11 months later, the average CCT value of 125.4 ± 8 sec., for 7 assays, was obtained.

A study was made to determine the optimum plasma concentration for use in the assay in order to establish the plasma control clotting time (CCT). Various dilutions of plasma were assayed and the results are shown in Fig. 2. A concentration of 0.33 ml. plasma per ml., in the final assay mixture, was chosen for experimental convenience and reliability. The clotting times obtained on the same lot of plasma on assays performed on *different days* are summarized in Table II. The change observed in Table II (9/7/66 to 12/15/66) is attributed to the introduction of a new preparation of the diatomaceous silicate reagent as indicated. The average value of 7 CCT determinations on lot No. 3 of sheep plasma, performed on the *same day* (12/19/66), during a regular assay was 92.8 sec., with a standard deviation of ± 2.02 sec., and a coefficient of variation of 2.19% (Table III). It was observed that thawed plasma, maintained at 0° (ice bath), displayed a continuous increase in clotting time as a function of the duration of storage as shown in Fig. 3. Attempts to correct for this effect of plasma inactivation, on standing during the assay procedure, provided no significant improvement in linearity of response.

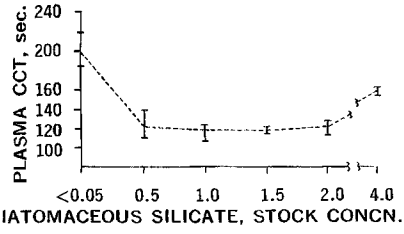

Fig. 1—Effect on the control clotting time (CCT) of citrated sheep plasma, in seconds, due to varying the concentration of the diatomaceous silicate in 0.025 M *calcium chloride. The concentration of citrated sheep plasma and 0.9% sodium chloride diluent were held constant.*

TABLE I—VARIATION OF CCT BETWEEN SHEEP PLASMA LOTS

Plasma Lot	Av. CCT
1	125.4 ± 8 sec. (7 assays)
2	94.4 ± 8 sec. (7 assays)
3	100.2 ± 8 sec. (6 assays)

12/19/66	92.8

[a] New preparation of diatomaceous silicate–calcium chloride reagent introduced.

For the assay of heparin potency, concentrations of the various heparin preparations were chosen which would result in a range of clotting times from 110 to 250 sec. corresponding to approximately 0.11 to 0.16 heparin units/ml. in the final assay mixture. A comparative assay was performed between U.S.P. heparin reference standard lot H (curve U), and the second international standard for heparin (curve I), Fig. 4. From the curves (Fig. 4) there were obtained slope values corresponding to about 0.001 Δ heparin units of activity/second. Additional slope values of calibration curves plotted for eight heparin assays employing sheep plasma lot No. 3, ranged from 0.0007 to 0.0016 units/second and together averaged 0.001 Δ units/second. The assay precision was shown in obtaining clotting times having a standard deviation of ± 2.77 sec. and a coefficient of variation of 1.71%, Table III. Details of Table III are also presented to illustrate sample data collection in the assay method.

The results of comparative assays employing U.S.P. heparin lot H and the second international standard for heparin are summarized in Table IV. The U.S.P. reference standard lot H is approxi-

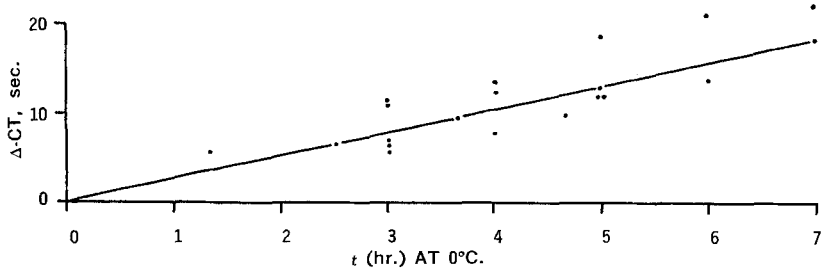

Fig. 3—Spontaneous inactivation curve (change in clotting time: Δ CT) of citrated sheep plasma, thawed, then stored at 0° in an ice bath. The slope of the curve shows a change of 0.0418 sec. in clotting time per minute of storage. The curve, illustrated, represents the average of seven assays, the slopes being 0.0309, 0.0342, 0.0366, 0.0437, 0.0445, 0.0474, and 0.0560 sec./min., respectively.

mately 10% higher in potency when compared to the second international standard for heparin.

To arrive at the percentage difference, shown in Table IV, the assumed potency in units/ml., of the unknown is divided into the difference in units/ml., between the unknown and the extrapolated potency derived from the standard curve. Reference to Fig. 4 will show that an assumed heparin potency of 0.120 units/ml. (curve U) is equivalent to an extrapolated value of 0.132 units/ml. (curve I), or a difference of 0.012 units representing a 10% higher potency.

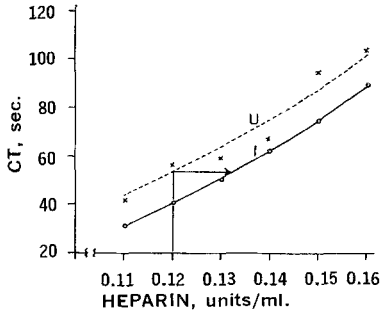

Fig. 4—Comparative assay of heparin potency. The U.S.P. heparin reference standard, curve U. *The second international standard for heparin, curve* I. *Clotting time (CT) in seconds, ordinate, were obtained by subtracting the plasma control clotting time (CCT) from the clotting time values obtained on the addition of heparin (HCT).*

8/25/66	7.2
9/2/66	11.0
12/15/66	11.5
12/19/66	10.0
	Av. 10.4%

Finally, it was of interest to determine the effect of autoclaving and irradiation on heparin potency. Fifty-milliliter solutions containing commercial samples of sodium heparin, in concentrations ranging from 0.5 mg./ml. to 16.0 mg./ml., were autoclaved at 121° for 45 min. Appropriate dilutions were made and the assays of these solutions revealed a negligible change from the control heparin activity.

Vacutainer[3] specimen tubes (3200KA), each containing about 140 units of dry sodium heparin, were irradiated by high energy electrons in a Hughes linear electron accelerator at dosages of 5 and 8 Mrads, at 6 to 7 Kw., 9 Mev., and 500 pulses per second. The assay revealed a loss in potency of approximately 15% as compared to appropriate controls.

[3] Vacutainer is a registered trademark of Becton, Dickinson and Co., Rutherford, N. J.

DISCUSSION

The accepted assay procedures for heparin are generally complex and subjective. The results of this investigation have led to the development of a rapid, simple, and objective *in vitro* procedure. Considerable effort was expended in obtaining plasma having reproducible and consistent control clotting times. It was found that, employing the precision coagulation timer and a diatomaceous silicate modified sheep plasma reagent, clotting times of approximately 100 sec. were obtained with a standard deviation of ± 2.5 sec. and a coefficient of variation of 2.0%. This was accomplished by the addition of 0.025 *M* $CaCl_2$, containing 1.5% of the diatomaceous silicate, to citrate sheep plasma. Just as in the Struver and Bittner method for the assay of thromboplastin activity (8), the diatomaceous silicate was found to serve as an excellent anion glass-activator for obtaining the useful clotting times. The effect of the diatomaceous silicate was not only to accelerate the clotting time but also to yield reproducible and predictable clotting time behavior without apparent interference with the heparin assay. Citrated sheep plasma, when stored in the frozen state for as long as 1 year, was found to be useful in the assay.

The spontaneous inactivation curve of citrated sheep plasma (Fig. 3) stresses the importance of assaying "standard" heparin preparations when comparisons are being made with unknown heparin preparations. The daily variations in clotting times, within the same lot of plasma, are difficult to interpret; however, these variations could be attributed to foreign contaminants, to subtle difference in concentrations of platelets, or to changes in other clotting factors.

In order to assay heparin, the differences in clotting time between the control and the samples containing an unknown heparin were obtained. A calibration plot was made of the differences in clotting time *versus* the heparin concentration in units/ml. (Fig. 4). No attempt was made to plot either curve by regression analysis because of the curvilinear characteristic. Curve I, based on observed CT values obtained with the second international standard for heparin, was amenable to visual plotting. No explanation, however, can be offered for the scatter of the observed U.S.P. heparin standard CT values used to draw curve U. This scatter, although random (Fig. 4), was observed with several of the comparative assays employing the U.S.P. sodium heparin reference standard; the second international standard for heparin gave very little scattering. Final potency values calculated from the illustrated curves, or from linear curves based upon a semilog plot, were the same.[4] Linearity was achieved as a function of heparin concentration in the range of from 0.11 to 0.16 units/ml. At lower concentrations of heparin, the curves become asymptotic and hence not suitable for assay, while at concentrations higher than 0.16 units/ml. there was an exponential increase in clotting times, rendering the curves inaccurate. Assay of heparin concentrations higher than 0.16 units/ml. required that dilutions be made to achieve clotting time values in the range of 110 to 250 sec.

U.S.P. heparin lot H exhibited a potency 10% greater than the second international standard for heparin by the method described; however, Burck (11), using the U.S.P. procedure for sodium heparin assay, noted a similar difference. It should be pointed out that the U.S.P. heparin reference standard is dispensed in the form of tablets with the units based on the weight of the tablet. A small variation in the composition of each tablet mixture may also contribute to the difference in reported activity as shown in Table IV. This observation was also noted by Burck (11).

It was of interest, in the course of this study, to determine the effect of autoclaving and irradiation on the stability of heparin preparations. Assays of sodium heparin solutions, autoclaved at 121° for 45 min., demonstrated no significant deterioration in the potency. This corroborates the findings of Pritchard (12) and Hejgard (13), who reported that autoclaving had little effect on the anticoagulant activity of heparin. Dry sodium heparin, irradiated at dosages of 5 and 8 Mrads, showed a 15% loss in potency indicating the relative stability of the material to high energy electrons.

Determination of Calcium in Official Calcium Phosphates

By JUNG SOOK KIM and MURRAY M. TUCKERMAN

The assay of official calcium phosphates for calcium can be brought into the general method for calcium determination by titration with EDTA using hydroxynaphthol blue indicator by dissolving the sample in a strictly limited amount of hydrochloric acid, passing an aliquot of the solution through a column of anion-exchange resin in the chloride form, washing out the calcium ion with water, and determining calcium in the eluate. The method is comparable in precision with the official method for calcium in dibasic calcium phosphate, but requires much less time.

In 1965 Butler, Maurina, and Morecombe (1) showed the utility of hydroxynaphthol blue as an indicator in the direct titration of calcium with disodium ethylenediaminetetraacetate (EDTA). All of the pharmaceutical substances official in U.S.P. XVII and N.F. XII which are assayed for calcium are assayed by direct titration with standard EDTA and this indicator with the exception of dibasic calcium phosphate U.S.P., which is assayed by the titrimetric determination of oxalate in a precipitated calcium oxalate with standard permanganate. This duality in methods arises from the present impossibility of a direct complexometric titration of calcium in the presence of large amounts of phosphate.

Calcium has been determined complexometrically in the presence of phosphate by addition of excess complexing agent and determination of the excess (2–9) and also after separation of calcium from phosphate by ion exchange (10–20). From a review of the literature it appeared that a simple, rapid, elegant, direct titrimetric determination of calcium in calcium phosphates was possible.

EXPERIMENTAL

Reagents—All reagents employed were reagent grade chemicals. All standard solutions employed were prepared and standardized according to the official compendia.

Methods—*A*—N.F. XI method (21).

B—Proposed Method—Charge a glass column about 37 cm. long and 2.5 cm. in diameter, fitted with a stopcock and delivery tip, with about 40 Gm. of Amberlite IRA-400 (Cl) resin previously hydrated for about 1 hr. Place about 500 mg. of dibasic calcium phosphate, previously ignited at 800° to constant weight and accurately weighed, in a 100-ml. beaker and dissolve it in 2.5 ml. of 1:2 hydrochloric acid by heating. Transfer the solution to a 100-ml. volumetric flask, dilute to volume, and mix well. Pass a 20.00-ml. aliquot of the sample solution through the ion-exchange column at a flow rate of about 0.5 ml. per minute, collecting the effluent in a 500-ml. conical flask. Wash the column with 175 ml. of water, passing the first 25 ml. at a rate of 0.5 to 1 ml. per minute, the next 50 ml. at about 4 ml. per minute, the next 50 ml. at about 8 ml. per minute, and the last 50 ml. at free flow, collecting the effluents in the same conical flask as the sample aliquot. Add 15 ml. of sodium hydroxide T.S. and about 300 mg. of hydroxy naphthol blue, A.R. indicator, and mix well. The pH of the solution should be between 12.5 and 13.0. Titrate the solution with standard 0.05 *M* disodium ethylenediaminetetraacetate to a change of color from purple to deep blue.

After passage of three samples the ion-exchange column is regenerated by passing through it about 200 ml. of 1 *M* sodium chloride solution at about 5 ml. per minute and washing with 3 to 4 L. of water until there is little free chloride present as shown by testing the effluent with silver nitrate.

RESULTS

Five determinations of a single sample by method *A* gave an average result of 98.9 ± 0.1%. Five determinations of the same sample by method *B* gave an average result of 99.1 ± 0.8%. The standard deviations were calculated from the range of values obtained by the method of Dean and Dixon (22).

Method *B* was also applied to tribasic calcium phosphate N.F. using an ignited sample of about 200 mg. Five determinations gave an average value for calcium of 37.5 ± 0.3%.

DISCUSSION

This assay is of interest from the philosophical standpoint of development of standard methods of assay for specific ions and also from the physical chemistry of the ion-exchange process. For reasons of convenience and economy, it was decided to attempt to use the anion-exchange resin in the commercially available chloride form rather than in the hydroxyl form which is expected to be more efficient. The resin has less affinity for the dihydrogen phosphate anion than for chloride (23).

Since the reactions of ion exchange are stoichiometric and reversible, one may write the equilibrium $aM_1/bR + bN_1/aX \rightleftarrows aN_1/aR + bM_1/bX$, in which M is the anion attached to the univalent resinate cation R and N is the anion added with the univalent

Received April 14, 1967, from the School of Pharmacy, Temple University, Philadelphia, PA 19122

Accepted for publication June 22, 1967.

Presented to the Drug Standards, Analysis and Control Section, A.PH.A. Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

Abstracted in part from a thesis submitted by Jung Sook Kim to the Graduate School, Temple University, Philadelphia, Pa., in partial fulfillment of Master of Science degree requirements.

cation X. If these letter symbols are allowed to stand for concentration, and the subscripts r and w are used to indicate the resin and the outside solution, respectively, then one can write the classical law of mass action $N_r{}^a M_w{}^b / M_r{}^a N_w{}^b \simeq K$. If K is approximately constant for a given exchange, the numerical value is a measure of preference of the resin for the ion. Note, however, that K is dimensionless only if a and b are equal, so that comparison of ion affinities can be made only for exchanges of ions of the same type, that is, univalent-univalent, univalent-bivalent, *etc.* Despite the limitations of the theory, there is general knowledge that for similar ions affinity increases with increasing ionic charge.

On the basis of the foregoing discussion it is seen that the concentration of hydrochloric acid is critical. There must be enough to dissolve the sample in a reasonable time but not so much chloride ion present as to prevent complete exchange of phosphate. Additionally, a low hydrogen-ion concentration favors the multivalent anion in the equilibrium $H_2PO_4^- \rightleftarrows H^+ + HPO_4^{-2}$.

The importance to be attached to the difference in standard deviations between methods A and B is difficult to evaluate. The standard deviation for the assay of dibasic calcium phosphate is expected to be about 0.4 for either method. A collaborative study with sufficient replicates is needed to establish any real difference in the reproducibility of the two methods. The two methods yield the same result within the expected standard deviation.

No comparisons can be made in the assay of tribasic calcium phosphate as the official method is the determination of phosphate.

CONCLUSIONS

The proposed method is much more rapid than the official method of assay for dibasic calcium phosphate, has acceptable reproducibility, and yields the same result as the official method.

Pharmaceuticals Stored in Plastic Containers

By HAROLD M. BEAL, ROBERT J. DICENZO, PAUL J. JANNKE, HENRY A. PALMER, JULES PINSKY*, MORRIS SALAME*, and TULLY J. SPEAKER

IN THE DEVELOPMENT of light weight highly mobile combat support hospitals and medical treatment facilities, the U. S. Army Medical Research and Development Command recognizes the need for the standardization of pharmaceutical containers in addition to the reduction of their weight, cube, and breakage. The following excerpt from the USAMRDC bulletin, "Development Requirements," describes the general characteristics for nonglass containers which are sought for drugs, biologicals, and reagents:

"Purpose: The purpose of this requirement is to develop a family of immediate containers for drugs, biologicals and reagents that will materially reduce the packaged bulk of such items. These containers are to be compatible with contents and be suitable for use in any field environment and under all tactical conditions. They will be of standard size and shape, light weight, small cube and chemical-gas-temperature-breakage resistant."

Quite logically, the question arose as to the stability of drugs packaged in containers other than glass. Since certain plastics possess, at least in part, the characteristics sought, a project

cation X. If these letter symbols are allowed to stand for concentration, and the subscripts r and w are used to indicate the resin and the outside solution, respectively, then one can write the classical law of mass action $N_r{}^a M_w{}^b / M_r{}^a N_w{}^b \simeq K$. If K is approximately constant for a given exchange, the numerical value is a measure of preference of the resin for the ion. Note, however, that K is dimensionless only if a and b are equal, so that comparison of ion affinities can be made only for exchanges of ions of the same type, that is, univalent-univalent, univalent-bivalent, *etc.* Despite the limitations of the theory, there is general knowledge that for similar ions affinity increases with increasing ionic charge.

On the basis of the foregoing discussion it is seen that the concentration of hydrochloric acid is critical. There must be enough to dissolve the sample in a reasonable time but not so much chloride ion present as to prevent complete exchange of phosphate. Additionally, a low hydrogen-ion concentration favors the multivalent anion in the equilibrium $H_2PO_4^- \rightleftarrows H^+ + HPO_4^{-2}$.

The importance to be attached to the difference in standard deviations between methods A and B is difficult to evaluate. The standard deviation for the assay of dibasic calcium phosphate is expected to be about 0.4 for either method. A collaborative study with sufficient replicates is needed to establish any real difference in the reproducibility of the two methods. The two methods yield the same result within the expected standard deviation.

No comparisons can be made in the assay of tribasic calcium phosphate as the official method is the determination of phosphate.

CONCLUSIONS

The proposed method is much more rapid than the official method of assay for dibasic calcium phosphate, has acceptable reproducibility, and yields the same result as the official method.

Pharmaceuticals Stored in Plastic Containers

By HAROLD M. BEAL, ROBERT J. DICENZO, PAUL J. JANNKE, HENRY A. PALMER, JULES PINSKY*, MORRIS SALAME*, and TULLY J. SPEAKER

IN THE DEVELOPMENT of light weight highly mobile combat support hospitals and medical treatment facilities, the U. S. Army Medical Research and Development Command recognizes the need for the standardization of pharmaceutical containers in addition to the reduction of their weight, cube, and breakage. The following excerpt from the USAMRDC bulletin, "Development Requirements," describes the general characteristics for nonglass containers which are sought for drugs, biologicals, and reagents:

"Purpose: The purpose of this requirement is to develop a family of immediate containers for drugs, biologicals and reagents that will materially reduce the packaged bulk of such items. These containers are to be compatible with contents and be suitable for use in any field environment and under all tactical conditions. They will be of standard size and shape, light weight, small cube and chemical-gas-temperature-breakage resistant."

Quite logically, the question arose as to the stability of drugs packaged in containers other than glass. Since certain plastics possess, at least in part, the characteristics sought, a project

concerned with the stability of pharmaceuticals packaged in polyethylene containers was jointly conducted by the School of Pharmacy, University of Connecticut, and the Monsanto Co., under the auspices of the U. S. Army Medical Research and Development Command. Because a package is a two-phase system consisting of a container and its contents, and since both phases can react with their environment, either individually or jointly, it was deemed essential for the performance of the containers to be evaluated by specialists in the properties, manufacture, and testing of plastic bottles.

Extensive experience has shown that virtually all pharmaceuticals undergo deterioration of some order with the passage of time. Both the rate and the extent of deterioration vary widely among drugs, and the rate usually is influenced by environmental conditions. The basic question which then arises is, "Do these same drugs decompose more rapidly when packaged in plastic than they do when packaged in glass?" One of the primary features of the study, therefore, becomes the comparison of the stability of a given pharmaceutical which has been packaged in both types of containers. Attention was not directed to studying the basic stability *per se* of any one drug. Because of their inherent nature, however, data which have been accumulated can and will serve as a basis for recommending that certain drug preparations should not be stored at all, or at most for limited intervals at certain temperature-humidity conditions, irrespective of what the containers might be.

A second feature of the study is the evaluation of the performance of the plastic containers, both separately and in conjunction with their contents, leading ultimately to the drafting of chemical and physical specifications for the polymer resin (and additives) and for the plastic containers as well.

EXPERIMENTAL DESIGN

Pharmaceuticals Used

The pharmaceuticals upon which the study is based include 96 of those used in greatest quantity by the U.S. Army Medical Service in the treatment facilities of its 400 bed evacuation hospitals. Representing a typical variety of medicinal agents, the samples include 45 kinds of tablets, 6 of capsules, 17 of liquids, 19 of powders, and 9 of ointments. The drugs to be used were designated by the Army Medical Research and Development Command, and were purchased by the Defense Medical Supply Center from the usual suppliers of the respective drugs to the army. Taken from single manufacturing lots which were less than 6 months old, the drugs were shipped directly to the project laboratories at the University of Connecticut. The pharmaceuticals are identified by nonproprietary name in Table I.

Containers and Closures

The choice of polyethylene as test container was based on the recommendation of Mr. Jules Pinsky. It was pointed out that high density polyethylene (0.95–0.96) was being used extensively in the packaging of foods and household commodities, and that the polymer resin formulations could be selected from those which had been accepted by the Food and Drug Administration for the packaging of foods and related items. This was not intended to imply that FDA acceptance of polyethylene for the packaging of foods predetermined the acceptability of the plastic for packaging drugs. Such limited acceptance, however, did serve as a logical point of departure because foods and drugs have much in common with regard to their complexity, gross stability, *etc.*

The plastic containers used for packaging experimental samples initially were 125-ml. oblong, amber (meeting U.S.P. requirements for light resistance) bottles of 0.96 d. polyethylene supplied and recommended by the Monsanto Co. as being best suited for this purpose. Their weight was approximately 15 Gm., and the nominal wall thickness was 0.030 in. The high density polyethylene bottles were used preferentially because of their rigidity and lower permeability characteristics. They are, however, more subject to stress cracking than are the lower density, more pliable containers. Therefore, when cracking occurred or when excessive loss of volatiles was a problem, samples were repackaged in either 0.95 d. or epoxy-lined polyethylene containers, as conditions warranted. Identical drug samples intended to serve as controls were packaged in 4-oz., wide mouth, square amber jars manufactured by Armstrong Cork Co. of U.S.P. type III glass.

Both types of containers were fitted with white coated tinplate caps in which the liner was a 0.035-in. pulpboard faced with white pigmented Vinyliner. In addition, each bottle was fitted with another laminated cap liner which consisted of polyethylene-coated aluminum foil on a Kraft paper backing. This liner is identified as Flexkin 200F. Mil B-131, Acme Backing Co. In the case of the polyethylene bottles, this liner was heat sealed onto the bottles immediately after they were filled with drug samples, thereby producing a sealed and continuous enclosure for the contents. This was regarded as an effective means of limiting the loss of volatile components to the permeation process. Sealing with an adhesive was tested, but found to be less desirable. Heat seals applied with a thermostatically controlled sealing iron were found by positive pressure testing to be uniformly effective. The polyethylene laminate was not sealed onto the glass bottles. Screw caps were applied to all bottles with a torque of 15 in.-lb. Thus, the polyethylene bottles were heat-sealed, reinforced by a metal cap, while the glass bottles had a comparable pressure seal only. Thereupon, the loss of weight by the drug in polyethylene could be attributed to permeation, whereas loss by the drug in glass was a function of liner-cap leakage.

Storage Conditions

Reserves of all commodities are subjected to various storage conditions, the nature of which are dependent upon numerous factors. These conditions, supplemented by the conditions encountered

in transit, represent what might be designated as the "storage history" of the commodity. The storage history of commodities for the civilian market within the continental United States reflects only rarely conditions which are beyond control, if and when control is desired. Military materiel, on the other hand, can be subjected to indefinite transportation and storage conditions in domestic and foreign depots where regulated environmental conditions may be desired, but are wholly impossible. For many reasons, therefore, the environmental conditions to which drugs in both types of containers were exposed include and extend beyond those usually applied in conventional stability testing programs involving products for civilian use. It should be recognized, therefore, that these broad extremes tend to establish stability requirements which generally embrace and extend beyond the performance demanded for civilian market needs.

Automatically controlled walk-in type environmental chambers were specially constructed for the project by Harris Refrigeration Co., Cambridge, Mass. Each of the six units bore recording devices such that the constancy of the respective environments (temperature and humidity) could be noted and recorded. The environmental conditions employed throughout the storage intervals were as follows: 140°F., 14% relative humidity (ambient); 100°F., 27% relative humidity (ambient); 100°F., 80% relative humidity (controlled); 73°F., 50% relative humidity (controlled); 73°F., 80% relative humidity (controlled); 40°F., 80% relative humidity (ambient); −65°F., ambient relative humidity cycling between −65°F. and 140°F.

The condition described as 73°F., 50% relative humidity is that which prevailed throughout the air-conditioned laboratory in which the project was conducted. Samples of pharmaceuticals exposed to this environment were stored on open metal shelving, protected from direct sunlight, yet exposed to the prevailing complement of daylight and fluorescent light.

The environment called "cycling" was programmed so that each sample was subjected to a 6-day cycle consisting of 2 days at 140°F., then 2 days at −65°F., and finally another 2 days at 140° F., whereafter the samples were equilibrated to room temperature for evaluation. Samples were prepared for storage under all other environmental conditions described for intervals of 6, 12, 24, and 48 weeks. If gross container failure was noted at the end of any one interval, in any one environment, that drug was repackaged in 0.95 d. or in epoxy-lined polyethylene bottles, as conditions warranted; ideally, the lower density bottles to overcome stress cracking, and the epoxy-lined bottles to minimize loss of volatiles from the formulation.

If any sample showed physical or chemical decomposition slightly beyond the tolerable limits at the end of an exposure interval, other than 48 weeks, it was carried through the next exposure interval as a matter of assurance. Gross physical or chemical decomposition, on the other hand, was cause for immediate termination of further testing.

Preparation of Samples for Storage

At the initiation of this study, it was recognized that the rate of progress was substantially predetermined by the rate of assaying, which in turn was dependent on analytical methods, personnel, and equipment. Programming of the samples throughout the test period was therefore developed with these controlling factors in mind.

Six samples of each pharmaceutical product, 3 in polyethylene and 3 in glass to serve as controls, were packaged for storage in each of the environments for the intervals stated. (This amounted to 16,704 individual sample bottles, not counting repacks necessitated by container failure. For the latter reason, an additional 528 sample bottles were packaged.) Samples approximating 100 Gm. were weighed to the nearest milligram into tared test bottles, such that changes in net weight during exposure could be recorded. This information was of interest to the subcontractor, whose responsibility it was to evaluate the significance of the loss of volatiles by permeation. Simultaneous with the transfer of pharmaceuticals from their bulk containers to test bottles, moisture content and alcohol content of each sample were determined where applicable.

Stability Evaluation

Testing the stability of pharmaceuticals is designed to determine quantitatively and/or qualitatively the changes which the products undergo during storage. The changes can involve chemical composition and physical characteristics, both of which are usually well defined and are of a proper order in a newly made drug product of high quality. Changes in these features are signs of deterioration or instability of the drug, and measurement or evaluation of them from time to time provides an insight into the stability of the product.

Chemical Testing—Assay procedures were drawn from three sources. When a procedure given in the "United States Pharmacopeia" or in the "National Formulary" was both stability-indicating and applicable on a practical basis to large numbers of samples, the official procedure was used. Some official methods were modified slightly for the simple purpose of improvement or to facilitate multiple runs. Forty official methods were employed; 26 methods were furnished (on a confidential basis) by the manufacturers of the respective drug products; 32 additional stability-indicating procedures were developed in the project laboratories. The remainder were modified official procedures.

Physical Testing—Quite aside from their aesthetic features, the physical characteristics of drug products serve a very important function in therapeutic efficacy. Changes in these characteristics can alter the intended performance in many instances. Furthermore, any drug which has undergone change in physical characteristics is regarded with suspicion as to its wholesomeness, security, and efficacy by both the dispenser and the consumer.

Evaluation of the physical stability of the pharmaceuticals was carried out by the usual methods. Uncoated tablets were subjected to friability, hardness, and disintegration or dissolution tests. Friability was determined with a Roche Friabilator. Tablet hardness was measured with a modified Strong-Cobb hardness tester. Disintegration testing involved the use of the U.S.P. basket-rack assembly. Dissolution tests were carried out on those tablets intended for extemporaneous preparation of solutions. Moisture content was determined

by the Karl Fischer method, where applicable. In a small number of instances, moisture determination by desiccation was necessary. Coated tablets, plain or enteric, were examined for cracked, crazed, or dulled coatings, and were also tested for disintegration, using the appropriate U.S.P. method. Gelatin capsules were examined for cracks, leaks, embrittlement, and for changes in the moisture level of the contents. Liquid pharmaceuticals were examined for crystal growth, precipitation, particulate matter, color change, and solvent loss. Suspension stability was evaluated by degree and ease of resuspension. The consistency of ointments was determined by means of a Haake Roto-Visco viscosimeter and by observation of the extent of separation. Powders were examined for evidence of color change and caking. Finally, all samples were subjected to the usual organoleptic tests, where applicable.

Container Testing—The performance of polyethylene bottles used in the study was evaluated by two criteria—namely, visible and invisible. As samples were removed from the environmental chambers, it was unavoidable that physical changes in some of the polyethylene bottles should be noted. Indeed, in a small number of instances, rupturing of a bottle and loss of contents was evidenced by leakage residues in the chambers even before those samples were scheduled for removal.

The visible types of change included rupturing of the bottle due to one factor or another (see under *Container Failure*), and the swelling or collapse of a bottle. The former is a very positive change and cannot possibly be misjudged. The latter (swelling or collapse), however, occurred to different extents ranging from the obvious to the debatable. For this reason, swelling or collapse of polyethylene bottles is seldom mentioned in the summary report in Table I.

The search for invisible changes in the polyethylene bottles was conducted by the Packaging Division, Monsanto Co., Bloomfield, Conn. At scheduled intervals, plastic bottles from each of the test sets were emptied of their contents and forwarded to the subcontractor, who analyzed them for changes in impact strength, elongation, melt index, tensile strength, evidence of carbonyl oxidation, environmental stress cracking, and/or tensile rupture. In addition, the Monsanto Co. conducted infrared analyses for product absorption by the test bottles and they evaluated the permeability characteristics of the bottles, based on weight changes due to loss of volatiles or gain of moisture during the storage periods. The IBM runs on these data, performed at Monsanto's Data Center in St. Louis, are on file at the project laboratories.

Definitions of Failure

Product Failure—Product stability must be judged on the basis of chemical and physical characteristics and the changes which they undergo. Before a given product can be declared stable or unstable, it is necessary to establish working definitions of these terms, because they are relative rather than absolute. As originally conceived, the purpose of this study was to compare the stability of a drug packaged in plastic with the stability of that drug packaged in glass. A criterion for chemical failure was adopted wherein it was regarded as a loss of more than 10% of the active ingredients initially present; that is to say, a drug was regarded as stable if, after a given storage interval, it retained at least 90% of its zero-time assay value.

The criteria for judging physical test data cannot be defined so neatly as that used in determining chemical failure. This is due to the subjective nature of the physical tests. In these cases, sound judgment based on experience with good practice and an appreciation for consumer acceptance became the sole criteria. Of the more objective physical tests, the only one with official limits is that for disintegration time; if the limit was exceeded, the tablet in question was considered to have failed. Wherever applicable, military specifications for disintegration time limits were applied to tablets having no official status.

Container Failure—A polyethylene container was considered to have failed when it did not protect its contents to the same extent as did glass, except for the 10% tolerance limit adopted. In addition, failure took place when the container ruptured due to a combination of temperature and contents acting as stress cracking agents and/or generating high internal pressure that exceeded the long-term tensile strength of the bottle. Serious loss of volatiles by permeation was also regarded as a form of container failure, as were exudation of lipoidal substances through the bottle wall and excessive absorption of the product by the polyethylene.

SUMMARY OF EXPERIMENTAL RESULTS

The extensive data accumulated during the study are summarized in Table I. Even in abstract form, the tabulation is of necessity lengthy; consequently, repetition has been eliminated as much as possible, without risking misinterpretation, and abbreviation has been utilized extensively. The full meaning of abbreviations and symbols and the identification of specific parameters are given herewith, such that the tabulation conveys the full description of the circumstances which attended the stored drug samples and their containers.

Storage Conditions—Temperatures designated in the identification of all storage conditions are given in degrees Fahrenheit. Relative humidity (R.H.) is associated only with those environments in which the humidity level was under positive control. In all other instances, humidity was ambient. The duration of storage is indicated by an expression such as ". . . /24 wk. at 140°," which means that after being stored for 24 weeks at 140°F., 14% R.H., the product in question was found to have undergone some kind of failure or change. Likewise, the expression ". . . at 140°/6 wk." means that the product was stored at 140°F., 14% R.H., for 6 weeks.

Chemical Stability—Chemical stability is a variform expression of chemical failure. The latter has already been described under *Product Failure* as a loss of more than 10% of the initial concentration of active ingredient. Within the project, it was necessary to differentiate between comparative changes in percentage concentration and the types of container in which the changes occurred. The degrees of failure and the related containers are identified as follows.

Type (C-1): no loss in glass, loss in polyethylene

TABLE I—PRODUCT STABILITY AND CONTAINER PERFORMANCE

Product[f]	Chemical Stability	Physical Stability	Container Performance
1, Sulfadiazine tablets U.S.P., 0.5 Gm.	Passed under all storage conditions/48 wk.	(P-1)/24 wk. at 140° and (P-3)/48 wk. at 140°; both exceed U.S.P. disintegration time	0.96; passed under all storage conditions/48 wk.; permeability negligible; slight absorption of product at 140°/48 wk.; no effect on container function
2, Acetylsalicylic acid tablets U.S.P., 0.325 Gm.	Passed 12 wk. at 140°; see physical failure; passed all other storage conditions/48 wk.	(P-3)/12 wk. at 140°; (P-4)/6 wk. at 140° in glass; salicylic acid crystals on tablets; samples exceed U.S.P. disintegration time	0.96; bottle tensile rupture/12 wk. at 140°; passed all other storage conditions up to and including 100°/48 wk.; permeability negligible
3, Acetylsalicylic acid, phenacetin, and caffeine tablets N.F.	Failed (C-3) within 6 wk. at 140°; passed all other storage conditions/48 wk.	(P-3)/6 wk. at 140°; salicylic acid crystals on tablets	0.96; passed under all storage conditions/48 wk.; permeability negligible
4, Sodium chloride tablets U.S.P., 0.65 Gm.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
5, Deleted from study			
6, Deleted from study			
7, Meprobamate tablets U.S.P., 0.4 Gm.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
8, Sulfisoxazole tablets U.S.P., 0.5 Gm.	Passed/48 wk. at 140°; see physical failure; passed under all other storage conditions/48 wk.	(P-3)/12 wk. at 140°; samples exceed U.S.P. disintegration time	0.96; passed under all storage conditions/48 wk.; permeability negligible
9, Calcium lactate tablets N.F., 0.65 Gm.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; moisture permeability 4.6% gain/48 wk. at 100°; glass control showed 2.5% gain; product permeability negligible
10, Ferrous sulfate tablets U.S.P., 0.325 Gm.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
11, Penicillin G tablets U.S.P., 250,000 units	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
12, Deleted from study			
13, Dried aluminum hydroxide tablets U.S.P., 0.325 Gm.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; moisture permeability 6.6% loss/48 wk. at 100°; product permeability negligible
14, Sodium chloride for solution tablets, 2.25 Gm.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
15A, Erythromycin tablets U.S.P., 0.25 Gm.	Passed under all conditions between 40° and 100°/48 wk., and under cycling; failed (C-3) within 6 wk. at 140°; passed/6 wk. at −65°; see physical failure	(P-3)/6 wk. at 140°; (P-3)/6 wk. at −65°; (P-3)/cycling; in all instances, coating dull, with extensive surface cracking; this failure terminated assaying of −65° samples after 6 wk.	0.96; passed under all storage conditions up to and including 100°/48 wk.;[a] product permeability negligible; moisture permeability 1.1% gain/48 wk. at 100°; glass control also showed 1.1% gain
15B, Erythromycin tablets U.S.P., 0.25 Gm.	Passed under all conditions between −65° and 100°/24 wk.; 140° and cycling samples not assayed; see physical failure	(P-3)/6 wk. at 140°; (P-3)/cycling; pitted, peeling, and dulled coatings responsible for no assays on 140° and cycling samples	0.96; passed under all storage conditions/24 wk.;[b] permeability negligible
16, Chloroquine phosphate tablets U.S.P., 0.5 Gm.	Passed/24 wk. at 140°; passed under all other storage conditions/48 wk.	(P-3)/12 wk. at 140°; (P-3)/12 wk. at −65°; cracked coatings	0.96; passed under all storage conditions/48 wk.; permeability negligible
17, Sodium salicylate tablets U.S.P., 0.325 Gm.	Passed under all storage conditions up to and including 100°; physical failure precluded assay of 140° samples	(P-3)/6 wk. at 140°; extensive cracking; (P-3)/48 wk. at −65° and (P-3)/cycling due to crazing and cracking	0.96; passed under all storage conditions up to and including 100°/48 wk.;[a] permeability negligible
18, Chlorpheniramine maleate tablets U.S.P., 4 mg.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; slight absorption of product at 140°/48 wk.; none at 100°; no effect on container function
19, Chlorpheniramine, phenylephrine, aspirin, phenacetin, and caffeine tablets	Failed (C-3)/6 wk. at 140°; passed under all other storage conditions/48 wk.	(P-3)/6 wk. at 140° and (P-3)/cycling; discoloration and excessive disintegration time	0.96; passed under all storage conditions/48 wk.; slight absorption of product at 140°/48 wk.; none at 100°; no effect on container function
20, Tripelennamine hydrochloride tablets U.S.P., 50 mg.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
21, Methocarbamol tablets, 0.5 Gm.	Passed under all storage conditions/48 wk.	(P-3)/6 wk. at 140° and (P-3)/cycling; marked discoloration and strong amine odor	0.96; passed under all storage conditions/48 wk.; permeability negligible
22, Chlorothiazide tablets N.F., 0.5 Gm.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
23, Sodium bicarbonate, charcoal, and peppermint tablets	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; bottles lost heat seal at 140°/6 wk., due to internal pressure; otherwise passed all storage conditions/48 wk.; permeability negligible

(*Continued on next page.*)

TABLE I—(*Continued.*)

Product[f]	Chemical Stability	Physical Stability	Container Performance
24, Sodium *para* - aminobenzoate, sodium salicylate, and ascorbic acid tablets	Passed/12 wk. at 140° and at −65°; storage terminated —see physical failure; passed all other storage conditions/48 wk.	(P-3)/12 wk. at 140° and (P-3)/12 wk. at −65°; cracked tablet coatings	0.96; passed under all storage conditions up to and including 100°/48 wk.;[a] permeability negligible
25, Acetylsalicylic acid – ethoheptazine tablets	Failed (C-3)/6 wk. at 140°; passed under all other storage conditions/48 wk.	(P-3)/6 wk. at 140° due to crystal growth and discoloration; (P-3)/24 wk. at 100°, 27% R.H., at 100°, 80% R.H., −65° and at cycling; tablets split into two layers during friability test	0.96; bottle tensile rupture after 12 wk. at 140°; passed under all other storage conditions up to and including 100°/48 wk.; permeability negligible
26, Isoniazid tablets U.S.P., 100 mg.	Passed under all storage conditions/48 wk.	(P-3)/48 wk. at 140°; excessive darkening in color	0.96; passed under all storage conditions/48 wk.; product permeability negligible; moisture permeability 1.3% gain/48 wk. at 73°; glass same; slight product absorption/48 wk. at 140°; less at 100°; no effect on container function
27, Alkaline aromatic soln. tablets	Passed under all storage conditions/48 wk.	(P-1)/12 wk. at 140°; loss of aromatics	0.96; passed under all storage conditions/48 wk.; permeability negligible
28, Propantheline bromide tablets U.S.P., 15 mg.	Passed under all storage conditions/48 wk.	(P-3)/24 wk. at 140°; crystal growth on tablet surface	0.96; passed under all storage conditions/48 wk.; permeability negligible
29, Benzethonium chloride tablets, 0.25 Gm.	Failed (C-3)/24 wk. at 140°; passed under all other storage conditions/48 wk.	(P-3)/12 wk. at 140°; tablets discolored and produced discolored solutions	0.96; passed under all storage conditions/48 wk.; permeability negligible; slight container collapse/24 wk. at 140°; slight absorption of product/48 wk. at 140°; none at 100°; no effect on container function
30, Urine sugar test tablets	Failed (C-3)/12 wk. at 140°; passed under all other storage conditions/48 wk.	(P-3)/24 wk. at 140°; tablets discolored	0.96; passed under all storage conditions/48 wk.; permeability negligible; extensive damage to container *after* storage beyond 48 wk. test period; due to tablet reaction with moisture when bottles were opened for sampling; containers burst from heat and pressure
31, Mephenesin tablets N.F., 0.5 Gm.	Passed under all storage conditions/48 wk.	(P-3)/48 wk. at 140°; crystal growth on tablet surface	0.96; bottle rupture due to stress cracking at 140°/12 wk.; passed under all other storage conditions up to and including 100°/48 wk.; permeability negligible
32, Phenobarbital tablets U.S.P., 30 mg.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
33, Deleted from study			
34, Potassium chloride tablets U.S.P., 0.325 Gm.	Passed under all storage conditions up to and including 100°/48 wk.; 140° samples passed/6 wk.; see physical failure	(P-3)/6 wk. at 140°; (P-3)/6 wk. at −65° and/cycling; coatings cracked and/or crazed	0.96; passed under all storage conditions/48 wk.; permeability negligible
35, Aluminum acetate soln. tablets	Failed (C-3)/6 wk. at 140° and/cycling; failed (C-3)/12 wk. under all other storage conditions	(P-3)/6 wk. at 140° and/48 wk. at 100°, R.H. 27%, and 100°, R.H. 80%; tablets crumble to powder	0.96; passed under all storage conditions/48 wk.; permeability of moisture 8.6% gain/48 wk. at 100°; glass control gained 5.5%; permeability product 3.5% loss; glass control lost 6.0%; moderate product absorption/48 wk. at 100°; no effect on container function
36, Ascorbic acid tablets	Failed (C-3)/24 wk. at 140°; passed under all other storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.95; passed under all storage conditions/48 wk.; permeability negligible; slight product absorption at 140°, but less at 100°; no effect on container function
37, Sodium cyclamate and sodium saccharin tablets N.F.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
38, Chloroquine and primaquine phosphate tablets	Passed under all storage conditions/48 wk.	(P-3)/6 wk. at 140°; marked discoloration and foul odor	0.96; passed under all storage conditions up to and including 100°/48 wk.;[a] product permeability negligible; moisture permeability 1.1% gain/48 wk. at 100°; glass control same
39, Reserpine tablets U.S.P., 0.25 mg.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
40, Methenamine mandelate tablets U.S.P., 0.5 Gm.	Passed under all storage conditions/48 wk.	(P-3)/6 wk. at 140°; tablets dull and cracked	0.96; passed under all storage conditions/48 wk.; permeability negligible
41, Deleted from study			

(*Continued on next page.*)

TABLE I—(*Continued.*)

Product[f]	Chemical Stability	Physical Stability	Container Performance
42, Griseofulvin tablets U.S.P., 0.25 Gm.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
43, Belladonna alkaloids with phenobarbital tablets	Failed (C-5)/24 wk. at 140°; passed under all other storage conditions up to and including 100°/48 wk.	(P-6)/24 wk. at 140°; samples darken in color	0.96; passed under all storage conditions/48 wk.; product permeability negligible; moisture permeability 2.1% loss/48 wk. at 100°; glass control 1.7% loss
44, Prednisone tablets U.S.P., 5 mg.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; product permeability negligible; moisture permeability 1.8% gain/48 wk. at 100°; glass control 1.1% gain
45, Ammonium chloride tablets U.S.P., 0.5 Gm.	Passed under all storage conditions up to and including 100°/48 wk.; 140° samples passed/24 wk.; see physical failure	(P-3)/6 wk. at 140°; (P-3)/6 wk. at −65° and/cycling; tablet coatings cracked and/or crazed	0.96; passed under all storage conditions up to and including 100°/48 wk.;[a] permeability negligible
46, Glutethimide tablets N.F., 0.5 Gm.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible; slight product absorption at 140°/48 wk.; less at 100°; no effect on container function
47, Probenecid tablets U.S.P., 0.5 Gm.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
48, Sodium aminosalicylate tablets U.S.P., 0.5 Gm.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; product permeability negligible; moisture permeability 2.3% gain/48 wk. at 100°; glass control 2.0% gain
49, Thiamine hydrochloride tablets U.S.P., 50 mg.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible; some product absorption/48 wk. at 140°; none at 100°; no effect on container function
50, Tetracycline hydrochloride tablets N.F., 0.25 Gm.	Passed under all storage conditions/48 wk.	(P-3)/48 wk. at 140°; excessive discoloration	0.96; passed under all storage conditions/48 wk.; permeability negligible; containers may show some collapse/48 wk. at 140°
51, Propoxyphene hydrochloride capsules U.S.P., 32 mg.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
52, Chloramphenicol capsules U.S.P., 0.25 Gm.	Passed under all storage conditions up to and including 100°/48 wk. and for 6 wk. at 140°	(P-3)/12 wk. at 140°; excessive discoloration	0.96; passed under all storage conditions/48 wk.; permeability negligible
53, Sodium diphenylhydantoin capsules U.S.P., 100 mg.	Passed under all storage conditions up to and including 100°/48 wk. and for 6 wk. at 140°; see physical failure	(P-3)/12 wk. at 140°; excessive discoloration	0.96; passed under all storage conditions/48 wk.; permeability negligible
54, Diphenhydramine hydrochloride capsules U.S.P., 50 mg.	Passed under all storage conditions up to and including 100°/48 wk. and for 12 wk. at 140°; see physical failure	(P-4)/24 wk. at 140°; product discolored; capsules embrittled in plastic bottles, but softened and stuck together in glass bottles	0.96; passed under all storage conditions/48 wk.; permeability negligible; increase in melt index/48 wk. at 140° about 10%; no change/48 wk. at 100° or 24 wk. at 140°; may be due to slight product absorption; no effect on container function
55, Oleovitamin A capsules, 50,000 units	Passed under all storage conditions/48 wk. except for 140° and cycling; see physical failure	(P-3)/6 wk. at 140° and/cycling; capsules fused into nearly solid mass	0.96; passed under all storage conditions up to and including 100°/48 wk.;[a] permeability negligible
56, Dextroamphetamine sulfate and amobarbital capsules, 15–97 mg.	Passed under all storage conditions up to and including 100°/48 wk.; see physical failure	(P-3)/6 wk. at 140°; discoloration and fusion of pellets within capsules	0.96; passed under all storage conditions up to and including 100°/48 wk.;[a] permeability negligible; elongation/48 wk. at 100° 170% higher than control; normal/24 wk. 100°; may be due to slight absorption of product; no effect on container function
57, Surgical soap with 5% hexachlorophene	Passed under all storage conditions between −65° and 100°/48 wk., and/6 wk. at 140°; see container failure	Passed under all storage conditions/48 wk.	0.96; bottle rupture due to stress cracking at 140°/24 wk. and under cycling; passed under all other storage conditions up to and including 100°/48 wk. may lose heat seals/6 wk. at 140°
58, Terpin hydrate elixir N.F.	Passed under all storage conditions up to and including 100°/12 wk.; see container failure	(P-3)/6 wk. at 140°; change in odor	0.96; bottle tensile rupture/6 wk. at 140°; passed under all other storage conditions up to and including 100°/48 wk.; product permeability 1.5% loss/48 wk. at 100°; moisture permeability negligible; 150% increase

(*Continued on next page.*)

TABLE I—(*Continued.*)

Product[f]	Chemical Stability	Physical Stability	Container Performance
			in resin elongation/48 wk. at 100°; normal values/24 wk. at 100° and/48 wk. at 73°; increase may be due to product absorption; no effect on container function
59, Phenylephrine hydrochloride soln. U.S.P., 1%	Passed under all storage conditions up to and including 100°/48 wk. and at 140°/12 wk.; see physical failure	(P-1)/6 wk. at 140°; (P-3)/12 wk. at 140°; (P-3)/24 wk. at 100°; discoloration	0.96; bottle tensile rupture/24 wk. at 140°; passed under all other storage conditions up to and including 100°/48 wk.; permeability negligible
60, Thimerosal tincture N.F.	Passed under all storage conditions from −65° up to and including 100°/48 wk.; see container failure	Passed under all storage conditions from −65° up to and including 100°/48 wk.	0.96; bottle tensile rupture/6 wk. at 140°; passed under all other storage conditions up to and including 100°/48 wk.; moisture permeability negligible; product permeability 2.7% loss/48 wk. at 100°; glass control 2.5% loss; 0.95 epoxy-lined bottles passed/6 wk. at 140°
61, Piperazine citrate syrup, U.S.P.	Passed under all storage conditions up to and including 100°/48 wk. and/6 wk. at 140°; physical failure/12 wk. at 140° precluded assaying of 12-wk. samples	(P-3)/12 wk. at 140°; (P-3)/48 wk. at 100°, R.H. 27% and at 100°, R.H. 80%; darkening in color	0.96; bottle rupture due to stress cracking at 140°/6 wk.; passed under all other storage conditions up to and including 100°/48 wk.; permeability negligible; some product absorption/48 wk. at 100°; none/24 wk. at 100° or/48 wk. at 73°; no effect on container function
62, Paregoric U.S.P.	Passed under all storage conditions up to and including 73°/48 wk.; see physical failure	(P-3)/6 wk. at 140°, at 100°, R.H. 27%, at 100°, R.H. 80% and at cycling; loss of aromatics	0.95; bottle tensile rupture/12 wk. at 140°; passed under all other storage conditions up to and including 73°/48 wk.;[e] permeability negligible; 0.95 epoxy-lined bottles passed/6 wk. at 140°
63, Alcohol U.S.P.	Passed under all storage conditions up to and including 100°/48 wk.; see container failure	Passed under all storage conditions up to and including 100°/48 wk.	0.95; bottle tensile rupture/12 wk. at 140°; passed under all other storage conditions up to and including 100°/48 wk.; moisture permeability negligible; product permeabibity 2.2% loss at 100°/48 wk.; bottles may lose heat seals/6 wk. at 140°
64, Phenolated and mentholated calamine lotion	Product not assayed	(P-1)/6 wk. at 140°, at 100°, R.H. 27%, at 100° R.H. 80%, and at cycling; loss of menthol and phenol; (P-3)/6 wk. at 40° and at −65°; excessive separation and lowered viscosity	0.96; bottle stress crack/24 wk. at 140°; passed under all other storage conditions up to and including 100°/48 wk.; moisture permeability negligible; product permeability 1.3% loss at 100°/48 wk.
65, Benzalkonium chloride soln. U.S.P., 10%	Passed under all storage conditions up to and including 100°/48 wk.; container failure precluded assay of 140° samples	Passed under all storage conditions/48 wk.	0.96; bottle stress crack/6 wk. at 140°; passed under all other storage conditions up to and including 100°/48 wk.; permeability negligible; 0.95 epoxy-lined bottles passed/6 wk. at 140°
66, Thimerosal soln. N.F.	Passed under all storage conditions/24 wk.; 48-wk. samples not available for assay	Passed under all storage conditions/24 wk.[d]	0.96; bottle stress crack/24 wk. at 140°; passed under all other storage conditions up to and including 100°/24 wk.; permeability negligible
67, Glacial acetic acid	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; bottle tensile rupture/12 wk. at 140°; passed under all other storage conditions up to and including 100°/48 wk.; moisture permeability negligible; product permeability 7.7% loss/48 wk. at 100°; glass control 2.3% loss; some product absorption at 140°, less at 100°; no effect on container function
68, Glycerin U.S.P.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
69, Compd. benzoin tincture U.S.P.	Passed (loss of volatiles) under all storage conditions up to and including 100°/48 wk.; 140° samples lost by container failure	(P-2)/6 wk. at 140°; (P-3)/12 wk. at 140°; excessive loss of volatiles	0.96; bottle tensile rupture/12 wk. at 140°; passed under all other storage conditions up to and including 100°/48 wk.; moisture permeability negligible; product permeability 1.7% loss/48 wk. at 100°

(*Continued on next page.*)

TABLE I—(*Continued.*)

Product[f]	Chemical Stability	Physical Stability	Container Performance
70, Oxytetracycline oral suspension	Failed (C-3)/6 wk. at 140° and/48 wk. at 100°, passed under all other storage conditions up to and including 73°/48 wk.	(P-3)/6 wk. at 140° and/12 wk. at 100°; discoloration	0.96; passed under all storage conditions/48 wk.; permeability negligible
71, Glycyrrhiza fluid extract U.S.P.	Passed under all storage conditions up to and including 100°/48 wk.; see container failure	Passed under all storage conditions up to and including 100°/48 wk.	0.96; bottle tensile rupture/6 wk. at 140°; passed under all other storage conditions up to and including 100°/48 wk.; moisture permeability negligible; product permeability 2% loss/48 wk. at 100°; 0.95 epoxy-lined bottles passed/6 wk. at 140°
72, Belladonna tincture U.S.P.	Passed under all storage conditions up to and including 100°/48 wk.; see container failure	Passed under all storage conditions up to and including 100°/48 wk.; see container failure	0.95; bottle stress crack/6 wk. at 140°; passed under all other storage conditions up to and including 100°/48 wk.; moisture permeability negligible; product permeability 2.5% loss/48 wk. at 100°; 0.95 epoxy-lined bottles passed/6 wk. at 140°
73, Trisulfapyrimidines oral suspension U.S.P.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; bottle stress crack/12 wk. at 140°; passed under all other storage conditions up to and including 100°/48 wk.; permeability negligible
74, Deleted from study			
75, Sodium bicarbonate U.S.P.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
76, Ammonium chloride U.S.P.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
77, Talc U.S.P.	Sample not assayed	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible; moderate product absorption at 140°; no effect on container function
78, Zinc oxide U.S.P.	Passed under all storage conditions/48 wk.; only 48-wk. samples assayed	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
79, Boric acid U.S.P.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
80, Bismuth subcarbonate U.S.P.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible; 83% increase in elongation/48 wk. at 140° which is 22% greater than normal variation; 48-wk. bottles at 100° closer to normal value; may be due to product absorption and plasticization of polyethylene; no effect on container function
81, Pumice U.S.P.	Samples not assayed	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
82, Potassium phenoxymethyl penicillin for oral soln., 3,200,000 units	Passed under all storage conditions/48 wk.	(P-3)/6 wk. at 140° and during cycling; darkening in color and development of foreign odor	0.96; passed under all storage conditions/48 wk.; permeability negligible
83, Acetylsalicylic acid U.S.P.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.95; passed under all storage conditions/48 wk.; permeability negligible
84, Sodium citrate U.S.P.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
85, Potassium iodide U.S.P.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible; melt index increase 17% at 140°/48 wk., but normal at 140°/24 wk. and at 100°/48 wk.; slight absorption of product at 140°, but none at 100°; no effect on container function
86, Sodium borate U.S.P.	Failed (C-3)/24 wk. at 140°; passed under all other storage conditions up to and including 100°/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
87, Terpin hydrate N.F.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
88, Citric acid U.S.P.	Passed under all storage conditions/48 wk.	(P-1)/48 wk. at 140°; loss of water; (P-3)/48 wk. at 100°; samples caked	0.96; passed under all storage conditions/48 wk.; product permeability negligible; moisture permeability 1.0% loss/48 wk. at 100°
89, Monohydrated sodium carbonate U.S.P.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible

(*Continued on next page.*)

TABLE I—(*Continued.*)

Product[f]	Chemical Stability	Physical Stability	Container Performance
90, Calamine U.S.P.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible; increase in elongation 83% which is 22% higher than normal expected at 140°; may be due to product absorption; no effect on container function
91, Magnesium carbonate N.F.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; product permeability negligible; moisture permeability 3.3% loss/48 wk. at 100°; glass control 6.2% loss
92, Magnesium oxide U.S.P.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
93, Precipitated sulfur U.S.P.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible
94, Green soap N.F.	Passed under all storage conditions/48 wk. on basis of pH value	(P-2)/12 wk. at 140° and at 100°, R.H. 27% and at 100°, R.H. 80%; discoloration; (P-2)/24 wk. under all other storage conditions; discoloration progressively increasing with time, ultimately dark brown	0.96; bottle stress crack/48 wk. at 140°; passed under all other storage conditions up to and including 100°/48 wk.; increase in melt index 10%/48 wk. at 140°; normal value for bottles at 100°/48 wk. and at 140°/24 wk.; may be due to product absorption; no effect on container function
95, Ointment base	Product not assayed	(P-3)/12 wk. at 140° and/12 wk. at −65°; excessive separation of phases	0.96; passed under all storage conditions up to and including 100°/48 wk.; also for at least 24 wk. at 140°; borderline acceptability/48 wk. at 140°; slight to moderate increase in tensile strength and melt index/48 wk. at 140°; permeability negligible; some product absorption
96, Hydrophilic ointment U.S.P.	Product not assayed	(P-3)/6 wk. at 140°, /cycling and/12 wk. at −65°; excessive separation of phases	0.96; passed under all storage conditions up to and including 100°/48 wk.;[e] permeability negligible; increase in melt index 35% at 100°, but normal value for 73°/48 wk.; container collapse may occur in the 73° to 140° range/48 wk.; slight product absorption; no effect on container function
97, Zinc oxide ointment U.S.P.	Passed under all storage conditions/48 wk.	(P-3)/6 wk. at 140° and/cycling; excessive separation	0.96; passed under all storage conditions up to and including 100°/48 wk.;[e] permeability negligible; increase in melt index 20% at 100°; normal value/48 wk. at 73°; may be due to product absorption; no effect on container function
98, Nitrofurazone ointment N.F.	Failed (C-3)/6 wk. at 140°; passed under all other storage conditions up to and including 100°/48 wk.	(P-3)/12 wk. at 140°; darkening of color	0.96; passed under all storage conditions up to and including 100°/48 wk.;[e] permeability negligible
99, Modified tar compd. ointment	Passed under all storage conditions up to and including 73°/48 wk.; passed/6 wk. at 100°, R.H. 27% and at 100°, R.H. 80%; see physical failure	(P-3)/6 wk. at 140°; (P-3)/12 wk. at 100°, R.H. 27% and 100°, R.H. 80%; (P-3)/24 wk. at −65°; separation of phases	0.96; passed under all storage conditions up to and including 73°/24 wk.; after 48 wk. at 73° product absorption is too high; tar odor outside of bottles/6 wk. at 140° and/12 wk. at 100°; 0.95 epoxy-lined bottles passed/6 wk. at 140°; no tar odor on outside of bottles
100, Anhydrous lanolin U.S.P.	Passed under all storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; bottle stress crack/12 wk. at 140° and/48 wk. at 100°; passed under all other storage conditions up to and including 73°/48 wk.; melt index increases 90%/48 wk. at 140°; normal value/6 wk. at 140° and/48 wk. at 73°; may be due to product absorption; permeability negligible; 0.96, 0.95, and 0.95 epoxy-lined bottles showed seepage or leakage of product/6 wk. at 140°
101, Ammoniated mercury ointment U.S.P.	Passed under all storage conditions/48 wk.	(P-3)/12 wk. at 140°; excessive separation	0.96; passed under all storage conditions up to and including 100°/48 wk.;[e] in-

(*Continued on next page.*)

TABLE I—(*Continued.*)

Product[f]	Chemical Stability	Physical Stability	Container Performance
			crease in melt index 18% at 100°; normal value at 73°; slight product absorption at 100°, none at 73°; no effect on container function
102, Zinc oxide paste U.S.P.	Failed (C-3)/48 wk. at 140°; passed under all other storage conditions/48 wk.	Passed under all storage conditions/48 wk.	0.96; passed under all storage conditions/48 wk.; permeability negligible; increase in tensile strength 16% at 140°; value normal at 100°/48 wk.; increase in melt index 300% at 140° but only 10%/48 wk. at 100°; may be due to product absorption; no effect on container function

[a] Only 6 wk./140° bottles available; all passed. [b] Assay procedure difficulties delayed initiation of storage such that 48-wk. data are not available. [c] Only 12-wk./100° bottles tested; all passed. [d] Time elapsed due to failure of assay procedure prevented storage of samples for 48 wk. [e] Only 12-wk./140° bottles available; all passed. [f] Names and compendia designations for drugs are as of U.S.P. XVI and N.F. XI since the study commenced while those editions were official.

greater than 10%; type (C-2): loss in glass less than 10%, loss in polyethylene at least 15% greater; type (C-3): parallel or nearly parallel loss in glass and in polyethylene, both being in excess of 10%; type (C-4): loss in polyethylene less than 10%, loss in glass at least 15% greater; type (C-5): no loss in polyethylene, loss in glass greater than 10%; type (C-6): uncertain interpretation of data because of magnitude of experimental error.

Parenthetically, it is interesting to note that only type (C-3) and type (C-5) were encountered; the other possibilities are listed merely to emphasize their absence in the study.

The expression employed throughout to describe chemical stability—namely, "passed under all storage conditions/48 wk.," means that the samples from all environments assayed at the end of 6, 12, 24, and 48 weeks had not lost more than 10% of their initial content of active constituent. Environments and intervals for which this did not hold true are characterized by the expression "failed (C-x)/6 wk. at 140°," and variations thereon. This means that the concentration of active constituent did drop by more than 10% during the 6-week interval when stored at 140°F.

In instances when a sample underwent gross physical failure, it was not practical to assay it; attention is therefore called to the physical failure. In other instances, samples were lost because of container rupture and were not available for assay. Attention is then directed to container failure described in the same tabulation.

Physical Stability—It is noteworthy that the word "failed" is deliberately omitted from all descriptions of physical behavior of drug samples during storage. In some instances, as when coated tablets literally exploded, there is no doubt about the physical failure. In many instances, however, there was a physical change whose significance, as regards the usability of a drug which tested out well chemically, is open to debate. None of those products was declared to have failed outright; their departure from the normal condition is noted, and the reader is urged to impose his own evaluation of the significance of the change.

Physical changes occurred in different degrees and in both kinds of containers. The relationships are identified as follows.

Type (P-1): little or no change in glass, major change in polyethylene; type (P-2): some change in glass, major change in polyethylene; type (P-3): major change in both glass and polyethylene; type (P-4): some change in polyethylene, major change in glass; type (P-5): little or no change in polyethylene, major change in glass; type (P-6): uncertain applicability of other relations as in types (P-1), (P-2), (P-3), (P-4), and (P-5).

Whenever a physical change occurred (failure?), it is so indicated; for example, "(P-3)/6 wk. at 140°," which means that the product in question underwent a parallel change in glass and in polyethylene during 6 weeks of storage at 140°F. Similar expressions are to be interpreted in like manner. If specific reference is made to a physical change at a given environment, it is to be understood that the product maintained its physical integrity at all other environments which have not been so mentioned. The expression "passed under all storage conditions/48 wk." means that the product, taken from all environments, was found to be physically acceptable or intact at the end of 6, 12, 24, and 48 weeks. Variations of this are indicated where they apply. Insofar as is possible, the nature of the physical change which occurred is identified.

Container Performance—Each comment on container performance opens with the identification, *e.g.*, 0.96, of the kind of polyethylene bottle to which the subsequent comments apply. Outright and visible failure of a bottle is positively stated in each instance where it occurred. A common expression used in describing container performance is "passed under all storage conditions/48 wk." This is intended to mean that the polyethylene bottles so described were tested at the end of 48 weeks of exposure and were found to pass all of the evaluating tests described here. Any exceptions to this generalization are specifically noted. In all instances, the container testing program involved comparisons between the test bottles and unused polyethylene controls, and the results are expressed as changes from the normal control values. The specific tests which were applied include the following.

Impact Resistance—The purpose of this test is to determine whether the drug or the environment exercised any deleterious effect on the impact or breakage resistance of the bottle. Test bottles rinsed free of adhering drug were filled (120 ml.) with 50% ethanol and conditioned for 24 hr. at

−10°F., whereupon they were capped and dropped (while cold) from a height of 17 ft. Normal virgin containers do not break on impact.

Average Tensile Strength (ASTM D412-64T)—This is the standard test for the physical strength of plastics. A strip of plastic cut from the wall of a sample bottle is stretched in an Instron tester at the relative rate of 20 in. per minute. The maximum tensile force applied during stretching to the point of rupture is the tensile strength of the specimen.

Average Ultimate Elongation (ASTM 412-64T)—Conducted in conjunction with the tensile strength measurement, this value describes the maximum elongation of the specimen before rupture occurs. It is the ratio of the length of the sample at rupture to its initial length, expressed as per cent.

Melt Index (ASTM 1238-65T)—This is the standard test for measuring flow rate (decigrams/minute) of a molten plastic. It is inversely proportional to the molecular weight, provided other variables are not involved. If the plastic has absorbed any chemical which can act as a plasticizer, the flow rate, or the melt index, will not correlate with the molecular weight.

Infrared Analysis—Comparison of the I.R. absorption spectra for a sample taken from a test bottle and for the unused plastic discloses whether the polyethylene has absorbed drug components or has degraded. A Perkin-Elmer model 21 infrared spectrophotometer was used to scan the samples between 2 and 15 μ. Product absorption in the range of 1% is readily detectable. These spectrograms are on file at the University of Connecticut.

Moisture Permeability—Standard procedure for the plastics industry measures moisture permeability at 100°F., and standard acceptance limits it to 3% per year.

RECOMMENDATIONS

Based on measurements and observations made during the study, it is possible to offer recommendations concerning the use of high density polyethylene bottles for the packaging of drugs, and concerning limitations on the over-all storage of drugs. While the initial intent of the project was to draw a comparison between drug stability in glass and drug stability in plastic containers, the authors would be remiss in their professional responsibilities if they neglected to mention those obvious limitations on the storage of drugs, irrespective of container and environment identity, which they encountered. It must be understood that any recommendations which are offered are limited in their scope to such parameters as are defined in the testing program conditions. Any projection of these recommendations and any extrapolation of the test results become individually assumed responsibilities. Indeed, because of product variation from one manufacturer to another, it may be well for each to use these results merely as guidelines in the testing of his own products.

The major recommendations which have resulted from this study are grouped in two broad categories, based on whether the polyethylene bottles were found to be acceptable or unacceptable containers for the pharmaceuticals in question, strictly within the limits imposed by the test conditions. These recommendations are listed together with the item numbers to which they pertain. (See Table I for number identification and pertinent details.) An asterisk (*) preceding an item number indicates that the regular 0.96 d. polyethylene bottle failed under certain test conditions because of cracking or excessive loss of volatiles from the drug product contained therein. In these cases, epoxy-lined 0.95 d. polyethylene bottles were substituted and were tested for 6 weeks under the same environmental conditions which had caused prior failure of the 0.96 d. bottles. In most instances, the epoxy-lined bottles withstood the test for the 6-week period, but their long-term behavior at environmental extremes is not known.

The instances of acceptability of polyethylene bottles as drug containers are outlined in Table II.

TABLE II—INSTANCES OF ACCEPTABILITY OF POLYETHYLENE BOTTLES AS DRUG CONTAINERS

1. Polyethylene bottles *are* acceptable containers for these items (passed under all conditions of testing):

Items No.		
4	*39*	*79*
7	*42*	*80*
9	*44*	*81*
11	*46*	*83*
13	*47*	*84*
14	*48*	*85*

[a] Throughout the various storage intervals, this item remained intact in the tightly closed containers. However, after all of the tests had been completed, the tablets in glass showed marked physical deterioration, while those in polyethylene had reacted with such intensity that the bottles were partially melted and ruptured. This deterioration was due to the hygroscopic character of the tablets which caused them to take on moisture when their original containers were opened for sampling.

CONCLUSIONS

Certain general conclusions of outstanding nature can be drawn, and numerous others can be derived, from the observations recorded in Table I. Among the most significant are the following.

1. Polyethylene bottles can be used for packaging most of the pharmaceuticals tested under the various environmental conditions. Their performance with regard to the protection of their contents is parallel to that of glass, in most instances.

2. Outright incompatibility of the polyethylene bottle with its contents was rarely encountered under the test conditions.

3. In most instances, the polyethylene bottles themselves stood up well, both chemically and physically.

4. Polyethylene bottles of 0.95 d. offered no apparent advantage over the 0.96 d. bottles where the latter failed because of tensile rupture and/or stress cracking.

5. In most instances of drug failure, whether chemical or physical, failure of the same nature and magnitude occurred both in polyethylene and in glass containers. Thereupon, such failure must have been environmentally induced.

6. The vast majority of product and/or container failures which did occur are associated with the environmental extremes, namely, −65°F., and 140°F., and cycling; the 140°F. temperature was the most damaging.

7. Product and/or container failures were few in number between 40°F. and 100°F.

8. Differences in humidity, *e.g.*, 100°F., 27% R.H., and 100°F., 80% R.H., did not play a significant part in product stability or in container performance. This may be due to the fact that polyethylene is one of the best moisture barrier plastics known.

9. The majority of product failures which did occur were of the physical type rather than of the chemical type.

10. The most common failure among coated tablets was the cracking or crazing of the coating at the very low temperature (−65°F.) and during cycling.

11. Pharmaceuticals which contain highly volatile solvents, such as acetone and alcohol, invariably cause rupture of the polyethylene bottles due to high internal pressure, when stored at elevated temperature. Packaging in 0.95 d. polyethylene bottles provides little or no advantage.

12. Aspirin tablets and formulations containing aspirin failed both chemically and physically within 6 weeks, when stored at 140°F., 14% R.H. At all other temperatures, such tablets were stable throughout the 48-week storage intervals. It is noteworthy that the raw chemical, aspirin U.S.P., is stable even at 140°F., presumably because of the nearly anhydrous character of the chemical.

Isopropanol–Water Granulating Solution Ratio Effect on Physical Tablet Parameters

By LEONARD L. KAPLAN

A chewable multivitamin tablet formulation containing dry malt solids as binder was used as the model in this study to determine the effect of varying the ratio of isopropanol–water granulating solution on hardness, thickness, and disintegration parameters of tablets. Tablet granulations were prepared using (*a*) water, (*b*) isopropanol 25 per cent–water 75 per cent, (*c*) isopropanol 50 per cent–water 50 per cent, (*d*) isopropanol 75 per cent–water 25 per cent, and (*e*) isopropanol. Granulations (*a*) through (*d*) were compressed at a target hardness of 5 to 6 Kg. and a tablet weight of 650 mg. on the Stokes model F single-punch machine. Quantitative determinations of the physical tablet parameters were made initially following the controlled compression, and at selected storage time intervals. Granule size distribution evaluation showed an empirical relationship between solution ratios and granule size distribution as the determinant of differences in tablet thickness. Statistical analysis of the model initial and storage data revealed no significant effects on tablet hardness and disintegration.

THE PURPOSE of this report is to relate the effect of selected volume to volume ratios of isopropanol–water granulating solutions on the subsequent physical properties of a chewable multivitamin tablet formulation[1] containing dry malt solids as the binder. Underlying this objective is the determinant of a satisfactory minimal quantity of water sufficient for the granulation process so as to produce granules suitable for tableting the model formulation with prescribed chewable characteristics, utilizing isopropanol as the distributant co-solvent.

Pertinent references in the recent pharmaceutical literature concerned with granulating procedures have, for the most part, discussed the evaluation of granulating agents and methods (1, 2), the evaluation of new equipment (3), and the measurement of the physical properties of the produced compressed tablets (4). The thrust of this study is to relate the influence of the selected isopropanol–water granulating solutions on the granulations formed, and on the physical properties of the resultant compressed tablets intended to be chewed. In designing this formulation, it was recognized that dry malt solids[2] assumes an adhesive property when wetted with water, and is insoluble and nonadhesive in isopropanol. This adhesive nature of dry malt solids favored its use as the binder in this formulation. It was known that it could be added to the primary blend as a dry powder, and subsequently would form granules of a compressible character when granulated with water. Furthermore, it was known that the resultant tablets would be easy to chew without adhering to the teeth. It was decided to investigate the use of isopropanol in combination with water as the granulating solution in order to determine the minimal quantity of water to achieve granules suitable for tableting and to ensure adequate distribution of the water-wetted binder throughout the multivitamin powder blend.

EXPERIMENTAL

Formulation—The model formulation for a 1000-tablet batch quantity consisted of a primary blend of thiamine mononitrate 1.2 Gm., riboflavin 2.2 Gm., calcium pantothenate 1.5 Gm., pyridoxine HCl 0.6 Gm., niacinamide 11 Gm., ascorbic acid 33 Gm., dry malt solids 25 Gm., and diluent fillers and flavors *q.s. ad.* 600 Gm. Following the granulating procedures, vitamin A–D dry (500,000 units, 50,000 units per Gm.) 10 Gm., vitamin B_{12} (1:100) 1.5 Gm., tartaric acid 5.0 Gm., magnesium stearate 5.0 Gm., and cornstarch *q.s.* were added to the granules, yielding a total batch weight for compression of 650 Gm.

Granulating Procedures—One hundred milliliters of granulating solutions was prepared of each of the following: (*a*) water, (*b*) isopropanol 25%–water 75% v/v, (*c*) isopropanol 50%–water 50%, (*d*) isopropanol 75%–water 25%, and (*e*) isopropanol.

Five batches of the primary multivitamin blend were prepared and granulated with each of the five granulating solutions in a Hobart[3]-type 4-qt. mixer set at number two speed control. The resultant agglomerated masses were spread on trays at a 0.5-in. thickness, and dried at 100°F. to a moisture content of no more than 1% as determined on the Cenco moisture balance. Following the drying process, the dried materials were reduced to granules by passing through the model D Fitzpatrick comminutor, number two screen, slow speed, knives forward. Granulations (*a*), (*b*), (*c*), and (*d*) were satisfactory for further processing and were so submitted. Granulation (*e*) prepared with isopropanol resulted in an amorphous, nonflowing powder, and was rejected as unsuitable for normal tableting procedures.

Granule Analyses—A granule size distribution study was conducted on each of the four primary blend granulations (*a*) through (*d*), utilizing the Cenco-Meinzer sieve shaker. The results of this analysis are shown in Table I expressed as the percentage retained on screen mesh sizes 0–16, 16–24, 24–30, 30–40, 40–60, and the residual passing through the 60-mesh screen as fines. These residual quantities are plotted against the percentage of water in the granulating solutions as shown in Fig. 1. The resultant negative, straight-line slope suggests an inverse linear relationship between the ratio of water in the granulating solution and the percentage of residual fines in the granulation.

The granule distribution data are presented in Table II on a percentage cumulative retention basis on mesh screens 16, 24, 30, 40, and 60. The plot of these data against the percentage of water in the granulating solutions is shown in Fig. 2. These slopes reveal an increasing degree of influence of the proportion of water in the granulating solutions on the per cent granules retained cumulatively on the 40- and the 60-mesh screens. The per cent granules retained on the 16-, 24-, and 30-mesh screens does not reveal an appreciably consistent pattern of increased retention with the increased granulating solution water ratios.

Tableting Procedures—Following the addition of the balance of the formula ingredients and subsequent mixing in a twin-shell type blender for 20 min. to ensure uniform dispersion of all ingredients, each of the four granulations (*a*), (*b*), (*c*), and (*d*) was compressed on the Stokes model F single-punch tablet machine, using 0.5-in. standard concave punches.

The target tablet weight was 650 mg., and the target hardness was 5 to 6 Kg. hardness, as measured with the Stokes tablet hardness tester. The thickness of the tablet thus became a variable dependent on the compression characteristics of each of the granulations. In a previously published article (5), the author studied the compression characteristics of pharmaceutical materials, *per se*. It was reported that the thickness of compressed materials varied with the volumetric fill weight of the die cavity, which in turn appeared to be a function of the density of the material subjected to compression. Following the compression of each of the four granulations (*a*), (*b*), (*c*), and (*d*), the weight, hardness, thickness, and disintegration of the tablets were determined. These results are shown in Table III.

Figure 3 represents the plots of the per cent granules cumulatively retained on the 60-mesh screen and the thickness of the compressed tablets prepared with each of the four granulations. The resultant slope is empirically suggestive of an inverse relationship between these two variables.

Friability tests were conducted, utilizing the Roche Friabilator apparatus. In this procedure, 20

[a] Average loss of 20 tablets.

tablets of each of the four granulations were placed in the apparatus, and the apparatus rotated at 24 r.p.m. for periods of 3 min., 6 min., and 9 min. in order to introduce a time dimension in the evaluation of the relative friability of the four tablet formulations. The results obtained in terms of average tablet weight loss are presented in Table IV. No significant differences were noted among the four formulations.

Storage Data—Following storage for 4 months at ambient room temperature in amber glass bottles, samples of each of the four formulations were subjected to hardness testing and disintegration determination. The storage data are presented in Table V. Statistical computation of the difference between the initial hardness and disintegration data means presented in Table III and the storage data means revealed no statistically significant changes in these parameters.

The Student *t* test (Eq. 1) was calculated for each

$$tn1 + n2 - 2 = \frac{\bar{X}_1 - \bar{X}_2}{Sp\sqrt{1/n_1 + 1/n_2}} \quad \text{(Eq. 1)}$$

of the four formulations, at 28 degrees of freedom for the hardness data, and at 10 degrees of freedom for the disintegration data, at the p 0.05 significance level. The initial mean values of Table III are identified as $\bar{X}_1$, and the storage data means as $\bar{X}_2$. The Sp standard deviation values were computed using Eq. 2, in which S_1^2 is the estimated variance of the initial Table III data, and S_2^2 is the estimated variance of the Table V storage data.

TABLE V—FOUR MONTHS' STORAGE DATA

Formula	Hardness,[a] Kg.	Disintegration,[b] min.
(*a*)	4.9	7
(*b*)	6.0	8
(*c*)	5.9	11
(*d*)	5.7	12

[a] Means of 15 tablets. [b] Means of 6 tablets.

$$Sp = \sqrt{\frac{(n_1 - 1)S_1^2 + (n_2 - 1)S_2^2}{n_1 + n_2 - 2}} \quad \text{(Eq. 2)}$$

For the hardness data, the tabled critical t value is 2.048. For the disintegration data, the tabled critical t value is 2.228. Computation of t values for the hardness data for the four formulations: (*a*) 2.02, (*b*) 2.03, (*c*) 1.95, (*d*) 2.03. Computation of t values for the disintegration data: (*a*) 2.17, (*b*) 2.04, (*c*) 1.99, (*d*) 1.97. The hypotheses that there are no differences between initial and storage data sets of means are accepted.

SUMMARY

Using a chewable multivitamin tablet formulation containing dry malt solids as the binder, a series of isopropanol–water granulating solutions was evaluated along with water alone and isopropanol alone.

It was found that the higher the ratio of water content in the granulating solution, the lesser the percentage of residual fines that passed through a 60-mesh screen. However, the percentage of granules that were 30-mesh or larger was not significantly influenced by the higher water content. It was found that the presence of some water content was necessary with this formulation to achieve a suitable granulation. The isopropanol alone granulating solution was unsatisfactory for use.

The tablets prepared were evaluated in terms of the physical parameters: weight, hardness, thickness, disintegration, and friability. No difference was noted in the tablet friability of the four compressed granulations. The thickness obtained appeared to be dependent on the percentage of residual fines in the granulations, maintaining the weight and hardness of compression as constants. There was an unexplained lengthening in the initial disintegration of the tablets prepared with the higher isopropanol content granulating solutions.

Evaluation of the 4 month's storage samples revealed no statistically significant changes occurring in the hardnesses and disintegrations of the four tablet formulations.

Synthesis of Halogen Substituted Derivatives of 4,4-Bis(4-hydroxyphenyl)pentanoic Acid and Their Antifungal Properties

By RASHMIKANT M. PATEL*, DAVID P. CAREW, and JOHN L. LACH

Several derivatives of 4,4-bis(4-hydroxyphenyl)-pentanoic acid and 10-undecenoic hydroxamic acid were prepared. Their antifungal activity was tested against *Trichophyton mentagrophytes* (ATCC 9533). Six of the ten compounds tested exhibited greater activity than undecylenic acid under the conditions of the test.

MANY COMPOUNDS have been synthesized and evaluated for their antimicrobial activity. These include quinones, quaternary ammonium salts, sulfur containing derivatives, hydroxamic acids, halogenated phenols, and acid esters (1–6). Among these diverse chemical types, compounds having a phenol nucleus such as hexachlorophene, bithionol, and resorcinol have a prominent place in many soaps, ointment, and scrub lotions.

A previous study with the fungus *Trichophyton rubrum* and with streptococci indicated that diphenolic acid[1] [4,4-bis(4-hydroxyphenyl)pentanoic acid] possesses antifungal and antibacterial activity *in vitro* (7). Since diphenolic acid is a suitable intermediate for the preparation of other compounds with possible antifungal activity, it was of interest to prepare its halogenated derivatives and some of their esters.

Since some hydroxamic acid derivatives have been shown to exhibit antifungal activity, the hydroxamic acid of the widely used undecylenic acid was also prepared and evaluated for its antifungal property.

EXPERIMENTAL

4,4-Bis(3,5-dichloro-4-hydroxyphenyl)pentanoic Acid—A 1-L. round-bottom flask, fitted with an efficient condenser carrying a calcium chloride drying tube, was set up on a steam bath in a hood. In the flask were placed 28.6 Gm. (0.1 mole) of 4,4-bis-(4-hydroxyphenyl)pentanoic acid and 67.5 Gm. (0.5 mole) of sulfuryl chloride, and the mixture was warmed on the steam bath for 1 hr. Ten more milliliters of sulfuryl chloride was added to the reaction flask and the warming was continued for about 30 min. Excess sulfuryl chloride was removed by attaching a water pump through an empty safety flask to the reaction flask. The crude product was washed with boiling water, dried at 60°, and recrystallized from benzene.

4,4-Bis(3,5-dibromo-4-hydroxyphenyl)pentanoic Acid—In a 1-L. three-necked flask, fitted with a mechanical stirrer, dropping funnel, and a condenser, were placed 28.6 Gm. (0.10 mole) of diphenolic acid and 360.0 ml. of glacial acetic acid. A solution of 40.0 ml. (1.6 mole) of bromine in 40.0 ml. of glacial acetic acid was placed in the dropping funnel and added to the diphenolic acid solution during a 30-min. period and stirred continuously for 22 hr. The flask was heated on a steam bath and air was passed through the side neck to remove excess bromine. The mixture was poured into a beaker containing a saturated solution of sodium bisulfite in water. The resulting semisolid mass was washed with cold water and placed in a beaker containing boiling water, and stirred until the semisolid mass solidified. The hot water was decanted, and the crude product was dried at 60°, and recrystallized from benzene.

Esterification of Halogenated Acids—Methyl and propyl esters were prepared according to the following procedure. A mixture of purified halogenated diphenolic acid (0.05 mole), appropriate alcohol (75 ml.), and concentrated sulfuric acid (5 ml.) was refluxed for 5 hr. The reaction mixture was poured into a beaker containing ice, neutralized with a saturated solution of sodium bicarbonate, filtered, and washed with water. The crude ester was vacuum dried and recrystallized from benzene.

N-Decyl and cyclohexyl esters were prepared by reaction of appropriate acid chloride with the alcohol under consideration. The general procedure was as follows. In a 250-ml. conical flask, fitted with a condenser, was placed 0.05 mole of halogenated acid and 59.0 Gm. (0.5 mole) of thionyl chloride. The reaction mixture was heated on a steam bath for 0.5 hr. At the end of the reaction period, 50.0 ml. of dry benzene was placed in the flask and excess thionyl chloride distilled under vacuum. A solution of 0.05 mole of the appropriate alcohol in 30.0 ml. benzene was added to the flask containing acid chloride and refluxed for 1 hr. After removing benzene, the crude product was treated with a saturated solution of sodium bicarbonate, filtered, washed, dried, and recrystallized from an acetic acid–water mixture. The recrystallization solvents, melting points, yields, and elemental analyses are given in Table I.

10-Undecenoic Hydroxamic Acid—Separate solutions of 14.0 Gm. (0.2 mole) of hydroxylamine hydrochloride in 80.0 ml. of methyl alcohol and 16.8 Gm. (0.3 mole) of potassium hydroxide in 40.0 ml. of methyl alcohol were prepared at the boiling point of the solvent. Each was cooled to 35° and the one containing alkali was added with shaking to hydroxylamine hydrochloride solution. Any excessive rise of temperature was prevented by occasional cooling in an ice bath. After the alkali had been added the mixture was allowed to stand

in an ice bath for 5 min. to insure complete precipitation of potassium chloride. Then 19.8 Gm. (0.1 mole) of methyl 10-undecenoate was added with thorough shaking and the mixture was filtered immediately with suction. The filtrate was placed in a conical flask and allowed to stand at room temperature. After 2 days, crystals were filtered, washed with a minimum amount of absolute ethyl alcohol, and air dried. A mixture of the potassium salt and 100.0 ml. of dilute acetic acid was stirred and heated on a steam bath until a clear solution was obtained. It was allowed to cool at room temperature and finally placed in an ice bath. The precipitated hydroxamic acid was recrystallized twice from glacial acetic acid–water, whereupon colorless crystals were obtained. The yield was 11.0 Gm. (55%), m.p. 72–73°.

Anal.—Calcd. for $C_{11}H_{21}NO_2$: C, 66.32; H, 10.62; N, 7.02. Found: C, 67.03; H, 10.92; N, 7.22.

Determination of Fungicidal Activity—A study of the fungicidal properties of the compounds whose synthesis has just been reported was conducted. The testing procedure was a modification of the methods of Burlingame (8), Golden (9), and Reddish (10). The test organism *T. mentagrophytes* (ATCC 9533) was used exclusively. Since the compounds to be tested for fungicidal activity were insoluble in water, ethanolic solutions were prepared. Solutions of 0.1%, 0.5%, and 1.0% in ethanol (95%) were made. Ten tests for each of the three concentrations were run for each compound.

Test Procedures—Petri dishes containing 20 ml. Sabouraud dextrose agar were inoculated with a culture of *T. mentagrophytes*. The inoculated plates were incubated at a temperature of 28° for 15 days. On the day of the test 1-cm. disks of agar and fungus were removed from the Petri dishes with a sterile cork borer (10 mm. diameter). Each disk was immediately aseptically transferred to a test tube containing 10 ml. of a particular concentration of the solution of the compound under test. The test tube was agitated slowly for 2 min. and the disk was transferred to a test tube containing 10 ml. sterile Sabouraud dextrose broth. This tube was agitated slightly for a period of 3 min. to free the mycelia of any soluble or miscible material. The disk was then transferred to a test tube containing 10 ml. of a 30% aqueous acetone solution where it was kept for 5 min. to remove any traces of adhering antifungal compound. The disk was transferred to a test tube of sterile Sabouraud dextrose broth for a 2-min. period in order to remove any traces of acetone. Finally the disk was removed from the broth and placed culture side down on the surface of a sterile slant of Sabouraud dextrose agar contained in a 25 × 150 mm. test tube. The inoculated slants were incubated at a temperature of 28° for 25 days. Controls were run along with each compound and these consisted of agar-fungus disks which were treated as above except that the initial alcoholic solution did not contain any chemical compound being tested. Evidence of growth in control tubes was always evident in a few days after inoculation. In addition to the newly synthesized compounds, the known antifungal agent undecylenic acid was used for comparison. Since the testing procedure was designed to determine fungicidal activity, any evidence of fungal growth after a 25-day period was regarded as a negative result. Table II lists the results of the fungicidal testing procedure.

TABLE II—RESULTS OF FUNGICIDAL TESTING

Compd. No. or Name	No. of Tubes Exhibiting Growth After 25 Days[a] 0.1%	0.5%	1.0%
1	10	8	6
2	10	10	10
3	4	4	3
4	6	4	4
5	4	4	0
6	6	4	2
7	8	6	6
8	4	4	4
Diphenolic acid	10	3	3
Undecylenic acid	8	4	2
10-Undecenoic hydroxamic acid	2	0	0

[a] The maximum number of tubes exhibiting growth for each concentration is 10.

CONCLUSION

From Table II it can be seen that 10-undecenoic hydroxamic acid exhibited the greatest amount of fungicidal activity. Propyl 4,4-bis(3,5-dichloro-4-hydroxyphenyl) pentanoate was the next most active fungicidal compound tested. Six of the ten compounds tested exhibited greater activity than undecylenic acid under the conditions of the test.

The undecylenic hydroxamic acid, because of its activity against *T. mentagrophytes*, was further tested and showed good activity against the following organisms: *Microsporum audouini* ATCC 9079, *Microsporum canis* ATCC 10241, *Trichophyton mentagrophytes* (*gypseum*) ATCC 9129, *Trichophyton mentagrophytes* (*interdigitale*) ATCC 9972, *Candida albicans* ATCC 10231, *Trichophyton rubrum* ATCC 10281, *Stemphylium solani* ATCC 11128, and *Stemphylium species* ATCC 9569.

Activity of Different Segments of Rabbit Gastrointestinal Tract

By THEODORE H. EICKHOLT, ROGER H. BOX, and NOLAN D. COURVILLE

Five different segments of the rabbit intestinal tract, (duodenum, jejunum, ileum, ascending and descending colon), were used to record the normal activity of these segments using an isolated muscle bath technique. Kymograph recordings and transducer-recorder recordings were compared. Contractions per minute, interval between contractions, and amplitude of contractions were observed and evaluated. In the transducer recorded series, *t* tests indicated statistically significant difference for all comparisons of contractions per minute. From 60 comparisons of normal rabbit intestinal activity using *t* tests, only 5 comparisons were not found to be significantly different at *P* 0.05.

THE WEIGHTS and linear measurements of several segments of the gastrointestinal tract of the rabbit have been investigated by Latimer and Sawin (1). Other tissues and organs have been studied (2–5), but the variations in the normal activity of different segments of the rabbit gut so often employed in drug testing and drug experimentation require delineation.

It was, therefore, the purpose of this study to record some of the variations observed in the different segments of the rabbit intestine and subject them to statistical evaluation for reference when a similar preparation was used experimentally. Two systems, typical kymograph and transducer systems, were employed to further delineate differences in observations of activity of rabbit intestinal segments.

EXPERIMENTAL

Adult, albino rabbits were anesthetized with ether and 2–3 cm. segments of duodenum, jejunum, ileum, ascending and descending colon were expediently removed. The segments were individually maintained in oxygenated Tyrode's solution in a constant-temperature bath at 38° prior to their placement in the isolated muscle bath. The Tyrode's solution contained sodium chloride 0.8%, potassium chloride 0.02%, calcium chloride 0.02%, magnesium chloride 0.01%, sodium bicarbonate 0.1%, sodium diphosphate 0.005%, and glucose 0.1%.

The first series of experiments utilized constant-temperature muscle baths and kymographs. Tyrode's solution (100 ml.) was used to bathe the segment; temperature was maintained at 38° and the preparation was oxygenated using an air flow bubbled through the solution. The segment was attached to the muscle hooks, one stationary and the other being connected to a lever and stylus, such that the segment was completely submerged in the Tyrode's solution. The muscle lever was made to record on a slowly rotating carbon black kymograph drum. A synchronous timer recorded the time on the same tracing. The only constant tension placed upon the segment was that of the weight of the lever which in turn was centered on its fulcrum and

Activity of Different Segments of Rabbit Gastrointestinal Tract

By THEODORE H. EICKHOLT, ROGER H. BOX, and NOLAN D. COURVILLE

Five different segments of the rabbit intestinal tract, (duodenum, jejunum, ileum, ascending and descending colon), were used to record the normal activity of these segments using an isolated muscle bath technique. Kymograph recordings and transducer-recorder recordings were compared. Contractions per minute, interval between contractions, and amplitude of contractions were observed and evaluated. In the transducer recorded series, *t* tests indicated statistically significant difference for all comparisons of contractions per minute. From 60 comparisons of normal rabbit intestinal activity using *t* tests, only 5 comparisons were not found to be significantly different at *P* 0.05.

THE WEIGHTS and linear measurements of several segments of the gastrointestinal tract of the rabbit have been investigated by Latimer and Sawin (1). Other tissues and organs have been studied (2–5), but the variations in the normal activity of different segments of the rabbit gut so often employed in drug testing and drug experimentation require delineation.

It was, therefore, the purpose of this study to record some of the variations observed in the different segments of the rabbit intestine and subject them to statistical evaluation for reference when a similar preparation was used experimentally. Two systems, typical kymograph and transducer systems, were employed to further delineate differences in observations of activity of rabbit intestinal segments.

EXPERIMENTAL

Adult, albino rabbits were anesthetized with ether and 2–3 cm. segments of duodenum, jejunum, ileum, ascending and descending colon were expediently removed. The segments were individually maintained in oxygenated Tyrode's solution in a constant-temperature bath at 38° prior to their placement in the isolated muscle bath. The Tyrode's solution contained sodium chloride 0.8%, potassium chloride 0.02%, calcium chloride 0.02%, magnesium chloride 0.01%, sodium bicarbonate 0.1%, sodium diphosphate 0.005%, and glucose 0.1%.

The first series of experiments utilized constant-temperature muscle baths and kymographs. Tyrode's solution (100 ml.) was used to bathe the segment; temperature was maintained at 38° and the preparation was oxygenated using an air flow bubbled through the solution. The segment was attached to the muscle hooks, one stationary and the other being connected to a lever and stylus, such that the segment was completely submerged in the Tyrode's solution. The muscle lever was made to record on a slowly rotating carbon black kymograph drum. A synchronous timer recorded the time on the same tracing. The only constant tension placed upon the segment was that of the weight of the lever which in turn was centered on its fulcrum and

Received January 17, 1967, from the Department of Pharmacology, School of Pharmacy, Northeast Louisiana State College, Monroe, LA 71201
Accepted for publication June 5, 1967.

raised only until the attachment *via* muscle hooks was tight enough to transfer the segment's movement to the lever and recording stylus.

The conditions for the second series of experiments for comparison were the same as above except intestinal activity was recorded *via* an E & M physiograph isotonic myograph transducer on an E & M physiograph. A timer was an integral part of the recorder and the paper speed was 0.05 cm./sec. The only constant tension placed upon the segment was that of the weight of the movable armature (2.2 Gm.) and of the lever which in turn was centered on its fulcrum and raised only until the attachment *via* muscle hooks was tight enough to transfer the segment's movements to the transducer and recording physiograph. In both systems relaxation was attempted with minimal stretching to best approximate normal conditions.

The myograph had amplitude and calibration controls and all observed pen deflections were equilibrated to the standard pen deflection displacements.

In each experiment, the segments were allowed to acclimate to the muscle bath environment. Acclimation was determined by consistency and/or rhythmicity of contractions.

Following acclimation in both series of experiments, normal intestinal activity for the different intestinal segments was recorded. Five to seven different rabbits were used to provide different individual samples of duodenum, jejunum, ileum, ascending and descending colon. Tracings of a minimum of 15 min. were obtained for each of the 5 different segments in each series. From each tracing of each individual gut segment, amplitude of contraction, interval between contractions, and contractions per minute were measured. Three separate measurements of the three parameters above were made on each tracing providing an average of the three for that particular parameter of that single gut segment. These averages were in turn averaged for the 5 to 7 samples of each individual gut segment. This provided 15 to 21 actual measurements for the averages of the three parameters. Standard deviations were calculated and t tests were made between all possible combinations of intestinal segments.

RESULTS

Table I summarizes the averages and standard deviations of the amplitude of contraction, interval between contractions, and contractions per minute obtained in the first series of experiments recording on the smoked kymograph.

The t test values from the kymograph recorded series for all combinations of intestinal segments on the three parameters, contractions per minute, interval between contractions, and amplitude of contractions, indicated significant differences at P 0.05 for 28 of the total 30 comparisons.

Table II summarizes the averages and standard deviations of the amplitude of contraction, interval between contractions, and contractions per minute obtained in the second series of experiments recording with the myograph transducer.

The t test values from the transducer recorded series for all combinations of intestinal segments on the three parameters indicated significant differences at P 0.05 for 27 of the total 30 comparisons.

SUMMARY AND CONCLUSIONS

Five different segments of the rabbit intestinal tract, duodenum, jejunum, ileum, ascending and descending colon, were utilized in recording normal activity of these segments using an *in vitro* isolated muscle bath technique. One series of experiments was recorded using a typical smoked kymograph, while the second series for comparison employed an isotonic myograph transducer and multichannel recorder.

Contractions per minute, interval between contractions, and amplitude of contractions were recorded, determined, averaged, standard deviations calculated, and t tests performed on all possible segment combinations. In the kymograph recorded series, the contractions per minute decreased with progression to the lower segments of the intestinal tract. The interval between contractions increased which would correlate with the decreased contractions per minute. All t values for comparing

TABLE I—SUMMARY OF AVERAGES AND STANDARD DEVIATIONS OF MEASUREMENTS OF RABBIT INTESTINAL ACTIVITY OBTAINED FROM KYMOGRAPH RECORDINGS

	No. of Samples	Contractions/min.	Interval Between Contractions, sec.	Amplitude of Contraction, mm.
Duodenum	6	16.9 ± 2.01	3.1 ± 0.6	22.0 ± 7.40
Jejunum	6	13.8 ± 1.63	3.7 ± 0.7	36.1 ± 20.10
Ileum	6	13.3 ± 3.21	4.6 ± 1.1	12.0 ± 7.55
A. colon	6	6.2 ± 3.97	6.0 ± 4.1	2.8 ± 1.84
D. colon	6	4.9 ± 1.56	10.0 ± 4.3	19.5 ± 1.98

TABLE II—SUMMARY OF AVERAGES AND STANDARD DEVIATIONS OF MEASUREMENTS OF RABBIT INTESTINAL ACTIVITY OBTAINED FROM TRANSDUCER RECORDINGS

	No. of Samples	Contractions/min.	Interval Between Contractions, sec.	Amplitude of Contraction, mm.
Duodenum	7	16.7 ± 1.68	3.9 ± 0.1	2.56 ± 2.50
Jejunum	7	12.4 ± 2.31	5.0 ± 1.5	6.53 ± 3.46
Ileum	7	10.5 ± 1.27	6.2 ± 1.1	9.17 ± 0.68
A. colon	5	2.1 ± 0.83	15.0 ± 8.2	1.68 ± 0.57
D. colon	5	4.3 ± 1.68	13.4 ± 5.0	3.91 ± 2.38

all possible combinations of intestinal segments showed statistically significant differences at P 0.05 except two. The jejunum–ileum and A. colon–D. colon contractions per minute comparisons were not significantly different; however, the two other adjacent segments comparisons here were significantly different.

In the transducer recorded series, the contractions per minute again decreased with progression to the lower intestinal tract and the intervals between contractions again increased. The A. colon was the only exception to this trend in these two cases and may be due to more sensitive recording.

In this series the t values indicated statistically significant differences for all comparisons of contractions per minute which would be very important for drug comparison effects upon the intestinal tract.

The comparison of interval between contractions between A. colon and D. colon, however, was not significantly different. The reverse was true in the kymograph series in the comparisons between jejunum–ileum and A. colon–D. colon; the interval between contractions was significant but the contractions per minute were not significantly different. The transducer system would appear to better record the contractions per minute.

Two comparisons of amplitude of contractions in the transducer series also were not significantly different. They were duodenum–A. colon and duodenum–D. colon.

It would appear that this study and evaluation of normal rabbit intestinal activity could serve as a basis for further drug activity studies employing the rabbit intestinal tract and furthermore, in determining the preferential intestinal segment of a drug's activity.

Inhibition of Cortisone-Induced Cleft Palate in Mice by Cobaltous Chloride

By GILBERT KASIRSKY, RONALD F. GAUTIERI, and DAVID E. MANN, JR.

Young primipara CF-1 mice were mated overnight and those with vaginal plugs (day zero) were considered pregnant. Animals were divided into five groups of 26 each and subjected to the following treatment: group *A* received 2.5 mg. of cortisone acetate i.m. on days 11, 12, 13, and 14; group *B* received cobaltous chloride, 25 mg./Kg. i.p. on day 11 only followed by cortisone acetate, 2.5 mg. i.m. on days 11, 12, 13, and 14; group *C* received physiological saline, 0.1 ml. i.m. on days 11, 12, 13, and 14; group *D* represented untreated controls; group *E* received cobaltous chloride, 25 mg./Kg. i.p. on day 11 only followed by saline, 0.1 ml. i.m. on days 11, 12, 13, and 14. Mice were laparotomized and fetuses were examined on day 18. Group *A* (cortisone), 140 of 185 fetuses developed cleft palate (75.6 per cent incidence); group *B* (cobaltous chloride–cortisone), 24 of the 190 fetuses had clefts (12.6 per cent incidence); group *C* (saline), none of the 201 fetuses showed clefts; group *D* (untreated controls), none of the 194 fetuses had clefts; group *E* (cobaltous chloride–saline), 27 of the 208 fetuses had cleft palate (12.9 per cent incidence). Also, the incidence of cleft palate by litters was group *A*, 100 per cent; group *B*, 23.1 per cent; group *C*, 0 per cent; group *D*, 0 per cent; group *E*, 50 per cent.

DURING A recent evaluation of the relative antitumorigenic properties of cortisone (1), cobaltous chloride (2), and sodium cobaltinitrite (3, 4) in CF-1 mice subjected to the minimal carcinogenic dose$_{50}$ (MCD_{50}) of methylcholanthrene, several striking similarities became apparent in the character of the histological responses evoked by each drug, for not only was there a significant reduction of tumor incidence, but also the remarkable absence of cutaneous inflammation. The latter observation may be related to a report of an accentuation of anti-inflammatory activity of δ-1 hydrocortisone by the addition of a cobalt atom to the C-20 carbonyl function (5). Because interference with normal closure of the palatine shelves in certain strains of mice by cortisone is well documented (6), and furthermore, because previous studies in this laboratory have uncovered certain cortisone-like characteristics of two inorganic cobalt compounds, it thus became the primary objective of this investigation to discern the nature and extent of any cobalt–steroid interactions in terms of greater or lesser anomalies in the mouse fetus.

EXPERIMENTAL

Groups of 30 female mice of the CF-1 strain, weighing approximately 25 Gm., were individually

all possible combinations of intestinal segments showed statistically significant differences at P 0.05 except two. The jejunum–ileum and A. colon–D. colon contractions per minute comparisons were not significantly different; however, the two other adjacent segments comparisons here were significantly different.

In the transducer recorded series, the contractions per minute again decreased with progression to the lower intestinal tract and the intervals between contractions again increased. The A. colon was the only exception to this trend in these two cases and may be due to more sensitive recording.

In this series the t values indicated statistically significant differences for all comparisons of contractions per minute which would be very important for drug comparison effects upon the intestinal tract.

The comparison of interval between contractions between A. colon and D. colon, however, was not significantly different. The reverse was true in the kymograph series in the comparisons between jejunum–ileum and A. colon–D. colon; the interval between contractions was significant but the contractions per minute were not significantly different. The transducer system would appear to better record the contractions per minute.

Two comparisons of amplitude of contractions in the transducer series also were not significantly different. They were duodenum–A. colon and duodenum–D. colon.

It would appear that this study and evaluation of normal rabbit intestinal activity could serve as a basis for further drug activity studies employing the rabbit intestinal tract and furthermore, in determining the preferential intestinal segment of a drug's activity.

Inhibition of Cortisone-Induced Cleft Palate in Mice by Cobaltous Chloride

By GILBERT KASIRSKY, RONALD F. GAUTIERI, and DAVID E. MANN, JR.

Young primipara CF-1 mice were mated overnight and those with vaginal plugs (day zero) were considered pregnant. Animals were divided into five groups of 26 each and subjected to the following treatment: group *A* received 2.5 mg. of cortisone acetate i.m. on days 11, 12, 13, and 14; group *B* received cobaltous chloride, 25 mg./Kg. i.p. on day 11 only followed by cortisone acetate, 2.5 mg. i.m. on days 11, 12, 13, and 14; group *C* received physiological saline, 0.1 ml. i.m. on days 11, 12, 13, and 14; group *D* represented untreated controls; group *E* received cobaltous chloride, 25 mg./Kg. i.p. on day 11 only followed by saline, 0.1 ml. i.m. on days 11, 12, 13, and 14. Mice were laparotomized and fetuses were examined on day 18. Group *A* (cortisone), 140 of 185 fetuses developed cleft palate (75.6 per cent incidence); group *B* (cobaltous chloride–cortisone), 24 of the 190 fetuses had clefts (12.6 per cent incidence); group *C* (saline), none of the 201 fetuses showed clefts; group *D* (untreated controls), none of the 194 fetuses had clefts; group *E* (cobaltous chloride–saline), 27 of the 208 fetuses had cleft palate (12.9 per cent incidence). Also, the incidence of cleft palate by litters was group *A*, 100 per cent; group *B*, 23.1 per cent; group *C*, 0 per cent; group *D*, 0 per cent; group *E*, 50 per cent.

DURING A recent evaluation of the relative antitumorigenic properties of cortisone (1), cobaltous chloride (2), and sodium cobaltinitrite (3, 4) in CF-1 mice subjected to the minimal carcinogenic dose$_{50}$ (MCD_{50}) of methylcholanthrene, several striking similarities became apparent in the character of the histological responses evoked by each drug, for not only was there a significant reduction of tumor incidence, but also the remarkable absence of cutaneous inflammation. The latter observation may be related to a report of an accentuation of anti-inflammatory activity of δ-1 hydrocortisone by the addition of a cobalt atom to the C-20 carbonyl function (5). Because interference with normal closure of the palatine shelves in certain strains of mice by cortisone is well documented (6), and furthermore, because previous studies in this laboratory have uncovered certain cortisone-like characteristics of two inorganic cobalt compounds, it thus became the primary objective of this investigation to discern the nature and extent of any cobalt–steroid interactions in terms of greater or lesser anomalies in the mouse fetus.

Groups of 30 female mice of the CF-1 strain, weighing approximately 25 Gm., were individually

TABLE I—INHIBITION OF CORTISONE-INDUCED CLEFT PALATE IN MICE BY COBALTOUS CHLORIDE

Group	Treatment	No. Litters	Litters with CP	No. Fetuses	No. Fetuses with CP	% with CP
A	Cortisone, 2.5 mg. i.m., days 11, 12, 13, 14	26	26	185	140	75.6
B	Cortisone, 2.5 mg. i.m., days 11, 12, 13, 14 Cobaltous chloride 25 mg./Kg. i.p., day 11	26	6	190	24	12.6
C	Physiological saline, 0.1 ml. i.m., days 11, 12, 13, 14	26	0	201	0	0
D	Untreated controls	26	0	194	0	0
E	Physiological saline, 0.1 ml. i.m., days 11, 12, 13, 14 Cobaltous chloride, 25 mg./Kg. i.p., day 11	26	13	208	27	12.9

placed in a breeding cage with a male of the same strain at 4 p.m. every Wednesday and Thursday. The following morning (9:00–9:30 a.m.), females were returned to their own cages and those with vaginal plugs were considered pregnant and put aside in individual cages. The morning of the appearance of the vaginal plug was designated day 0 (gestation period 0–19 days). Pregnancy was confirmed by the weight gain which becomes apparent on or after day 8, or the placental sign which appears on day 10. The diet consisted of Purina laboratory chow and tap water, both given *ad libitum*. Food was placed in ample amounts on the floor of each cage and water was obtained through stainless steel drinking tubes which were attached to 4-oz. bottles. Excreta pans were arranged to permit coprophagy. Care was taken to minimize drafts and noise, and environmental temperature was maintained at 25° throughout the experiment.

Pregnant animals were divided into 5 groups comprising 26 mice each and subjected to the following treatment.

Group A—Each mouse received an intramuscular injection of 2.5 mg. of cortisone acetate[1] on days 11, 12, 13, and 14.

Group B—Each animal received an intraperitoneal injection of cobaltous chloride, 25 mg./Kg. (10% aqueous solution), on day 11 only followed by cortisone acetate, 2.5 mg. i.m., on days 11, 12, 13, and 14.

Group C—Each animal received an intramuscular injection of physiological saline solution, 0.1 ml., on days 11, 12, 13, and 14.

Group D—Untreated controls.

Group E—Each animal received an intraperitoneal injection of cobaltous chloride, 25 mg./Kg., on day 11 only followed by saline, 0.1 ml. i.m., on days 11, 12, 13, and 14.

All compounds were injected with a 26-gauge, 0.5-in. needle attached to a 1-ml. syringe which had been previously rinsed with sterile water for injection.

A single injection of the cobalt compound was administered intraperitoneally at 9:30 a.m. on the eleventh day of gestation. Injections of cortisone acetate were administered 5 min. after the cobalt administration on day 11. Subsequent injections of the steroid on days 12, 13, and 14 were also given intramuscularly, alternating the sites of injections from one hind leg to the other (biceps femoris muscle).

[1] Merck Sharp and Dohme, West Point, Pa.

EXAMINATION OF FETUSES

On day 18, which is 12 to 24 hr. prior to expected delivery, the mice were sacrificed by cervical dislocation and laparotomized immediately.

The abdominal wall of the mother was incised from the vaginal opening to an area just below the xiphihumeralis along the linea alba. Incisions were also made diagonally through the rectus abdominis, obliquus externus, and transverse abdominis to form a flap.

Before opening the uterine horns, fetal swellings and resorption sites (metrial glands) were recorded and the uterus was excised for removal of the fetuses. Before weighing and sexing, the fetuses were placed on blotting paper to remove excessive amniotic fluid, whereupon they were observed under an Ednalite magnifier for the presence of gross anomalies (2 × magnification).

Following the preliminary examination, the fetuses were prepared for further study. In order to evaluate skeletal structure, every third fetus was immersed in a modified clearing and staining solution according to the Staples and Schnell modification of the Spaltheholtz method (7). The remainder of the fetuses was fixed in Bouin's solution for 2 weeks in preparation for free hand razor blade sectioning as described by Wilson (8). This method allows for the evaluation of malformations in a large number of animals with a minimum expenditure and delay.

RESULTS

The incidence of cleft palate obtained for the various groups of mice at the termination of this study is recorded in Table I as follows.

Group A—Twenty-six pregnant mice which received cortisone acetate, 2.5 mg. i.m., on days 11, 12, 13, and 14 of gestation responded with a

75.6% incidence of fetal cleft palate. All of these litters had some clefts, the total number of fetuses having been examined was 269, with 3 born dead (84 of these were placed in alizarin red S solution for bone staining). Average weights of pregnant mice and fetuses were 46.2 and 0.86 Gm., respectively; number of resorptions was 49.

Group B—Twenty-six pregnant mice which received cobaltous chloride ($CoCl_2.6H_2O$), 25 mg./Kg. i.p., on day 11 only and cortisone acetate, 2.5 mg. i.m., on days 11, 12, 13, and 14, had a 12.6% incidence of cleft palate. Only six litters in this group had clefts. The total number of fetuses examined was 259, with 3 born dead (69 of these were placed in the alizarin red S solution for bone staining). The average weights of pregnant mice and fetuses were 44.3 and 1.10 Gm., respectively; number of resorptions was 38.

Group C—Twenty-six pregnant mice received physiological saline solution, 0.1 ml. i.m., on days 11, 12, 13, and 14 of gestation. None of these litters had cleft palate; however, one fetus was exencephalic. The total number of fetuses examined was 288, with 3 born dead (87 of these were placed in alizarin red S solution for bone staining). The mean weights of pregnant mice and fetuses were 51.7 and 1.21 Gm., respectively; the number of resorptions was 13.

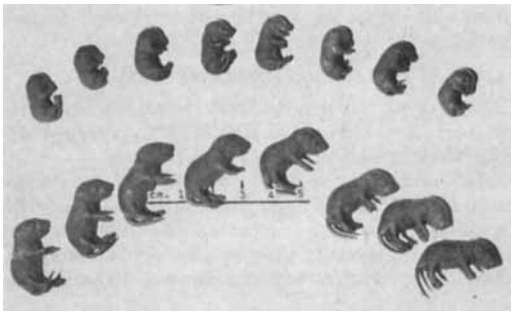

Fig. 1—Key: top, growth retardation produced by cortisone acetate, 2.5 mg. i. m.; bottom, inhibition by cobaltous chloride pretreatment, 25 mg./Kg. i. p.

Group D—This group of 26 pregnant mice was untreated and showed no incidence of cleft palate. The mean weights of pregnant mice and fetuses were 52.8 and 1.47 Gm., respectively; the number of resorptions was 13.

Group E—The final group of 26 pregnant mice received cobaltous chloride, 25 mg./Kg i.p., on day 11 only and saline solution, 0.1 ml. i.m., on days 11, 12, 13, and 14. Thirteen of these litters had some fetuses with clefts. The total number of fetuses examined was 293 (85 of these were placed in alizarin red S solution for bone staining). The incidence of cleft palate, average weights of pregnant mice and fetuses, and number of resorption sites were 12.9%, 49.6 and 0.99 Gm., and 31, respectively. A high incidence of complete fetal resorptions was observed in this group, 13 of the 26 animals.

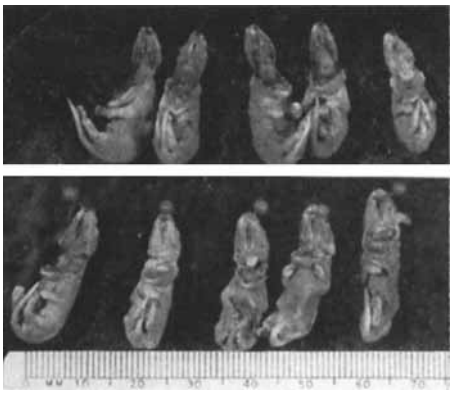

Fig. 2—Key: top, cleft palate induced by cobaltous chloride, 25 mg./Kg. i. p.; bottom, cleft palate induced by cortisone acetate, 2.5 mg. i. m.

DISCUSSION

The original premise which prompted this study concerning cobalt–steroid interrelationships in modifying fetal development was based upon recent findings during experiments with methylcholanthrene carcinogenesis in mice that two inorganic cobalt compounds, cobaltous chloride (2) and sodium cobaltinitrite (3, 4), manifested cortisone-like characteristics (*i.e.*, anti-inflammatory and antitumorigenic actions). The results (Table I) reveal additional similarities such as growth retardation, as denoted by group *A* (cortisone) and group *E* (cobaltous chloride–saline) having the lowest mean fetal weights, and cleft palate induction (Fig. 2 and Table I) by cobaltous chloride alone, and the prevention of both of these events by the cobalt compound in the presence of cortisone (Fig. 1 and Table I). It appears that the cobalt–steroid interaction may occur at the same site through competitive inhibition, for each alone induces clefts while together marked inhibition occurs. It should be noted, however (Fig. 2), that cobaltous chloride alone does not produce a macroscopically identical fissure to that caused by cortisone. On the contrary, cortisone-induced cleft palate is measurably more pronounced than that produced by cobaltous chloride. Whether this reflects a dosage relationship or difference in mechanism of action from that of cortisone remains to be clarified.

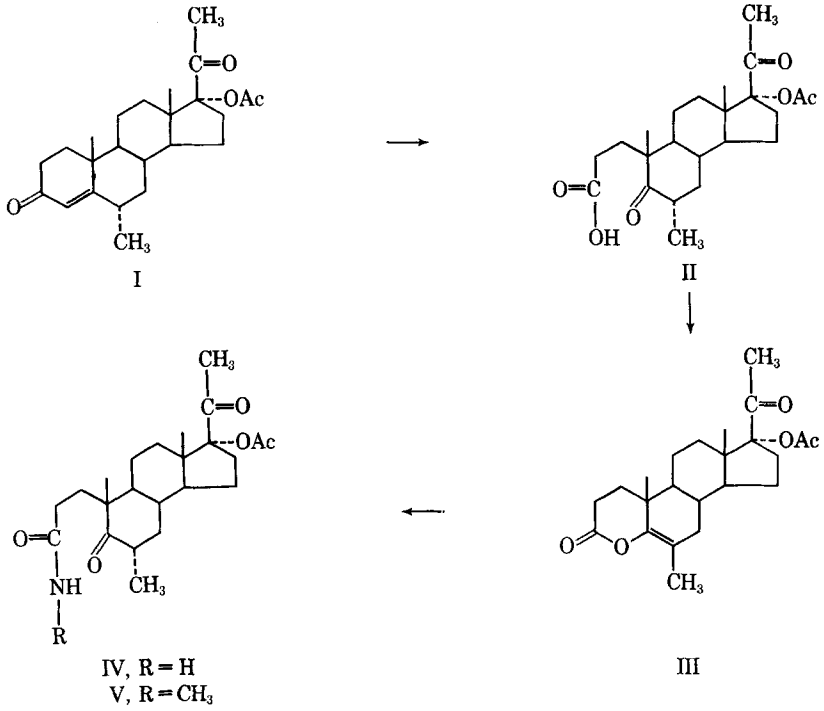
Secosteroids as Progestational Agents

By ARVIN P. SHROFF

This paper describes the synthesis of a few secosteroids. Their proton magnetic resonance spectra in $CDCl_3$ and C_6H_6 were investigated to evaluate the Δ values of the C-18, C-19, and C-6 methyl groups. The progestational activity of these compounds as evaluated in the Clauberg test is also described.

PROGESTATIONAL AGENTS have come into prominence in the last decade because of greatly increased potency. This has been accomplished through alteration of the basic structure of the progesterone or testosterone molecule. These include dehydrogenation, demethylation, or introduction of a methyl group, hydroxyl group, acetoxy group, and/or halogen atoms. At first interest was in the replacement of a carbon atom of the cyclopentanoperhydrophenanthrene system by nitrogen. A number of compounds resulting from these types of modification have been reported to be of potential biological interest (1).



Scheme I

Ozonization of the α,β-unsaturated ketone, 17α-acetoxy-6α-methylpregn-4-ene-3,20-dione (I), followed by oxidative decomposition of the ozonide with hydrogen peroxide gave 17α - acetoxy - 6α-methyl-3,5-seco-4-norpregna-5,20- dion - 3 - oic acid (II). (Scheme I.) The configuration of C-6 methyl was confirmed by PMR. The resonance peaks for C-6 methyl in deuterochloroform and benzene (Table 1) did not show any shift ($\Delta = 0$) and this indicates equatorial (α) conformation (2). The C-19 axial methyl, on the other hand, shows a significant shift ($\Delta = 0.38$) as observed by Williams and Baccha (2). The keto acid (II) was refluxed in a mixture of acetic anhydride and acetyl chloride (3) to give the lactone, 4 - oxa - 17α - acetoxy - 6 - methylpregn - 5 - ene-3,20-dione (III). The C-6 methyl group was deshielded, as expected by 0.70 p.p.m. (in $CDCl_3$). Shielding of C-19 methyl to the extent of 0.33 p.p.m. indicates that the benzene–solute complex formation occurred to the same extent as in keto acid (II). Treatment of lactone (III) with ammonia and methylamine gave the open chain amides (IV and V). The Δ values for C-19 and C-6 methyl groups suggest that the C-6 methyl group is equatorial. The infrared and ultraviolet data, along with PMR, confirm the assigned structures for IV and V.

Biological Data—Progestational activity of these compounds (II–V) was quantitatively evaluated in the Clauberg test as described earlier (4). The dose and the McPhail index are recorded in Table II.

EXPERIMENTAL

All melting points were taken with a Fisher-Johns melting point apparatus and are uncorrected. The ultraviolet and infrared data were obtained on Cary model 11 and Beckman IR-5 spectrophotometers, respectively. The proton magnetic resonance spectra were determined on a Varian A-60 spectrometer, in deuterochloroform and benzene, using tetramethylsilane as an internal standard (0 p.p.m.). All p.p.m. values are the centers of the signals. Elemental analyses were performed by Midwest Microlab, Inc., Indianapolis, Ind.

17α - Acetoxy - 6α - methyl - 3,5 - seco - 4 - norpregna-5,20-dion-3-oic Acid—A solution of 5.0 Gm. (0.013 mole) of 17α-acetoxy-6α-methylpregn-4-ene-3,20-dione in 30 ml. of ethyl acetate and 100 ml. of glacial acetic acid was cooled in an ice-water bath and ozonized for 1.5 hr. To this 5 ml. of 30% hydrogen peroxide was added, followed by 2000 ml. of water. The mixture was refrigerated for 2 hr. before adding an additional 100 ml. of water. The white semisolid was collected by filtration and dissolved in ether. The ethereal solution was extracted several times with 5% sodium hydroxide. The extracts were combined and acidified with concentrated hydrochloric acid. The cloudy solution was once again extracted with ether and the ether layer was washed several times with water until neutral to litmus. It was dried over sodium sulfate and evaporated to give a semisolid which could be recrystallized from ether–hexane to give 4.5 Gm. (79%) of 17α-acetoxy-6α-methyl-3,5-seco-4-norpregna-5,20-dion-3-oic acid, m.p. 216–218°. $[\alpha]_D$ +8.6° (1.0 c $CHCl_3$). $\lambda_{max.}^{CHCl_3}$ 2.81 μ, 5.77 μ, 5.85 μ. PMR in $CDCl_3$, 0.72 p.p.m. (C-18); 1.10 p.p.m. (C-19); 0.97 p.p.m. (C-6).

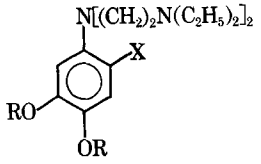
Synthesis and Physical Properties of the Antimalarial Agent 4-(2-Bromo-4,5-dimethoxyphenyl)-1,1,7,7-tetraethyldiethylenetriamine (RC-12) (WR-27,653)

By LESLIE M. WERBEL, EDWARD F. ELSLAGER, MARLAND P. HUTT, and J. M. VANDENBELT

Several synthetic routes to the antimalarial agent 4-(2-bromo-4,5-dimethoxyphenyl)-1,1,7,7-tetraethyldiethylenetriamine (RC-12) (WR-27,653) were evaluated. The preferred scheme involved alkylation of 4-aminoveratrole with excess 2-chlorotriethylamine in dimethylformamide at 140–145° to give 4-(4,5-dimethoxyphenyl)-1,1,7,7-tetraethyldiethylenetriamine, which was brominated in acetic acid to give the desired product. The physical and biological properties of the drug are summarized.

SEVERAL DECADES ago it was discovered that certain pyrocatechol amine derivatives possess interesting antimalarial properties (1, 2). Among them, dimeplasmin (I*a*) was reported to be as active as pamaquine against trophozoite-induced *Plasmodium cathemerium* and *P. relictum*, and to be substantially less toxic for the mouse, rat, dog, and cat. However, dimeplasmin was clearly less active than quinine in controlling parasitemia and fever resulting from *P. falciparum* infections in man (3–5). Results

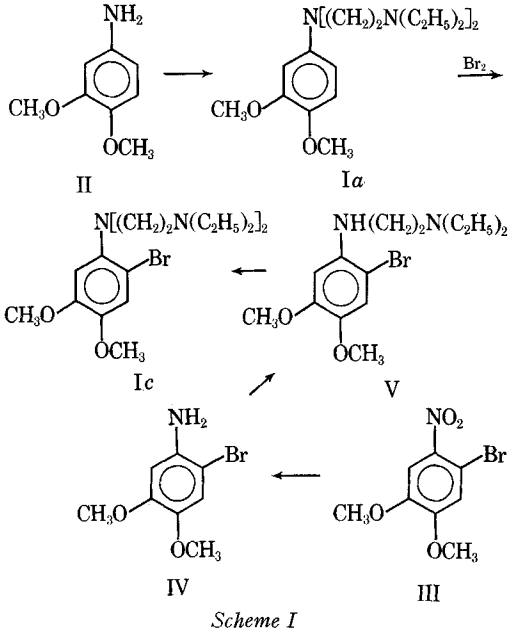


I

a, X = H; R = CH_3 (dimeplasmin)
b, X = Br; R = CH_2CH_3 (diapromin)
c, X = Br; R = CH_3 (RC-12)

of limited clinical studies with the related compound diapromin (I*b*) were likewise disappointing (6). Therefore, interest in this class of compounds waned.

More recently, interest in the antimalarial properties of the pyrocatechol amines was reawakened by the demonstration that 4-(2-bromo-4,5-dimethoxyphenyl) - 1,1,7,7 - tetraethyldiethylenetriamine (I*c*) (RC-12) had a pronounced effect on the exo-erythrocytic stages of *P. cathemerium* in canaries (7, 8). This observation stimulated an appraisal of the antimalarial effects of this agent against *P. cynomolgi* in the monkey (9). Although the drug *per se* had little promise as a schizonticidal or suppressive agent in monkeys, it showed significant promise as a prophylactic or radical curative agent. These authors concluded that RC-12 might find use when: (*a*) the combination of chloroquine–primaquine is not effective in causal prophylaxis, as appears to be the case where there is chloroquine resistance; (*b*) there is a need for a curative agent which can produce benefits in less than 10–14 days; and (*c*) there are fears of enhanced susceptibility to the hematotoxicity of primaquine (9). In anticipation that RC-12 might prove useful in connection with malaria problems encountered by the armed forces in Southeast Asia, the U. S. Army Medical Research and Development Command requested that suitable methods be developed for the laboratory synthesis and characterization of this substance. (Scheme I.)



Scheme I

General methods for the preparation of various pyrocatechol amines were described many years ago by Schulemann and Kropp (1), but to our knowledge the synthesis and properties of I*c* have not been described in the literature. In the present work several synthetic approaches to I*c* were evaluated. Among them, the following route proved to be most useful: alkylation of 4-aminoveratrole (II) with excess 2-chlorotriethylamine in dimethylformamide at 140–145° gave, in 57% yield, 4-(4,5-dimethoxyphenyl)-1,1,7,7-tetraethyldiethylenetriamine (dimeplasmin) (I*a*) which was 98–100% homogeneous by vapor phase chromatographic analysis. Attempted bromination of I*a* with bromine in carbon tetrachloride or with *N*-bromosuccinimide was unsuccessful; however, bromine in acetic acid at 55-60° afforded

Received April 19, 1967, from the Research Laboratories Parke, Davis and Co., Ann Arbor, MI 48106

This investigation was supported by contract DA-49-193-MD-2754 from the U. S. Army Medical Research and Development Command, Washington, D. C.
WR-27,653 is the code number assigned to this drug by the Walter Reed Army Institute of Research.
The authors thank Mr. C. E. Childs and his colleagues for the microanalytical and vapor phase chromatography data.

essentially homogeneous *Ic* in 41% yield. The material thus obtained was identical in all respects with an authentic sample of RC-12 base. The amounts of *Ia* and *Ic* formed in these reactions, as indicated by GLC analyses, were considerably larger than he amounts of pure materials isolated, and the use of more sophisticated distillation equipment would undoubtedly increase yields substantially.

Alternatively, alkylation of 2-bromo-4,5-dimethoxyaniline (IV) (10) with a slight excess of 2-chlorotriethylamine at 90–100° for 2.5 hr. (1) gave a mixture of 37% unchanged aniline (IV), 58% of the monoalkylated product (V), and 5% of *Ic* based on vapor phase chromatographic analysis. Extending the heating time to 27 hr. gave a mixture of 90% V and 10% *Ic*. Treatment of the latter mixture with 2-chlorotriethylamine at 130–140° for 10 hr. increased the amount of *Ic* in the mixture only to 25%. An attempt to bisalkylate IV directly with an excess of 2-chlorotriethylamine at 140–150° for 18 hr. gave a complex mixture which contained between six and eight components based on VPC analysis. The 2-bromo-4,5-dimethoxyaniline (IV) (10) used as starting material was prepared by bromination of either 4-amino-1,2-dimethoxyaniline or the corresponding acetamide, or preferably by catalytic reduction of 4-bromo-5-nitro-1,2-dimethoxybenzene (III) (11).

The infrared and NMR spectra of RC-12 appear quite normal. The absence of any obvious coupling of the aromatic protons, *cf.* clean doublet at 6.71, 6.91 p.p.m. in the NMR spectrum (in CCl_4 with tetramethylsilane as internal standard), supports the existence of 2 *para* protons and thus the structural orientation as proposed (*Ic*).

The ultraviolet absorption spectrum of RC-12 is similar to that of simpler analogous structures (Table I). In methanol, the spectrum has a secondary band (*13*) at lower wavelength and lower intensity than the corresponding amine IV. This shift to lower wavelength reflects the well known phenomenon of inhibition of resonance interaction between the tertiary aromatic amine and the benzene ring by the bromine in the *ortho* position (12). The primary band is not resolved. The authors have observed that bromobenzenes substituted in the *ortho* position by very weak donor groups characteristically show intense absorption at lower wavelength, in which this band may not be resolved.

The spectra of the cationic forms of compounds IV and *Ic* should be like that of 4-bromoveratrole, since the cation cannot resonate with the ring. This is evident for compound IV which shows a characteristic shift with acid to lower wavelength, with band wavelengths and intensities similar to those of 4-bromoveratrole. RC-12 (*Ic*), on the other hand, shifts very little with acid, indicating that the aromatic amine has not been affected. Attempts to protonate the aromatic amine in very strong acid were only partially successful. In 25% concentrated sulfuric acid, the secondary band shifted several millimicrons, and resolution of the primary band occurred. In still stronger acid, a slight further shift occurred, but other effects appeared also, including darkening of the solutions.

The basicity of the aromatic amine in RC-12 is thus seen to be strongly decreased as a result of its s ructural orientation. The ionization constants determined experimentally are in accord with this conclusion. Introduction of bromine *ortho* to the amine in II reduces the pK'a from 4.6 to 2.6 (IV) (Table I). Introduction of the basic side chain also decreases the basicity of the aromatic amine, as indicated by a pK'a of about −0.1 for compound *Ia*, determined spectrophotometrically. Both these effects would be operative in *Ic*. The predicted pK'a is as low as −2, a value beneath the pH to which the compound could be subjected without development of other effects.

EXPERIMENTAL

Melting points are corrected. Vapor phase chromatograms were run on an F & M No. 810 instrument using a 6-ft. × 1/4-in. 5% SE-30 on Anakrom ABS 90-100 mesh column at 250° with a nitrogen carrier gas flow rate of 60 ml./min.

Preparation of 2-Bromo-4,5-dimethoxyaniline (IV)—A solution of 13.1 Gm. (0.05 mole) of 4-bromo-5-nitro-1,2-dimethoxybenzene (Eastman Kodak) in 150 ml. of tetrahydrofuran was hydrogenated over 2 Gm. of Raney nickel at 25° and an initial pressure of 49.5 psig. The catalyst was removed by filtration and the solvent removed *in vacuo*. The residue was taken up in ether, the ether solution was filtered to remove some insoluble material, and dry hydrogen chloride was bubbled into the ether filtrate. The white precipitate was removed by filtration, washed with ether, and dried *in vacuo* at 50°

TABLE I—ULTRAVIOLET[a] AND pK'a DATA ON RC-12 AND INTERMEDIATES

	Solvent	λ	ε	λ	ε	pK'a[b]
4-Bromoveratrole	MeOH	283	2,800	232	8,900	...
II	MeOH	292	3,000	236	7,900	4.6
ortho-Bromoaniline	MeOH	293	2,600	236	8,200	
IV·HCl	MeOH, 0.05 *N* in NaOH	304	4,100	237	8,800	2.6
	MeOH, 0.05 *N* in HCl	284	3,300	234	9,200

to give 10.2 Gm. (76%) of 2-bromo-4,5-dimethoxyaniline hydrochloride, m.p. 203-204° dec. A portion recrystallized from ethanol gave m.p. 202.5–203.5° dec.

Anal.—Calcd. for $C_8H_{10}BrNO_2 \cdot HCl$: C, 35.78; H, 4.13; N, 5.22. Found: C, 36.11; H, 4.30; N, 5.10.

Preparation of 4-(4,5-Dimethoxyphenyl)-1,1,7,7-tetraethyldiethylenetriamine (Ia)—A mixture of 99.2 Gm. (0.647 mole) of 4-aminoveratrole (Hi Laboratories), 387.7 Gm. (2.59 moles) of freshly distilled chlorotriethylamine (generated from the hydrochloride salt),[1] and 165 ml. of dimethylformamide was heated with stirring for 20.5 hr.[2] by means of an oil bath kept at 140–145°. After cooling to room temperature, the reaction mixture was treated with 10% aqueous sodium hydroxide solution[3] and chloroform.[4] The chloroform extract was dried over sodium sulfate and the chloroform removed on a rotary evaporator. The resulting oil was suspended in 10% aqueous sodium hydroxide solution[5] and extracted with ether.[6] The ether solution was dried over sodium sulfate and the ether removed on a rotary evaporator. The residual crude product (196 Gm.) was distilled under vacuum through a 6-in. Vigreaux column[7] to give 128.8 Gm. (57%) of 4-(4,5-dimethoxyphenyl)-1,1,7,7-tetraethyldiethylenetriamine, b.p. 163–165°/0.17–0.20 mm., shown by vapor phase chromatography to be 98–100% homogeneous.

Anal.—Calcd. for $C_{20}H_{37}N_3O_2$: C, 68.33; H, 10.61; N, 11.95. Found: C, 67.99; H, 10.54; N, 11.89.

Preparation of 4-(2-Bromo-4,5-dimethoxyphenyl)-1,1,7,7-tetraethyldiethylenetriamine (Ic)—To a solution of 82.2 Gm. (0.234 mole) of 4-(4,5-dimethoxyphenyl)-1,1,7,7-tetraethyldiethylenetriamine in 500 ml. of glacial acetic acid was added dropwise with stirring at room temperature 41.0 Gm. (0.256 mole) of bromine.[8] The addition required 50 min., and the final temperature of the solution was 41°. The mixture was stirred for 1 hr. at room temperature and then for 1 hr. at 55–60°. The acetic acid was removed on the rotary evaporator. The cooled residue was made alkaline with a 50% aqueous sodium hydroxide solution[9] and extracted first with ether and then with benzene.[10] The extracts were washed with water[11] and dried over sodium sulfate. The solvents were removed *in vacuo* leaving about 82 Gm. of crude product which was subjected to distillation with an oil diffusion pump.[12] After removing the forerun up to 150°/0.005 mm., two fractions, b.p. 150–151°/.005–.001 mm. (28.0 Gm.), were collected which were shown by vapor phase chromatography to contain about 95% of Ic. Two additional fractions, b.p. 149–150°/<.001 mm. (28.5 Gm.) and 151.5–149°/.001– <.001 mm. (13.1 Gm.), were collected and shown to be essentially homogeneous Ic (98–99%). These two fractions represent a yield of 41%. The product is a yellow-brown viscous liquid with a retention time of 12.25 min. under the conditions of vapor phase chromatography indicated above.

Anal.—Calcd. for $C_{20}H_{36}BrN_3O_2$: C, 55.81; H, 8.43; Br, 18.57; N, 9.76. Fraction b.p. 149–150°/<.001 mm. Found: C, 55.75; H, 8.41; Br, 18.75; N, 9.68. Fraction b.p. 151.5–149°/.001– <.001 mm. Found: C, 55.96; H, 8.61; Br, 18.80; N, 9.62.

The NMR spectrum of RC-12 in CCl_4 was determined on a Varian A-60 using tetramethylsilane as an internal standard. The peaks (p.p.m.) integrate for the following relative intensities: singlet 6.71 (1H), singlet 6.91 (1H), singlet 3.75 (6H), multiplet 3.00 (4H), multiplet 2.43 (12H), triplet 0.93 (12H).

[1] Shirley, D. A., "Preparation of Organic Intermediates," John Wiley & Sons, Inc., New York, N. Y., 1951.

[2] Attempted fusion of a model monoalkylated material with 2 equivalents of diethylaminoethyl chloride at 140° up to 14 hr. resulted in only 56% conversion to the bisalkylated material.

[3] About 200–300 ml. of 10% sodium hydroxide was used.

[4] The mixture was extracted four times with 250-ml. portions of chloroform.

[5] About 200 ml. was used. This is to remove any inorganic material which has been carried into the chloroform extract. The presence of small amounts of this material leads to difficulties in the distillation.

[6] Extracted four times with 250-ml. portions of ether.

[7] The pot was heated with an oil bath (silicone) maintained at 200–250°. The oil bath was heated by an Agit-Therm magnetic stirrer which also served to agitate a stirring bar in the distillation pot.

[8] The beaker used to weigh out the bromine was rinsed with 10 ml. of acetic acid and this was added to the bromine in the dropping funnel. Room temperature was approximately 26°.

[9] About 50 ml. was used.

[10] Two extractions using about 250 ml. of ether each followed by two extractions with 250-ml. portions of benzene.

[11] Two portions of approximately 250 ml. each.

[12] A 4-in. Vigreaux column heated with an electric heating tape was used for this distillation. The pot was heated (200–250°) and stirred as described in *Footnote 7*.

Bioassay of Different Formulations of Aspirin by Means of Human EEG

By CARL C. PFEIFFER, LEONIDE GOLDSTEIN, HENRY B. MURPHREE, and MARTHA HOPKINS

Several commercial formulations of aspirin were compared for potency and duration of action. Quantitative human EEG was employed as the bioassay. The effects of aspirin as determined by this technique are highly reproducible and dose-related, resembling qualitatively the effects of common "antianxiety" drugs. The results show that differences in formulation lead to differences in pharmacological effect.

INNUMERABLE claims appear continually about the relative efficacy and speed of action of different formulations of aspirin. Careful evaluation of these is important, because aspirin is probably the most heavily consumed of all drugs. Serum salicylate concentrations give information about absorption from the gastrointestinal tract into the blood stream, but are not directly informative about the time course of the concentrations of aspirin at its pharmacological sites of action. The latter can be determined only by means of some kind of bioassay, preferably in humans, since man is the species of interest where the consumption of this drug is concerned. Aspirin does not reliably influence pain thresholds or other varieties of experimentally induced pain which can be employed in humans, although some information has been gained from dogs by means of the intra-arterial bradykinin technique of Lim (1). Clinical pain can be demonstrably influenced by aspirin, but not with sufficient precision to differentiate among various formulations. Therefore, a new approach has been needed to delineate with sensitivity and accuracy the time course and potencies of aspirin preparations in their pharmacological actions in humans.

The authors have reported previously (2) that aspirin has characteristic, highly reproducible effects upon the quantitative electroencephalograms (EEG) of normal human volunteers. The present report describes the results obtained when the earlier trials were replicated with larger numbers of subjects given varying doses and when different commercial preparations of aspirin were compared. Some related drugs were again studied concurrently for comparison.

METHODS

The method employed quantitative analysis of the EEG, recorded "monopolarly" from the left occipital area. Fifty-four subjects, 31 male reformatory inmates and 16 male and 7 female members of the laboratory staff, ages 18 to 30, took part in a total of 279 experimental sessions. During the first hour of a standard 7-hr. session, the electrodes were affixed and a 10-min. recording was obtained. Immediately after this, the drug (or placebo) was administered orally. Thereafter, 10-min. recordings were made every hour for 6 hr. During all recordings the subjects were reclining with eyes closed in a dimly lighted, quiet room. Between recordings, the subjects were free to move around or to sit and read in a lounge adjoining the EEG recording room.

Quantitation of the EEG was performed with an electronic integrator (3, 4). This device transforms the complex EEG signals into pulses which are recorded concomitantly with the direct tracings. The number of pulses for any given time period is directly proportional to the cumulated electrical energy. Calibration is by the application of known energy constants, and the values obtained therefore can be related to fixed standards. The basic time-unit chosen for analysis was 20 sec. (that is, 2 pages of standard EEG); thus any 10-min. recording yielded 30 successive measurements. The number of pulses during each 20-sec. period was automatically totalized and printed on paper tape. Artifacts were easily removed from the counts since each set of numbers could be related to the page of direct recording from which it was obtained.

All the corresponding values from each predrug and postdrug run, as obtained from all subjects involved in each study, were averaged, and the mean energy content (MEC) for the group was thus determined. Observed differences in MEC were tested for statistical significance by means of the t test. In addition, a careful analysis of variability within subjects was performed for each time period. It has been previously shown (5) that this parameter of quantitated EEG data is highly informative, not only for the detection and characterization of drug effects, but also for baseline features. For example, it has been found that male chronic schizophrenics have much less EEG variability than nonpsychotics (5). Statistical significances of the differences in variability were determined from F ratios. The within-subject variabilities are shown in the tables as coefficients of variation (CV). This is to allow averaging of the variability in the records of subjects who have different MEC values.

Since the drugs were ordinary commercial preparations obtained locally, it was not always possible to have identical-appearing placebo and active medication tablets. However, in most cases the tablets were similar in form and color. Strict double-blind design was followed in all other respects. Cross-over of subjects from one study to another served to minimize possible biases.

RESULTS

Table I gives the results obtained with effective doses of the different forms of commercially avail-

N = 20	CV	18	21	23	26	23	25	19

[a] MEC, mean integrated energy levels of the EEG. [b] CV, coefficient of variation (standard deviation × 100/mean). [c] N, number of subjects. (The actual number of measurements used to compute the variance was ($N \times 30$) − N; thus 580 in the case of generic aspirin.) [d] The asterisk denotes statistically significant departure from control levels (t tests for MEC, F ratios for variances) at the 0.05 level or better.

able aspirin. In most of the experimental trials the effective dose was 3 tablets or about 1.0 Gm. As can be seen, two significant changes occurred after all the dosage forms, namely, a decrease in MEC and an increase in CV. This is the characteristic effect of aspirin. The times of onset and peak of action were different, but the dual trend was present in all cases. With brand aspirin, the shifts occurred sooner and lasted longer than with generic aspirin. The most pronounced effects were observed following the administration of brand buffered aspirin. With this drug a significant dose-response relationship was shown in that 2 tablets had a relatively smaller and shorter-lasting action than 3 tablets. This is illustrated in Fig. 1. Placebo did not produce significant changes. The threshold dose for significant EEG effects was found to be 2 tablets; 1 tablet (330 mg.) was ineffective.

It will be noticed that the initial levels of the MEC varied in magnitude among the different groups. This is due to random assortment of the subjects with high or low amplitude of the so-called "α-waves." On the other hand, the coefficient of variation was found to be constant (within the limits of statistical variation) from group to group.

From the standpoint of visual inspection of records, the changes in MEC and CV corresponded to what is sometimes called "EEG drowsiness," *i.e.*, flattening of the amplitude of α-waves with sporadic occurrence of waves corresponding to light sleep and even some high amplitude slow waves.

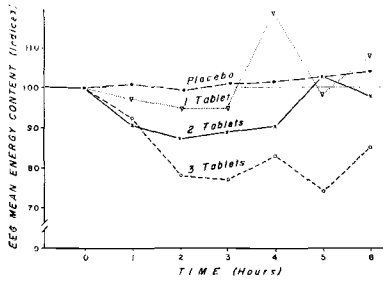

Fig. 1—Dose-response curves of the effect of brand buffered aspirin on the quantitative EEG of 4 groups of 10 subjects each.

Of the other antipyretic compounds studied, sodium salicylate, salicylamide, and acetaminophen had negligible effects (Table II). Significant increases in the CV occurred 1, 2, 4, 5, and 6 hr. after phenacetin, but there was no significant shift in the MEC. The lack of effect of sodium salicylate might be a result of its slow rate of absorption (6), since the time course of the EEG changes after aspirin correlates with previously reported curves of the serum levels of salicylates following oral administration (7). Another kind of analgesic, codeine, was studied at 2 dose levels, 32 and 64 mg. orally. After 32 mg., a dose which is commonly employed clinically for analgesic effect, no changes in the EEG were detected (Table II). The larger dose of codeine, 64 mg., caused significant increases in variability with no alteration in the MEC; thus it resembled phenacetin in effect but was unlike aspirin.

When the aspirin data are compared with those obtained from other classes of compounds, a striking resemblance to the effects (8) of those drugs which are variously called "minor tranquilizers" or "anti-anxiety" drugs is observed. In Table III, data from experiments performed with normal subjects given 3 such agents are presented. Although differences in time course and extent of change occurred, the characteristic decrease in MEC and increase in CV were present nonetheless. It should be emphasized that these changes are characteristic of the anti-anxiety class of drugs only; neither stimulants nor potent depressants nor any other kind of psychotropic agent yet tested produces the same kind of action. For example, stimulants decrease both the MEC and the variability of the EEG; major tranquilizers increase the MEC and decrease the CV. It would thus appear that in normal subjects aspirin produces changes in occipital electrical activity very similar to those caused by anti-anxiety agents. Since this effect is not mimicked by a more potent analgesic, codeine, it is probably not related to analgesia *per se*.

DISCUSSION

The drugs used in these studies were purchased

[a] See Table I for explanation of the symbols used.

from local commercial sources. The identification of the brands used is not germane to this scientific report. The authors believe that this study indicates that careful pharmaceutical formulation produces a greater "aspirin effect" on the human brain. The careful selection of buffers and binders is important. It is well known that acetylsalicylic acid in the presence of moisture undegoes hydrolysis to salicylic and acetic acids. The question can be raised as to whether the reported differences between "generic" and "brand" aspirin are due to the relative commercial turnover of these different preparations, in other words, to the time duration between production and consumption; this could be faster in the case of "brand" products, with the result of a higher concentration of acetylsalicylic acid. No attempt was made to determine the extent to which this assumed difference could have biased the data, primarily because the aim was to reproduce as nearly as possible the conditions under which the different forms of aspirin are used in everyday life. Various commercial firms claim that bottled aspirin will remain stable for many years. This is probably true, since no date limit is required for its medical use.

The results of this study raise questions about the extent to which people take aspirin for effects other than relief of pain, fever, or inflammation, and their reasons for doing so. Because the EEG effects of aspirin are similar to those of compounds such as phenobarbital, meprobamate, and chlordiazepoxide, it is possible that other effects may also be similar and may thus account for the popularity of aspirin which, unlike the other drugs, can be purchased over the counter and taken without any pejorative connotations. Even if aspirin is not obviously effective in marked anxiety, it may be sufficiently active to relieve the lesser anxieties and tensions which occur in everyday life. Some support for this has appeared in two reports (9, 10) of studies which employed psychological rating scales to assess the effects of aspirin in groups of hospital attendants, nurses, and other employees. Significant reductions in "depression" and "fearfulness" occurred after aspirin administration. The authors have thus confirmed the psychological findings by an independent and objective study of human brain waves.

Dissolution Kinetics of Benzoic Acid in High Concentrations of Surface-Active Agents

By E. L. PARROTT and V. K. SHARMA

The dissolution kinetics of benzoic acid has been studied in the presence of certain surface-active agents. The addition of tyloxapol, polysorbate 80, sodium lauryl sulfate, and poloxakol to the dissolving fluid increased the apparent solubility of benzoic acid. In considering the experimentally determined dissolution rate as a function of solubility, it appears that the dissolution process in solutions of tyloxapol, polysorbate 80, and sodium lauryl sulfate concurs with the diffusion layer concept, while the dissolution process in the presence of poloxakol is best described by an interfacial barrier model.

IT IS WELL RECOGNIZED that the dissolution rate can be the rate-limiting step in the biological availability of drugs administered in the solid state. Wagner (1) has discussed the relation of dissolution kinetics to biological availability. Wurster and Taylor (2) have reviewed factors which influence the dissolution rate. In a recent review Higuchi (3) presented models for three mechanisms of dissolution rate behavior of solids.

Since surface-active agents are often a constituent of liquid and solid pharmaceuticals, a more complete understanding of the effect of surface-active agents on the dissolution rates of solids is of interest in the design of these dosage forms. Limited information has been published regarding the effect of surface-active agents on dissolution rate (4–7). Generally these investigations have been conducted in the region of the critical micelle concentration (CMC) of the surface-active agent employed. The purpose of this work is to investigate the effect of high concentrations of surface-active agent on dissolution rate of a relatively water-insoluble compound.

EXPERIMENTAL

Materials—The surface-active agents were commercial lots which were used without further purification. Poloxakol[1] is an oxyethylene polymer which contains 80% polyoxyethylene and has an approximate molecular weight of 8700. Tyloxapol[2] is a condensation product of *tert*-octylphenol with ethylene oxide having an average molecular weight of 2800. U.S.P. polysorbate 80[3] and sodium lauryl sulfate;[4] benzoic acid, citric acid, and disodium hydrogen phosphate were reagent grade.

Dissolution Rate Determinations—The procedure for tablet production and the dissolution apparatus were similar to that previously described (8). Spherical $^3/_8$-in. diameter tablets of pure benzoic acid were used. All determinations were made at 25° and at a stirrer speed of 324 r.p.m. At hourly intervals the 2 L. of dissolving fluid was changed, and the tablet was weighed and its diameter measured with a micrometer. At each concentration of surface-active agent, the dissolution rate was determined in triplicate with the rates falling within a 3% range.

Solubility Studies—An excess of benzoic acid and aqueous solutions of the surface-active agent were rotated in 50-ml. amber bottles in a constant-temperature bath at 25 ± 0.1° for 24 hr. An aliquot was withdrawn from each bottle using a pipet fitted with a filter. After diluting with distilled water, the absorbance was measured with a Beckman DU spectrophotometer, and the solubility of the benzoic acid was determined by means of a standard curve.

In the analysis of samples containing polysorbate 80, sodium lauryl sulfate, and poloxakol, distilled water was used as a blank since the samples were diluted 400-fold and there was no absorption by the surface-active agents. The absorbance was measured at 272.5 mμ. The concentration of benzoic acid was determined from a standard curve prepared by measuring in known concentrations of surface-active agents the absorbances of known concentrations of benzoic acid which had been diluted in a similar manner.

The strong absorption of tyloxapol in the region of 280 mμ necessitated the use of an extraction procedure. In preparing a standard curve using chloroform as the solvent it was found that there was a shift in the absorption maximum of benzoic acid to 273.5 mμ. In the analytical procedure a 10-ml. sample was diluted 100-fold with distilled water, and 25 ml. of this dilution was extracted with three 25-ml. portions of chloroform. The combined chloroform extract was filtered into a 100-ml. volumetric flask and adjusted to 100 ml. with chloroform. The absorbance was measured at 273.5 mμ. The concentration of benzoic acid was determined from a standard curve prepared by measuring in known concentrations of tyloxapol the absorbances of known concentrations of benzoic acid which had been extracted in the manner described.

RESULTS AND DISCUSSION

Solubilization—In dilute aqueous solutions in which the surface-active agent is molecularly dispersed, compounds of low water solubility, such as benzoic acid, do not dissolve to a greater extent than they would in water; however, at concentrations of surface-active agent in excess of the CMC the total solubility is increased. The amount of benzoic acid solubilized by micellar interaction ($C_s - C_0$) is represented by the difference between the total solubility (C_s) in a solution of a surface-active agent and the solubility (C_0) in water (9). The quantity ($C_s - C_0$) is linearly dependent on the concentration of the surface-active agent.

10.00	53.55	17.48	14.25

The data for tyloxapol given in Table I and plotted in Fig. 1 are typical of the experimental results for the solubilization of benzoic acid at 25° in various concentrations of surface-active agent. The linear relationship between solubilization and concentration of surface-active agent was also found to exist in solutions of polysorbate 80, sodium lauryl sulfate, and poloxakol, as shown in Figs. 2 to 4.

Dissolution Rate in Concentrations of Surface-Active Agent Exceeding the CMC—When a single component, one phase solid of macroscopic size dissolves without disintegration and without chemical reaction in an agitated solvent, the dissolution rate (R) at a given temperature may be expressed by the Noyes and Whitney equation:

$$R = \frac{dw}{dt}\frac{1}{S} = k\,(C_s - C) \qquad \text{(Eq. 1)}$$

where dw/dt is the amount of solute dissolved per unit time, S is the surface area, C_s is the solubility, C is the concentration of the solute, and k is a constant.

When $C_s \gg C$ the dissolution rate will be:

$$R = k\,C_s \qquad \text{(Eq. 2)}$$

Numerous reports have substantiated this relationship which states that the dissolution rate is proportional to the solubility of a compound (8, 10–12).

Since any dissolution interaction may affect C_s and consequently alter the dissolution rate, it was thought that micellar solubilization, which increased the solubility of benzoic acid, would increase its dissolution rate. The experimentally determined dissolution rate and the corresponding quantity $(C_s - C_0)$ for benzoic acid in various concentrations of tyloxapol are given in Table I and Fig. 1. With an increase in the concentration of tyloxapol, there is an increase in the solubility and an increase in the dissolution rate. The dissolution rate attains its maximum value at 5% tyloxapol, and the dissolution rate decreases upon further increases in the concentration of the surface-active agent.

Similarly, as shown in Fig. 2 an increase in the concentration of polysorbate 80 results in an increased solubility and an increased dissolution rate. A maximum dissolution rate is reached at 9% polysorbate 80.

Qualitatively the experimental results are in accordance with Eq. 2; however, with micellar solubilization the micelle phase must be considered and according to the diffusion layer concept (3):

$$R = \frac{D}{h}C_0 + \frac{D'}{h}(C_s - C_0) \qquad \text{(Eq. 3)}$$

where h is the effective diffusion layer thickness, D is the diffusion coefficient, C_0 is the solubility of the solute molecule, and D' is the diffusion co-

efficient of the micelle-solubilized solute and (C_s − C_0) is the solubility increase due to solubilization.

As the concentration of tyloxapol and polysorbate 80 is increased, the increase in dissolution rate becomes progressively less, and at high concentrations the dissolution rate is decreased. If this effect were due to the influence of viscosity, it would be reflected in Eq. 3 in the diffusion coefficients which by the Stokes-Einstein equation are inversely proportional to the viscosity (13). If dissolution were an interfacially controlled process, viscosity should have little effect on the dissolution rate. If dissolution were a diffusion-controlled process, an increase in viscosity should decrease the dissolution rate (2). The fact that both tyloxapol and polysorbate 80 in high concentrations cause a decrease in dissolution rate suggests that the dissolution process is primarily diffusion controlled and would support the diffusion layer concept as the model of their dissolution behavior; however, a further study is necessary to substantiate this suggestion.

The effect of sodium lauryl sulfate on the dissolution rate of benzoic acid and prednisolone in the region of the CMC has been reported (14, 15). In this region the solubilities and dissolution rates of both compounds were increased. In the present study the effect on solubility and dissolution rate was determined in concentrations greatly in excess of the CMC. The system was buffered to pH 3 with McIvaine's buffer in order to suppress ionization and minimize salt formation which would contribute to the solubility of benzoic acid by a mechanism other than micellar solubilization.

As shown in Fig. 3, the dissolution rate of benzoic acid is increased with increased concentrations of sodium lauryl sulfate; however, a maximum dissolution rate is reached at 9% sodium lauryl sulfate. Further increases in the concentration of sodium lauryl sulfate result in a decrease in dissolution rate.

The dissolution rate may be considered to be determined by 2 consecutive reaction rates: the rate of reaction at the interface and the rate of diffusion from the interface. If the reaction at the interface is infinitely fast, the Nernst and Brunner concept of dissolution by diffusion from a saturated film existing at the interface is acceptable. This appears to be the dissolution model of benzoic acid in solutions of sodium lauryl sulfate. If the surface reaction is the rate-limiting step, the dissolution kinetics would be different from that expressed by Noyes and Whitney.

The solubility of benzoic acid is a linear function of the concentration of poloxakol. It might be postulated that poloxakol is too hydrophilic to form micelles, but that it increases the solubility through association or hydrogen bonding of the benzoic acid to its polyoxyethylene groups. As shown in Fig. 4 the dissolution rate of benzoic acid in poloxakol is not proportional to the concentration of the surface-active agent. This suggests that the dissolution process occurs by a mechanism other than a primarily diffusion-controlled process.

Dissolution Rate in Concentrations of Surface-Active Agent Less Than the CMC—As shown in Table I, in concentrations of tyloxapol less than the CMC, the dissolution rate of benzoic acid is not significantly increased by the addition of the surface-active agent. Since no solubilization was shown to occur in this region, any increase in dissolution rate may be attributed to a lowered interfacial tension which improved the wetting of the surface and increased the effective surface area (13). Similar results were found with poloxakol.

The greatest effect of wetting the surface was shown with polysorbate 80. Although the solubility was not increased, at 0.001, 0.002, and 0.003% polysorbate 80, the dissolution rates were 45.9, 46.8, and 47.5 mg./cm.^{2}/hr., respectively.

SUMMARY

A linear relationship between solubilization of benzoic acid and concentration of a surface-active agent was found to exist in solutions of polysorbate 80, sodium lauryl sulfate, tyloxapol, and poloxakol. At concentrations of these surface-active agents less than the CMC, the dissolution rate was only slightly increased due to improved wetting of the surface. At concentrations exceeding the CMC, the dissolution rate was increased to a maximal rate by an increase in concentration of tyloxapol, polysorbate 80, and sodium lauryl sulfate. This behavior agrees with the diffusion layer theory. At higher concentrations the dissolution rate decreased; however, this may be rationalized by the diffusion layer theory when the micelle phase and its diffusional coefficient are considered. The dissolution rate of benzoic acid was retarded by poloxakol.

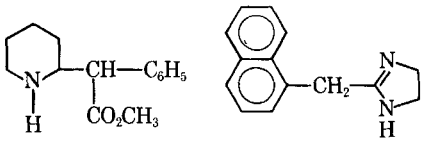
Phenylalkylamines

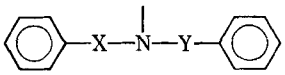
By JOSEPH SAM*

The syntheses of 1- and 2-aralkylpyridines and piperidines and phenylalkylamines are described.

THE ARRAY of compounds which contain the phenylalkylamine moiety and which possess useful biological properties is impressive. The investigation with various phenylalkylamines has culminated in the preparation of compounds with a narrow spectrum of sympathomimetic activity, useful in specific conditions. For example, the incorporation of the alkylamine portion in a heterocyclic molecule such as methyl α-(2-piperidyl)phenylacetate (I) and 2-(1-naphthylmethyl)-2-imidazoline (II) provides compounds with specific central nervous system stimulant (1, 2) and nasal decongestant activity (3, 4), respectively. The preparation of di-(phenylalkyl) amines represented by structure III has led to the development of compounds useful in the management of bronchoconstrictor disorders (5, 6) and in vascular constrictive diseases (7).

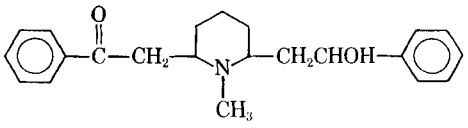


I II



III

Because of the pronounced biological effects exhibited by di-(phenylalkyl)amines (III) and because of the desirable properties elicited by the incorporation of the alkylamine portion in a cyclic structure (8), it was of interest to prepare both mono- and di-(phenylalkyl)amines containing the pyridine and piperidine ring (Tables I and III). The compounds listed in Table III also bear some structural similarity to the alkaloid lobeline (IV) (9).



IV

The pyridine derivatives listed in Table I were prepared by (*a*) the reaction of picolinealdehyde with acetophenones (10), or (*b*) by the reaction of 3,4-dimethoxybenzaldehyde with α-picoline (11), or (*c*) by the reaction of 2-vinylpyridine with *N*-methyl-β-hydroxyphenethylamine (V) (13, 14), or (*d*) by the Pd-C catalyzed reduction of the ethylenic groups of the products obtained in (*a*) and (*b*). (Scheme I.)

The piperidine derivatives (VIII) of Table III were prepared by the catalytic reduction of pyridinium bromides (VII) (Table II). (Scheme II.)

Hypotensive activity (15) and neurosedative activity (16) have been observed recently in similar compounds. Included also in this study are several nonpiperidine derivatives (Table IV). Preliminary pharmacological evaluation did not indicate any pronounced biological activity in the compounds that were studied.

EXPERIMENTAL[1]

α - {([2 - (5 - Ethyl - 2 - pyridyl)ethyl]methylamino)methyl}benzyl Alcohol (VI)—A mixture of 40 Gm. (0.3 mole) of 5-ethyl-2-vinylpyridine, 46 Gm. (0.3 mole) of *N*-methyl-β-hydroxyphenethylamine, 18 Gm. of glacial acetic acid, and 200 ml. of methanol was refluxed for 18 hr. The methanol was distilled *in vacuo*. The residual oil was added to ice and neutralized with 10% sodium hydroxide. An ether extract of the mixture was dried over anhydrous sodium sulfate. Evaporation of the ether and distillation of the oil gave product, n_D^{26} 1.5489.

1 - (4 - Chlorophenyl) - 3 - (2 - pyridyl) - 2 - propene-1-one (IX)—To 2 Gm. of piperidine cooled in an ice bath were added 2 Gm. of glacial acetic acid, 15 Gm. (0.1 mole) of 4′-chloroacetophenone, and 11 Gm. (0.1 mole) of picolinealdehyde, respectively. The resulting mixture was heated on a steam bath for 2 hr. and then cooled. An ether extract of the oily material was washed thoroughly with water and dried over anhydrous potassium carbonate. Evaporation of the solvent *in vacuo* left a dark brown oil which solidified on standing.

1,5 - Bis - (4 - chlorophenyl) - 3 - (2 - pyridyl)-pentane-1,5-dione (XII)—A solution of 4 Gm. (0.1 mole) of sodium hydroxide in 40 ml. of water and 20 ml. of ethyl alcohol was treated with 15.5 Gm. (0.1 mole) of 4′-chloroacetophenone. The mixture was cooled in an ice bath and treated with 10.7 Gm. (0.1 mole) of picolinealdehyde in one lot. The mixture was shaken intermittently during a 1-hr. period. The oil that separated solidified; it was removed by filtration, washed with methanol, and recrystallized.

1 - (4 - Nitrophenyl) - 3 - (2 - pyridyl) - 2 - propene-1-one (XI)—The procedure for the preparation of 1 - (4 - chlorophenyl) - 3 - (2 - pyridyl) - 2 - propene-1-one was followed using 16.5 Gm. (0.1 mole) of 4′-nitroacetophenone and 11 Gm. (0.1 mole) picolinealdehyde.

4′ - Chloro - 3 - (2 - pyridyl)propiophenone (X)—A solution of 44 Gm. (0.18 mole) of 1-(*p*-chlorophenyl)-3-(2-pyridyl)-2-propene-1-one in 200 ml. of warm methanol was hydrogenated at 52 p.s.i. in the presence of 1 Gm. of 5% Pd-C catalyst. Reduction was complete in 30 min. The catalyst was removed by filtration and the solvent was distilled under reduced pressure.

2-(3,4-Dimethoxystyryl)pyridine (XIII)—A solution of 93 Gm. (1 mole) of 2 picoline, 166 Gm. (1 mole) of veratric aldehyde in 204 Gm. (2 moles) of acetic anhydride was refluxed for 66 hr., cooled, and poured into ice water. The mixture was extracted with ether and dried over anhydrous sodium sulfate. Evaporation of the solvent and distillation of the residual oil gave product.

2-(3,4-Dimethoxyphenethyl)pyridine (XIV)—The procedure described for the preparation of X was followed using 93 Gm. (0.385 mole) of 2-(3,4-dimethoxystyryl)pyridine; reduction was complete after 18 hr.

Pyridinium Bromides (VII, Table II)—A solution of 0.2 mole of desired pyridine and 0.2 mole of phenylalkyl bromide in 100 ml. of acetonitrile was heated under reflux on a steam bath for 48 hr. and then cooled. The solid was removed by filtration, washed with cold acetone, and thereafter recrystallized from a suitable solvent. In some cases ether was added to the cooled acetonitrile solution to precipitate the pyridinium bromide.

[a] M, Methanol; M–W, methanol–water; B, benzene; MEK, methyl ethyl ketone. [b] 2-Hydroxy-1-indanyl. [c] 1-Oxo-2-indanylmethyl. [d] Hydrochloride. [e] 2-Indanylmethyl.

Hydrogenation of Pyridines to Piperidines (Table III)—*Method A*—A solution of 0.1 mole of the desired 1-substituted pyridinium bromide in 200 ml. of water was hydrogenated at 50–60 p.s.i. at approximately 40–50° in the presence of 0.4 Gm. of platinum oxide catalyst until the theoretical amount of hydrogen was absorbed (5–18 hr.). The mixture was concentrated *in vacuo* on a water bath, treated with methanol, and thereafter filtered to remove the catalyst. The filtrate was concentrated *in vacuo* on a water bath and the residual material either was recrystallized from a suitable solvent or was converted to the base, isolated in the usual manner, and distilled.

Method B—A mixture of 0.2 mole of desired pyridine and 0.2 mole of phenylalkyl bromide was heated on a steam bath for 1 hr. The residual oil was dissolved in water and hydrogenated as described under *Method A*.

Method C—A solution of 0.2 mole of desired pyridine and 0.2 mole of phenylalkyl bromide in 100 ml. of acetonitrile was refluxed on a steam bath for 20–30 hr. and thereafter cooled and diluted with ether. The mixture was extracted with 200 ml. of water. The aqueous solution was warmed on a steam bath to expel any ether present and then hydrogenated as described under *Method A*.

1-Phenethyl-3-piperidylmethyl Chloride (VIIIa)—*Method D*—A solution of 28 Gm. (0.13 mole) of 1-phenethyl-3-piperidylcarbinol in 100 ml. of chloroform was added dropwise to a solution of 30 ml. of thionyl chloride in 100 ml. of chloroform. The solution was allowed to remain at room temperature for 18 hr. and then refluxed for 3 hr. The solvent and excess thionyl chloride were distilled *in vacuo*. The residual solid was dissolved in ice water, neutralized with 10% sodium hydroxide, extracted with chloroform, and dried over anhydrous potassium carbonate. Evaporation of the solvent and distillation of the residual oil gave product, n_D^{26} 1.5303.

1-Phenethylisonipecotohydrazide (VIIIi)—*Method E*—A solution of 10 Gm. (0.04 mole) of methyl 1-phenethylisonipecotate and 10 Gm. (0.2 mole) of hydrazine hydrate in 30 ml. of water was refluxed 3 hr. The solvent was distilled under reduced pressure and the residual solid was recrystallized.

α - {[2 - (5 - Ethyl - 2 piperidyl)ethyl]methylamino)methyl}benzyl Alcohol—The procedure described under *Method A* for the preparation of *N*-substituted piperidines (VIII) was followed. From 13 Gm. (0.05 mole) of the corresponding pyridine derivative (VI) there was obtained 12 Gm. (88%) of product, b.p. 178–180° (0.6 mm.), $n_D^{24.5}$ 1.5218.

1-(3,4-Dimethoxyphenethyl)-2-indanol (XV)—A mixture of 13.2 Gm. (0.1 mole) of indene oxide, 18.1

Gm. (0.1 mole) of 3,4-dimethoxyphenethyl amine, and 150 ml. of benzene was refluxed on a steam bath for 6 hr. The benzene was evaporated and thereafter the dark brown oily residue was heated on a steam bath for 6 hr. The residual material solidified on cooling.

2-Benzylaminomethyl-1-indanone (XVI)—To a mixture of 14 ml. of concentrated hydrochloric acid and 14 Gm. (0.13 mole) of benzylamine were added 18.5 Gm. (0.14 mole) of 1-indanone and 12 ml. (4.1 Gm., 0.14 mole) of 37% formaldehyde solution. The resulting mixture was heated on a steam bath for 40 min. and thereafter cooled and filtered. The residual material was washed with two 50-ml. portions of methanol to give 20 Gm. (53%) of white solid, m.p. 190–193° dec.

2 - Dimethylaminomethyl - 4 - (1 - indanyl)-phenol (XVII)—A solution of 21 Gm. (0.1 mole) of 4-(1-indanyl)phenol in 100 ml. of isopropanol was treated with 18 ml. of 25% aqueous dimethylamine solution and 10.5 ml. of a 37% formaldehyde solution and thereafter refluxed on a steam bath for 1.5 hr. The solvent was distilled *in vacuo*. The residue was treated with dilute hydrochloric acid and extracted with ether. The acid solution was neutralized with ammonium hydroxide and extracted with ether. The latter ether extract was dried over anhydrous magnesium sulfate and then evaporated to dryness. The residual material (10 Gm., 40%), which melted at 51–56°, was recrystallized.

2-Hydroxy-3-methoxybenzylmethylamine (XVIII)—The procedure for the preparation of X was followed using 31 Gm. (0.7 mole) of 2-hydroxy-3-methoxybenzalmethylamine. Reduction was complete after 18 hr.

N - Benzyl - N - (2 - indanylmethyl)methylamine (XIX)—A mixture of 10.6 Gm. (0.05 mole) of 2-bromomethylindan and 25 Gm. of *N*-benzylmethylamine was refluxed for 6 hr. Thereafter the mixture was cooled and extracted with dilute hydrochloric acid. The acid solution was neutralized and extracted with ether. The ether extract was dried over anhydrous magnesium sulfate and then distilled to give product.

A hydrochloride (XX) was prepared in the usual manner and recrystallized.

Placebo Effect of Saline on Locomotor Activity in Several Strains of Mice

By W. M. DAVIS, W. T. KING, and M. BABBINI

The effect of intraperitoneal injection of 0.9 per cent saline solution upon locomotor activity of six strains of mice was observed in actometer cages. Whether tested singly or in groups of four, a depressant effect of saline upon activity was seen. The strains differed significantly in activity levels, but not in degree of effect of saline on activity. Group testing had differing degrees of effect on activity counts compared to single-mouse tests in the several strains.

A REDUCTION in the locomotor activity of mice which received an injection of physiological saline in comparison to the activity of uninjected mice has been reported by Schnitzer and Ross (1). They found that this effect was dependent upon more than the act of handling the mouse or handling plus intraperitoneal insertion of a hypodermic needle. Meier (2) confirmed their findings with 0.9% saline group compared to a sham-injected group even while using only one-half the volume (0.005 ml./Gm.) administered by the former workers. Schnitzer and Ross (3) later failed to observe an inhibitory effect of saline when they used younger mice than those of their first report; however, testing at a higher room temperature may have been responsible for the difference. Meier's confirmation was by means of younger mice than were used in either of the other reports.

Meier *et al.* again reported inhibition of locomotion by saline injection incidental to other observations involving four inbred strains of mice (4). They stated that the ranking of post-saline activities of the strains was significantly different from the ranking of activities in a previous noninjection test, but without presenting fully the data to describe this finding. Further evidence regarding the genetic factor as a possible variable in the "placebo effect" of saline in-

TABLE I—EFFECTS OF SALINE INJECTION ON LOCOMOTOR ACTIVITY OF SIX STRAINS OF MICE TESTED SINGLY OR IN GROUPS OF FOUR

Mean 30-min. Activity Count[a] (Log-Transformed)					
Single Mice			Grouped Mice		
Strain	No Inject.	Saline	Strain	No Inject.	Saline
NLW	2.990	2.810	NLW	3.522	3.409
C57BL/6	2.948	2.904	C57BL/6	3.452	3.360
DBA/2	2.934	2.855	C3H/An	3.381	3.331
BALB/c	2.913	2.905	CBA	3.335	3.353
C3H/An	2.847	2.796	DBA/2	3.324	3.235
CBA	2.778	2.714	BALB/c	3.322	3.300

[a] $N = 12$ in all cases.

RESULTS

Locomotor activity values under the several treatment conditions are shown in Table I. Results of the analysis of variance performed on the log-transformed data[4] are shown in Table II. The analysis revealed significant main effects of both saline injection ($p < 0.005$) and of strains ($p < 0.005$), and quite expectedly, of grouping ($p < 0.005$).

In view of the nonsignificant interaction of injection and strains, further analysis of the injection effects within strains was unwarranted. Further details of the between-strains differences contributing to the significant strains effect were determined by means of Duncan's multiple range test (8). This test was performed separately on the data for singly-tested and group-tested mice because of the significant interaction of strains and groupings, but after combining injected and noninjected groups in view of the nonsignificant interaction of injection with strains. Results of these multiple comparisons between strains are given in Table III. The significant interaction between grouping and strains, along with obvious difference in ordering of the strains under single and group tested conditions (Table III) suggested also the application of Duncan's test to the differences for each strain between values of single and grouped mice. The results of this test (Table IV) indicate that in addition to the differences in motility between strains as shown in Table III there is a significant difference in the effect of grouping on motility in different strains. The obvious and expected increase in counts when four mice are tested rather than one was in fact significantly more pronounced in the CBA, NLW, and C3H/An strains than in the DBA/2 and BALB/c. This suggests that the increase of counts with grouping is, for some strains at least, not merely a physical phenomenon as a consequence of the increased number of mice in the actometer, but also a behavioral phenomenon involving social factors.

TABLE II—ANALYSIS OF VARIANCE ON LOG-TRANSFORMED ACTIVITY DATA

Term	Degrees of Freedom	Sum of Sq.	Mean Sq.	F	p
Treatments	(23)	19.381	0.842	30.07	<.005
Injection	1	0.280	0.280	10.00	<.005

Error	264	7.482	0.028	...	...
Total	287	26.863	0.093	...	...

jection on locomotor activity of mice seemed desirable. Since spontaneous locomotor activity is well known as a behavioral phenotype which is influenced by genetic differences between strains of laboratory mice (5, 6), it is of particular interest whether the effect of saline injection would occur independently of genotype. As all the previous reports of this phenomenon were based on observations of individual mice, it also seemed desirable to test for the effect in the case of small groups as are often used in studying locomotor effects of drugs. In summary, locomotor activity of groups of four mice and of single mice from six strains under noninjection and saline-injection conditions have been compared.

EXPERIMENTAL

Observations of locomotor activity were made in three commercially manufactured[1] photocell activity devices (7). All actometer units were exposed to each level of all the experimental variables. The number of counts, each representing the interruption of one of the six light beams distributed symmetrically around the ring-shaped track, was recorded by digital counters.

Inbred male mice of the C57BL/6, DBA/2, C3H/An, CBA, and BALB/c strains[2] and random-bred male mice of a Swiss-Webster albino strain (NLW)[3] were received at about 30 days of age and were between 8 and 12 weeks old when 60 from each strain were used in these experiments. A 0.9% saline solution in distilled water was administered intraperitoneally in a volume of 0.01 ml./Gm. Locomotor activity recording was begun immediately after injection and continued for 30 min. The handling of noninjected mice was approximately the same as for the saline group, but sham-injection (*i.e.*, needle penetration) was not performed as Schnitzer and Ross (1) had found needle insertion had little or nothing to do with reduction of activity.

DISCUSSION

The earlier reports (1, 2, 4) of the activity-inhibiting effect of intraperitoneal saline treatment in mice are further confirmed and extended by these positive results. The question of age as a factor in the effect which was suggested by one negative report (3) is contradicted since the mice used in this case were also considerably younger than those of the initial report (1). An additional attribute of this

[4] Log-transformation was performed in order to eliminate the proportionality between the means and variances of single mice *versus* groups of mice that occurred in the untransformed data.

TABLE III—RANKING AND COMPARISON OF MEAN LOCOMOTOR ACTIVITY OF SIX STRAINS OF MICE COMBINED ACROSS NONINJECTION AND SALINE TREATMENTS

	Mice Tested Singly[a]					
Strain	CBA	C3H/An	DBA/2	NLW	BALB/c	C57BL/6
Activity	2.733	2.821	2.894	2.900	2.908	2.926

	Mice Tested in Groups[a]					
Strain	DBA/2	BALB/c	CBA	C3H/An	C57BL/6	NLW
Activity	3.820	3.311	3.344	3.356	3.406	3.465

[a] Values not sharing underline differ significantly ($p < 0.05$).

TABLE IV—COMPARATIVE EFFECTS OF GROUPING ON ACTIVITY IN SIX STRAINS MEASURED AS MEAN DIFFERENCES FROM SINGLY TESTED MICE[a]

Strain	DBA/2	BALB/c	C57BL/6	C3H/An	NLW	CBA
Difference	0.386	0.403	0.480	0.535	0.565	0.611

[a] Values not sharing underline differ significantly ($p < 0.05$).

phenomenon indicated by these data is its occurrence in mice tested in groups, as well as those tested singly. Although the present observations include four of the same inbred strains utilized in the study by Meier *et al.* (4), the data do not confirm their implication that the effect of saline treatment varies between strains. While there was a superficial suggestion in the untransformed data that the degree of response to saline might differ between strains, the nonsignificant injection x strain interaction term failed to support such an inference. Any such trend surely was not consistent enough to be detected by the analysis.

The pharmacological basis for the phenomenon of saline inhibition of activity remains quite unknown. The authors have termed it a placebo effect following the definition of Wolf (9), "... any effect attributable to a pill, potion or procedure, but not to its pharmacodynamic or specific properties." It surely cannot have the same explanation as that given for a placebo effect of saline injection upon locomotor activity of rats (10), *i.e.*, simple Pavlovian conditioning of the depressant effect of a previously administered pharmacologically active agent, scopolamine.

Cerebral Drug Metabolism Investigated by Isolated Perfused Brain *In Situ*

By G. BENZI, F. BERTÉ, A. CREMA, and G. M. FRIGO

The *in situ* isolated brain, supplied by an extracorporeal pump-oxygenator system, shows a drug metabolizing activity. The tested substances (aminopyrine and oxazepam) show a disappearance from the extracorporeal blood of dog and monkey related to the metabolic transformations (demethylation, acetylation, or glucurono-conjugation) and to the fixation at the cerebral tissues.

IN A PREVIOUS PAPER (1) the authors described a method to investigate *in situ* the metabolizing activity of the liver connected normally with the body, except for blood circulation, which was supplied by a pump-oxygenator system. In such conditions, the liver functional tests remained within normal limits throughout the experiment, and it was possible to study the rate of some hepatic metabolizing activities, such as demethylation, acetylation, and glucurono-conjugation. In the course of systematic investigations on drug metabolism and tissue distribution (2–4) the research was extended to the metabolic activity of the brain, isolated *in situ* in the

[a] Values not sharing underline differ significantly ($p < 0.05$).

phenomenon indicated by these data is its occurrence in mice tested in groups, as well as those tested singly. Although the present observations include four of the same inbred strains utilized in the study by Meier *et al.* (4), the data do not confirm their implication that the effect of saline treatment varies between strains. While there was a superficial suggestion in the untransformed data that the degree of response to saline might differ between strains, the nonsignificant injection x strain interaction term failed to support such an inference. Any such trend surely was not consistent enough to be detected by the analysis.

The pharmacological basis for the phenomenon of saline inhibition of activity remains quite unknown. The authors have termed it a placebo effect following the definition of Wolf (9), "... any effect attributable to a pill, potion or procedure, but not to its pharmacodynamic or specific properties." It surely cannot have the same explanation as that given for a placebo effect of saline injection upon locomotor activity of rats (10), *i.e.*, simple Pavlovian conditioning of the depressant effect of a previously administered pharmacologically active agent, scopolamine.

living animal. A cat's brain perfusion method *in vivo* was described in 1947 by Geiger and Magnes (5) and modified by Geiger and associates (6, 7). Experiments of brain perfusion were performed either on the severed head (8–10) or with incomplete separation of the brain circulation from the head circulation (11) and from the systemic circulation *in situ* (12–17).

According to Geiger (6), the choice of experimental animals depends on the vascular anatomy of the head and the reasonable availability. The monkey is more suitable for the isolation of the arterial side of the circulation, since no major communication exists between the brain and the rest of the body, except *via* the internal carotid and the vertebral arteries; nevertheless, the blockage of the vertebral sinuses is difficult. The dog is suitable for availability and size, but it shows a *rete mirabile* between the brain and the extracerebral circulation, and a rather large anterior spinal artery. It is impossible to separate the arterial side of the cerebral circulation from that of the extracranial circulation in the cat, because the blood from the carotid arteries reaches the Willis' circle through a *rete mirabile*. Thus, the Geiger procedure (18) consists mainly of the isolation and the occlusion of all the venous outlets of the cat's brain and of opening a new outlet by tapping the cerebral sinuses. In view of the possibility of extending the research to the isolated fetus (19), the dog and monkey were chosen because of their size.

To test the metabolizing activity of the brain isolated *in situ*, some transformations of aminopyrine (demethylation and acetylation) and oxazepam (glucuronide-conjugation) have been examined.

METHOD

The experiments were carried out on 18 dogs (10.3 to 19.7 Kg.) and 6 monkeys (*C. hamadryas*, 8.2 to 12.8 Kg.) preanesthetized with urethan (0.4 Gm./Kg. i.p.). Anesthesia was induced and maintained in closed circuit by nitrous oxide, cyclopropane, or ethyl ether. The animals were given artificial ventilation after tracheal intubation by Warne tube, following succinylcholine chloride (1 mg./Kg. i.v.) administration. Arterial blood pressure was measured from a cannula inserted into a femoral artery. Extradural electrodes were set in place some days before.

The operative procedure consists mainly of the isolation of the jugular external veins in the dog or the jugular internal veins in the monkey, and the isolation of the common carotid arteries and ligature of all their branches except the internal carotid arteries. The vertebral vessels are ligated before their entrance into the transverse foramen of C2 or C3. The numerous muscular branches arising from the vertebral vessels, the anastomosis between vertebral and carotid arteries, the anastomosis between vertebral and jugular veins, the internal jugular veins in the dog or the external jugular veins in the monkey, the vascular muscular branches of the neck, the vessels running under the carotid arteries and vagus nerves, the zygomatic, maxillary, auricular, and supra-orbital vessels are occluded by ligature or compression. The occlusions of the sinus columnae vertebralis and of the anterior spinal artery were made (*a*) by opening the rachis in C2, ligating the dog's spinal artery according to the method of Greeley and Greeley (20), and compressing the venous vessels; (*b*) by opening the rachis between C2 and C3, and compressing all the vessels around the spinal cord.

Both isolated jugular veins were ligated, cannulated, and connected with the venous reservoir of the pump-oxygenator system through the gravitational flow. Both the isolated carotid arteries were cannulated and connected with the pump-oxygenator system; at this point the perfusion started.

Hematocrit, clotting-time, and arterio-venous blood oxygen were measured from samples of both extracorporeal and systemic circulation.

The brain perfusion apparatus employed consists of a venous reservoir, an oxygenator with gasmeter, a roller-type pump with flowmeter, a blood filter, an apparatus to eliminate blood foam, a perfusion pressure regulator with manometer, and a blood exchanger with telethermometer.

Before the extracorporeal brain perfusion, the pump-oxygenator system was filled with 400–500 ml. of heparinized, defibrinated blood. This blood was previously obtained from the animal infused with blood from donor animals. The collected blood was filtered through cloth, preserved by ampicillin (1:10,000), and stored in a refrigerator. Before the perfusion, the blood was filtered, diluted with Tyrode's solution (to O_2 capacity = 13 ± 1 vol. %), and added to glucose (10%). The priming blood was circulated through the pump-oxygenator system fully oxygenated and warmed. A flow of O_2–CO_2 mixture (95:5) into the oxygenator was maintained at the rate of 4–8 L./min.; during the extracorporeal brain perfusion, the blood flow rate was kept very high (8–10 ml./min./Kg.). In most experiments, it was possible to maintain the blood pressure constantly equal to the initial systemic pressure of the animal (100 to 140 mm. Hg).

The time of brain perfusion was limited to 60 or 90 min. and was related to the presence of cerebral electric activity.

The eventual leakage of perfusate into the systemic circulation was evaluated (*a*) during the metabolic research, by taking samples from the general circulation of the blood and of the lymph to verify the absence of the tested substance or its metabolites; (*b*) at the end of the metabolic research by adding either a dye or a radiopaque substance to the blood of the extracorporeal circuit.

The metabolizing activity of the brain was investigated *in situ* by (*a*) the demethylation, by evaluating the transformation of aminopyrine to 4-aminoantipyrine using the method of Brodie and Axelrod (21) after addition of 50–100 mcg./ml. of aminopyrine into the extracorporeal circuit; (*b*) the acetylation, by evaluating the transformation of 4-aminoantipyrine to *N*-acetyl-4-aminoantipyrine under the above-mentioned conditions; (*c*) the glucuronoconjugation, by evaluating the transformation of oxazepam to glucuronide, using the method of Walkenstein *et al.* (22) after addition of 10–20 mcg./ml. of oxazepam into the extracorporeal circuit.

RESULTS

The *in situ* isolated brain shows a metabolizing activity. In the extracorporeal circuit of both the dog and monkey, the decrease of aminopyrine plasma levels is 16% (14 to 21%) in 60 min., and 21% (17 to 23%) in 90 min.; the decrease of oxazepam plasma

levels is 22% (20 to 25%) in 60 min., and 25% (23 to 30%) in 90 min. The drugs' disappearance is partially replaced by their metabolites.

The affinity of aminopyrine and oxazepam for the brain tissues seems similar. Furthermore, no significant difference is noted on the brain metabolizing activity in the two different ways of occlusion of the sinus columnae vertebralis.

Figure 1 is a typical example of the rate of transformation of aminopyrine in two metabolites. The demethylation and the acetylation are quite similar in the dog and monkey.

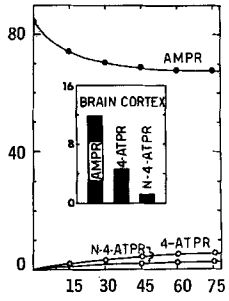

Fig. 1—Aminopyrine metabolism studied by the isolated brain perfusion in situ *in a monkey* (C. hamadryas) *weighing 12.8 Kg. Blood in extracorporeal circuit = 500 ml.; blood flow rate of the extracorporeal circuit = 115 ml./min.; initial concentration of aminopyrine in the plasma of the extracorporeal circuit = 86.5 mcg./ml. An ordinate, the plasmatic concentration (mcg./ml.) of aminopyrine* (AMPR), *4-aminoantipyrine* (4-ATPR), *and N-acetyl-4-aminoantipyrine* (N-4-ATPR), *assayed for 75 min. (in abscissae) after aminopyrine addition. Insert shows the brain cortex concentration (mcg./Gm. in ordinate) of aminopyrine and its two metabolites, assayed after 75 min. of the extracorporeal brain perfusion with addition of aminopyrine.*

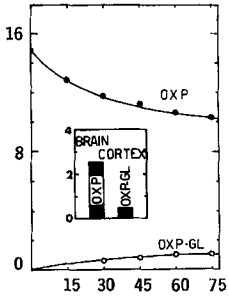

Fig. 2—Oxazepam metabolism studied by the isolated brain perfusion in situ *in a monkey* (C. hamadryas) *weighing 10.7 Kg. Blood in extracorporeal circuit = 480 ml.; blood flow rate of extracorporeal circuit = 95 ml./min.; initial concentration of oxazepam in the plasma of the extracorporeal circuit = 15.3 mcg./ml. An ordinate, the plasmatic concentrations (mcg./ml.) of oxazepam* (OXP) *and its glucuronide* (OXP-GL) *assayed for 75 min. (in abscissae) after oxazepam addition. Insert shows the brain cortex concentration (mcg./Gm. in ordinate) of oxazepam and its glucuronide, assayed after 75 min. of the extracorporeal brain perfusion with addition of oxazepam.*

Figure 2 is a typical example of the glucurono-conjugation of the isolated brain; also the glucurono-conjugation is quite similar in both species.

CONCLUSIONS

The brain isolated *in situ* shows a drug metabolism evaluated by studying the demethylation and the acetylation of aminopyrine and the glucurono-conjugation of oxazepam. In dogs and monkeys, the decrease of aminopyrine plasma levels is 16% and of oxazepam is 22% in 60 min. In studies (1) on the isolated liver *in situ* it was found that the half-time for aminopyrine ranged from 10 to 14 min. in the dog, and from 16 to 21 min. in the monkey, and for oxazepam from 7 to 10 min. in both animals.

These great differences on drug metabolism between brain and other tissues *in situ* seem to be interesting, particularly when the action on the nervous system is not induced by the drug itself, but by its metabolic products.

SUMMARY

The cerebral drug metabolism of dog and monkey has been investigated by the *in situ* isolated brain supplied by an extracorporeal pump-oxygenator system.

To test the brain metabolizing activity, some transformation of aminopyrine (demethylation and acetylation) and oxazepam (glucuronide-conjugation) was examined.

The drugs disappeared from the extracorporeal blood at the rate of 16% for aminopyrine and of 22% for oxazepam in 1 hr.; at the same time their metabolic products appeared. The concentration in the brain cortex of the substances has been evaluated also.

Xenon Trioxide Oxidation of Certain Alcohols

By HAROLD J. RHODES and MARTIN I. BLAKE

A series of alcohols, aliphatic and aromatic, was oxidized with xenon trioxide. Oxidation to carbon dioxide and water was effected by adding a known excess of xenon trioxide to the reaction mixture. The excess reagent was determined iodometrically. Of the alcohols tested only triphenylcarbinol resisted oxidation. Essentially quantitative recoveries were obtained for ethanol, normal, secondary, and tertiary butyl alcohols, benzyl alcohol, benzohydrol, and cinnamyl alcohol.

THE PREPARATION and oxidizing properties of xenon trioxide in aqueous solution have been described by Williamson and Koch (1) and Appelman and Malm (2). Jaselskis and his associates have studied the xenon trioxide oxidation of a variety of organic structures including vic-diols, certain primary and secondary aliphatic alcohols, and a number and variety of acids. Quantitative analytical procedures sensitive in the microgram range were developed for these compounds. Those studies have been referred to in an earlier paper (3) which described the xenon trioxide oxidation of benzyl alcohol and benzaldehyde.

The present investigation concerns the determination and stoichiometry involved in the oxidation of certain aliphatic and aromatic alcohols. These include ethanol, normal, secondary, and tertiary butyl alcohols, benzyl alcohol, benzohydrol, triphenylcarbinol, and cinnamyl alcohol. This selection of alcohols permitted a correlation of chemical structure and oxidation capacity.

EXPERIMENTAL

Solutions and Reagents—Xenon trioxide solution (0.0199 *M* to 0.0493 *M*) was prepared by diluting a concentrate (0.2 *M*) with water. The preparation of the concentrated xenon trioxide solution by hydrolysis of xenon hexafluoride has been described by Appelman and Malm (2).

The following stock solutions of the different alcohols were prepared: 0.157 *M* ethanol, 0.253 *M* *n*-butyl alcohol, 0.101 *M* *sec*-butyl alcohol, 0.0915 *M* *tert*-butyl alcohol, 0.0100 *M* and 0.0020 *M* benzyl alcohol, 0.0020 *M* benzohydrol, 0.0020 *M* cinnamyl alcohol, and a suspension of triphenylcarbinol in water (50.0×10^{-3} mmoles in 10 ml. of water).

Sulfuric acid, 10% w/v, and starch test solution. All chemicals and solvents were reagent grade.

Procedure—Aliquots of the alcohol stock solution containing between 0.5×10^{-3} and 20×10^{-3} mmole of the alcohol were added by micropipet to a series of 50-ml. glass-stoppered conical flasks. Ten milliliters of distilled water was added to each flask. Xenon trioxide solution in known excess was added to each solution. The flasks were stoppered and swirled gently to assure homogeneous distribution of the reactants. The reaction mixtures containing the aliphatic alcohols were allowed to stand at room temperature for at least 17 hr. The oxidation of the aromatic alcohols was permitted to continue for longer periods of time; 5 days for cinnamyl alcohol, 6 days for benzyl alcohol, 8 days for benzohydrol, and 30 days for triphenylcarbinol. In each series one flask contained no alcohol and served as a blank. At the end of the reaction period 5.0 ml. of 10% sulfuric acid solution and 1.0 Gm. of potassium iodide were added to each flask. The liberated triiodide was titrated with standard sodium thiosulfate solution using a 10-ml. microburet. As the end point was approached 3 drops of starch solution was added and the titration was continued until the solution turned colorless. The number of millimoles of xenon trioxide consumed in the oxidation was determined from the normality of the thiosulfate solution and the difference in the volumes consumed by the blank and the sample. The millimoles of xenon trioxide consumed in the oxidation was plotted against the millimoles of alcohol added. The slope and *y*-intercept were determined from the data by the least squares method.

In preliminary studies reaction mixtures were prepared of all alcohols and xenon trioxide in minimum excess. The rate of oxidation was followed by analyzing for xenon trioxide consumed after varying periods of time.

Because of the low solubility of triphenylcarbinol in water, 50.0×10^{-3} mmole of the alcohol was dispersed in 10 ml. of water. An excess (493.0×10^{-3} mmole) of xenon trioxide solution was added and the solution was stirred with a magnetic stirrer for 30 days at room temperature. After varying periods of time, an aliquot of the supernatant was analyzed for unspent xenon trioxide.

Gas-liquid chromatography (GLC) and thin-layer chromatography (TLC) were employed to detect whether reaction products other than carbon dioxide and water were formed under the reaction conditions employed. The details of these procedures were described in the previous paper (3); however, pertinent GLC and TLC data are included here.

RESULTS AND DISCUSSION

A series of alcohols of varying structure were oxidized with xenon trioxide. Oxidation of the aliphatic alcohols proceeded rapidly forming carbon dioxide and water as the only reaction products. Although preliminary studies indicated that for the aliphatic alcohols reaction was complete in less than 4 hr., a 17-hr. reaction period was selected for these compounds. The pH of all reaction mixtures was about 4. Analysis of the reaction mixtures by GLC and TLC indicated that oxidation was complete; neither starting alcohol nor intermediate oxidation products were detected. With the water-soluble aromatic alcohols, benzyl alcohol, benzohydrol, and cinnamyl alcohol, a 17-hr. reaction period gave incomplete oxidation, as evidenced by the detection of

oxidation products and unreacted alcohol employing GLC and TLC methods of analysis. The benzyl alcohol reaction was found to contain benzaldehyde, benzoic acid, and unreacted benzyl alcohol. Complete oxidation was noted, however, after 6 days. Benzophenone, benzoic acid, and unreacted benzohydrol were detected in the benzohydrol reaction mixture. However, after 8 days no detectable quantities of organic compounds were observed. The cinnamyl alcohol reaction mixture showed the presence of the corresponding aldehyde and acid along with the unreacted alcohol. After 5 days oxidation was complete. TLC and GLC data characterizing benzyl alcohol, benzaldehyde, and benzoic acid were reported in the previous paper (3). The results for the other alcohols and their corresponding oxidation products are shown in Table I.

Because of poor solubility, a heterogeneous system was used for studying the oxidation of triphenylcarbinol. The xenon trioxide content of the reaction mixture remained unchanged even after a 30-day reaction period. The reaction mixture was extracted with ether and the ether extract was examined by GLC and TLC. Triphenylcarbinol was the only compound identified in the extract. This alcohol appears to be resistant to xenon trioxide oxidation. GLC and TLC data for triphenylcarbinol are shown in Table I.

The results of the oxidation studies are shown in Table II. The concentrations of the alcohol and xenon trioxide before reaction, the amount of xenon trioxide actually consumed in the reaction, and the ratio of xenon trioxide to alcohol involved in the reaction are recorded in the table. A plot of alcohol concentration *versus* xenon trioxide concentration consumed in the oxidation gives a straight line which intersects the ordinate above the origin. The y-intercept and slope, obtained by least square treatment of the data shown in Table II, and the theoretical slope are recorded in Table III. A similar approach was used by Jaselskis and Warriner (4) for the oxidation of methanol, ethanol, and 2-propanol. They attributed the nonstoichiometric nature of the reaction to secondary processes which occur in the oxidation. Theoretically, the curve should pass through the origin ($c = 0$) and the slope of the line should correspond to the ratio of xenon trioxide to alcohol, assuming complete oxidation to CO_2 and H_2O. Such a plot is useful as a calibration curve for determining

Synthesis of Ketoximino Esters as Antihistaminics

By S. L. LEE, B. B. WILLIAMS, and M. M. KOCHHAR*

In a search for new antihistamines, a series of oximino esters of 2-, 3-, and 4-benzoylpyridine oxime and 2-benzoylthiophene oxime was prepared. The respective ketones were oximinated in pyridine with hydroxylamine hydrochloride. The esterification was conducted in benzene with equimolar quantities of acetyl chloride, oxime, and a basic reagent. Twelve new oximino esters were synthesized and evaluated for their antihistaminic activity. All synthesized compounds exhibited antihistaminic activity with almost no anticholinergic action. The propionyl analogs showed the most significant antihistaminic effectiveness.

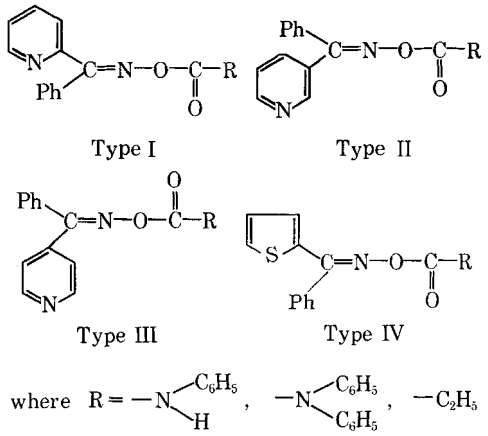
BOVET (1) issued preliminary reports concerning the first effective synthetic antihistaminic drugs. Since that time, a multitude of compounds have been prepared and tested for antihistaminic activity. The chemical structures of these antihistaminic drugs vary, yet the prominent compounds exert similar pharmacological and therapeutic action. Several review articles (2–5) have appeared in the literature. Some of the many useful antihistaminic agents differ sufficiently to hold out hope of attaining drugs which would be more specific for a given allergic manifestation.

Most commonly used drugs can be classified as derivatives of ethanolamine, ethylenediamine, aminopropane, phenothiazine, or piperazine (6). Almost all of these compounds contain a terminal tertiary nitrogen, generally having dimethyl substitution or part of the heterocyclic structure. In the ethanolamine series, the most effective group attached to the oxygen atom has been found to be the benzhydryl radical (7); whereas in the ethylenediamine series, several different radicals on the second nitrogen of the chain have led to active compounds. Several physical properties of antihistaminics have been studied in an effort to relate them to activity of the various drugs (8), but no direct relationship can be made between physical properties and antihistaminic activity.

These observations prompted the investigations reported in this paper. The object of the present work was to prepare and examine some of the oximino esters of benzoylpyridines and benzoylthiophene and to determine whether they possessed significant antihistaminic action.

DISCUSSION

The compounds which were selected for synthesis are the oximino esters of benzoylpyridines and benzoylthiophenes (types I, II, III, and IV).



The preparation of 12 new esters of type I, II, III, or IV, starting with respective benzoylpyridines and 2-benzoylthiophene, was accomplished by modifying the methods described in the literature (9, 10).

The oximes selected in this study included representatives of both syn- (types I and III) and anti- (types II and IV) configuration. The esters were not geometrically confirmed since it was assumed that esterification did not alter configuration. The purpose of including compounds of both configurations was to allow some comparison of antihistaminic effect of the isomers. Pharmacological screening provided no evidence of effect of geometric configuration on intensity of antihistaminic action.

The basic unit for all effective agents contains the ethylamine skeleton in one form or another. It is interesting that the ethylamine skeleton also corresponds to the side chain of the histamine molecule and to part of the imidazole ring. With this in mind the authors attempted replacement of the

ethylamine side chain with oximino linkage to see its effect on antihistamine activity. The terminal nitrogen is an amide nitrogen having one or two phenyl substituents (compounds I, II, IV, V, VII, VIII, X, and XI). These compounds exhibited antihistaminic activity ranging from 0.5 to 0.1 of diphenhydramine. This very clearly indicates that the ethylamine side chain is not an essential feature. The authors feel that a region of high electron density in that neighborhood is essential for the binding of drug to the receptor. This is further substantiated by synthesis of the propionyl derivatives (III, VI, IX, and XII) in which the carbonyl oxygen exhibits a higher electron density. These exhibited higher antihistaminic activity, 0.5 to 0.2 of diphenhydramine. This also indicates that the terminal nitrogen is not absolutely essential for biological activity. The oximino group should certainly alter the partition coefficient of the compound and thus affect its distribution in the body. Additionally, the oximino linkage should affect the intrinsic reactivity and stereochemistry of a given compound as well as its susceptibility toward metabolic degradation.

Most of the antihistaminic drugs have a minimum of two aryl or aralkyl groups or their equivalent in a polycyclic ring system or one aryl and one heterocyclic ring system. The authors' experimental compounds have benzoylpyridines or 2-benzoylthiophene. This moiety of the drug is the flat portion and this might occupy the flat area on the receptor.

Another very striking similarity among some of the known antihistaminics is the interatomic distances.[1] The interatomic distances between the terminal nitrogen atom of histamine and the 1 and 3 nitrogens of the imidazole ring are 6.12 and 4.52 Å., respectively. The interatomic distance between the pyridine nitrogen and the dimethylamino nitrogen of mepyramine, 2-[(2-dimethylaminoethyl) (*p*-methoxybenzyl) amino] pyridine, is 6.12 Å. The distance between the methoxy oxygen and the terminal nitrogen of mepyramine is 4.52 Å. In methapyrilene,2-[(2-dimethylaminoethyl)-2-thenylamino]-pyridine, the distance between pyridine *N* and terminal nitrogen is 6.12 Å. The distances in some of the more potent antihistaminics are very close to the above-mentioned compounds. The interatomic distances in the synthesized compounds are very comparable to histamine, mepyramine, methapyrilene, diphenhydramine, *etc.* In 2-diphenylcarbamyloximino benzoylpyridine (II) and 2-phenylcarbamyloximino benzoylpyridine (I), the interatomic distances between the pyridine nitrogen and the carbamyl nitrogen and between the pyridine nitrogen and the ether oxygen are 6.16 Å. and 4.2 Å., respectively. Similarly the interatomic distances in compounds IV, V, VII, VIII, X, and XI are very comparable with some of the known antihistaminics.

Studies of spatial dispositions, bond angles, and other physicochemical properties might possibly reveal correlations.

PHARMACOLOGIC EVALUATION

Antihistaminic potency was estimated by use of isolated strips of guinea pig ileum. The lowest concentration which blocked the spasmogenic effect of histamine was determined for the 12 test compounds and for diphenhydramine according to the procedure of Zielenski (11). A Phipps and Bird isolated tissue apparatus was used which provided for temperature maintenance of reservoirs of physiological solution and provided also for upward draining and replacement of physiological solution in the tissue chamber. Contractions were recorded with an E and M myograph photoelectric force transducer and physiograph recording system. Histamine phosphate (0.2 ml. of a 0.055% solution) was added to give a concentration of 5.5×10^{-6} in the tissue chamber. The test compound in water or aqueous propylene glycol was added followed in 1 min. by histamine in the same quantity as the first addition. Failure of needle deflection on addition of the challenge dose of histamine was considered the end point. Strips of ileum were washed after presentation of each concentration of test drug and replaced after two tests or in event of failure of a strip to respond to histamine after washing. For most of the end point concentrations at least one replication was done. Table I presents data from the antihistaminic activity tests.

Synthesis of Oximes

2-Benzoylpyridine Oxime—2-Benzoylpyridine (5.49 Gm., 0.03 mole), hydroxylamine hydrochloride (3.5 Gm., 0.05 mole), and pyridine (20 ml.) in ethanol were refluxed for 12 hr. The bulk of the ethanol was removed under reduced pressure and the mixture was poured into cold water. The crude product thus obtained was recrystallized from ethanol which afforded the oxime, m.p. 151–152.5°. [Lit. (12) m.p. 150.5–152.5°.]

3-Benzoylpyridine Oxime—The above procedure was adapted to this preparation. A pure sample of this compound melted at 160.5°. [Lit. (13) m.p. 161°.]

4-Benzoylpyridine Oxime—The method of Kochhar *et al.* (10) was adapted to this oxime. The oxime

[1] Interatomic distances were estimated from Dreiding

[2] Reported melting points are uncorrected. A Thomas-Hoover Unimelt apparatus was used for melting point determination. Schwarzkopf Microanalytical Laboratory, Woodside, N.Y., conducted the elemental analyses.

exhibited m.p. of 153°. [Lit. (14) m.p. 152–155°.]

2-Benzoylthiophene Oxime—The procedure mentioned under 2-benzoylpyridine oxime was followed. The pure sample gave a m.p. of 113°. [Lit. (14) m.p. 113–114°.]

Synthesis of Oximino Esters[3]

2-Phenylcarbamyloximino Benzoylpyridine (I)—*Method A*—2-Benzoylpyridine oxime (1.98 Gm., 0.01 mole), pyridine (1 Gm. 0.0126 mole), and phenylisocyanate (2.38 Gm., 0.02 mole) were refluxed for 1 hr. A brownish solid residue was obtained on cooling the mixture. The solid residue was washed with distilled water until there was no pyridine odor. Three repeated recrystallizations from ethanol afforded a pure analytical sample, m.p. 167–168° dec. Strong bands in the I.R. at 5.8 μ ($-\overset{\overset{O}{\|}}{C}-O-$) and 6.2 μ ($-C=N-$) are indicative of $-C-O-$ and $-C=N$, respectively; yield was 95% of theory.

3-Diphenylcarbamyloximino Benzoylpyridine (V)—*Method B*—In a three-neck flask, fitted with a stirrer, condenser, and dropping funnel, were placed 3-benzoylpyridine (1.98 Gm., 0.01 mole), pyridine (25 ml., the minimum amount which will dissolve the oxime), and benzene (100 ml.). The mixture was stirred and diphenylcarbamylchloride (2.31 Gm., 0.01 mole) in benzene (100 ml.) was added dropwise. After the completion of addition, the mixture was refluxed for 12 hr. with stirring. The mixture was cooled, washed with 10% potassium bicarbonate (5 times), and then washed with water (4 times), and the benzene phase was dried over anhydrous magnesium sulfate. On evaporation of benzene under reduced pressure a solid residue was obtained which on recrystallization from a mixture of ethanol–methanol afforded a pure sample, m.p. 193° dec. The I.R. gave a sharp band at 5.75 μ indicative of ester linkage. Yield was 52% of theory.

2-Propionyloximino Benzoylthiophene (XII)—*Method C*—2-Benzoylthiophene oxime (2.03 Gm., 0.01 mole) dissolved in the minimum quantity of pyridine was placed in a round-bottom flask. The mixture was diluted with benzene (200 ml.). On addition of propionylchloride (1.15 Gm., 0.016 mole) dropwise while stirring, a white suspension formed. This mixture was stirred for 4 hr. at room temperature, refluxed for 12 hr., cooled, and benzene washed with 10% potassium bicarbonate and water successively, and dried as in method *B*. On evaporation of benzene, under reduced pressure, an oily residue was obtained which on repeated washing

[3] See Table II for physical constants and analytical data.

with cold water gave a solid residue. The crude mixture was recrystallized from methanol, and yielded a pure sample, m.p. 112–113°. The I.R. gave a sharp peak at 5.70 μ indicative of ester. Yield was 38% of theory.

New Compounds: Synthesis of Some Phosphorus–Nitrogen Compounds for Pharmacological Study I

By A. ABOU-MOUSTAFA, M. KHALIFA, and H. EL MANGOWRI

The synthesis of some phosphorus–nitrogen compounds *via* the condensation of phosphorus trichloride with a number of sulfa drugs is described. With sulfacetamide, sulfathiazole, and sulfadimidine three molecules of the sulfa compound condensed with one molecule of the acid (sulfamethazine) chloride although the molecular ratio of the reactants was 2 of the former to 1 of the latter. On the other hand, with sulfanilamide and sulfapyridine the condensation took place according to the ratio mentioned earlier.

THE INTEREST in the synthesis of phosphorus–nitrogen compounds arises from the fact that some of these compounds are of potential medicinal value. Cates *et al.* in a series of publications (1–5) reported the synthesis of nearly 60 such compounds and those containing substituted *p*-toluidine and 2-aminopyridine moieties were prepared for evaluation as antineoplastic agents. Likewise, it has been reported that the *N*-arylsulfonylphosphinimide derivatives synthesized by Oyamada have tumor inhibiting activity against mammary carcinoma (6).

Several attempts were made to condense sulfanilamide with phosphorus trichloride. Condensation in reagent dioxane according to the method of Cates (1, 4) proved to be unsatisfactory due to the immediate formation of an insoluble addition complex which did not dissolve even when the reflux was continued for several hours. The addition product afforded the starting sulfa compound after being worked up. The use of other nonpolar solvents such as carbon tetrachloride (6–8), absolute

[a] A, aqueous alcohol; B, absolute alcohol. [b] Liquid crystal. Melting points were performed by the capillary tube method and are uncorrected. [c] Analyses performed by Janssen Pharmaceutica, Beerse, Belgium.

The present investigation, however, is concerned with the synthesis of some phosphorus compounds *via* the condensation of phosphorus trichloride with ether (2–4, 9), and dry benzene (2, 9) which were used by other investigators proved unsuitable because sulfanilamide itself is insoluble in these solvents and it was recovered unchanged from the reaction mixture. Accordingly, attention was directed to the use of polar solvents. Audrieth and

New Compounds: Synthesis of Some Phosphorus–Nitrogen Compounds for Pharmacological Study I

By A. ABOU-MOUSTAFA, M. KHALIFA, and H. EL MANGOWRI

The synthesis of some phosphorus–nitrogen compounds *via* the condensation of phosphorus trichloride with a number of sulfa drugs is described. With sulfacetamide, sulfathiazole, and sulfadimidine three molecules of the sulfa compound condensed with one molecule of the acid (sulfamethazine) chloride although the molecular ratio of the reactants was 2 of the former to 1 of the latter. On the other hand, with sulfanilamide and sulfapyridine the condensation took place according to the ratio mentioned earlier.

THE INTEREST in the synthesis of phosphorus–nitrogen compounds arises from the fact that some of these compounds are of potential medicinal value. Cates *et al.* in a series of publications (1–5) reported the synthesis of nearly 60 such compounds and those containing substituted *p*-toluidine and 2-aminopyridine moieties were prepared for evaluation as antineoplastic agents. Likewise, it has been reported that the *N*-arylsulfonylphosphinimide derivatives synthesized by Oyamada have tumor inhibiting activity against mammary carcinoma (6).

Several attempts were made to condense sulfanilamide with phosphorus trichloride. Condensation in reagent dioxane according to the method of Cates (1, 4) proved to be unsatisfactory due to the immediate formation of an insoluble addition complex which did not dissolve even when the reflux was continued for several hours. The addition product afforded the starting sulfa compound after being worked up. The use of other nonpolar solvents such as carbon tetrachloride (6–8), absolute

The present investigation, however, is concerned with the synthesis of some phosphorus compounds *via* the condensation of phosphorus trichloride with ether (2–4, 9), and dry benzene (2, 9) which were used by other investigators proved unsuitable because sulfanilamide itself is insoluble in these solvents and it was recovered unchanged from the reaction mixture. Accordingly, attention was directed to the use of polar solvents. Audrieth and

Received February 27, 1967, from the Pharmaceutical Chemistry Department, Faculty of Pharmacy, Riyadh University, Riyadh, Saudi Arabia.
Accepted for publication May 10, 1967.
The authors express their appreciation to Dr. A. A. Khowaiter, Riyadh University, for research facilities which made this investigation possible and to Professor Y. M. Abou-Zeid, Cairo University, for his interest.

[1] The products at present are under preliminary screening for possible antineoplastic action or any useful pharmacological activity.

[a] B, absolute alcohol; C, aqueous acetic acid. [b] Liquid crystal. Melting points were performed by the capillary tube method and are uncorrected. [c] Analyses performed by Janssen Pharmaceutica, Beerse, Belgium.

Toy (8) in their work on the preparation of *N*-substituted derivatives of phenyl esters of amido and diamido phosphoric acid reported the use of pyridine–chloroform and the same mixture was later used by Cates (1). In the present investigation the pyridine–chloroform mixture (2:1) was successfully used in all the condensations.

That the phosphorus atom in the synthesized compounds is linked to the N^4 of the sulfa drug was shown qualitatively by the failure of all the condensation products to diazotize and by their solubility in dilute alkali and insolubility in dilute mineral acids.

EXPERIMENTAL

The condensation was carried out according to the following general procedure.

Phosphorus trichloride (0.01 mole), dissolved in pyridine–chloroform (25 ml.), was gradually added to the sulfa compound (0.02 mole). The mixture was refluxed for 24 hr. with all except sulfanilamide in which case refluxing for 12 hr. was sufficient. Then the solvent was distilled *in vacuo*, and the yellowish brown viscous residue was suspended in dilute hydrochloric acid, filtered, and washed with water until the washings gave a negative chloride test with silver nitrate T.S. The product, after being dried, was crystallized from the appropriate solvent. (See Tables I and II.)

New Compounds: Synthesis of Some Sulfazopyridine Derivatives for Pharmacological Study

By H. Y. ABOU-ELENEIN, M. KHALIFA, and Y. M. ABOU-ZEID

The synthesis of some sulfazopyridine derivatives is described.

SINCE THE discovery of sulfamidochrysoidine[1] (1), a large number of sulfamoyl phenylazo dyes was made and their chemotherapeutic action was studied against various bacterial infections. In recent years combinations of sulfonamides and azo dyes are widely used as urinary disinfectants. The authors now report the synthesis of some azo dyes containing a sulfonamido moiety together with a diaminopyridyl moiety (I).

Received February 6, 1967, from the Faculty of Pharmacy, Cairo University, Cairo, United Arab Republic.
Accepted for publication May 4, 1967.
The products at present are under preliminary screening for possible antimicrobial action or any useful pharmacological activity.

I

Derivatives having the above general formula were synthesized by coupling diazotized sulfonamides with 2,6-diaminopyridine hydrochloride. Attempts to prepare 2,6-diaminopyridine by amination of pyridine with sodamide in the presence of solvents were unsuccessful; in the absence of solvents, a 20% yield was obtained. Two methods were applied for diazotizing the sulfa compounds: (*a*) the standard procedure and (*b*) the alternate one, which consists of dissolving the sulfonamide in sodium hydroxide first. The diazotized sulfa compound

thus obtained was then coupled with 2,6-diaminopyridine hydrochloride and in all cases the azo dye was isolated by adjusting the pH of the reaction mixture to 6.5–7.

EXPERIMENTAL[2]

2,6-Diaminopyridine—Sodium amide was obtained by dissolving freshly cut sodium (27.6 Gm.) in anhydrous liquid ammonia (600 ml.) in the presence of 0.5 Gm. ferric nitrate as catalyst. The flask containing the suspension of sodium amide was fitted with a dropping funnel containing 39.4 Gm. of dry pyridine which was added cautiously while the ammonia was allowed to escape through the soda-lime tube. After all the ammonia was driven out (by removal of the dry ice–ether bath) and after the temperature of the apparatus reached the laboratory temperature, the dry ice condenser was replaced by a vertical condenser protected by a calcium chloride tube, and the funnel was replaced by a thermometer which dipped into the reaction mixture. The flask was heated in an oil bath, the temperature of the reaction mixture being maintained at 170° until hydrogen ceased to evolve (9–10 hr.). The solid cake which separated on cooling was treated with 10% sodium hydroxide solution until the vigorous decomposition stopped and then with water to complete the hydrolysis of the sodium salt. The product which was obtained in 20% yield (10 Gm.) melted at 120–122° as reported (2) after one crystallization from benzene.

Diazotization Procedures—(*a*) The sulfonamide (0.01 mole) was dissolved in 20 ml. of 25% hydrochloric acid by gentle warming, diluted with 100 ml. of water, and cooled to 0–5°. This solution was diazotized by the dropwise addition of a cold solution of 0.012 mole sodium nitrite in water. It was set aside for 15 min. at a temperature not exceeding 5° after complete addition of the nitrite.

(*b*) The sulfonamide (0.01 mole) was dissolved in 20 ml. of 25% sodium hydroxide solution, 0.012 mole of sodium nitrite was added with continuous stirring and then acidified by the dropwise addition of 25 ml. of hydrochloric acid. It was left for 10 min. after complete addition of the acid, the temperature being maintained at 0–5° during the diazotization.

Coupling Procedure—The diazonium salt solution prepared above was gradually added with continuous stirring to a solution of 2,6-diaminopyridine (0.01 mole) dissolved in 10% hydrochloric acid (temperature should not exceed 5° during the addition), and left aside for 15 min. for complete reaction. The pH of the medium was then adjusted to about 6.5–7 by the addition of dilute sodium hydroxide solution with stirring. The azo dye which precipitated was filtered at the pump and crystallized either from aqueous ethanol or absolute ethanol. (See Table I.)

[2] Melting points were performed by the capillary tube method and are uncorrected.

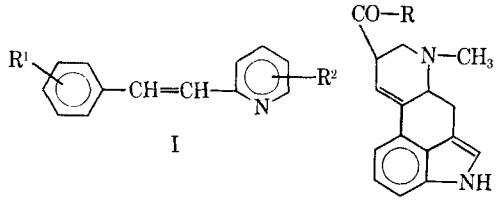
New Compounds: Pyridylacrylonitrile Derivatives

By JOSEPH SAM*

The preparation of several pyridylacrylonitriles (V), the hydrolysis to an acid (VII), and subsequent conversion to an ester (VIII) are described.

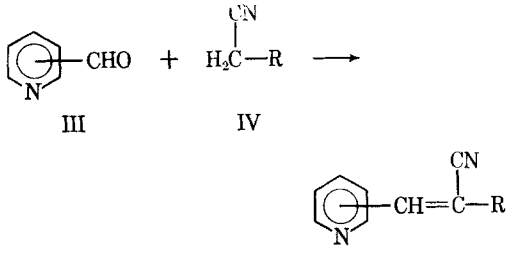
THE AVAILABILITY of pyridinealdehydes prompted the investigation of a number of their derivatives for potentially useful biological agents. Others (1–9) have described the preparation of similar compounds. Substituted 2-stilbazoles (I) or the corresponding hydrogenated derivatives bear some structural similarity to the ergot (II), veratrum, and reserpine alkaloids and also to the synthetic and steroidal estrogens. The nitriles (V) also have some structural similarity to the ergot alkaloids.



I

II

The reaction of pyridinealdehydes (III) with substituted acetonitriles (IV) was catalyzed by piperidine and provided yields of 64 to 96% of the desired acrylonitriles (V). (Scheme I.)



III IV V

Scheme I

The hydrolysis of 2-(*p*-chlorophenyl)-3-(2-pyridyl)acrylonitrile (VI) with concentrated sulfuric acid provided the corresponding acid (VII) which was subsequently reacted with ethanolic hydrogen chloride to yield the ester (VIII). (Scheme II.)

On the basis of the successful reductive cyclization of α-(2′-nitro-4′,5′-dimethoxyphenyl)-β-phenylacrylonitrile (IX) to 3-benzyl-5,6-dimethoxyindole (X) (6) (Scheme III), a number of unsuccessful attempts were made to cyclize β-cyano-4′,5′-dimethoxy-2′-nitro-2-stilbazole (XI) to 5,6-dimethoxy-3-(2-pyridylmethyl)indole (XII) by the same procedure. (Scheme IV.)

The reductive cyclization of XI to 3-cyano-2-(pyridyl)indoles (XIII) has been reported (7).

Table I summarizes the physical characteristics of the compounds that were investigated.

the exception of 3,4-dimethoxy-6-nitrophenylacetonitrile) were purchased from commercial sources. The latter nitrile was prepared according to the procedure described in the literature (6).

Pyridylacrylonitriles (Table I)—A cooled solution of 0.1 mole of desired nitrile and 0.1 mole of pyridinealdehyde in 100–150 ml. of absolute ethanol or methanol was treated with 8.5 Gm. (0.1 mole) of piperidine and thereafter refluxed for 1–5 hr. The solution was concentrated to a small volume. The solid was removed by filtration and recrystallized from a suitable solvent.

α-(p-Chlorophenyl)-β-(2-pyridyl)acrylic Acid—A carefully prepared solution of 7 Gm. (0.03 mole) of α-(*p*-chlorophenyl)-β-(2-pyridyl)acrylonitrile in 100 Gm. of concentrated sulfuric acid was heated on a steam bath for 0.5 hr. Thereafter, the solution was cooled and poured into 500 ml. of water. The solid (7 Gm., 90%) was removed by filtration and dissolved in 10% aqueous sodium hydroxide. The resulting solution was filtered and the filtrate was neutralized with acetic acid. The solid was removed by filtration and recrystallized from benzene, m.p. 147–148° dec.

Ethyl α-(p-Chlorophenyl)-β-(2-pyridyl)acrylate—A solution of 50 Gm. of hydrogen chloride in 200 ml. of absolute ethanol was treated with 26 Gm. (0.1 mole) of α-(*p*-chlorophenyl)-β-(2-pyridyl)acrylic acid. The resulting solution was refluxed for 4 hr. and thereafter concentrated *in vacuo* to dryness. The residual material was washed with 300 ml. of water and recrystallized from ethanol.

A methiodide was prepared by refluxing the compound above with excess methyl iodide in acetonitrile for 30 hr.

New Compounds: Synthesis of *N*-Haloacyl Analogs of 1-(*N*-β-Hydroxyethyl-4-piperidyl)-3-(4-piperidyl)propane as Potential Antineoplastic Agents

By WILLIAM D. ROLL

A series of haloamide analogs of 1-(*N*-β-hydroxyethyl - 4 - piperidyl) - 3 - (4 - piperidyl)propane has been synthesized for the purpose of studying their potential anticarcinogenic activity.

DURING THE past few years a number of potential mono- and difunctional alkylating agents have been prepared in this laboratory for the purpose of studying chemotherapeutic activity-structure relationships in regard to their value as antineoplastic agents. Based upon the experimental observations obtained in this laboratory (1–4) and those of other investigators (5–9), the synthesis of haloacetyl and halopropionyl derivatives of 1-(*N* - β - hydroxyethyl - 4 - piperidyl) - 3 - (4 - piperidyl)propane was undertaken.

It is theoretically possible that these compounds interfere with vital enzymatic systems or nucleic acids within a cancer cell through reversible and/or irreversible bonding to amine, sulfhydryl, or phosphoryl groups under physiological conditions. As noted by Triggle (10), the specificity of chemotherapeutic alkylating agents probably will reside in the carrier portion of the structure rather than in the alkylating moiety. Through this and following studies it is hoped that some additional information regarding the definition of the carrier moiety and specificity of action will be forthcoming, and that a structure will evolve which will possess a selective action against tumor cells.

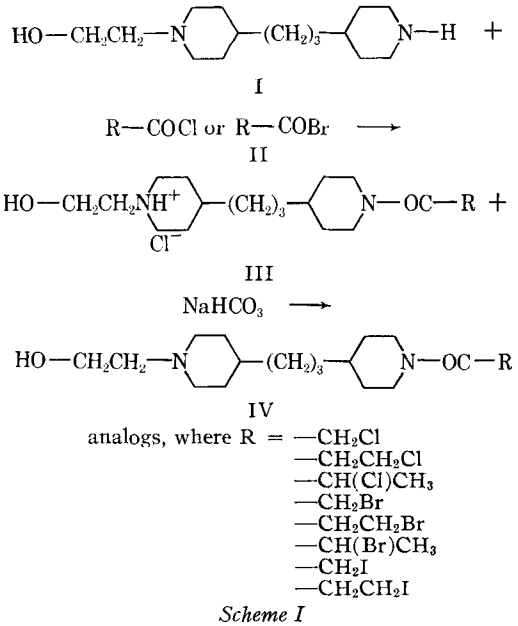
EXPERIMENTAL

The synthetic scheme for the preparation of the analogs of 1-(*N*-β-hydroxyethyl-4-piperidyl)-3-(4-piperidyl)propane[1] may be summarized as follows. (Scheme I.) To a solution of 5.02 Gm. (0.02 mole) of the parent amine (I) in 15 ml. of anhydrous

Received April 14, 1967, from the College of Pharmacy, University of Toledo, Toledo, OH 43606
Accepted for publication June 19, 1967.
Presented to the Medicinal Chemistry Section, A.PH.A. Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

[1] Supplied by Reilly Tar and Chemical Corp., Indianapolis, Ind.



Scheme I

chloroform was added 0.02 mole of the haloacyl halide (II) (in anhydrous chloroform). An exothermic reaction occurred as the acylating agent was added dropwise at room temperature. When the addition of the acylating agent (II) was complete, the reaction mixture was refluxed for 30 to 60 min. The chloroform was evaporated *in vacuo*, and the solid remaining was dissolved in a minimum amount of absolute ethanol and the *in vacuo* evaporation operation repeated. The solid (III), a hygroscopic hydrochloride or hydrobromide salt, was treated with sodium bicarbonate and chloroform to give the crude product. The crude haloamides were recrystallized twice from aqueous ethanol to give the pure products listed in Table I. The iodoamides were synthesized as previously reported (1).

The infrared spectra of the compounds were obtained with a Perkin-Elmer Infracord. The melting points were determined with a Fisher-Johns melting point apparatus and are corrected values.

DISCUSSION AND RESULTS

The series of eight derivatives prepared in this work are: 1-(*N*-β-hydroxyethyl-4-piperidyl)-3-(*N*-chloroacetyl - 4 - piperidyl)propane, 1 - (*N* - β - hydroxyethyl - 4 - piperidyl) - 3 - (*N* - bromoacetyl-4 - piperidyl)propane, 1 - (*N* - β - hydroxyethyl - 4 - piperidyl) - 3 - (*N* - bromoacetyl - 4 - piperidyl)-propane, 1 - (*N* - β - hydroxyethyl - 4 - piperidyl) - 3 - (*N* - iodoacetyl - 4 - piperidyl)propane, 1 - (*N* - β - hydroxyethyl - 4 - piperidyl) - 3 - (*N* - β - chloropropionyl - 4 - piperidyl)propane, 1 - (*N* - β - hydroxyethyl - 4 - piperidyl) - 3 - (*N* - β - bromopropionyl - 4 - piperidyl)propane, 1 - (*N* - β - hydroxyethyl - 4 - piperidyl) - 3 - (*N* - β - iodopropionyl-4 - piperidyl)propane, 1 - (*N* - β - hydroxyethyl - 4-piperidyl) - 3 - (*N* - α - chloropropionyl - 4 - piperidyl)propane, and 1 - (*N* - β - hydroxyethyl - 4 - piperidyl) - 3 - (*N* - α - bromopropionyl - 4 - piperidyl)propane.

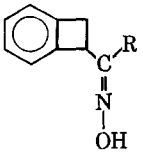
Stereochemical Assignments of 1-Benzocyclobutenyl Ketoximes

Sir:

The 1-benzocyclobutenyl ketoximes, listed in Table I, exhibit muscle relaxant characteristics (1). No assignments of the oxime configurations were made for the compounds used in the pharmacological tests. This study was undertaken to establish the configurations of the oximes.

TABLE I—1-BENZOCYCLOBUTENYL KETOXIMES



Compd.	R	Oxime Configuration Relative to R
I	Methyl	*syn*
II	Phenyl	*anti*
III	*n*-Butyl	*syn*
IV	Benzyl	*syn*
V	Cyclohexyl	*syn*

Initially, NMR appeared to be useful for assigning the stereochemistry of I. Oximes of structurally related ketones (benzyl methyl ketone and α-phenethyl methyl ketone) were prepared. Only a single isomer (*syn* to the methyl group) could be detected for each compound on thin-layer chromatography using benzene–ethyl acetate (10:1) as the solvent system. Only a single isomer is reported in the literature for each compound (2). Silica gel was the adsorbent for this experiment and all other chromatography in the study. Since both isomers of the model compounds were not available, no definite assignment could be made for I based upon comparisons with the NMR spectra of the model oximes.

A Beckmann rearrangement was run on I with phosphorus pentachloride in anhydrous ether (3). The resulting amide had a peak in the infrared spectrum at 7.35 μ which is characteristic of CH_3CO—groups (4). This amide is consistent with a *syn* assignment for I, since the group *anti* to the oxime hydroxyl migrates in the Beckmann rearrangement (3). Basic hydrolysis and ether extraction gave a solid amine which had aromatic and aliphatic C-H absorption in its infrared spectrum, confirming the stereochemistry of I.

Compound II, after Beckmann rearrangement, basic hydrolysis, and ether extraction, afforded an amine which had a R_f value identical to aniline on thin-layer chromatography with benzene–methanol (95:5). In this solvent system, the amine from I failed to migrate from its origin. Thus, II was assigned an *anti* configuration.

When III, IV, and V were treated with the same series of reactions, the amines produced had the same R_f value as the amine from I on thin-layer chromatography with *n*-butanol–acetic acid–water (4:1:1). The amines failed to migrate in the benzene–methanol system. A tentative *syn* assignment for III, IV, and V was made. The hydrolysis residues from II, III, IV, and V were acidified and extracted with ether. These acids exhibited individual R_f values on thin-layer chromatography with benzene–dioxane–acetic acid (90:25:4). The acids from III, IV, and V had R_f values identical to valeric, phenylacetic, and cyclohexane carboxylic acids, respectively. This observation confirmed the assignments of the stereochemical configuration of III, IV, and V.

Interpretation of *In Vitro* Dissolution Data Relative to the Gastrointestinal Absorption Characteristics of Drugs in Tablets

Sir:

The recognition that the gastrointestinal absorption of drugs administered in the form of compressed tablets is frequently rate-limited by the process of dissolution (1–3) has led to numerous studies of the effect of tablet formulation factors on the *in vitro* dissolution rate(s) of the active ingredient(s). The difficulty and expense of clinical trials, and the desirability of utilizing the eventually marketed dosage form as early as possible in clinical studies of a new drug, have resulted in the use of *in vitro* dissolution tests as a means for selecting the most promising tablet formulation(s) from among several experimental preparations. It is the purpose of this communication to outline some hazards in the interpretation of results obtained from *in vitro* dissolution test procedures which have not been calibrated exactly on the basis of *in vivo* data.

Two experimental tablet formulations of aspirin (0.32 Gm. per tablet) were recently made available to the authors.[1] These were conventional compressed tablets, differing essentially only in the particle size of aspirin, and designed to yield gastrointestinal absorption characteristics in the upper and lower range of rates ordinarily encountered with commercial products. The tablets designated as type *A* were prepared with finely milled aspirin (80-mesh and finer) while the type *B* tablets contained relatively coarse aspirin (all particles larger than 20-mesh). Gastrointestinal absorption studies were carried out on 6 ambulatory subjects (trial *1*); the early phase of this clinical trial was repeated once with these 6 subjects and 2 others (trial *2*) in order to obtain additional data and to assess the degree of intrasubject variability. The tablets were swallowed whole, with 200 ml. water, in the morning on an empty stomach. No food was permitted for 2 hr. following tablet ingestion. Blood samples were obtained at various times and the concentration of total salicylate in the plasma was determined by the method of Brodie *et al.* (4) after heating the plasma with 2 *N* hydrochloric acid at 100° for 10 min. The results are summarized in Table I[2] and indicate that aspirin in type *A* tablets is absorbed about 3 times as rapidly *on the average* as it is when given in type *B* tablets.

TABLE I—TOTAL SALICYLATE CONCENTRATION (mg./L.) IN THE PLASMA AS A FUNCTION OF TIME AFTER ORAL ADMINISTRATION OF 0.65 GM. ASPIRIN AS TWO TABLETS OF TYPE *A* AND TYPE *B* IN TWO TRIALS

Time, min.	Tablets *A* Mean	S.D.[a]	Tablets *B* Mean	S.D.
		Trial 1[b]		
10	24.7	13.9	5.5[c]	1.8
20	41.0	17.8	12.8[c]	4.7
30	46.1	14.8	18.7[c]	6.2
60	48.7	10.7	32.0[c]	7.1
120	48.0	9.0	43.8	8.2
240	34.7	8.0	34.5	6.0
360	23.0	6.5	24.2	6.2
		Trial 2[d]		
10	17.8 (15.5)[e]	8.3	7.2[c] (7.8)[e]	4.1
20	41.0 (38.5)	16.5	15.0[c] (16.7)	5.7
30	51.4 (49.7)	19.9	21.5[c] (24.3)	9.0

[a] Standard deviation (the meaningfulness of this value is limited due to inter-subject variations in apparent volume of distribution). [b] Average of 6 subjects (5 F, 1 M); av wt., 67.5 Kg.; av. age, 27.7 yr. [c] Significantly different from tablets *A* ($p < 0.01$). [d] Average of 8 subjects (5 F, 3 M); av. wt., 70.0 Kg.; av. age, 28.0 yr. [e] Figures in parentheses are data for the 6 subjects who participated in trial *1*.

In vitro dissolution rates were determined by the beaker method of Levy and Hayes (5) with recently described modifications (2), using the precision stirring apparatus of Levy and Tanski (6). The times required for dissolution of one third, one half, and two thirds of the drug content of one tablet (*i.e.*, $t_{1/3}$, $t_{1/2}$, and $t_{2/3}$) were determined graphically from cumulative dissolution plots. These measurements were made at stirring rates of 50, 60, and 75 r.p.m., using an average of six tablets each. The results of these experiments are shown in Fig. 1. The inset in the figure shows the $t_{1/3}$ ratios (type *B*:type *A*) for the tablets as a function of stirring rate. It can be noted that this ratio changed from less than unity at 50 r.p.m. to almost 15 at 75 r.p.m.[3]

This striking sensitivity of relative dissolution rates to small changes in stirring intensity has profound implications. Only at about 55 r.p.m. (by interpolation) is the ratio of *in vitro* dissolution rates similar to the ratio of the *average in vivo* absorption rates. A small change in agitation intensity (such as is obtained by a change in stirring rate by ±10 r.p.m. or by a change in the dimensions of the dissolution apparatus) can yield results either contrary to those obtained *in vivo* or showing much greater differences from those observed in the clinical

[1] The authors thank Dr. John H. Wood and the Bristol-Myers Products Division for preparing the experimental tablet preparations used in this study.

[3] The reader is referred to *References 7* and *8* for a discussion of the physicochemical basis of these observations.

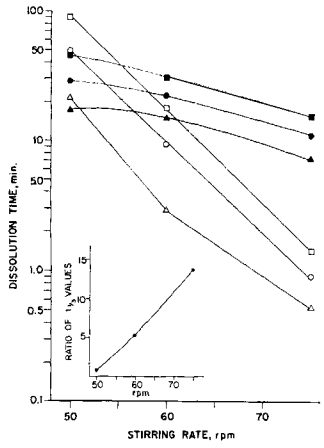

Fig. 1—Dissolution rate of aspirin from type A *(open symbols) and type* B *(solid symbols) tablets as a function of stirring rate. Triangles,* $t_{1/3}$; *circles,* $t_{1/2}$; *squares,* $t_{2/3}$. *Inset: ratio of* $t_{1/3}$, *type* B : *type* A *tablets, as a function of stirring rate.*

study. It must be emphasized that the preparations studied were conventional type tablet preparations rather than specialty dosage forms such as sustained-release or "buffered" formulations. The results of the investigation described here show clearly that dissolution test procedures which have not been calibrated *exactly* on the basis of *in vivo* measurements are unlikely to reflect the gastrointestinal absorption characteristics of the preparations tested and may in fact yield very misleading data.

The pronounced sensitivity of the dissolution rate of a drug in tablet form to agitation intensity has some interesting clinical implications. It suggests that subjects who are consistently rapid or slow absorbers, such as were noted in a previous study from this laboratory (2), may be individuals who by reason of certain anatomic or physiological characteristics of their gastroin testinal tract cause ingested tablets to be subjected to relatively intensive or mild agitation, respectively. As a corollary, one would expect to find the same type of differences in *in vivo* absorption kinetics with rapid and slow absorbers as were noted in *in vitro* dissolution kinetics at high and low stirring rates, respectively. Accordingly, plasma salicylate levels obtained after administration of type *A* and type *B* tablets were compared in a consistently rapid and a consistently slow absorber (as judged on the basis of data obtained in two tests with type *A* tablets) from among the group of subjects who participated in this study. The results, expressed as ratios of plasma salicylate concentration after type *A* to those obtained after type *B* tablets, are listed in Table II. They show, as predicted, that

Table II—Relative Absorption Rate of Aspirin from Type *A* and Type *B* Tablets in a Rapid and a Slow Absorber[a]

Subject	Ratio of Salicylate Concn. in Plasma Type *A* : Type *B* Time, min. 10	20	30
Rapid absorber	2.7	3.1	2.6
Slow absorber	0.8	1.0	1.1

[a] Based on data obtained in 2 trials per subject per tablet type.

differences in absorption rate of drug in the two types of tablets are clearly evident in the rapid absorber, but are essentially absent in the slow absorber.

Extending this reasoning one step further, one would expect less inter-subject variation in the rate of drug absorption from type *B* tablets (which show very little dissolution rate dependency on agitation intensity) than from type *A* tablets (which show a pronounced dissolution rate dependency on agitation intensity). These effects are indeed evident in the clinical results obtained from the cross-over study in 6 subjects. The time of occurrence of peak salicylate levels in the plasma following administration of type *B* tablets was 120 min. in 5 subjects and 240 min. in the sixth subject. On the other hand, these times varied markedly following administration of type *A* tablets: 20 min. (1 subject), 30 min. (1 subject), 60 min. (2 subjects), and 120 min. (2 subjects). It should be noted, however, that there may be some bias in these results because of the longer sampling intervals at the later times.

The *in vitro* results illustrate the limitations and possible hazards in the use and interpretation of dissolution rate data derived from tests carried out under arbitrary conditions. It is now evident that small differences in agitation intensity or in the pH of the solvent (9) can have a pronounced effect on the relative dissolution rate of a drug in different tablet formulations. These problems are of course obviated by administering drugs such as aspirin in solution (10). Where it becomes necessary to select the most promising tablet formulation from among several experimental formulations available for clinical study, it would appear prudent to base this selection on dissolution rate data obtained over a range of agitation intensities and solvent pH.

The clinical data suggest that differences in absorption rates may, in the case of dissolution rate limited drug absorption, be due to differences in the intensity of agitation of the gastrointestinal content. Therefore, disease and environmental conditions (including stress, physical activity, food, and medication) which affect gastro-

intestinal motility (and gastric pH) may have a corresponding effect on dissolution rate limited drug absorption. It is possible, therefore, that 2 types of tablet formulations of a given drug may show pronounced dissolution rate differences in one kind of population or clinical environment, but not in another. However, it must be emphasized that the conclusions concerning these *in vivo* implications are clearly preliminary and require confirmation in a large population sample containing significant numbers of consistently rapid and slow absorbers.

Diffusional Model for Transport Rate Studies Across Membranes

Sir:

There has been much in the literature in recent years concerning the so-called "three-phase" model of drug absorption. Absorption studies in this area have concentrated mainly on the passive or diffusional transport of drugs. Most models currently proposed are kinetic outgrowths of the original Brodie-Shore-Hogben pH-partition thesis. In recent communications to this journal authors (1, 2) have proposed equations based on first-order kinetics, which give the amount of drug in each of the three phases *versus* time.

The importance of diffusion in drug absorption has been recognized (3). However, no strictly diffusional model of drug absorption has been proposed for the three-phase multicomponent diffusion problem that can physically describe, for example, pH effects.

The authors in these laboratories are exploring general diffusional models for gastrointestinal absorption of ionizing and nonionizing drugs. A proposed steady-state model, shown in Fig. 1 for the case of a weak base, RN, which can become protonated to give RNH^+, allows for intestinal and blood buffers. It is assumed here also that only the uncharged drug species can diffuse in the lipid phase. An important feature of this model is the inclusion of aqueous diffusional barriers on each side of the lipoidal membrane.

Preliminary results (Fig. 2) obtained for the steady-state case *via* computer correlate the combined effects of varying pKa and the partition coefficient (KLH). The units of G, the transport rate, are mmoles cm.$^{-2}$ sec.$^{-1}$. TH1 and TH3, the effective aqueous diffusion layer thicknesses on the left and right side of the membrane, respectively, are taken as equal for these calculations. TH2 is the effective thickness of the lipid phase. For low to moderate agitation conditions, TH1 should be around 50 to 200 μ (4). The authors would estimate TH2 to be effective somewhere between tens of microns to few millimeters.

In Fig. 2 most noticeable is the fact that steady-state transport rates are linear with increasing partition coefficients only up to a certain point

(KLH ~1), beyond which the aqueous diffusion layers give a limiting effect. Experimental data given by Hogben *et al.* (3) indicate that this leveling off effect does occur in rat intestine absorption studies. Hogben and his associates indicated in the same paper that the observed pattern of intestinal absorption demonstrated the crucial importance of drug diffusion to the intestinal wall when absorption conditions (high partition coefficient, drug present mostly in uncharged form) were otherwise favorable. We feel that this phenomenon should also be observed in *in vitro* absorption studies. The collodion-phospholipid membranes used by Misra *et al.* (5) averaged 20 μ in thickness. In this case the aqueous diffusion layers (50 to 200 μ) would probably be greater than the thickness of the membrane by the order of magnitude of 2.5 to 10. The diffusional leveling off effect, if a 20-μ membrane were to be inserted in the above model, would occur at partition coefficient values of about 10^{-2}. If the diffusion coefficient of the drug in the lipid is less than that in these calculations, the leveling off would occur at correspondingly larger KLH values.

The data curves (Fig. 2) are quite close at low pKa values until the pKa of the drug approaches the intestinal pH, at which point they become increasingly separated with increasing pKa. The linearity of *G* with increasing partition coefficient for a base with a pKa of 9 is seen to extend over a much wider range than for weak bases having lower pKa values. This indicates that, due to the lower amount of the uncharged species present per amount of charged species, the diffusion process is still dependent on the permeability of the lipid layer at partition coefficients in the neighborhood of unity.

An expression for the nonionizing drug case, under the same conditions as above, fits point-for-point the pKa = 3 curve in Fig. 2. Further work is underway concerning the case of weak acids in the intestine. Due to the generality of the model, additional factors such as micellar transport and complexation can be considered. Further studies should also treat the nonsteady-state case and the heterogeneous nature of the lipid barrier.

Nomenclature Correction of Certain Plant *n*-Alkanes

Sir:

Recently we initiated phytochemical studies on certain *Euphorbia* species because of the reported folkloric use of members of this genus (*E. ingens*, *E. bupleurifolia*, *E. clavarioides*, and *E. gorgonis*) as anticancer remedies (1). Indeed, certain of the euphorbias (*E. amygdaloides*, *E. drummondii*, *E. marginata*, *E. pilulifera*, and *E. resinifera*) have been shown to elicit antitumor activity in laboratory animals (2). During the course of one of our investigations, a considerable amount of waxy material was encountered, which readily deposited white plates from the usual crystallizing solvents. These plates gave a sharp melting point, indicative of either *n*-nonacosane or *n*-hentriacontane, and elemental analyses were in agreement with an identification as either of these *n*-alkanes. This prompted us to request samples of these two compounds from other investigators for comparative purposes. Samples of *n*-nonacosane isolated from *Chaerophyllum bulbosum* L. (3), *Euphorbia watanabei* Makino[1] (4), and *Arctostaphylos patula* Greene[1] (5), as well as *n*-hentriacontane from *Euphorbia lathyris* L. (6) and *Plantago asiatica* L. (7) were obtained.

Prior to using these samples for comparative purposes, they were each subjected to a gas chromatographic analysis using the conditions previously described (8). Of the five samples analyzed, only the *n*-nonacosane from *C. bulbosum* (3) was reasonably pure (about 97%). The *n*-nonacosane from *E. watanabei* (4) was actually 61% *n*-hentriacontane, and the *n*-nonacosane from *A. patula* (5, 8) was 60% *n*-hentriacontane. Samples of *n*-hentriacontane isolated from *E. lathyris* (6) and *P. asiatica* were complex mixtures, but each was more than 50% of the labeled hydrocarbon (Table I).

These studies re-emphasize the need for subjecting all *n*-alkanes isolated from plant sources to a gas chromatographic and/or mass spectrometric analysis before any identification of these compounds can be made, and their presence in plant material reported.

TABLE I—COMPOSITION OF *n*-ALKANES FROM SELECTED PLANTS

n-Alkane Reported	Plant Source	Ref.	*n*-Alkanes Found[a]									
			C_{25}	C_{26}	C_{27}	C_{28}	C_{29}	C_{30}	C_{31}	C_{32}	C_{33}	C_{34}

REVIEWS

Treatise on Analytical Chemistry. Part Two, *Analytical Chemistry of Inorganic and Organic Compounds:* Vol. 13 *Functional Groups.* Edited by I. M. KOLTHOFF and P. J. ELVING. Interscience Publishers, a Division of John Wiley & Sons, Inc., 605 Third Ave., New York, NY 10016, 1966. xxi + 528 pp. 16.5 × 24 cm. Price $20.00.

This is only one of the many volumes in this series intended to cover all aspects of modern and classical analytical chemistry. The first volume of Part I, "Theory and Practice," was published in 1959; volumes of both Parts I and II have been appearing nearly every year since.

Volume 13 is a continuation of the organic analysis section and covers various functional groups—active hydrogen, C-methyl, carbonyl, carboxyl, phosphorus-based, and divalent sulfur based.

Staff review

The Chemistry of Heterocyclic Compounds: Multi-Sulfur and Sulfur and Oxygen. Five- and Six-Membered Heterocycles. Part II. By DAVID S. BRESLOW and HERMAN SKOLNIK. Interscience Publishers, a division of John Wiley & Sons, Inc., 605 Third Ave., New York, N. Y 10016, 1966. xviii + 793 pp. 15 × 22.5 cm. Price $44.00. [For a review of Part I see *J. Pharm. Sci.*, **56**, 663(1967).]

Part Two of the twenty-first volume in the Weissberger series, "The Chemistry of Heterocyclic Compounds," records the chemistry of the six-membered multi-sulfur and sulfur-and-oxygen heterocycles. Methods of synthesis, structures, and reactions of these ring systems are emphasized equally, and physical properties are thoroughly tabulated and referenced. Elucidation of reaction mechanisms by present concepts and critical evaluation of the older literature are important features of the text.

More than 200 parent heterocycles are now listed for the sulfur and oxygen five- and six-membered heterocycles of this classification. Among the types of compounds found in Part Two are the following: dioxadithianes and dioxadithiins, trithianes and tetrathianes, cyclic sulfite and sulfate esters of 1,3-diols, dioxathianes and oxadithianes (including cyclic disulfonic anhydrides), oxathianes and oxathiins (including sultones), oxathia-, thia-, and thiaazaadamantanes, phenoxathiins (including other heterocyclic fusions and substituents), dithianes and dithiins (including cyclic disulfides, thioacetals, and thioketals), thianthrenes, and sulfur dyes. Corresponding selenium and tellurium systems are also included. The literature has been reviewed through 1962.

The pharmaceutical chemist should find much of interest in the variety of heterocyclic systems encountered in this volume, particularly since much of the chemistry described is not found in the standard texts of organic chemistry. Uses and applications, including pharmaceutical, are mentioned.

The index is extensive and differs to some extent from the ordinary. In addition to the inclusion of every derivative cited in the text, designation as to synthesis, property, reaction, or listing in a table is made. Reactants used in syntheses are indexed as well as uses and spectroscopic properties. This work is thorough, competent, and highly readable as well.

Extra Pharmacopoeia (Martindale). 25th edition. Edited by R. G. TODD. The Pharmaceutical Press, 17 Bloomsbury Square, London, England, 1967. xxviii + 1804 pp. 16 × 23 cm. Price $27.00.

"Martindale's Extra Pharmacopoeia" was first published in 1883. The 25th edition has been redesigned to enable the editors to include 80% more material than was in the 24th edition. However, it is relatively compact and is easy to read and use. One new feature is that each page is divided into two columns. This is particularly important to assure easy reading due to the number of lines per page. The latter was necessary to get this much material in a single volume. The book abounds in references, each consisting of a 5- to 20-line digest of essential information from the article with the source given in italics at the end of the digest instead of at the end of the chapter.

The editor has done a very selective job of deleting the old and incorporating the new. It contains many references to 1966 articles which is very current for a reference book of this type. Particularly useful is the information on new products, some of which have been approved by the FDA since the book was published on February 28, 1967, and others that are still under investigation in this country.

The book is divided into three main parts. Part 1 is the largest and contains 1500 pages devoted to monographs on drugs and drug preparations in current use. This most useful part is divided into 169 chapters, each covering closely related products, a total of about 2600 substances. The products are grouped pharmacologically, *e.g.*, under the title of Aluminum Hydroxide and other antacids, and Penicillin and other antibiotics. The latter covers 125 pages and contains such useful lists as antibiotics active predominantly against Gram-positive organisms, those with antifungal activity, and those that are resistant to acids and are effective when given

The latter covers 125 pages and contains such useful lists as antibiotics active predominantly against Gram-positive organisms, those with antifungal activity, and those that are resistant to acids and are effective when given

by mouth. The monographs for individual substances list several names for the substance (when there are several), gives the molecular formula, description of the substance, solubility, uses, dose, toxic effects, and contraindications, including abstracts from articles that cover such aspects as hazards of prescribing with other drugs, *etc.*

Part 2 covers about 600 "Supplementary Drugs and Ancillary Substances." These are not covered in as much detail as the substances in Part 1. Some of the supplementary drugs are new substances not yet well recognized and others are old products that are no longer widely used, but still important enough to necessitate the pharmacist having descriptive information readily available.

Part 3 gives useful information on the composition and the manufacturer's name of about 1600 over the counter proprietary items. Since the name or composition of these may differ from preparations available in the U. S., this section is less useful than the other sections to the American pharmacist.

Although this is a British publication and compiled primarily for use in England, any American pharmacist who wishes to maintain a reasonably complete library will find it helpful as it contains some useful information not in our usual reference books. To get the most value out of it, one must use it enough to become acquainted with its organization. One will find information on various proprietary products in all three parts of the book. The inside of the cover "wrapper" suggests that one always refer to the Master Index, but if one is looking for "abbreviations," they are not mentioned in it, but rather listed under the table of "Contents," which refers one to page xxiii. Despite this, the index is very comprehensive, listing over 32,000 entries so that any preparation can be traced from its official name, chemical name, synonym, or proprietary name. There is also an Index to Clinical Uses, listing diseases and drugs used in treating them.

I recommend this book as a reference for hospital, prescription, and industrial pharmacists.

Drugs Affecting the Peripheral Nervous System. Medicinal Research Series Vol. 1. Edited by ALFRED BURGER. Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10016, 1967. xxii + 620 pp. 15.5 × 23 cm. Price $27.50

This book, the first of a series, is intended to survey major topics in the area of pharmacodynamic agents acting on the nervous system; the approach is on a fundamental biochemical–pharmacologic basis. These volumes are a memorium to the late Fred Schueler who participated in the selection of authors.

There are ten chapters covering such areas as the molecular aspects of cholinergic mechanisms, muscarinic drugs, atropine-like agents, ganglionic drugs, adrenergic drugs, and others. For the most part standard drug classification has been followed. The structure-activity relationships of many compounds and series of compounds are given. In some areas the older data have been reinterpreted in the light of newer knowledge. In other areas this has not been done. Even so, one of the values of this book is the extensive documentation of the large number of chemical structures tested in each drug class. Although at least one new class of compounds is not extensively covered—the β-adrenergic blocking agents—on the whole the references are up-to-date.

Another plus value is the complete author index of the cited literature. This serves as an excellent system to locate older references in which the author's name is better known than the class of drugs he studied.

Some of the authors have ventured into predictive speculations. The chapter on cholinergic mechanisms is of this kind. Each author in this book has been intimately associated with the material presented in his chapter. Both university laboratories and drug industry laboratories are represented. The projected series, if up to the quality of this first volume, will be a worthwhile addition to any pharmacology library.

Index to Reviews, Symposia Volumes and Monographs in Organic Chemistry. For the period 1963–1964. Compiled and edited by NORMAN KHARASCH and WALTER WOLF. Pergamon Press, Inc., 44–01 21st Street, Long Island City, New York, N. Y. 11101, 1966. x + 326 pp. 21.5 × 28 cm. Price $17.50.

This is the third volume of this "Index." The earlier two volumes covered 1940–1960 and 1961–1962, respectively. The "Index" covers works in French and German, and English translations of Russian studies, as well as those in English. Presentation is by journals, *i.e.*, the journals are listed alphabetically with the titles of the review articles contained in each listed chronologically. Eighty-three journals and periodic publications and fifty-three symposia, collective volumes, and nonperiodical publications are covered. A separate listing of monographs dealing with organic chemistry and closely related topics which have been published in English, French, and German is also given. A complete author and subject index is included.

Index to Reviews, Symposia Volumes and Monographs in Organic Chemistry. For the period 1963–1964. Compiled and edited by NORMAN KHARASCH and WALTER WOLF. Pergamon Press, Inc., 44–01 21st Street, Long Island City, New York, N. Y. 11101, 1966. x + 326 pp. 21.5 × 28 cm. Price $17.50.

This is the third volume of this "Index." The earlier two volumes covered 1940–1960 and 1961–1962, respectively. The "Index" covers works in French and German, and English translations of Russian studies, as well as those in English. Presentation is by journals, *i.e.*, the journals are listed alphabetically with the titles of the review articles contained in each listed chronologically. Eighty-three journals and periodic publications and fifty-three symposia, collective volumes, and nonperiodical publications are covered. A separate listing of monographs dealing with organic chemistry and closely related topics which have been published in English, French, and German is also given. A complete author and subject index is included.

NOTICES

Organic Photochemistry. Vol. 1. Edited by ORVILLE L. CHAPMAN. Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10016, 1967. xi + 339 pp. 15.5 × 23 cm. Price $15.75.

Quelques Aspects de la Chimie des Medicaments. By A. LESPAGNOL, D. BAR, C. LESPAGNOL, and M. DAUTREVAUX. Masson et Cie, Editeurs, 120 Boulevard Saint-Germain, Paris VI^e, France, 1966. viii + 268 pp. 16 × 23.5 cm. Price 78F. Paperbound.

by mouth. The monographs for individual substances list several names for the substance (when there are several), gives the molecular formula, description of the substance, solubility, uses, dose, toxic effects, and contraindications, including abstracts from articles that cover such aspects as hazards of prescribing with other drugs, *etc.*

Part 2 covers about 600 "Supplementary Drugs and Ancillary Substances." These are not covered in as much detail as the substances in Part 1. Some of the supplementary drugs are new substances not yet well recognized and others are old products that are no longer widely used, but still important enough to necessitate the pharmacist having descriptive information readily available.

Part 3 gives useful information on the composition and the manufacturer's name of about 1600 over the counter proprietary items. Since the name or composition of these may differ from preparations available in the U. S., this section is less useful than the other sections to the American pharmacist.

Although this is a British publication and compiled primarily for use in England, any American pharmacist who wishes to maintain a reasonably complete library will find it helpful as it contains some useful information not in our usual reference books. To get the most value out of it, one must use it enough to become acquainted with its organization. One will find information on various proprietary products in all three parts of the book. The inside of the cover "wrapper" suggests that one always refer to the Master Index, but if one is looking for "abbreviations," they are not mentioned in it, but rather listed under the table of "Contents," which refers one to page xxiii. Despite this, the index is very comprehensive, listing over 32,000 entries so that any preparation can be traced from its official name, chemical name, synonym, or proprietary name. There is also an Index to Clinical Uses, listing diseases and drugs used in treating them.

I recommend this book as a reference for hospital, prescription, and industrial pharmacists.

Drugs Affecting the Peripheral Nervous System. Medicinal Research Series Vol. 1. Edited by ALFRED BURGER. Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10016, 1967. xxii + 620 pp. 15.5 × 23 cm. Price $27.50

This book, the first of a series, is intended to survey major topics in the area of pharmacodynamic agents acting on the nervous system; the approach is on a fundamental biochemical–pharmacologic basis. These volumes are a memorium to the late Fred Schueler who participated in the selection of authors.

There are ten chapters covering such areas as the molecular aspects of cholinergic mechanisms, muscarinic drugs, atropine-like agents, ganglionic drugs, adrenergic drugs, and others. For the most part standard drug classification has been followed. The structure-activity relationships of many compounds and series of compounds are given. In some areas the older data have been reinterpreted in the light of newer knowledge. In other areas this has not been done. Even so, one of the values of this book is the extensive documentation of the large number of chemical structures tested in each drug class. Although at least one new class of compounds is not extensively covered—the β-adrenergic blocking agents—on the whole the references are up-to-date.

Another plus value is the complete author index of the cited literature. This serves as an excellent system to locate older references in which the author's name is better known than the class of drugs he studied.

Some of the authors have ventured into predictive speculations. The chapter on cholinergic mechanisms is of this kind. Each author in this book has been intimately associated with the material presented in his chapter. Both university laboratories and drug industry laboratories are represented. The projected series, if up to the quality of this first volume, will be a worthwhile addition to any pharmacology library.

Review Article

Some Pharmaceutical Applications of Ultrasonics

By DONALD M. SKAUEN

IT IS DIFFICULT to imagine the scope of ultrasonics until one searches through the recent literature. On gathering material for this review the author has covered approximately 9000 references, a great many of which are allied to pharmacy. It is obvious that a complete review of the literature is impossible in this journal. References were selected which were, in the opinion of the author, most likely to stimulate interest and to illustrate the broad scope of ultrasonic technology.

It is apparent that much less attention has been paid to ultrasonics in pharmacy in the United States than in biology, medicine, chemistry, and engineering. This is brought out in the relatively few research papers in this field which have been published in the past two decades. It is also evident that many more research reports have appeared in foreign literature and in particular in the Russian literature than in our own country.

It would appear that part of the reluctance on the part of the pharmaceutical researcher to use ultrasonics in solving some of his problems has been the lack of standardized equipment or satisfactory standardizing techniques. It is now possible to obtain equipment which will indicate output on a meter and thus aid in standardizing procedures in so far as energy requirements are concerned. With the development of several colorimetric standardizing techniques, it is also possible to standardize procedures even though meters are not supplied with the equipment.

In addition, modern equipment in the ultrasonic field has kept pace with power requirements and actually has much more power than is presently needed in the pharmaceutical field.

For the purpose of this review, the author has divided the references into more or less distinct interest areas. In certain instances, there seems to be some overlapping but it does not appear to be very extensive.

EMULSIFICATION

One of the earliest reports of the use of ultrasound for dispersions of oil and water and mercury in water was by Wood and Loomis (1) in 1927. Richards (2) studied the emulsifying action of ultrasound shortly thereafter and came to the conclusion that the emulsification is due largely to the action of transverse waves in the walls of the glass vessel. He observed clouds of emulsion coming from the sides of the container when he used low intensity sound. He concluded from this that compressional waves within the liquid were not primarily responsible for the emulsifying action.

Bondy and Sollner (3–6) performed a series of experiments to clarify the mechanism of emulsification by ultrasonic waves. It was their conclusion that a so-called "cavitation" at the interface of water and oil caused emulsification. They found (3) that emulsions were obtained when con-

Received from the School of Pharmacy, University of Connecticut, Storrs, CT 06268

The author acknowledges the assistance afforded to him by several graduate students past and present.

ditions were such that cavities were formed and collapsed. Liquids irradiated in vacuum formed cavities, but the cavities did not collapse because the vapor pressure inside the cavities was practically in equilibrium with the outside pressure. If liquids were sealed under a gas and exposed to ultrasonic vibration, they were easily emulsified.

Bondy and Sollner (4) concluded from their observations that the mechanism of emulsification of mercury was quite different from that of oils and did not involve cavitation. They confirmed Richards' (2) mechanism, in which it was thought that droplets of water are thrown into the mercury, thin films of mercury form around them, and on bursting, a gray cloud of emulsion is driven into the water. Since this happened even *in vacuo*, cavitation was ruled out as the cause of emulsification.

Campbell and Long (7) were unable to form emulsions of mineral oil, peanut oil, and light liquid petrolatum at concentrations much above 10% with or without emulsifying agents at frequencies of 1000 and 500 kc. From this they concluded that the higher ultrasonic frequencies do not favor the formation of emulsions other than the dilute ones. When they used a generator at a 15-kc. frequency they were able to make a 50% peanut oil-in-water emulsion using triethanolamine stearate as the emulsifying agent. It was found that the globule size of this emulsion was smaller than the same emulsion prepared by hand shaking or by homogenization.

Audouin and Levavasseur (8) experimented with emulsification of peanut, linseed, olive, and mineral oils in an effort to determine the effect of frequency on results. They found that frequency was a predominant factor with regard to the possibility of formation and orientation of an emulsion in a certain direction (w/o or o/w) and only in this direction. The presence of an emulsifying agent normally thought to influence emulsification in the opposite direction did not change the type of emulsion. At a frequency of 960 kc., orientation occurred in the direction of water-in-oil even in the presence of sodium oleate, which normally orients in an oil-in-water direction. At 187 kc. and 320 kc., orientation occurred in the oil-in-water direction in spite of the presence of barium oleate, normally a water-in-oil director. They pointed out that an emulsion begun in a direction with a certain frequency continued to be formed in this direction, even if submitted to another frequency which normally gives an emulsion in the opposite direction. Frequencies of 576 kc. and 720 kc. seemed to have little tendency to form emulsions with most oils. Using a frequency of 25 kc. they first obtained an oil-in-water emulsion which was abruptly converted to a very concentrated water-in-oil emulsion after 15 min. insonation.

Audouin and Levavasseur (8) found that an elevation in temperature is unfavorable to emulsification and favorable to coagulation, due to lessened cavitation. With a small rise in temperature, there was a reduction in viscosity which favored emulsification. Beal and Skauen (9) came to the same conclusion since a temperature rise did not hinder emulsification; on the contrary, it rendered viscous oils more easily emulsified.

Esche and Wenke (10) state that the formation of an emulsion in an ultrasonic field occurs in cases where the viscosity of the dispersing medium is low—less than 120 cps. As the viscosity of the medium increases, there is greater absorption of acoustic energy with diminished cavitation.

While studying emulsifying agents under the influence of ultrasound, Tamas (11) found that the viscosities of tragacanth and polyethylene glycol 400 solutions were diminished by 50% and 20%, respectively. The particle size of emulsions was first reduced and then increased. They presumed that every kind of oil has an optimum frequency at which emulsions form. In addition, as ultrasonic intensity increases, cavitational forces increase, and the rate of emulsification increases.

There is some disagreement in relation to the relative importance of high- *versus* low-frequency equipment for emulsification purposes. Relative intensity of insonation has likewise been discussed by numerous investigators. Mounier *et al.* (12) prepared emulsions at frequencies from 958 kc. to 288 kc. and state that a stable oil-in-water emulsion is always formed. An emulsion prepared at one frequency is not destroyed at another frequency regardless of the oil.

According to Lifshits (13), homogeneous emulsions were formed at a sonic frequency of 7.6 kc. The dispersion of the emulsions increased with increase in the duration of irradiation. There was a limit to the decrease in mean globule size.

Neduzhii (14–16) studied the relationship of sound intensity to emulsification. At a frequency of 22 kc. with a water–dibutylphthalate system he found that a threshold intensity of sound was required to initiate emulsification and was different depending upon whether it was a water-in-oil or an oil-in-water emulsion. As the sound intensity was raised, the rate of emulsification increased. He suggests that the particle size of the dispersed phase is independent of the sound intensity. Neduzhii (16) also indicates that on

continued insonation there is a tendency for the particles to begin to coalesce.

Beal (9) investigated the effect of exposure time on a liquid petrolatum emulsion and reported that up to 30 min. there was a continued decrease in globule size.

While reports that highly dispersed and concentrated emulsions have been produced by ultrasonic means without emulsifiers (17), there is general agreement that the presence of emulsifying agents improves the stability and quality of emulsion systems.

Beal and Skauen (9) showed that hard soap was the emulsifier of choice for a mineral oil emulsion, with polyethylene glycol 400 monostearate and polysorbate 80 following in that order. This study proves the necessity to examine the effect of ultrasonics on various components of emulsions, since tragacanth when used as an emulsifier appeared to suffer degradation. Tamas (11) reported a 50% loss in viscosity with tragacanth and a 20% loss with polyethylene glycol 400 monostearate. Haavisto and Hagner (18) attempted to prepare emulsions of peanut oil and water without the aid of emulsifiers and found them to be nonhomogeneous and unstable. Using a 5% total sorbitan monoloeate–polyoxyethylene 20 sorbitan monopalmitate[1] (1:1) emulsifier, they found that superior emulsions could be made with 5, 20, and 40% peanut oil and an ultrasonic step-horn transducer.

Emulsions of mineral oil were prepared by Myers and Goodman (19) using a liquid whistle type of apparatus called a Rapisonic.[2] Liquids are pumped through an orifice at high pressures and velocities against a steel blade, causing the blade to vibrate at ultrasonic frequencies. When the system reaches a steady state, a cavitational field is produced. Results reported by the authors indicated that on microscopic examination the diameter of the globules was generally in the range of 1–3 μ.

Singiser and Beal (20) carried out a study comparing the efficiency of several ultrasonic generators and a colloid mill for the production of an emulsion. Their evaluation covered emulsions of heavy mineral oil, peanut oil, and safflower oil, and four emulsifiers—acacia, polyoxyethylene 20 sorbitan monopalmitate–sorbitan monooleate, poloxalkol[3]–sorbitan monooleate, and sodium lauryl sulfate. The Minisonic Mark 2[4] hydrodynamic generator produced emulsions superior to those made by any other apparatus. It would appear that the hydrodynamic apparatus is the best of the ultrasonic generators for large volume liquid processing. Major advantages, including faster through-put, no premix, faster emulsification, and reduced temperature requirements, are suggested by Marshall (21) and McCarthy (22) for this type of generator.

With the recent development of the step-horn type of ultrasonic transducer, it is possible to study various emulsion systems where small batches are involved and where power output is important. One of the advantages of this type of transducer is that the ultrasonic horn is in direct contact with the liquid being processed with the net transfer of maximum energy. Another advantage considered important for such devices is the availability of a variety of transducers with different power output. It is even possible for instruments to be made to match requirements.

Kann and Tester (23) used a step-horn transducer called the Sonifier[5] to produce an emulsion for a parenteral contrast medium for lymphography. It was their desire to prepare a 50% emulsion with a particle size less than 0.5 μ with a viscosity of 15–20 cps. at 30°. They reported satisfactory results with both the Sonifier and the Mini-Mill.

EXTRACTION

El'piner (24) has reviewed the literature very thoroughly in regard to viral and bacterial extraction and associated action of ultrasonic waves. He has, in addition, reported on the action of ultrasonic waves on unicellular and multicellular organisms.

This review therefore includes only those references which seem to be most significant with respect to the field of pharmacy.

Much of the early work in extraction was accomplished with equipment of low power output and relatively high frequency. With the recent development of the step-horn transducers with low frequency and high power output, it is expected that many more studies on effects of ultrasound on cells of pharmaceutical interest will appear.

Yamada and Ishida (25) studied the mechanism of fish oil extraction by means of ultrasonic waves. They reported that the muscle protein absorbed the ultrasonic energy selectively, for the temperature rise of the protein always preceded that of the oil layer by about 10°. The protein was coagulated by heat and water was released from

[1] Marketed as Span 80 and Tween 40, respectively, by Atlas Chemical Industries, Wilmington, Del.

[5] Branson Sonic Power Co., Danbury, Conn.

the muscle. The lipids of the connective tissue within the muscle were emulsified along with the water and flowed out.

Gomez and Matas (26) applied ultrasonic waves to seeds of *Strophanthus gratus* that had lost 50% of its strophanthin on storage. The yield of alkaloid was not improved and was actually diminished in alcoholic solution. The same authors (27) studied the observed loss of activity of extracts of *S. gratus* in terms of alkaloidal degradation and suggested hydrolytic effects due to ultrasonic stimulation.

Head *et al.* (28) studied the effect of ultrasonic waves on the extraction of *Cinchona succirubra*. Ultrasonic extractions at 20 kc. and 450 kc. were compared with conventional Soxhlet extraction under similar conditions. The ultrasonic extraction was more efficient than Soxhlet extraction, and there was no destructive action by the ultrasound on the alkaloids.

Adamski *et al.* (29) also treated cinchona species and showed an increase of 50% in the extraction yield when the bark was treated with ultrasound prior to maceration or percolation. They mention that the keeping qualities of the extracts were good but that decomposition of quinine was noticed with treatment lasting more than 30 min.

Using the Sonifier, Ovadia and Skauen (30) were able to increase not only the rate but the extent of extraction of cinchona bark. No destruction of alkaloids was noted even after 3 hr. insonation.

Colian and Tomas (31) reported that ultrasonic extraction of *Atropa belladonna* at 800 kc. produced 36.7% more alkaloids than mechanical agitation. The yield was only 2.4% superior to solvent extraction but extraction time was shorter. The amount of alkaloids did not increase after 15 min. insonation nor was decomposition observed. Wray and Small (32) also studied the effect of ultrasonic treatment on the extraction of belladonna leaf. Samples of maceration mixtures were put in surface treatment vessels and were subjected to ultrasonic treatment at 500 kc. for 20 min. Then Soxhlet extraction and ultrasonic extraction in a submersion treatment vessel were effected. The ultrasonic maceration shortened the maceration time from 8 hr. to 20 min., and the ultrasonic maceration followed by ultrasonic extraction resulted in considerable saving of time. Analysis of the extract showed no decomposition products of the alkaloids.

El'piner and Stekol'nikov (33) subjected various alkaloids to ultrasonic treatment, among them atropine and quinine. These alkaloids, they state, are attacked by ultrasound. Alkaloidal salts were treated for 15–90 min. at 800 kc. under saturated air, hydrogen, argon, or helium. The pH of all solutions decreased, with the greatest change in contact with air. Atropine lost its activity by such treatment under air but retained it in a hydrogen, helium, or argon atmosphere. Quinine also showed little change after exposures except in those cases where it was heated for 60–90 min. in contact with air.

Rauwolfia serpentina roots were extracted under ultrasonic irradiation by Bose *et al.* (34). Samples were subjected to ultrasonic maceration at 25 kc. for 5, 10, and 15 min. It was found that the maceration time was reduced from 8 hr. to 15 min. for the complete extraction of the alkaloids.

DeMaggio *et al.* (35) examined the effect of change in frequency on extraction yield of *Datura stramonium*. They state that a 15% increase in alkaloidal yield results when the frequency is increased during a 1–2 hr. insonation period.

DeMaggio and Lott (36) studied the influence of ultrasound on the maceration process as well as during the extraction of *D. stramonium*. The application of ultrasound during short periods of maceration was effective in producing a greater yield of alkaloids than conventional methods. When ultrasound was applied during the process of continuous solvent extraction, it proved to be slightly more efficient in liberating the desired alkaloids from the drug.

Shinyans'kii and his co-workers (37) exposed the dry leaves, seeds, seed pods, and stalks of the poppy plant to ultrasonic waves at 500 kc. for 15–17 min. in an aqueous medium. The extent of extraction of morphine was equivalent to 24 hr of conventional liquid extraction. A similar study was reported (38) using 22, 300, and 750 kc. on pods of opium poppies in an aqueous environment. Approximately 60% of the morphine was extracted into the aqueous phase during the first 10 min. At each frequency studied, there seemed to be no change in the amount extracted. Length of exposure to ultrasound was an important factor, since the yield decreased with increased exposure time because of decomposition of morphine. Changing the solvent system effected a corresponding increase in morphine yields.

Paradissis and Maney (39) irradiated ergot at 400 kc. and found that ergotoxin was evidently destroyed. When cationic surfactants and polyethoxylated aliphatic amine[6] were used extraction was improved. They also found that a frequency of 400 kc. was superior to 10 kc. for extraction of ergot.

[6] Ethomeen C-25, Armour Industrial Chemical Co., Chicago, Ill.

Pivnenko and Sotnikova (40) used a 500-kc. generator for the extraction of ergot alkaloids and found that extraction time was three times more rapid than by the USSR Pharmacopoeia method.

The efficiency of extraction of jaborandi leaf and ipecac root with the Sonifier was investigated by Ovadia and Skauen (30). The amount of alkaloids obtained by ultrasonic extraction of ipecac root was higher than that obtained by the U.S.P. XVI method, while the amount obtained by ultrasonic extraction of jaborandi under temperature controlled conditions was also greater than the B.P.C. 1949 extraction method. The amount of alkaloids extracted from ipecac root in 30 sec. was greater than the amount produced by Soxhlet extraction in 5 hr. Fifteen seconds of ultrasonic treatment resulted in greater yields of from jaborandi leaf than 5 hr. of Soxhlet extraction. After 0.5-min. extraction, jaborandi leaf alkaloids showed degradation, with almost complete degradation after 15 min. Kusano (41) reports no such loss of pharmacological activity of pilocarpine or atropine after ultrasonic irradiation.

Kazarnovskii (42) used ultrasonics as part of an extraction technique for obtaining epinephrine from adrenal glands. Ultrasound was helpful in obtaining complete extraction of all the adrenaline present.

Grochowska (43) reports on the use of ultrasound to aid in removal of barbiturates from human tissue. He states that the time of extraction is considerably shortened.

CRYSTALLIZATION

The use of ultrasonic energy during crystallization of supercooled melts is well documented. Danilov (44) found that the appearance of the first crystallization center of *o*-chloronitrobenzene was accelerated by ultrasound. When salol, naphthalene, and camphor were treated, an increase in rate of crystallization resulted (45). Danilov further reported a large increase in the number of nuclei in piperine after insonation (46). Ultrasonics has been applied to the crystallization of betol (47), thymol (48), benzophenone (48), and piperonal (48).

Supersaturated solutions have been treated with high-frequency sound resulting in smaller crystals and more uniform size distributions. The crystallization of tartaric acid was accelerated by ultrasound, and the crystals were found to be more finely dispersed and homogeneous (49). Thorium oxalate, when prepared by precipitation under ultrasonic treatment, yielded more uniform crystals with smaller particle size (50).

The production and growth of crystals of thymol, potassium alum, salol, Rochelle salt, and hyposulfite from supersaturated solutions treated with ultrasound was investigated by Chormonov (51). He stated that spontaneous crystallization was accelerated by ultrasound.

One of the most energetic workers in the field of ultrasonic crystallization of sugars has been Van Hook (52). He has been able to improve the crystal size distribution of the final crop as well as induce crystallization in such normally refractory supersaturated solutions as arabinose, fructose, sorbitol, glucose, and melibiose.

Progesterone was prepared as microcrystals by insonating a saturated solution of the hormone (53). Cohn (54) investigated the ultrasonic crystallization of hydrocortisone. He developed a procedure which allowed him to prepare low micron particles of hydrocortisone by direct insonation of a saturated solution. Fincher (55) insonated a supersaturated solution of sulfisoxazole and successfully prepared 1.7-μ crystals.

It has been stated (56) that the effect of ultrasound is due to the acoustic wind and to the mechanical vibrations of the crystal. This was based on the observations that the growth rate of a crystal in an ultrasonic field increases with the ultrasonic intensity and that the velocity of growth increases with decreasing supersaturation.

Berlaga (57, 58) reported that ultrasound increased the number of nuclei in betol, which caused a great increase in crystallization rate. He explained this by assuming that the field separates the fresh nuclei from ones formed previously. Levin (45) uses the same theory to explain the effect of ultrasound on the crystallization of salol, naphthalene, and camphor. Smaller crystals were obtained with increased intensity of vibration. It was stated that the decrease in size of primary crystals and the increased rate of crystallization are caused by the cavitation bubbles which separated the growing crystals at the crystal solution interface and carried them into solution. Kudryavtsev (59) suggested that the increased crystallization rate in ultrasonic crystallization is due to an increase in the number of crystallization centers as a result of ultrasonic scattering of the microcrystals forming in the melt.

Kapustin (48) and Polotskii (60) have felt that ultrasound increased the number of crystal nuclei by shattering or eroding the nuclei that occur in a normal manner. Sokolov (61) states that the mechanism is associated with the initiation of the cavitation process which disrupts the

growing crystal. After studying the effect of ultrasound on crystallization of potassium bitartrate, it was concluded that ultrasound augmented the formation of crystalline centers in the beginning stages of the process (62). Kapustin (63) indicates that ultrasonics breaks off microcrystals which act as fresh nuclei. Teumin (64) explains that the mechanism is due to "the formation of cavitation processes, which disintegrate the growing crystals, to radiation pressure, which transports the crystal fragments to the body of the melt where they form fresh crystallization centers, and to agitation, which results in temperature equalization throughout the entire volume, thereby assisting bulk crystallization." Babikov (65) in general agrees with Teumin but also includes the possible effect of ultrasound on the origination of primary crystallization centers, while Meleshko (66) attributes the crystallization effects to the dispersing action of the ultrasonic field.

Kapustin (67, 68) reported that ultrasound effects crystallization by producing many fresh nuclei from any seed. A small crystal of thymol fixed in a wooden holder was immersed in water in a tube. Liquid thymol was carefully layered on the water. No crystals arose on standing, but crystallization began when ultrasonics was applied to the bottom of the tube. He observed the field to break off minute particles from the seed which were carried to the interface. Identical tests without the seed did not initiate crystallization. Sokolov (69) also found that insonation produced more rapid crystallization when solutions of beet sugar and zinc sulfate were seeded prior to insonation.

Kapustin (70) studied the process of relieving supersaturation in an aqueous solution of potassium alum by ultrasonics and reports desaturation occurs in the presence and absence of nucleation.

Polotskii (71) presented photographic evidence to support the belief that ultrasound acts by dispersing nuclei. He observed cavitation at the crystal–melt interface of supercooled, chemically pure salol to cause strong dispersion of the newly formed crystals. In addition Polotskii (72) photographed the shattering of acicular crystallites of salol and a naphthalene–camphor eutectic shortly after their formation. Without ultrasound, this did not occur.

Van Hook (73) found that the number of crystallization centers increases with the duration of insonation in an autocatalytic way. Due to the limiting effect of prolonged treatment, it was suggested that ultrasound acted chiefly on newly formed crystallites. Nickus (74) makes a similar observation, stating that insonation at 25–50 kc. accelerated the formation of crystallization centers as well as increasing the crystallization rate of molten menthol. Kapustin (75) stated that ultrasonics brought about the formation of new crystallization centers only when a crystal reaches a certain size.

A number of workers have felt that ultrasound generates crystal nuclei. An investigation of the effect of ultrasound on supersaturated solutions of thymol, Rochelle salt, salol, and hyposulfite proved that ultrasound significantly accelerates the process of spontaneous crystallization and plays an essential role during the formation of nuclei (51).

Kapustin (76) stated that ultrasound affects the production of the first crystallization center. This was based on the action of ultrasound on *o*-chloronitrobenzene. The compound was heated to 100°, slowly cooled, and exposed to 10 sec. of 700 kc. ultrasound of varying intensities. The field did not affect the production of the first crystallization center above 20° but caused "spontaneous crystallization" at 18 to 20°. He explained that a system which is macroscopically homogeneous has a certain micro nonhomogeneity which varies little with time. Thus ultrasound could cause a redistribution of the micro nuclei and alter the probability of spontaneous production of crystals.

Brown (77) states that "the effect of ultrasonic irradiation on the crystallization process is similar to its effect on precipitation, *i.e.*, the cavitation produced offers nucleation centers for the crystals to initially form around, and it also breaks up any large crystals." Mazhul (78) studied ultrasonic crystallization and especially the electric fields associated with cavitation. His experiments led him to conclude that nucleation in the melt cannot be explained by the electric fields associated with cavitation. Rather the sites of cavitation themselves act directly as nuclei. He adds that cavitation cannot be taken as the sole cause of the effects, for weak fields which do not cause cavitation still increase the nucleation rate. After experimenting with betol, Mazhul (47) later stated that cavitational ruptures may themselves become crystallization centers under varying external pressures. Glinskii (79) agrees in reporting that the effect of ultrasound on primary crystallization is associated with a decrease of grain size in the melt under pressure. He shows on a theoretical basis that equal compression and rarefaction cause the same effect as to the number of crystal nuclei arising. The effect of ultrasound increases with lower supercoolings.

During the ultrasonic crystallization of sulfisoxazole (80) it was explained that ultrasonics aids crystallization "by supplying cavitation bubbles, which act as the site of nucleation."

In his work on the ultrasonic crystallization of sugar, Van Hook (81) proposed both a heterogeneous and a homogeneous mechanism. He appeared to agree with Mazhul and Brown when he stated that "if one irradiates a strong syrup with a bar transducer, cavitation loci appear at definite points according to the size, shape, and arrangement of the system. The crystal nuclei are generated, presumably within these small volumes. They may then be dispersed and grow to visible size." He also reported that irradiation of a "sterile, isolated solution" gave poorer results or no improvement in grain at all. This suggested to him a heterogeneous mechanism rather than the spontaneous generation of nuclei by the ultrasonic field.

Hem (82) reported reproducible reduced crystal size distributions from insonating a supersaturated solution, whose background particle count was controlled, at a fixed temperature. The crystallization temperature of both insonated and uninsonated samples was dependent on the number of heterogeneous nuclei present.

DISPERSION

The application of ultrasonic waves for the dispersion of coherent solid materials dates back to the classical work of Richards (2) in 1929. He reported unsuccessful attempts to disperse such solids as glass and quartz in liquids. Sollner (83) commenting on this work says that only brittle and soft substances of high cleavage seem to offer promise. He irradiated mica, gypsum, steatite, and hematite in water, producing colloidal or semicolloidal solutions.

Most of the early work was done with coherent solid bodies, but it has been shown that suspended particles can be dispersed. In all systems containing preformed particles the latter may be separated from one another by insonation. Sound-dispersed preparations do not show any special features, the sound-induced cavitation being merely an efficient mechanical dispersing agent (83).

The sonic peptization of gels and gel-like substances has been investigated (84–86). Using a liquid whistle, Ramaszeder (87) dispersed potato starch and suggests that the particle size of the starch granules can be reduced by increased time of insonation. He suggests the use of ultrasonic dispersion of starch granules as an alternative to mechanical homogenization (88).

The dispersion of dyestuffs and pigments by ultrasonics has been reported in the literature (89–91). Fischer (92) stated that the disintegrating effects of ultrasound is negligible, and the changes produced cannot be distinguished from those caused simply by heating and stirring of the pigment. However, since more powerful equipment has become available, other workers have reported some success in dye dispersion. Lifshits (93) compared dye dispersion using piezoquartz, magnetostrictor, and hydrodynamic ultrasonic devices and a mechanical mixer. He states that a higher degree of dispersion was obtained by ultrasound than by mechanical mixing. Prakash (94–97) has studied the fading of colors of various dyes such as Congo red, rhodamine B, bromocresol green, and safranine O. He explains the decolorization on the basis that the high cavitation energy is responsible for a molecular breakdown of the dye.

Chambers (98) reported the preparation of microcrystals of sulfathiazole using ultrasound. Direct sonic vibration of suspensions of the preformed crystals produced no measurable effect. An indirect method was developed consisting of the neutralization of a solution of the sodium salt of the drug while the reaction mixture was kept in violent agitation by sonic vibrations. The size of the resulting crystals was regulated by controlling the speed of admixture or the temperature of the reactants or both. The microcrystals produced were fairly uniform in size. Gartner (99) investigated the action of ultrasound at frequencies of 500, 800, and 1500 kc. on aqueous suspensions of magnesium carbonate, lead carbonate, and barium sulfate. Best results were obtained at a frequency of 500 kc. and at suspension concentrations of 0.002 Gm./ml. Misek (100) studied the suitability of ultrasonic energy for dispersing progesterone in suspensions. He used a surface-active agent to obtain a satisfactory dispersion and states that the degree of dispersion increased as the ultrasonic intensity increased. Several other parameters were also studied (101). It was found that the extent of dispersion decreased as the viscosity of the suspending liquid increased. The application of 15 lb. of pressure upon the suspension during insonation rendered dispersion most complete. Such dispersions showed that 85% of the suspended material was 10μ or less in size. At the frequencies studied, 300, 500, and 750 kc., the frequency of the ultrasonic vibrations had no effect on the dispersion. Araujo (102) insonated suspensions of zinc oxide, bismuth subcarbonate, sulfathiazole, and procaine penicillin G at 400 kc. In all the cases studied, they report that ultrasonic energy

reduces the particle size of the suspended medicament and retards its rate of sedimentation, providing a more stable preparation. The dispersive action of ultrasound on crystals of potassium dichromate in ethanol was observed by Kosolapov (103). Sheikh (104) suspended polyethylene spheres in water and subjected them to the action of ultrasonics at 100 kc. He found that there was a significant reduction in particle size only if a surfactant was present. Increasing insonation time brought about reduction up to 2 hr.

When dealing with the action of ultrasound on suspended material, one must be concerned with the fact that dispersion is not the only effect that can be obtained. Coagulation can also be brought about by ultrasonic irradiation of suspensions. Bondy and Sollner (6) have explained the action of ultrasound on dispersions. They suggest that dispersion requires an energy level exceeding a certain limit, and coagulation may therefore result below this energy limit. Dispersion may also be precluded by prevention of cavitation.

Thompson and Vilbrandt (105) investigated the effect of ultrasonic energy on the coagulation of clay particles and reported that mild intensity insonation (below cavitation threshold) increased the rate of coagulation, while intense insonation (above cavitation threshold) retarded settling of the clay due to dispersion and disruption of the aggregates.

Kruglitskii (106) obtained a more uniform disperse phase when montmorillonite was insonated at 19.5 kc. He reports cavitational breaking of bonds between the disperse phase and the dispersion medium. After 8.5 min., dispersion is maximum, and the clay structure formed has maximum bond energy and stability. Further treatment caused coagulation with the coagulated particles so stable that further treatment does not destroy them. Kruglitskii (107) reports that more satisfactory thixotropic properties and greater stabilities can be obtained by treating clay suspensions with ultrasound, colloids like carboxymethylcellulose, and sodium chloride or calcium chloride than by using any single one or combination of any two of these means.

OTHER PHYSICAL-CHEMICAL AND CHEMICAL EFFECTS

For a very thorough and instructive discourse the interested person is urged to read the text of El'piner (180).

The effect of ultrasonic waves on the degradation of natural and synthetic polymer solutions has been well established.

In 1949, Prudhomme and Graber (108) claimed that the rupture of high polymer chains was due entirely to cavitation. Time required for depolymerization was inversely proportional to the intensity of sound and directly proportional to the concentration, but the final degree (limiting degree) of depolymerization was independent of these factors. They also claimed that polymers of the same composition but different molecular weights approach the same limiting chain length with longer periods of insonation. Later, Prudhomme (109) confirmed his claim that the rupture of the polymers was due entirely to cavitation by insonating 1% aqueous solutions of carboxymethylcellulose at 960 kc. under vacuum, air, and CO_2. He showed that the forces of friction between solvent and polymer molecules are not the basis of the degradation process. Weissler (110) observed that the depolymerization of polystyrene in toluene occurred only in the presence of cavitation. A sample degassed by boiling under vacuum showed no cavitation and no appreciable molecular weight change. This study revealed that oxidants produced by ultrasonic waves cannot be responsible for degradation. Jellinek and White (111) tried to study the number and weight-average molecular weight distributions and number and weight-average chain lengths of polystyrene after insonation and found satisfactory agreement between calculated values for an assumed degradation mechanism and experimental results.

Head and Lauter (112) investigated the ultrasonic depolymerization of a number of natural and semisynthetic polymers. By relating viscosity measurements to molecular weights, they showed that most of the polymers followed a first-order rate equation for degradation. Okuyama (113) explained polymer rupture by ultrasound by stating that at the contracting step of a violently vibrating bubble, the polymer molecule takes a linearly extended configuration owing to the suction force of the bubble occurring by slipping and friction between solvent molecules and the extended part of the polymer. The partial chain is subject to a tensile force arising from friction, which is maximum at the middle carbon atom of the chain. If this force is greater than the critical tensile strength of the C—C bond, the polymer degrades. Zorina and El'piner (114) exposed an aqueous solution of dextran (mol. wt. 35,000) to 840 kc. ultrasound in atmospheres of oxygen, nitrogen, and argon. After 3–4 hr. of insonation the molecular weight decreased to a minimum value of about 20,000. When irradiated in an alkaline solution (pH 13) dialyzable particles were formed. They were also able to produce low molecular weight substances by ir-

radiating solutions of mono-, di-, and trisaccharides at pH 13. El'piner and Pyshkina (115) exposed a 5% solution of sodium carboxymethylcellulose solution to 740 kc. ultrasonics and found that in the presence of oxygen a decrease of molecular weight and viscosity occurred, while in the presence of hydrogen the molecular weight increased and the degree of hydration and viscosity decreased.

Kukoz (116) discussed some of the literature on the chemical action of ultrasonics. The results of experimental studies confirming the cavitation–photoelectrochemical theory of chemical action of ultrasound and experiments demonstrating the need of improving or modifying this theory are given. He mentions that free radicals, ions, and excited molecules of the medium can all play a definite role in ultrasonic action. Information is presented showing the contradictory view that chemical action of ultrasound is explainable by local increase in temperature or the mechanical–chemical effects. He makes the important point that the chemical action of ultrasound on an aqueous medium may be due to many factors, and the role of each of these factors must be analyzed separately in each concrete case.

Vaisman (117) investigated the stability of some medicinal solutions toward ultrasound. The resistance of a series of inorganic and organic pharmaceuticals in aqueous solutions of different concentrations to the action of ultrasound was studied with respect to the visual changes of the solutions, the pH changes, and in some cases the decomposition products. At 800 kc. for 15 min. insonation, sodium chloride, potassium chloride, ascorbic acid, and phenol did not undergo a change. Potassium iodide, sodium salicylate, resorcinol, epinephrine, and procaine HCl were oxidized, and magnesium sulfate and zinc sulfate were partially hydrolyzed.

Maffei (118) treated pure expressed olive oil with ultrasonic waves. He noticed a shift of fluorescence from yellow to blue and attributes this to trace amounts of substances formed by decomposition of the glycerides of the oil. He concluded that the alteration of the visible spectrum is connected with a partial decomposition of carotenoids and chlorophyll.

Faust (119) used a 400-kc. generator to observe its effects on glutathione showing oxidation of the reduced glutathione. Nearly one half of the tripeptide is reported to have been lost after 41 min. exposure.

Examination of protein fragments produced by ultrasonic treatment of aqueous solutions of serum albumin or trypsin showed that the ultrasonic treatment did indeed produce protein fragments. Such fragments are much more prevalent immediately following the irradiation than with the passage of time and disappear completely within 30–40 min. (120). Myosin and deoxyribonucleic acid specimens also showed this effect, yet gelatin failed to do so. Negative results were also obtained with substances such as glycine, alanine, cystine, glucose, and succinic acid. It was concluded that the fragmentation of these macromolecules caused by ultrasound produces macroradicals with half-life of the order of some minutes. A semiquantitative estimation showed that the molecules of serum albumin are cleaved into three parts, while those of trypsin are cleaved into two parts.

Miyagawa (121) reports acetates being hydrolyzed twice as rapidly as normal under the influence of 540 kc. ultrasonic waves. Mario (122) followed the rate of hydrolysis of aspirin with and without the influence of ultrasound. He states that there is an increase in the rate of hydrolysis using ultrasound that is comparable to the effect obtained by increasing the reaction temperature. On the other hand, Fenn (123) reported no significant difference in the rates of hydrolysis of procaine and butethamine hydrochlorides when insonated at 400 kc.

El'piner (124) followed the decomposition of sucrose in an ultrasonic field. The sucrose decomposed, as shown by the appearance in solution of reducing substances which increase in concentration with increased duration of exposure. The presence of carbon tetrachloride in buffered sucrose solutions enhances the rate of decomposition. Buchnea (125) subjected solutions of sucrose, glucose, and fructose to ultrasonic waves at various frequencies for times up to 100 hr. under various conditions. With increasing frequency the temperature of the solution increased, favoring splitting of sucrose. In the presence of oxygen, sucrose decomposed more rapidly with the formation of carbon dioxide and formic acid. With hydrogen, only slight inversion occurred without acid formation. The rate of inversion increased with sucrose concentration, but none resulted if the solution was cooled. The decomposition of the hexoses depended mainly on oxidation. Zapior (126) also reported an increase in rate of sucrose hydrolysis especially in strongly acid solutions but stresses the fact that the temperature was verified indirectly by use of a thermometer in the water bath.

El'piner (127–129) subjected insulin to ultrasonic irradiation and reported changes in the molecule which are influenced by the nature of the atmosphere in which treatment was performed. In the presence of oxygen or argon the

hormonal activity decreases, while in a hydrogen atmosphere the activity is increased. Chromatographic analysis showed that the hormone lost different substituent groups depending on the atmosphere used.

After ACTH in aqueous solution was exposed to 800 kc. ultrasound for 1 to 4 hr., a solution of yellow color and distinctive odor was produced (130). End-group analysis showed that methionine rather than serine became the end group. Longer exposure produced a solution which failed to respond to the usual end-group analysis.

Gramicidin-S was treated with ultrasound in ethyl alcohol by El'piner (131). This resulted in the formation of glyoxalic acid, but no great change in spectrophotometric analysis was noted in 8 hr. whether it was conducted in an atmosphere of oxygen or argon. However, the biological activity of the antibiotic was increased in these atmospheres. No such increase in activity was observed after treatment in a hydrogen atmosphere.

Gerraughty (132) explored the possibility of using the energy of ultrasound to effect the direct esterification of sterically hindered acids. The methyl, ethyl, *n*-propyl, and *n*-butyl esters of *o*-thymotic and ursolic acids were prepared. Branched chain esters of the acids, however, could not be made.

A number of investigators have studied the effect of ultrasonic irradiation on distilled water. Akiya (133) showed that irradiated water forms H_2O_2, HNO_2, and HNO_3. The amount of these formed is related to the intensity of the ultrasonic waves. At maximum intensity the amount of these substances varies with the length of radiation. He also reported the liberation of iodine from an acid potassium iodide solution under ultrasonic activity. Grabar (134) also mentions the decomposition of water by supersonics into H_2 and O_2. When water is subjected to ultrasonic waves at frequencies of 404 and 960 kc. in the dark, a nonuniform blue luminescence is produced which is independent of the pH or the presence of oxygen (135). Even in the absence of oxygen, water treated with ultrasonics develops oxidizing powers which are retained after treatment is stopped. A photochemical reaction probably occurs by which water is converted to H_2O_2, H, and O.

Bhar (136) observed that when a solution of potassium iodide was insonated, decomposition resulted with the amount of iodine liberated being proportional to the strength of the ultrasonic field and inversely proportional to the strength of the iodide solution. Others (137–139) studied various aspects of the oxidation of potassium iodide solutions, such as the effect of frequency, the kinetics of oxidation, and the mechanism of oxidation.

Weissler (140) developed a simple colorimetric procedure to measure cleaning efficiency of ultrasound. This was based on the liberation of chloride ion from carbon tetrachloride in an aqueous solution. Lur'e (141) indicates that the equation for the above reaction at a pH of 12 is as follows: $CCl_4 + H_2O \rightarrow Cl_2 + 2HCl + CO$. As the duration of insonation increased from 10–60 min., the degree of decomposition went from 60.3% to 100%. Liu (142) suggests the use of the reaction cited above as a technique to test for cavitation-activity measurements. He reports that chlorine is liberated from carbon tetrachloride in a linear relationship with time. A linear relationship to cavitation can also be plotted. Prakash (143) observed a similar result when he irradiated chloroethane in aqueous solution. He suggests that the reaction is governed by ultrasonic cavitation.

MISCELLANEOUS

Cleaning by high frequency sound is now a standard procedure in many industries. Central sterile supply departments are routinely washing glassware, surgical instruments, syringes, and needles in automatic ultrasonic equipment.

Clayton (144), Mamer (145), and McKay (146) discuss the use of ultrasound in the hospital environment. Beal and Skauen (147) were able to show that hypodermic syringes could be cleaned in a satisfactory manner by high-frequency sound. They later compared the cleaning efficiency of ultrasound with other methods used in hospital practice using radioactive iodide-^{131}I soils (148).

Palmer and Skauen (149) compared various cleaning methods for catheters using an iodide-^{131}I contaminated soil. Ultrasound cleaning was proven to be unfavorable in this study and was attributed to the "soft" nature of rubber catheters. Gligorijevic (150) found this to be a factor in a similar study, and he concludes that decontamination with ultrasound depends on the surface and the material.

Witekowa (151) felt that ultrasound might be used in various absorption phenomena. Accordingly, he treated a sample of charcoal with an aqueous solution of methylene blue and irradiated it with ultrasound. The suspension was treated with water, then filtered. The concentration of the methylene blue in the filtrate was determined colorimetrically. The quantity of absorbed methylene blue was 8–10% higher in the insonated sample than the control and increased

with power and frequency of ultrasound. He explains the increase on the basis of increased degree of fineness and a change of electrochemical properties of the charcoal.

Soloff (152) reviews the use of ultrasound for the sealing of various types of plastics. While this is a recent development, it would appear to offer certain benefits to the pharmaceutical industry.

Kuppusami (153) offers the suggestion that ultrasound can be used for determining the critical micelle concentration of surfactants. In his experiments he measured ultrasonic velocity in solutions of sodium dodecyl sulfate, cetyltrimethylammonium bromide, potassium laurate, and tetrahydroanacardol ammonium monosulfate. Each showed a reversal in slope of the velocity *versus* concentration curve in the region of the critical micelle concentration in agreement with the literature. This decrease in ultrasonic velocity he explains on the basis of internal pressure.

A list of reviews and books pertinent to the subject is included under *References* (154–185).

Anti-Inflammatory Evaluation of Cryogenine

By HARVEY R. KAPLAN*, RICHARD E. WOLKE†, and MARVIN H. MALONE

Cryogenine was effective in limiting the development of artificially induced inflammatory responses in acute and chronic experiments in rats. Cryogenine altered the acute edematous reaction to plantar injection of carrageenin and inhibited development of increased foot thickness induced by plantar injection of nonviable mycobacterial adjuvant in chronic studies. Histopathologic examinations did not suggest actions that would interfere with the anti-inflammatory evaluations. Cryogenine demonstrated a low order of analgesic (rat tail flick) and antipyretic (peptone fever) activity, and was capable of partially reversing edema and pain produced by silver nitrate injections in the ankle joints of rats. Cryogenine blocked serotonin, bradykinin, and histamine responses in guinea pig ileum; and pretreatment limited serotonin-induced pedal edema in rats and blocked histamine-induced intradermal wheals in the rabbit. Cryogenine was ineffective as a fibrinolytic agent. Prototype nonsteroidal anti-inflammatory compounds as well as agents with structural similarities to cryogenine were also investigated. Cryogenine may, like aspirin, manifest its anti-inflammatory activity through a combination of selective central and nonspecific peripheral mechanisms.

CRYOGENINE (vertine) was first isolated from *Heimia salicifolia* Link and Otto in 1963 by Blomster *et al.* (1), and its chemical structure has been proposed (2) and confirmed (3). The folklore concerning this Mexican plant is interesting and includes mention of its abilities to induce bizarre central nervous system reactions (4–6). The initial pharmacologic studies of Robichaud *et al.* (7) on both plant extracts and purified cryogenine alkaloid revealed qualitative and quantitative similarities between the two with the most interesting activity being the production of a selective central nervous system depression in unanesthetized animals. The general pharmacodynamics of cryogenine and other of the naturally occurring alkaloids have been reported in the literature (8, 9). Preliminary evaluation in this laboratory also indicated that cryogenine possessed activity in an acute anti-inflammatory screen in rats. These initial data suggested that cryogenine could be a new chemical prototype with nonsteroidal anti-inflammatory activity. Most recently Jiu has reported (10) that ethanol extractives from the plant showed depressant central nervous system activity, anti-atherogenic potential, and anti-inflammatory ability.

EXPERIMENTAL

General—During the investigations cryogenine was employed either as an aqueous suspension of

free base in 0.25% agar or as a solution of the acetate salt prepared by dissolving the base in 0.5% v/v of glacial acetic acid. As is often the case with the pharmacologic evaluation of natural products, the relatively limited availability of test alkaloid restricted extensive replication of the experimental procedures. The young adult albino rats used in this study were of the Wistar strain and obtained from the E. G. Steinhilber Co., Oshkosh, Wis. Unless otherwise specified here, the animals were allowed continuous access to Purina laboratory chow and tap water.

Acute Anti-Inflammatory Evaluation Using Carrageenin-Induced Edema—Nonfasted male and female rats were employed and the experimental procedures were similar to those described by Winter *et al.* (11). Test drugs were administered orally (10 ml./Kg.) in order to minimize counter-irritation phenomena often seen after parenteral injection. To insure a uniform degree of hydration among the individual rats, each animal received a supplementary amount of water so that the total volume administered to each rat was 5.0 ml. One hour following the oral administration, 0.1 ml. of the phlogistic agent (1% suspension of carrageenin in sterile 0.9% saline) was injected aseptically into the plantar aponeurosis of the left hind paw using a 27 gauge 0.5 in. needle attached to a 0.25 ml. capacity syringe. The width or volume of the injected paws was determined immediately after the carrageenin injection and 3 hr. later. For width determinations, a vernier caliper was used with medial foot thickness measured to the nearest 0.1 mm. When volume measurements were obtained, a modified plethysmographic apparatus similar to that described by Harris and Spencer (12) was employed by which foot volume was determined to the nearest 0.01 ml. Rectal temperatures were recorded throughout the test period using a precalibrated thermistor-type thermometer.

Assay of Cryogenine Versus Phenylbutazone—Plethysmographic measurements were made following the administration of 0.05 ml. of 1% carrageenin. A randomized complete block experimental design was utilized with a low (50 mg./Kg.) and a high (100 mg./Kg.) level for both cryogenine acetate and sodium phenylbutazone. Each treatment consisted of three experimental units per day with the assay conducted on 3 separate days resulting in a final number of 9 units for each of the four treatments. On any one day, the rats were equally but randomly assigned among the four test treatments. The statistical evaluation was patterned after the methods of Bliss and Calhoun (13).

Multiple Drug Comparisons—The plethysmographic technique was employed with 0.05 ml. of 1% carrageenin injected into the paw as the phlogistic substance. Young unfasted adult rats (2 male and 2 female) were assigned to the treatment groups in a random fashion. Drugs were administered orally as suspensions in 0.25% agar. The treatment effects were analyzed employing the multiple range test of Duncan (14).

Chronic Anti-Inflammatory Evaluation—Nonfasted male rats were randomly caged in groups of 5 and allowed to equilibrate with their environment for 1 week prior to experimentation. Daily determinations of body weight, medial foot thickness (caliper method), and average food and water consumption were made. Commencing on day 0 animals were dosed daily for 2 weeks (day 0 through 13) with the test agents. These drugs were administered orally as suspensions in 0.25% agar (10 ml./Kg.). On day 1 all animals received an injection of a suspension of *Mycobacterium butyricum* (Difco Laboratories 0640-33) in light liquid petrolatum prepared according to the method of Nuss (15). Twenty milliliters of the petrolatum was added to 100 mg. of the desiccated organisms in a Kontes hand homogenizer. After fine subdivision the resultant suspension was autoclaved at 15 lb. pressure for 20 min., allowed to cool, and placed into a refrigerator overnight. Prior to injection the suspension was allowed to equilibrate to room temperature and resuspended by shaking by hand. Each rat was injected with 0.05 ml. into the right plantar aponeurosis using a 27 gauge 0.5 in. needle directed medially following its insertion under the skin in order to avoid back seepage and to minimize local vascular involvement. Medication was discontinued on days 14 through 30; however, body weight, foot thickness, and food and water consumption measurements were continued throughout the duration of the experiment. The percentage inhibition of increased foot thickness for the injected foot was calculated according to the methods of Newbould (16) on days 13 and 30. Gross skeletal specimens of the "arthritic" paws were prepared on day 40 using the antiformin method (17).

Tissue taken for histopathologic examination included sagittal sections of both femorotibial articulations and transverse sections of metatarsal areas, myocardium, liver, spleen, lung, kidney, and abdominal skin. Following euthanasia, the tissue was fixed in 10% formalin. Osseous sections were decalcified by means of a thermo-agitating bone decalcifier employing an 18% solution of formic and hydrochloric acids. After decalcification, sections were placed into a saturated solution of lithium carbonate for a period of 24 hr., rinsed, and replaced in formalin. Tissue blocks were embedded in paraffin, sectioned at 10 μ, and stained with hematoxylin and eosin.

Antipyretic Evaluation Using Peptone-Induced Fever—Male rats were acclimatized overnight in a temperature controlled room (23°). Control rectal temperatures of the animals were recorded using a thermistor-type thermometer with the flexible probe inserted to a depth of 5 cm. and held in position for 35 sec. The rats were rendered febrile by the injection of 0.6 ml. of a 5% aqueous solution of peptone tryptic digest of casein (N-Z amine type E tryptic digest, Sheffield Chemical Co. 02-537) which had been previously filtered clear and incubated in a Dubnof shaker at 37.5° for 12 hr. The site of the subcutaneous injection was in the dorsal region of the rat's neck. Four hours after injection of the pyrogen, core temperatures were recorded again. Any animal showing a temperature elevation of less than 1° was not considered adequately febile and was discarded from the test. At this time 5 rats were assigned randomly to each of the treatment groups and the drugs administered orally. At +1 and 2 hr. following drug administration, the rectal temperatures were determined. During the experiment food was withheld, although water was freely accessible.

Analgesic Evaluation—A modified conduction

dolorimeter (Metro Scientific, Inc. ME-5410) was utilized for measuring the rat tail flick response to a standard thermal stimulus. Only male rats possessing healthy nonkeratinized tails were employed. In order to record accurately the reaction times to the thermal stimuli, a photocell and an electric timer were adapted to the instrument so that as the rat's tail was placed over the photocell opening, a circuit was closed activating both the heater and the electric timer. Subsequent removal of the tail opened the circuit and stopped the timer. Control reaction times for each animal were determined just prior to drug administration and at +15, 30, 45, 60, and 120 min. after injection. The per cent analgesia was calculated by considering a reaction time of 20 sec. minus the control reaction time as the equivalent of 100% analgesia. Exposure to the thermal stimulus for longer than 20 sec. is generally regarded as undesirable since irreversible damage to the sensory receptors in the tail may occur.

Simultaneous Analgesic and Anti-Inflammatory Testing—The method employed was a modification of the technique initially developed by LaBelle and Tislow (18). Freshly prepared aqueous 1% silver nitrate was injected (0.2 ml.) into the right paw between the Achilles tendon, ankle, and heel bones *via* the plantar surface of the paw using a 27 gauge needle. This technique allows only insignificant amounts of silver nitrate to penetrate the foot areas subsequently measured for edema. It has been suggested that a local release of endogenous mediators acting in a humoral manner are responsible for the inflammation (19). Eighteen hours after injection of silver nitrate, the animals' reaction to pain in the injected paw was evaluated. This required the abrupt manual flexion of the ankle joint with scoring of the vocalization (squeal) and struggling using an arbitrary scale of 0 to +3 (0 = no squealing and struggling, +1 = audible squeals but no struggling, +2 = definite squealing and some struggling, +3 = loud squeals and violent struggling). Any animal either failing to produce a pain response of +2 or 3 or not showing a measurable edema (caliper technique) was eliminated from the experiment. Rats meeting criteria were subdivided randomly into the treatment groups and the drugs then administered orally as suspensions. Animals were scored for pain responses at hourly intervals for 5 hr. and at the end of this time foot widths were determined again. At the time of the silver nitrate injection, the animals were taken off food and at the time of the drug administration taken off water for the balance of the experiment.

Antiphlogistic Evaluation Using a Histamine-Induced Intradermal Wheal—Unanesthetized albino rabbits of either sex obtained from local suppliers were securely fastened to rabbit boards in a supine position. Abdominal hair was carefully removed 2 hr. prior to the experiment using electric clippers. Each shaved abdomen was then marked with 8–10 circular regions (approximately 30 mm. in diameter) using a felt marking pen. The test drugs were injected intraperitoneally 30 min. prior to intradermal injection of 0.3 ml. of 0.02 mg./ml. (as base) of histamine diphosphate into the center of each of the marked regions. Fifteen minutes after the intradermal injections, trypan blue was administered intravenously (1 ml./Kg. of a 1% aqueous solution) and the colors of the histamine-induced wheals rated at +30, 60, and 180 min. later using the scoring scale of Hoppe *et al.* (20).

Serotonin-, Bradykinin-, and Histamine-Induced Pedal Edema—Serotonin creatinine sulfate (0.01 mg. as the base), synthetic bradykinin (0.05 mg.), or histamine diphosphate (0.15 mg. as base) contained in an injection volume of 0.05 ml. were administered into the plantar aponeurosis of rats. Inflammation was measured (caliper technique) at 30-min. intervals for 180 min. following injection of the phlogiston. Cryogenine base was administered orally as a suspension 1 hr. prior to the pedal injections.

Antagonism Studies on Isolated Guinea Pig Ileum—Nonfasted virgin female guinea pigs obtained from local suppliers were sacrificed by cranio-vertebral dislocation and 2–3 cm. segments of ileum immediately excised and placed into calibrated 50 ml. baths containing fresh Tyrode's solution (37.5°) constantly oxygenated with a 95% O_2 and 5% CO_2 gas mixture. Isotonic frontal recording levers were used to record longitudinal contractions of the tissues. Bath concentrations of 1×10^{-6} *M* for serotonin (creatinine sulfate), histamine (diphosphate), and synthetic bradykinin were used to induce reproducible submaximal contractions of the tissue. After thoroughly washing out the agonists, various log molar concentrations of cryogenine (acetate) were incubated (1×10^{-9} to 1×10^{-7} *M*) with the ileum for 5 min. prior to addition of the agonists in order to ascertain its effects on the reference contractions. A fresh individual ileum segment was used to study the effects of cryogenine in regard to each agonist.

Fibrinolytic Evaluation—The method of von Kaulla (21) was employed with the reference clots formed from human plasma by the addition of 0.25 ml. of 5% calcium chloride to each 5.0 ml. of plasma used. The preformed clots were suspended in various molar concentrations of the drugs studied and then incubated at 37° for 24 hr. Evaluation of fibrinolytic activity was made at the end of this time and expressed as per cent lysis of clot. Any cloudiness of the solution, shrinking of the clot, or sediment formation was also noted.

RESULTS

Acute Anti-Inflammatory Evaluation Using Carrageenin-Induced Edema—The results as summarized in Table I show cryogenine to possess significant antiphlogistic activity at an oral dosage of 100 mg./Kg. when compared to the acetic acid vehicle

TABLE I—ANTI-INFLAMMATORY ACTIVITY OF 100 mg./Kg. OF CRYOGENINE ORALLY IN RATS WITH ACUTE CARRAGEENIN-INDUCED PEDAL EDEMA

Treatment	Mean % Increase Paw Width	Paw Vol.	Level of Significance Observed *P*
Cryogenine	13.4 (2–24)[a]	...	0.01–0.05
Acetic acid control	26.8 (18–36)[b]	...	...
Cryogenine	...	27 (2–61)[b]	<0.001
Acetic acid control	...	118 (51–197)[b]	...

[a] Observed range of 5 observations 3 hr. after carrageenin injection. [b] Observed range of 6 observations 3 hr. after carrageenin injection.

controls. The inflammatory state induced by carrageenin did not elevate core temperature and treatment with either cryogenine alkaloid or the vehicle control did not cause significant changes in rectal temperature.

Assay of Cryogenine Versus Phenylbutazone—Calculation of the 2 × 2 assay revealed that cryogenine has 0.86 times the anti-inflammatory potency of phenylbutazone in this acute test procedure. The 95% confidence limits for the potency are 0.61–1.11. The λ of the assay (calculated as either s/b or as $s_M\sqrt{N/2}$) equaled 0.22. Cryogenine and phenylbutazone may be considered equipotent orally since there was no significant difference between drugs (P = 0.25–0.50) and no significant departure from parallelism (P = >0.50).

Multiple Drug Comparisons—The results of this one level experiment as treated by Duncan's multiple range test (14) are summarized in Table II

TABLE II—MULTIPLE DRUG COMPARISIONS OF ANTI-INFLAMMATORY ACTIVITY IN RATS WITH ACUTE CARRAGEENIN-INDUCED PEDAL EDEMA

Treatment	Oral Dosage, mg./Kg.	Mean Increase in Paw Vol., ml.	Significant Subsets[a]
Control	...	0.45(0.37–0.56)[b]	A
Cinnamic acid	100	0.44(0.32–0.66)	A
Control	...	0.44(0.39–0.54)	A
Papain	400	0.35(0.29–0.40)	B
Sparteine	100	0.34(0.30–0.38)	B
Cryogenine	100	0.27(0.19–0.36)	B
Indomethacin	5	0.22(0.18–0.31)	B
Chloropromazine	100	0.21(0.05–0.33)	B

[a] The treatment effects represented by A and B differ significantly from each other (P = 0.05); however, the treatments within these subsets do not differ significantly (P = 0.05) from one another. [b] The figures within the parentheses represent the observed range of the 4 experimental values.

and show a division of the various treatment effects into two major subsets of means. The anti-inflammatory properties of cryogenine were confirmed. Although both cinnamic acid and sparteine have some structural chemical relationships to cryogenine, only sparteine could be considered as having some potential for anti-inflammatory activity. It should be noted here that in the two previous experiments cryogenine was administered as the soluble acetate salt, whereas in this experiment the base itself was administered orally as a suspension.

Chronic Anti-Inflammatory Evaluation—The effects of cryogenine and phenylbutazone therapy on the progression of the artificially-induced, chronic "arthritic" state in rats is presented graphically in Fig. 1 and 2. Table III also summarizes the results for several other selected reference compounds tested concurrently by this procedure. These compounds can categorically be classified as either well documented reference anti-inflammatory agents (phenylbutazone, indomethacin, DMSO, chloroquine, hydrocortisone), structurally related moieties of cryogenine (cytisine, sparteine, cinnamic acid), or pharmacologically related agents (chlorpromazine, papaverine, atropine) (7–9). The dosages employed are either those suggested in the literature or previously determined in these laboratories to be effective and apparently nontoxic for the rat after acute administration. The protection afforded by cryogenine and by phenylbutazone when compared with a nontreated control is very apparent in Fig. 3 which pictures representative gross specimens 40 days following the *M. butyricum* adjuvant administration. Secondary lesions in other tissues similar to those described in the literature by Newbould (16) were observed; however, the variability of lesions as to frequency, size, and site did not allow them to be used as a test metameter.

Two of the three control animals selected for histopathologic evaluation had no lesions of the

[a] Administered as suspensions in 0.25% agar from day 0 through day 13, with the mycobacterium adjuvant injected into the right foot on day 1. [b] Percentage inhibition = $100[1 - (a - x)/(b - y)]$ where y = mean thickness right feet of controls before adjuvant, b = mean thickness right feet of controls on specified day, x = mean thickness right feet of treated rats before adjuvant, and a = mean thickness right feet of treated rats on specified day. [c] The adjuvant-injected paw was soaked for 1 min. daily. [d] Values not determined quantitatively. [e] Absolute differences between the larger and smaller values.

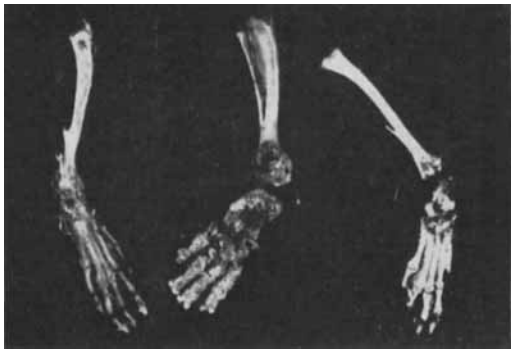

Fig. 3—Typical gross skeletal specimens of adjuvant-injected rat paws. Cryogenine-treated (left), non-treated controls (center), and phenylbutazone-treated (right).

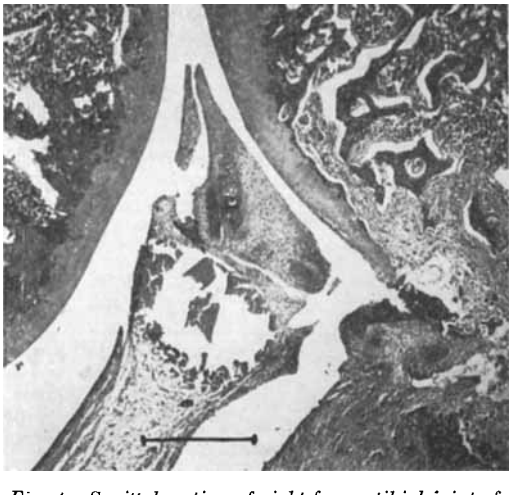

Fig. 4—Sagittal section of right femorotibial joint of a control animal with granulomatous reaction and destruction of the tibial cartilage seen at right. Marked distance = 0.5 mm.

femorotibial articulations, while all three revealed changes in the metatarsal areas. Lesions present in the most severely affected control animal were similar to those described by Glenn and Grey (22) with suppurative granulomas and fibrosis in zones of primary and secondary ossification bordering the femorotibial joint. Destruction of articular cartilage, an occasional finding, appeared secondary to the progressing subchondral granulomatous response. Within the joint proper, the synovial membrane was swollen, edematous, hyperplastic, and invaded by lymphocytes, mast cells, and mononuclear cells (Fig. 4). Progressive involvement resulted in fibrosis of the synovial membrane with an occasional pannus-like proliferation completely filling the joint cavity between the articular surfaces. Transverse sections of metatarsal areas had multiple subdermal granulomas and foci of mononuclear cells. A striking periosteal new bone proliferation was present about the periphery of all metatarsal bones. New bone was highly cellular, coarsely woven, and easily differentiated from mature cortical lamellar bone from which it was separated by a distinct basophilic cement line (Fig. 5). A decreased inflammatory response was observed in femorotibial sections of the cryogenine-treated rats (Fig. 6). Suppurative granulomatous reaction was seen in one instance in the tibial metaphysis and, with the exception of edema of the synovial membrane, pathologic changes were not present within the joint cavity. Metatarsal sections from cryogenine-treated animals revealed lesions as severe as those seen in the control rats (Fig. 7).

One rat received 100 mg./Kg. of cryogenine orally daily from day 0 through day 13 but did not receive an injection of the mycobacterium adjuvant. Examination of the soft tissues revealed no lesions of the myocardium, liver, lung, kidney, spleen, or abdominal skin.

The possibility of spurious anti-inflammatory activity can be detected by the adjuvant-induced polyarthritis procedure when chronic toxic mani-

festations are noted. In Table III this is illustrated by decreased quantal survival rates (chloroquine, atropine, chlorpromazine), changes in the total body weight (chloroquine, hydrocortisone), reduced food and water consumption (chloroquine), and gross changes in general appearance and reactivity (chloroquine, atropine, chlorpromazine). Sparteine and cinnamic acid did not show any cryogenine-like activity. Cytisine may have some potential, although this activity appears to be short-lived and correlated with a decreased rate of body weight gain. In this experiment cryogenine, phenylbutazone, and indomethacin all appear as desirable anti-inflammatory agents, with indomethacin being considerably more potent than the other two.

Antipyretic Evaluation Using Peptone-Induced Fever—Figure 8 represents the results of the antipyretic evaluation. At +4 hr. and just prior to drug administration there was no significant difference between the respective means and variances of the three randomly assembled, experimental groups ($P > 0.50$). At +5 hr. there was no significant difference between the controls and the cryogenine-treated rats ($P = 0.25$–0.50), while there was a highly significant difference between the controls and aspirin-treated ($P = <0.001$) and the cryogenine-treated and aspirin-treated groups ($P = <0.001$). Subsequently, at +6 hr. a highly significant difference was still present between the untreated controls and the aspirin treated ($P = <0.001$) and the cryogenine-treated and aspirin-treated ($P = <0.001$). Moreover, there was a significant difference between the controls and the cryogenine-medicated animals ($P = 0.01$–0.025). Aspirin was most effective in that an oral dosage of 300 mg./Kg. almost totally abolished the pyretic response (69 and 91% reduction at 1 and 2 hr. after dosage, respectively). Cryogenine base at an oral dosage of 100 mg./Kg. was much less effective, although a 41% reduction of the peptone-induced fever was observed 2 hr. after administration.

Analgesic Evaluation—Table IV presents a summary of the analgesic evaluation using the rat tail flick technique which is considered generally to be most valid in the detection of narcotic analgesics. Cryogenine had an apparent low order of activity using this procedure; however, this may be

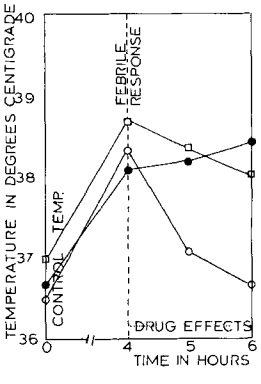

Fig. 8—Effects of orally administered cryogenine and aspirin on peptone-induced fever in the rat. Key: □, 100 mg./Kg. cryogenine; ○, 300 mg./Kg. aspirin; ●, untreated controls.

TABLE IV—ANALGESIC SCREENING OF CRYOGENINE AND REFERENCE AGENTS

Treatment	Dosage, mg./Kg.[a]	Mean % Analgesia[b] +15	+30	+45	+60	+120 min.
Control	...[c]	−2	−2	−6	−4	+2
Cryogenine	100	−10 (0)[d]	+17 (+)	+1 (±)	+3 (+)	−2 (±)
Phenylbutazone	100	+1 (±)	−2 (±)	−2 (±)	−2 (±)	−1 (±)
Morphine	10	+68 (+)	+86 (+)	+88 (+)	+80 (+)	+87 (+)

[a] Cryogenine was administered orally, continuing the mode of administration established in the earlier experiments where it was felt necessary to minimize possible counter-irritating influences of parenteral administration on the anti-inflammatory testing. However, all of the other agents and the control group were injected intraperitoneally as is usual with analgesic testing. Five rats per test group. [b] Per cent analgesia = 100 $[(R_x - R_0)/(20 - R_0)]$ where R_0 = pretreatment reaction time in seconds and R_x = post-treatment reaction time in seconds at the time specified. [c] The mean reaction times in seconds (observed range) for the 25 control animals are—preinjection: 4.58 (2.7–10.2); +15 min.: 4.46 (2.9–9.0); +30 min.; 4.41 (2.5–7.6); +45 min.: 3.94 (2.7–6.5); +60 min.: 4.22 (2.4–5.7); and +120 min.: 3.81 (2.7–6.0). [d] Key: 0, no significant analgesia in that the mean per cent analgesia is lower than −2 standard errors of controls; ±, mean per cent analgesia is included within ±2 standard errors of controls; +, significant analgesia in that the mean per cent analgesia is greater than +2 standard errors of controls.

due to its capacity to block conditioned responses (8) rather than to true analgesic ability. Without doubt cryogenine at effective anti-inflammatory dosage levels lacks morphine-like analgesic potency.

Simultaneous Analgesic and Anti-Inflammatory Testing—Both cryogenine and phenylbutazone demonstrated analgesic activity (Fig. 9), but it was significantly less both as to degree and duration than the response produced by indomethacin. None of the agents produced the degree of analgesia produced by morphine. By +5 hr. cryogenine, phenylbutazone, and indomethacin had caused reductions of the developed pedal edemas (10, 11, and 8%, respectively, 4 rats per treatment), whereas the control and morphine-treated animals demonstrated slight increases in the edematous response (0.4 and 2%, respectively). Using this technique it is quite apparent that the morphine-like narcotic analgesics can be distinguished readily from the nonsteroidal anti-inflammatory compounds which have an analgesic component.

Antiphlogistic Evaluation Using a Histamine-Induced Intradermal Wheal—Histamine diphosphate uniformly elicited the classic blue wheal in nontreated animals with the maximal score of 16 noted at all time intervals. Premedication with diphenhydramine HCl (20 mg./Kg. intraperitoneally) partially blocked the inflammatory response with mean scores of 0, 0.8, and 2.0 noted at +30, 60, and 180 min. after the histamine injection. Cryogenine (10 mg./Kg. intraperitoneally) completely blocked the action of histamine producing mean scores of 0, 0, and 0.2 at +30, 60, and 180 min., respectively. In addition, cryogenine produced a noticeable sedative action on the secured rabbit.

Serotonin-, Bradykinin-, and Histamine-Induced Pedal Edema—The progression of the edematous responses in the control and cryogenine-treated animals is illustrated in Fig. 10. The edemas produced by all of the phlogistic agents approached maximal response within 30 min. after injection. The histamine inflammation appeared much less pronounced in comparison to that produced by serotonin and synthetic bradykinin. The total areas under the respective curves were determined with the aid of a compensating polar planimeter. Cryogenine pretreatment afforded statistically significant protection ($P < 0.05$) against serotonin-induced edema. No significant protection ($P > 0.05$) was seen against bradykinin or histamine.

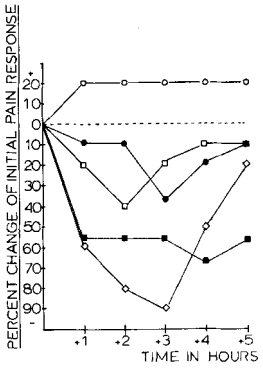

Fig. 9—Analgesic evaluation of orally administered cryogenine and other reference agents against silver nitrate-induced pain. Key: □, 100 mg./Kg. of cryogenine; ■, 100 mg./Kg. of indomethacin; ●, 100 mg./Kg. of phenylbutazone; ◇, 25 mg./Kg. of morphine; ○, untreated controls.

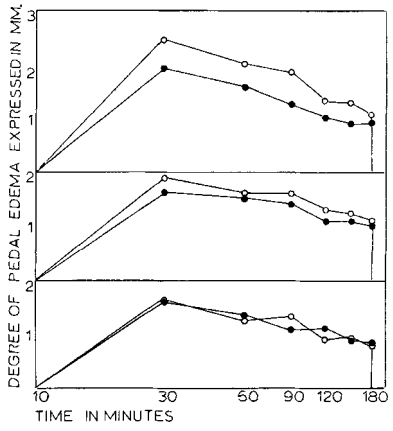

Fig. 10—Effect of oral cryogenine premedication on serotonin (top), bradykinin (middle), and histamine (bottom) induced pedal edema. Key: ●, 100 mg./Kg. of cryogenine; ○, nonmedicated controls. Five rats per each test group.

Antagonism Studies on Isolated Guinea Pig Ileum—At final bath concentrations of $10^{-7}M$, cryogenine almost totally blocked contractions induced by the reference agonists: serotonin, histamine, and bradykinin. In the cases of bradykinin and serotonin, the inhibition could not be reversed by increasing the concentration of the agonist; however, a partial reversal was possible in dealing with histamine.

Fibrinolytic Evaluation—A summary of the results is given in Table V. The various concentra-

TABLE V—FIBRINOLYTIC SCREENING OF CRYOGENINE AND REFERENCE AGENTS

Chloroquine diphosphate	0	0	0	0	0	0

[a] Sufficient amount of the drug was weighed to produce 0.05 *M* stock solution upon dilution to 10 ml. Either NaOH or HCl was used to facilitate solution and/or adjust the final pH to 7.4. Cryogenine, phenylbutazone, and indomethacin were not totally soluble at a pH of 7.4; therefore, their saturated solutions (37°) were filtered through glass wool until clear. Appropriate dilutions were made with triple distilled water to make the final bath volume 2.5 ml. [b] Concentration was not tested. [c] No detectable lysis; some cloudiness of perfusion liquid noted. [d] No detectable lysis; some sediment formation noted.

tions of cryogenine, sparteine, and chloroquine did not produce visible lysis of the preformed clots. In the incubated test solutions of cryogenine, some degree of cloudiness was observed and in solutions of sparteine a white sediment was apparent. These phenomena may be expected considering the possible interactions between the soluble drug and the macromolecular matrix of the clot. Both phenylbutazone and indomethacin produced varying degrees of clot lysis.

DISCUSSION AND CONCLUSIONS

Cryogenine was shown to be partially effective in preventing the development of artificially induced inflammatory responses in rats using both acute (carrageenin) and chronic (*M. butyricum* adjuvant) experimental procedures. The possibility of interference due to "counter-irritation" was minimized by using the oral route of administration. In both acute and chronic evaluations, cryogenine appeared to be equipotent to phenylbutazone. Histopathological studies indicated that cryogenine may have some anti-inflammatory activity at the femorotibial joint. It is important to emphasize that the efficacy of cryogenine in both acute and chronic procedures appeared to be unrelated to toxic phenomena. After treatment(s) with cryogenine there were no indications of malaise and no deaths were recorded. The histopathological evaluation of a cryogenine-treated rat (100 mg./Kg. orally for 14 days) revealed no lesions of the organs examined.

Although cryogenine has been demonstrated to induce hypothermia in normothermic acclimatized animals upon intraperitoneal injection (7), it possessed only slight antipyretic activity in rats rendered febrile by peptone administration and then it was clearly inferior to aspirin in this respect. Cryogenine produced only equivocal analgesic activity utilizing the rat tail flick thermal technique. This low order of activity may be due to cryogenine's ability to alter conditioning phenomena. Untreated control animals usually show negative mean per cents of analgesia since they become conditioned to the heat stimuli and actually remove their tails from the area prior to actually receiving their threshold painful stimulus. Robichaud *et al.* (8) have shown cryogenine to be active after intraperitoneal administration in blocking conditioned responses in both nondiscriminated (continuous) avoidance and conditioned discrete avoidance escape situations. It is not uncommon to find anti-inflammatory, antipyretic, and analgesic activity for a single chemical entity. Rosenkilde (23) points out that the two central actions (antipyretic and analgesic) are apparently linked to a peripheral activity (anti-inflammatory). Since cryogenine did show some analgesic and antipyretic potential and was capable of partially reversing both silver nitrate-induced edema and pain responses, it may have both central and peripheral mechanisms involved in its anti-inflammatory activity.

Cryogenine inhibited responses both *in vivo* (histamine in the rabbit and serotonin in the rat) and *in vitro* (histamine, serotonin, and bradykinin in isolated guinea pig ileum) by certain suspected mediators of the inflammatory process. However, its action appeared to be relatively nonspecific since the results did not implicate any one mediator.

Tetracyclines I

Separation and Examination by Thin-Layer Chromatography

By PETER P. ASCIONE, JOHN B. ZAGAR, and GEORGE P. CHREKIAN

A thin-layer chromatographic (TLC) method for the examination of tetracyclines has been developed. This technique provides a rapid means for the separation and identification of tetracyclines and their derivatives in a wide variety of mixtures. Acid-washed diatomaceous earth served as the support. The support was treated with a buffer consisting of 0.1 *M* ethylenediaminetetraacetic acid disodium salt (EDTA) at pH 7.0, glycerin, and polyethylene glycol 400 (PEG 400). The developing solvent was ethyl acetate saturated with 0.1 *M* EDTA at pH 7.0. While the work reported was limited to demethylchlortetracycline (DMCTC), tetracycline (TC), and chlortetracycline (CTC), it has also been successfully used with other tetracyclines.

AT THIS TIME, a technique is needed for thin-layer chromatography for separating tetracyclines, whether in specifically prepared mixtures or in mixtures resulting from failure of the strains used to produce pure tetracylcines. Such a technique should be applicable not only to separating mixtures of tetracyclines, but also for studying their stability in pharmaceutical formulations.

The application of TLC for the separation of antibiotics was presented by Nicolaus, Coronelli, and Binaghi (1) in which several tetracyclines were examined in many solvents using various adsorption layers. Kapadia and Subba Rao (2) described a circular thin-layer separation employing sequestering agents in a silica gel layer for better resolution. Sonanini and Anker (3) studied the chromatography of tetracyclines using a support impregnated with glycerin, which maintained moisture in the support. A method for quantitation on thin-layer was reported by Simmons, Koorengevel, Kubelka, and Seers (4) using microcrystalline cellulose as a support. These TLC methods used in the separation of tetracyclines as described by the various workers (1–4) were examined in these laboratories. However, more than two tetracyclines could not be resolved by a single system on one chromatogram, and the resolution of the related compounds of each tetracycline could not be accomplished without a great deal of streaking and tailing.

This report presents the results of preliminary work in which various adsorbants, sequestering agents, PEG 400–glycerin mixture, and pH were directed toward obtaining clear separations. Satisfactory separation of the tetracyclines and their related compounds was achieved on diatomaceous earth, impregnated with EDTA at pH 7.0, glycerin–PEG 400, using ethyl acetate as the developing solvent.

Received May 22, 1967, from the Department of Analytical Development, Quality Control Section, Lederle Laboratories, Division of American Cyanamid Co., Pearl River, NY 10965

Accepted for publication August 11, 1967.

The authors thank Mrs. D. Budd, Literature Services Department, for valuable assistance with this report.

EXPERIMENTAL

Reagents—Disodium ethylenediaminetetraacetate A.C.S., glycerin A.C.S., polyethylene glycol 400 U.S.P., ammonium hydroxide A.C.S., ethyl acetate A.C.S.

Buffer—Mix 5 ml. of 20% v/v PEG 400 in glycerin with 95 ml. of 0.1 *M* EDTA previously adjusted to pH 7.0 with ammonium hydroxide.

Developing Solvent—Equilibrate 120 ml. of ethyl acetate with 20 ml. of 0.1 *M* EDTA previously adjusted to pH 7.0. Use the organic layer to develop the plates.

Preparation of Support—Wash diatomaceous earth[1] with hot 6 *N* hydrochloric acid until the washings no longer contain calcium or iron. Wash with water until a neutral pH is obtained and then dry at 105°.

Preparation of Plates—Prepare glass plates (20 × 20 cm.) according to the method of Lees and DeMuria (5). Place a double thickness of 1-cm. masking tape[2] on opposite edges of the plate. Triturate a slurry of 8 Gm. of acid-washed diatomaceous earth and 16 ml. of buffer in a glass mortar until smooth. Pour this slurry onto the plate and spread over the surface with a stout glass rod using the taped edges of the plate to control the thickness of the layer; press the glass rod against the taped edges at one end and slide to the opposite end in one motion. Air-dry the plate for 35–50 min. or until the layer surface appears whitish gray. Remove the tape from the edges of the plate and use immediately.

Preparation and Application of the Samples—Prepare a methanol solution of each of the tetracyclines to be chromatographed using a concentration of 1 mg./ml. At the same time, prepare standards of tetracyclines to be carried through the same procedure. Apply 1 μl. of each solution at 1-cm. intervals, 1.5 cm. from one edge of the plate. Inscribe a solvent-front line across the surface of the plate 12 cm. from the origin.

[1] Marketed by Desaga/Brinkmann Co. under the trademark of Kieselguhr G.

[2] Scotch brand tapes, cores No. 0300, 3M Co., St. Paul, Minn.

Development of Chromatogram—Line a rectangular glass jar (20 × 8 × 20 cm.) internal dimensions) with Whatman 3 MM chromatography paper. Pour the mobile phase into the glass jar. After the glass jar has equilibrated for 30 min., chromatograph the plates. When the mobile phase reaches the solvent-front line, remove the plate and air-dry for 2–3 min. Rechromatograph the plate for additional resolution. The plates may be developed for a third or fourth time if necessary.

After the plate has dried under ambient condition for 30 min., examine it under long wavelength ultraviolet light. The sample spots are identified by comparison with individually chromatographed tetracycline standards.

RESULTS AND DISCUSSION

The use of EDTA, glycerin, and pH buffer to improve separation in chromatographic procedures of tetracyclines has been reported (1–3). However, in this investigation these methods were unsuccessful in resolving more than two tetracyclines by a single solvent system on one chromatogram. Also, during the development of these chromatograms, tailing, streaking, and possible degradation occurred which was undesirable.

When Silica Gel G was used as a support on thin layer, the tetracyclines were strongly adsorbed and could not be eluted satisfactorily. On diatomaceous earth, the tetracycline could be developed with various solvent systems, but with pronounced tailing and little resolution of the various tetracyclines.

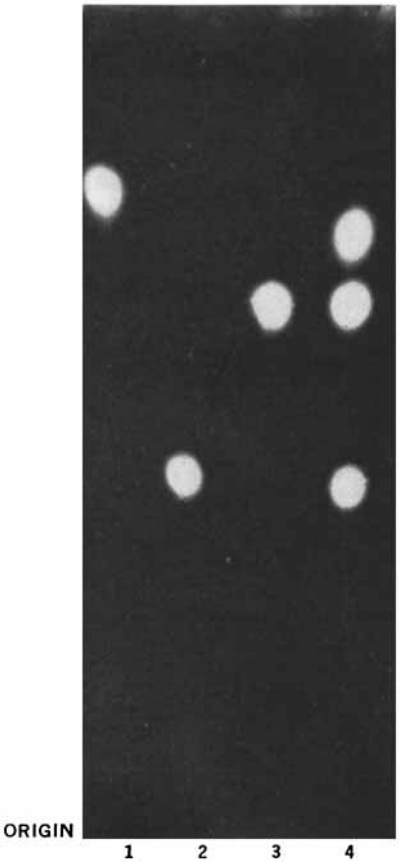

Fig. 1—Thin-layer chromatography of tetracyclines. Key: 1, CTC; 2, TC; 3, DMCTC; 4, mixture.

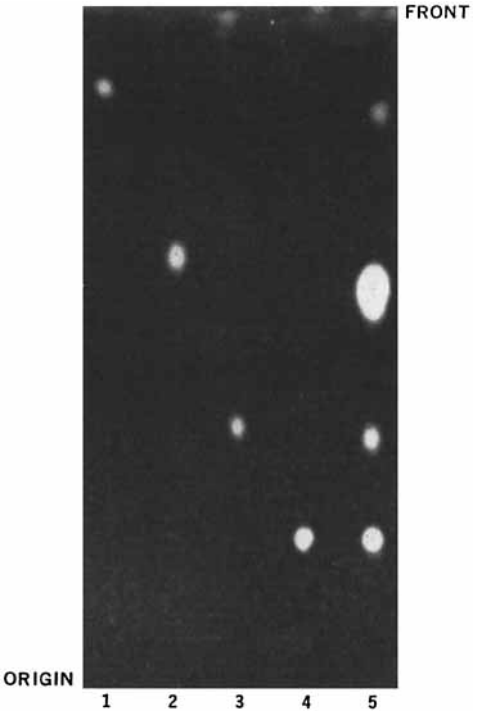

Fig. 2—Thin-layer chromatography of demethylchlortetracycline. Key: 1, ADMCTC; 2, DMCTC; 3, DMTC; 4, EDMCTC; 5, mixture.

Kelly and Buyske (6) found that paper impregnated with 0.1 *M* EDTA greatly improved paper chromatograms of tetracyclines. In our work, thin-layer chromatograms were developed without streaking and tailing by using diatomaceous earth which first had the binder removed and then EDTA added.

Sonanini and Anker (3) studied the chromatography of several tetracyclines by impregnating the support with glycerin to maintain a constant water concentration and thus obtain better resolution of the tetracycline. For this reason we used a mixture of glycerin and PEG 400 for the resolution of closely related tetracyclines.

Figures 1–4 show separations using these various techniques—acid-washed diatomaceous earth impregnated with EDTA–PEG 400–glycerin, and ethyl acetate as the solvent. Figure 1 shows the separations and resolution of three tetracyclines, CTC,[3] TC,[4] and DMCTC,[5] which were specifically prepared. Figures 2, 3, and 4 show the separation and resolution of each tetracycline, such as might result from failure of the strains to produce pure tetracycline, as well as possible degradation during storage. In Fig. 2, DMCTC is separated from

anhydrodemethylchlortetracycline (ADMCTC), demethyltetracycline (DMTC), and epidemethychlortetracycline (EDMCTC); Fig. 3, TC from anhydrotetracycline (ATC), CTC, and epitetracycline (ETC); and Fig. 4, CTC from anhydrochlortetracycline (ACTC), TC, and epichlortetracycline (ECTC).

The apparatus, reagents, developing solvents, plate preparation, and sample application were all evaluated to eliminate unnecessary steps and/or variables for obtaining useful chromatograms. All glassware was scrupulously clean, and only reagents of low native fluorescence were used. The support, diatomaceous earth, was acid-washed to remove the binder and other acid-soluble materials which might contribute to streaking and tailing. The glycerin-PEG 400 mixture maintained the necessary level of moisture that produced well-separated, sharply defined spots. The buffer at pH 7.0 minimized the danger of degradation of the tetracyclines.

Excess moisture due to insufficient drying of the plate reduced the rate of movement of the tetracycline and necessitated chromatographing three or four times. Too little moisture caused elongated spots and poor resolution. Standards were always run for comparative evaluation of samples.

By visual observation under long wavelength ultraviolet light, as minute a quantity as 50 nanograms was easily seen. Additional work is being done in the area of fluorescence analysis using a recording and scanning spectrophotofluorometer which will permit detection of even lower levels of materials, plus quantitation of these tetracyclines and their related compounds.

Tetracyclines II

Separation and Determination by Column Chromatography

By PETER P. ASCIONE, JOHN B. ZAGAR, and GEORGE P. CHREKIAN

A column chromatographic method for the determination of demethylchlortetracycline (DMCTC), tetracycline (TC), and chlortetracycline (CTC) was developed. The chromatogram involved the separation of these tetracyclines from their related compounds on a column of acid-washed diatomaceous earth treated with a buffer consisting of 0.1 *M* ethylenediaminetetraacetic acid disodium salt (EDTA) at pH 6.0 and pH 7.0, glycerin, and polyethylene glycol 400 (PEG 400), followe dby a modified spectral determination of column eluates. Although only DMCTC, TC, CTC, and their related compounds were studied in the work reported here, it appears reasonable to assume that the technique described could be extended to the assay of other tetracyclines.

THE MOST widely used and official method of analysis of tetracyclines is the microbiological assay which is based on the ability of tetracyclines to inhibit growth of certain organisms. Inhibition of growth is used as a direct measure of activity and/or potency of these tetracyclines.

However, the microbiological assay is subject to inherent sources of error which limits its precision to ±15%. Specificity is also limited by the fact that several tetracycline-related compounds exhibit activity toward the test organism similar to the parent compound.

The methods currently in use for the determination of tetracyclines and related compounds are based on spectral behavior in the ultraviolet. The procedure of Woolford and Chiccarelli (1), which determined TC in CTC, is based upon the change in spectrophotometric absorption in acid and basic aqueous media. A second paper by Chiccarelli *et al.* (2) described an additional assay method for TC and CTC based on the formation of anhydro compounds, and the fact that CTC heated at pH 7.5 is cleaved to isochlortetracycline, whereas TC under the same conditions is relatively stable. Doskocil and Vondracek (3) determined TC and CTC with a method based on the different rates at which tetracyclines are inactivated in alkaline medium. A differential spectrophotometric method has been used in these laboratories for determination of related compounds.

Various chromatographic methods—paper, column, and thin-layer—are being used for the quantitation and investigation of tetracyclines. Selzer and Wright (4) described paper chromatography of tetracyclines and epimers using complex solvent systems and buffered paper. Kelly and Buyske (5) used sequestering agents in paper chromatography. Whatman modified cellulose phosphate cation-exchange paper has been used also (6). Hrdy and Vesely (7) described column chromatography using powdered cellulose impregnated with tartrate buffer. A column chromatographic method was developed by Kelly (8) for the determination of both anhydrotetracycline (ATC) and 4-epianhydrotetracycline (EATC) in the presence of large quantities of TC. The use of Sephadex G25 polydextran in columns was reported by Griffiths (9). However, these procedures lack the necessary accuracy and/or specificity for proper evaluation of the true tetracycline content.

A thin-layer chromatographic (TLC) method was developed in these laboratories for the separation and examination of tetracyclines (10). The separation was carried out on acid-washed diatomaceous earth[1] impregnated with 0.1 *M* EDTA pH 7.0, glycerin, and PEG 400, with ethyl acetate as a solvent. With modification of both the thin-layer chromatography and spectrophotometric methods, a column method was developed.

Although the method, as described, is concerned only with crystalline samples, this technique has also made it possible to determine individual tetracyclines in fermentation-process control samples in which mixtures resulted from failure of the strain used to produce a pure tetracycline, in manufacturing processes in which potency was determined in finished products, and also in the study of stability of each individual tetracycline in pharmaceutical formulations, which will be reported later.

EXPERIMENTAL

Materials and Methods

Apparatus—Chromatographic column, 1.3 cm. × 40 cm. (Bellco VIP 50-ml. pipet, graduated in 0.2 ml., with the delivery tip cut off at the 48-ml. graduation). Glass tamping rod, with a diameter 1 mm. less than the internal diameter of the chromatographic column.

Preparation of Acid-Washed Diatomaceous Earth[2]—Slurry 200 Gm. of diatomaceous earth with 750 ml. of 6 *N* HCl for 10–15 min. Filter off diatomaceous earth and wash with distilled water until pH is neutral. Slurry the diatomaceous earth in 500 ml. of a solution of equal volumes of ethyl acetate and methanol for 10–15 min. Filter and vacuum dry at 60°.

Reagents—EDTA, pH 6.0 and 7.0: dissolve 37.2 Gm. of ethylenediaminetetraacetic acid disodium salt in approximately 800 ml. distilled water. Adjust the pH to 6.0 or 7.0 with ammonium hydroxide and dilute to 1 L. with distilled water.

Twenty per cent v/v polyethylene glycol 400 (PEG 400) in glycerin: to 80 ml. of glycerin, add sufficient PEG 400 to make 100 ml. Mix well.

Buffer, pH 6.0 and 7.0: to 95 ml. of EDTA pH 6.0 or 7.0 add sufficient 20% v/v PEG 400 in glycerin to make 100 ml. Shake well.

Benzene, chloroform, *n*-butanol, and methanol, reagent grade.

Alkaline methanol solution: dilute 5 ml. concentrated ammonium hydroxide with 95 ml. of methanol.

Determination of Demethylchlortetracycline[3] and Related Compounds

Procedure—*Column Support*—Mix 100 Gm. acid-washed diatomaceous earth with 50 ml. of buffer, pH 7.0, in a plastic bag or in a glass jar on rollers, until the diatomaceous earth is uniformly moist.

Column Preparation—Place a disk of filter paper (Whatman 541, approximately 1.2-cm. diameter) into the bottom of the column, as a plug. Weigh 8 ± 0.1 Gm. of column support and add to the column in three portions. After each addition settle the diatomaceous earth by firmly tapping the lower end of the column on a padded bench top from a height of 2 to 4 in. while maintaining the column in a perpendicular position. Then lightly tamp the surface with the glass tamping rod. The column height should be about 10.5 to 11.5 cm.

Sample Preparation—*Demethylchlortetracycline HCl*—Weigh accurately about 20 mg. DMCTC HCl, transfer to a 25-ml. volumetric flask with 4 ml. distilled water, and dissolve. Dilute to mark with buffer, pH 7.0. Prepare not more than 30 min. before assay. Pipet 1.0 ml. of sample into a 50-ml. beaker. Add 2 ± 0.1 Gm. of acid-washed diatomaceous earth, stir well, and pack on the column. "Rinse" the beaker with 0.5 ± 0.1 Gm. of column support, add to the column, and tamp well.

Demethylchlortetracycline Neutral—Accurately weigh 18 mg. of DMCTC neutral, transfer to a 25-ml. volumetric flask using 3 ml. of 0.1 *N* HCl, and dissolve. Add 15 ml. of buffer, pH 7.0, followed by 3 ml. of 0.1 *N* NaOH, swirl, and dilute to 25 ml. with buffer, pH 7.0. Prepare this solution not more than 30 min. before assay. Pipet 1.0 ml. of this solution into a 50-ml. beaker, add 2 ± 0.1 Gm. of acid-washed diatomaceous earth and transfer to the column as described above.

Development of Column—Use a 25-ml. graduate as the primary receiver under the column. Add 25 ml. of 40% benzene in chloroform to the column. When the solvent level reaches the top of the column packing, add 50 ml. of 30% benzene in chloroform. After collecting 22 ml. (cut *1*), remove the primary receiver and replace with 50-ml. volumetric flask. Collect the eluate in this flask until the level of the solvent in the column again reaches the top of the packing. Replace the 50-ml. volumetric flask (cut *2*) with a 10-ml. graduate, and add 30 ml. of chloroform to the column. When the volume of eluate in the graduate reaches 8 ml. (cut *3*), replace the graduate with a 50-ml. glass-stoppered graduate and continue collecting the eluate. When the chloroform reaches the top of the packing, add 40 ml. of 50% *n*-butanol in chloroform. When the 50-ml. glass-stoppered graduate contains 29.0 ml. (cut *4*), replace with another 50-ml. glass-stoppered graduate and collect all of the last solvent added to the column (cut *5*).

Assay of Column Eluates—To cut *2* (DMCTC), add cut *3*, and mix well. Add 2.0 ml. of alkaline methanol solution and dilute to volume with chloroform. Determine the absorbance of this solution in a 1-cm. cell against chloroform at a wavelength of 372 mμ on a suitable spectrophotometer within 10 min. after making the solution alkaline. To cut *4* demethyltetracycline (DMTC), add 1.0 ml. of alkaline methanol solution and mix. Determine the absorbance of this solution in a 5-cm. cell against chloroform at a wavelength of 366 mμ within 10 min. after making the solution alkaline. To cut *5* epidemethylchlortetracycline (EDMCTC) add 2.0 ml. alkaline methanol, adjust the volume to the nearest milliliter graduation with chloroform, mix, and record the volume. Determine the absorbance of this solution in a 5-cm. cell against chloroform at a wavelength of 372 mμ within 10 min. after making the solution alkaline.

Determination of Tetracycline[4] and Related Compounds

Procedure—The column support, column, and sample preparation are the same as for DMCTC.

Development of Column—Use a 25-ml. graduate as the primary receiver under the column. Add 20 ml. of benzene to the column. When the solvent level reaches the top of the column packing, add 60 ml. of chloroform. After collecting 25 ml. (cut *1*), remove the primary receiver and replace with a 50-ml. volumetric flask. Collect the eluate in this flask until the level of the solvent in the column again reaches the top of the packing. Replace the 50-ml. volumetric flask (cut *2*) with a 10-ml. graduate and add 40 ml. of 50% *n*-butanol in chloroform to the column. When the volume of eluate in the graduate reaches 8 ml., replace the 10-ml. graduate (cut *3*) with a 50-ml. glass-stoppered graduate and collect all of the last solvent added to the column (cut *4*).

[3] Marketed by Lederle Laboratories, Division American Cyanamid Co., under the trademark Declomycin.

[4] Marketed by Lederle Laboratories, Division American Cyanamid Co., under the trademark Achromycin.

Assay of Column Cuts—To cut *2* (TC), add cut *3*, and mix well. Add 2.0 ml. of alkaline methanol solution and dilute to volume with chloroform. Determine the absorbance of this solution in a 1-cm. cell against chloroform at a wavelength of 366 mμ on a suitable spectrophotometer within 10 min. after making the solution alkaline. To cut *4* epitetracycline (ETC), add 2.0 ml. of alkaline methanol, adjust the volume to the nearest milliliter graduation with chloroform, mix, and record the volume. Determine the absorbance of this solution in a 5-cm. cell against chloroform at a wavelength of 366 mμ within 10 min. after making the solution alkaline.

Determination of Chlortetracycline[5] and Related Compounds

Procedure—Column support, column, and sample preparation are the same as for DMCTC, but at pH 6.0.

Development of Column—Use a 25-ml. graduate as the primary receiver under the column, add 25 ml. of 80% benzene in chloroform to the column. When the solvent level reaches the top of the column packing, add 50 ml. of 40% benzene in chloroform. The development of this column to completion is described under *Procedure* for DMCTC continuing from and including cut *1*.

Assay of Column Cuts—The cuts are treated as directed under *Procedure* for DMCTC with cut *2* (CTC) and cut *5* epichlortetracycline (ECTC) read at 377 mμ, and cut *4* (TC) read at 366 mμ.

RESULTS AND DISCUSSION

Earlier investigation into the separation of tetracyclines by thin-layer chromatography suggested the development of this column chromatographic technique. Thin-layer chromatograms of these tetracyclines (10) showed the possible occurrence of related compounds in each tetracycline. In developing the column, various modifications were made to adapt the basic TLC system. The mobile phase was varied on the column from low to high polarity, starting with benzene–chloroform and ending with *n*-butanol–chloroform. The pH was varied from 6.0 to 7.0, but the ratio of PEG 400 to glycerin was maintained at 1:5.

The effectiveness of the column for separating each tetracycline from its related compounds was demonstrated by the use of TLC (10). Figures 1–3 show the chromatography of subsequent column eluates. According to the results of TLC, the tetracyclines were separated on a column of acid-washed diatomaceous earth treated with EDTA, PEG 400–glycerin at pH 6.0 or 7.0, using benzene, chloroform, and butanol as the developing solvents. In Fig. 1, DMCTC is separated from anhydrodemethylchlortetracycline (ADMCTC), demethyltetracycline (DMTC), and epidemethylchlortetracycline (EDMCTC). The column eluates were collected in fractions of 5 ml. and examined by TLC. The TLC shows the distribution of the DMCTC components isolated on the column and having R_f values similar to those of standard test references. In Fig. 2, TC is separated from anhydrotetracycline (ATC), CTC, and epitetracycline (ETC) on a column as described previously; in Fig. 3, CTC is separated from anhydrochlortetracycline (ACTC), TC, and epichlortetracycline (ECTC) on a column as described above but at a pH 6.0.

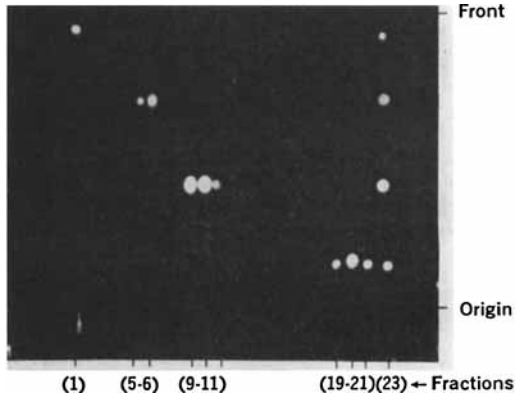

Fig. 2—Thin-layer chromatography of tetracycline column fractions. Key: 1, ATC; 5–6, CTC; 9–11, TC; 19–21, ETC; 23, reference standard mixture.

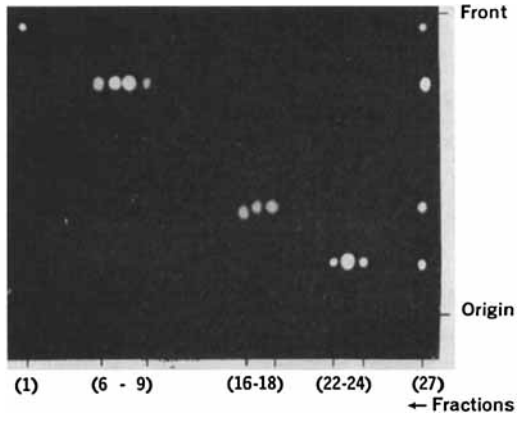

Fig. 3—Thin-layer chromatography of chlortetracycline column fractions. Key: 1, ACTC; 6–9, CTC; 16–18, TC; 22–24, ECTC; 27, reference standard mixture.

The effectiveness of the column and thin-layer chromatographic techniques for the determination of each tetracycline was corroborated by use of microbiological assays. The TLC-chromatogramed spots of tetracyclines were scraped and assayed by the pad-plate diffusion method while the column-chromatographed cuts were assayed by the turbidimetric method. In general, the microbiological results correlated well with the chromatographic data.

For convenience and ease of handling a 1.3-cm. × 40-cm. glass column was chosen. The pH of the buffer was adjusted to eliminate degradation during assay as well as to produce the desired chromatogram of the tetracycline. In the work reported, the sequestering agent (EDTA) was used in the development of TLC and the column. Kelly and Buyske (6) reported that EDTA showed strong chelating properties which improved the separation of tetracyclines. Benzene, chloroform, ethyl acetate, and *n*-butanol were tried as developing solvents, but none served well alone. The best separations were obtained when mixtures of the solvents were used.

Absorption Spectra—Absorption spectra in the region of 300 to 500 mμ were determined on a Cary model 11 recording spectrophotometer. Standard solutions of each tetracycline hydrochloride containing 0.8 mg./ml. were prepared by dissolving 80 mg. of standard in 10 ml. of methanol and then diluting to 100 ml. with chloroform. Two milliliters of the chloroform solution was transferred to a 50-ml. volumetric flask. Forty milliliters of chloroform and 2.0 ml. of alkaline methanol were added, and then diluted to 50 ml. with chloroform. Figures 4–6 show the effect of alkaline methanol, an auxochromic agent, on the absorption spectra of DMCTC, TC, and CTC. In each instance the alkaline methanol had a hypochromic as well as a hyperchromic effect. The wavelengths where maximum absorption occurred when alkaline methanol was introduced into the tetracycline chromaphoric system are as follows: DMCTC, 372 mμ; TC, 366 mμ; CTC, 377 mμ.

Standard calibration curves of DMCTC, TC, and CTC hydrochlorides were prepared with alkaline methanol reagent in chloroform solutions. Three standard curves are presented in Fig. 7. Typical linear Beer's law plot of absorbance *versus* tetracycline concentration range from 0.1 mg./50 ml. to 1.0 mg./50 ml. for all three tetracyclines.

The absorptiometric system obtained a maximum absorbance value immediately upon the addition of the alkaline methanol reagent and this absorbance remained constant over a practical length of time. (Table I.) This should conservatively estimate the

span of time suitable for accurate quantitation. For example, data in Table I indicate at least 10 min. of stability in absorbance when CTC is being tested, and 30 min. stability for DMCTC and TC.

TABLE I—STABILITY OF TETRACYCLINES IN CHLOROFORM SOLUTION CONTAINING ALKALINE METHANOL

Time, min.	DMCTC, 372 mμ	TC, 366 mμ	CTC, 377 mμ
0	0.459	0.527	0.418
2	0.459	0.527	0.418
4	0.459	0.527	0.418
6	0.459	0.527	0.418
8	0.459	0.527	0.418
10	0.459	0.527	0.417
12	0.459	0.527	0.417
14	0.459	0.527	0.417
16	0.459	0.527	0.416
30	0.458	0.527	0.414

The concentrations of the three compounds tested were 0.80 mg./50 ml. for demethylchlortetracycline hydrochloride, tetracycline hydrochloride, and chlortetracycline hydrochloride, respectively.

The absorptivity for DMCTC, TC, and CTC was determined at the wavelength of maximum absorbance and found to be 2.89×10^{-2} for DMCTC, 3.071×10^{-2} for DMTC, 3.29×10^{-2} for TC, and 2.65×10^{-2} for CTC, as the hydrochlorides. The absorptivity is defined as the absorbance at the wavelength of each particular tetracycline for a solution containing 1 mcg. of tetracycline hydrochloride per milliliter, using a 1-cm. cell. Through examination of standards available in these laboratories, the absorptivity for each tetracycline and its epimer was found to be the same. The determination of absorbances of the column eluates after the addition of the auxochromic agent provided a quantitative spectrophotometric method for assaying tetracyclines in solvent solutions when compared with standards treated in like manner.

In Vivo Method for the Simultaneous Determination of Potassium and Sodium Depletion

By GORDON S. BORN, STANLEY M. SHAW, and JOHN E. CHRISTIAN

An *in vivo* radiotracer technique utilizing whole body liquid scintillation counting for the simultaneous detection of ^{42}K and ^{24}Na retention within the intact animal was developed. The technique allowed direct comparison of the retention of potassium and sodium in treated and control animals. The differences in retention indicated the kaliuretic and natriuretic effects of proven diuretic agents. Experimentation with standards was used to develop the simultaneous technique for ^{42}K and ^{24}Na determination. The method was tested *in vivo* in rats and swine, using furosemide and hydrochlorothiazide to show the effects of these diuretic agents in altering potassium and sodium metabolism, to illustrate the adaptability of the method in studies with various animal species, and to confirm the versatility of the method with a whole body liquid scintillation detector of the "human type." Results indicated the technique to be a sensitive method for measuring alterations in potassium and sodium metabolism in rats and swine caused by the diuretic agents.

RADIOTRACER techniques utilizing *in vivo* whole body liquid scintillation counting have been used in studying the effects of diuretics on either potassium or sodium metabolism. Using ^{22}Na, Rupe, Bousquet, and Christian (1) evaluated compounds for their natriuretic and diuretic activity in rats. Born *et al.* (2) and Seno (3), using ^{42}K, studied the kaliuretic properties of diuretics in the rat. Shaw, Kessler, and Christian (4) investigated the kaliuretic and natriuretic properties of a diuretic by using ^{42}K and ^{24}Na in separate studies in swine. The advantages of the whole body liquid scintillation counting technique over photometric methods of determining potassium and sodium elimination have been stated in the above references. However, an undesirable aspect of the whole body liquid scintillation counting technique was the inability to study the kaliuretic and natriuretic properties of a diuretic in the same group of animals in a single experiment.

In Vivo Method for the Simultaneous Determination of Potassium and Sodium Depletion

By GORDON S. BORN, STANLEY M. SHAW, and JOHN E. CHRISTIAN

An *in vivo* radiotracer technique utilizing whole body liquid scintillation counting for the simultaneous detection of ^{42}K and ^{24}Na retention within the intact animal was developed. The technique allowed direct comparison of the retention of potassium and sodium in treated and control animals. The differences in retention indicated the kaliuretic and natriuretic effects of proven diuretic agents. Experimentation with standards was used to develop the simultaneous technique for ^{42}K and ^{24}Na determination. The method was tested *in vivo* in rats and swine, using furosemide and hydrochlorothiazide to show the effects of these diuretic agents in altering potassium and sodium metabolism, to illustrate the adaptability of the method in studies with various animal species, and to confirm the versatility of the method with a whole body liquid scintillation detector of the "human type." Results indicated the technique to be a sensitive method for measuring alterations in potassium and sodium metabolism in rats and swine caused by the diuretic agents.

RADIOTRACER techniques utilizing *in vivo* whole body liquid scintillation counting have been used in studying the effects of diuretics on either potassium or sodium metabolism. Using ^{22}Na, Rupe, Bousquet, and Christian (1) evaluated compounds for their natriuretic and diuretic activity in rats. Born *et al.* (2) and Seno (3), using ^{42}K, studied the kaliuretic properties of diuretics in the rat. Shaw, Kessler, and Christian (4) investigated the kaliuretic and natriuretic properties of a diuretic by using ^{42}K and ^{24}Na in separate studies in swine. The advantages of the whole body liquid scintillation counting technique over photometric methods of determining potassium and sodium elimination have been stated in the above references. However, an undesirable aspect of the whole body liquid scintillation counting technique was the inability to study the kaliuretic and natriuretic properties of a diuretic in the same group of animals in a single experiment.

Received April 14, 1967, from the Bionucleonics Department, School of Pharmacy and Pharmacal Sciences, Institute for Environmental Health, Purdue University, Lafayette, IN 47907
Accepted for publication July 21, 1967.
Presented to the Drug Standards, Analysis and Control Section, A. PH. A. Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.
This investigation was supported in part by a grant from Lloyd Brothers, Inc., Cincinnati, Ohio.

The purpose of the following research was to develop an *in vivo* technique for the simultaneous detection of both potassium and sodium retention, thereby achieving simultaneous determination of the kaliuretic and natriuretic properties of a diuretic. The technique would limit biological error, reduce investigational time, and allow greater economy resulting from the utilization of fewer animals.

Following the administration of radioactive potassium and sodium, and their equilibration with the body stores of the electrolytes, whole body radioactivity was determined by dual channel counting, to establish the amount of each radionuclide present in the body. Subsequent measurements were made during drug or control dosage. Direct comparisons between the radionuclide retentions of treated and control animals allowed the evaluation of drugs for kaliuretic and natriuretic properties.

EXPERIMENTAL

The investigation was divided into three parts which were: development of the technique, study of the natriuretic and kaliuretic effects of furosemide[1] and hydrochlorothiazide[2] in the laboratory rat, and a study of the saluretic effects of furosemide in swine. The first study, which was conducted using the PUSAC (5), was carried out to develop a whole body liquid scintillation counting technique which would allow the resolution of the component parts from a ^{42}K and ^{24}Na mixture. The PUSAC was modified to allow dual channel counting by splitting the signal from the preamplifier with a tee connector and directing the split signal through separate amplifiers, pulse height analyzers, and scalers. One pulse height analyzer was calibrated to monitor the 1.26 Mev. Compton peak of ^{42}K with a 9% window (5.0 Mev. full scale). The other was calibrated to monitor the 2.5 Mev. Compton peak from ^{24}Na with a 20% window (3.2 Mev. full scale). The base line discriminators on both analyzers were set to maximize the sample-squared-to-background ratios at the stated window widths. Three mixtures of ^{42}K and ^{24}Na, with varying but known amounts of each radionuclide, were prepared. Additional standards of the single radionuclides at the same concentration were prepared. Mixture *1* was a standard containing both ^{24}Na and ^{42}K in the same concentration as the ^{24}Na standard 1 and the ^{42}K standard 1; other mixed samples were similarly prepared. Counts were taken on the standards and the mixtures of known concentration at 0, 6, 18, 30, and 42 hr. after preparation to simulate an *in vivo* study. At each time interval, the net count rate was obtained in each channel. The counting procedure yielded a counting error for the net sample counts of 5% or less at the 95% confidence level.

[1] Furosemide is 4-chloro-*N*-(2-furyl-methyl)-5-sulfamoyl-anthranilic acid. This compound was supplied by Lloyd Brothers, Inc., Cincinnati, Ohio, and is marketed as Lasix.

[2] 6 - Chloro - 3,4 - dihydro - 7- sulfamoyl - 2*H* - 1,2,4-benzothiadiazine-1,1-dioxide. The compound was supplied by Merck Sharp and Dohme, West Point, Pa., as Hydrodiuril.

Observed net count rates for the mixtures (from both the potassium and sodium channels) were mathematically manipulated, resolving the relative amount of each radionuclide present. The simultaneous equation method was used to eliminate interference in each channel caused by spectral overlap of the other radionuclide. The ratio of any portion of the spectra to other portions was constant and independent of the activity.

The net count rate of a composite spectrum of the radionuclides ^{42}K and ^{24}Na, for the Compton peak channel of ^{42}K (N_K) may be written as:

$$N_K = K_K + f_{NaK}\, Na_{Na} \qquad \text{(Eq. 1)}$$

where K_K = count rate contribution by ^{42}K to the Compton-peak channel of ^{42}K, f_{NaK} = interference factor which expresses the fractional contribution of the Compton-peak channel of ^{24}Na to the Compton-peak channel of ^{42}K.

Similarly, the net count rate in the ^{24}Na channel (N_{Na}) may be written as:

$$N_{Na} = Na_{Na} + f_{KNa}\, K_K \qquad \text{(Eq. 2)}$$

where Na_{Na} = count rate contribution by ^{24}Na to the Compton-peak channel of ^{24}Na, f_{KNa} = interference factor which expresses the fractional contribution of the Compton-peak channel of ^{42}K to the Compton-peak channel of ^{24}Na.

Equations 1 and 2 are simultaneous linear independent equations containing two unknowns, K_K and Na_{Na}. The net count rates (N_K, N_{Na}) of the composite sample are obtained from the composite spectrum, and interference factors (f_{NaK}, f_{KNa}) obtained experimentally from standard spectra.

The solution to Eqs. 1 and 2 by substitution is:

$$K_K = N_K \cdot \frac{1}{1 - f_{NaK} f_{KNa}} - N_{Na} \cdot \frac{f_{NaK}}{1 - f_{NaK} f_{KNa}}$$

and

$$Na_{Na} = N_{Na} \cdot \frac{1}{1 - f_{KNa} f_{NaK}} - N_K \cdot \frac{f\mathrm{KNa}}{1 - f_{KNa} f_{NaK}}$$

Now let

$$C_1 = \frac{1}{1 - f_{NaK} f_{KNa}}$$

$$C_2 = \frac{f_{NaK}}{1 - f_{NaK} f_{KNa}}$$

$$C_3 = \frac{1}{1 - f_{KNa} f_{NaK}}$$

$$C_4 = \frac{f_{KNa}}{1 - f_{KNa} f_{NaK}}$$

The following new equations result:

$$K_K = C_3 N_K - C_4 N_{Na}$$
$$Na_{Na} = C_1 N_{Na} - C_2 N_K$$

where K_K = ^{42}K in the potassium channel, Na_{Na} = ^{24}Na in the sodium channel, N_K = observed count rate in the ^{42}K channel, N_{Na} = observed count rate in the ^{24}Na channel, and C_1, C_2, C_3, C_4 = constants whose value was derived from the ^{42}K and ^{24}Na standards.

The resolved potassium (K_K) and sodium (Na_{Na})

standard data at the first observation period were taken to represent 100% values. Both net count rates for later time intervals were corrected for counter efficiency changes, resolved, and then corrected for radioactive decay. Half-life values of 12.5 hr. for ^{42}K and 15.0 hr. for ^{24}Na were used. The per cent of potassium and sodium found in each of the three mixed samples was calculated and averaged for each observation period and the error (difference between observed value and 100%) calculated.

In using the simultaneous method to compare the effects of furosemide and hydrochlorothiazide upon potassium and sodium, two rat trials at different dosage levels were conducted. In addition to the simultaneous determination in trial *A*, an integral sodium study was conducted. In trial *B* an integral potassium determination was conducted as well as the simultaneous study, allowing comparison of the interference free (single radionuclide) integral and the simultaneous (dual radionuclide) detection methods. The PUSAC was utilized as previously described in this paper for the dual studies and as described by Born *et al.* (2) for the integral studies.

Female Sprague-Dawley albino rats (175–225 Gm.) were divided into groups consisting of 6 rats each. The animals were housed in individual metabolism cages. Twenty-four hours prior to the initiation of whole body counting, the animals were injected intraperitoneally with the isotope(s) in 0.5 ml. of neutral aqueous solution to allow equilibration of the radionuclides with body stores. For the simultaneous determinations, based upon supplier assay,[3] about 1 μc. of ^{42}K and 0.1 μc. of ^{24}Na were given each rat. In the case of the single radionuclide studies, approximately 3 μc. of ^{42}K or 0.3 μc. of ^{24}Na was administered. At the time of radionuclide administration, fasting was initiated and continued throughout the experiment. Distilled drinking water was allowed *ad libitum*. Immediately after initial determination of whole body radioactivity (time 0), the test drug (furosemide or hydrochlorothiazide) was administered. The animals were dosed again at each counting period (each animal receiving 220 mg./Kg./day in trial *A* and 250 mg./Kg./day in trial *B*). Whole body counts were made at 8, 16, 24, 32, and 40 hr. The net sample counts from each animal were manipulated as before to resolve the relative potassium and sodium counts. The resolved count rates for each radionuclide were treated separately, using a digital computer and Fortran programming for correcting data for radioactive decay, calculating the per cent ^{42}K and ^{24}Na retention in each animal, computing the average per cent retention of each electrolyte for the drug treated *versus* the control groups, and computing the Student *t* value for this difference in per cent retention.

To demonstrate the adaptability of the dual radionuclide detection method to other whole body counters, as well as to other test animals, domestic pigs were utilized in the Sinco-p (6) which was calibrated to allow dual channel counting of ^{24}Na and ^{42}K. A 20% window width (3.2 Mev. full scale) for each channel was used with this counter. The base line for each window was selected by maximizing the sample-squared-to-background ratio using ^{42}K and ^{24}Na standards.

Pigs of both sexes (25–30 lb.) were randomly divided into 2 groups of 3 animals. One group was designated the control group, and the other group selected for drug therapy. The animals were housed in metabolism cages throughout the experimental period. Forty-eight hours prior to the first drug administration, whole body ^{40}K was determined, the animals being immobilized in a steel container (4). Twenty-four hours prior to drug administration, ^{42}K (about 5 μc.) and ^{24}Na (about 1 μc.) were administered intraperitoneally to allow equilibration with body stores. Fasting, with water allowed *ad libitum*, was initiated and continued throughout the experiment. Following radionuclide equilibration, each animal was counted at 0, 6, 12, 24, 30, and 36 hr. Furosemide (100 mg./Kg./day) was administered in 2 equal aliquots at 12-hr. intervals starting at time zero.

The calculation of data was the same as previously described. However, natural ^{40}K radioactivity in each swine was subtracted from the net sample count of each channel before proceeding with further calculations.

RESULTS AND DISCUSSION

Table I shows the results of the study with standards which was undertaken to show the feasibility of a simultaneous method for detection of ^{42}K and ^{24}Na. The 100% values for ^{42}K and ^{24}Na at time zero were assigned, while the percentages at later time intervals were calculated. As can be seen, the greatest difference between known and observed standard activity was about 3% for ^{24}Na and less for ^{42}K. The sources used in this study had widely varied proportions of ^{42}K and ^{24}Na, representing extremes not often encountered in controlled experiments with animals. With observed count rates from ^{42}K and ^{24}Na approximating each other, as in the animal studies, the over-all error of simultaneous determinations should be reduced.

Table I—Per Cent of Isotope Found in Known Sources by the Simultaneous Method

Time[a] Elapsed	% [b] ^{42}K	% [b] ^{24}Na	% Error [c] ^{42}K	% Error [c] ^{24}Na
0	100.0	100.0	0.0	0.0

42	97.3	98.2	2.7	1.8

[a] Time elapsed in hours from first determination. [b] Average per cent for three samples. [c] One hundred per cent minus calculated per cent.

Table II shows the differences in per cent sodium retention between drug and control animals observed in trials *A* and *B*, and the calculated Student *t* values for these differences. As may be seen in Table II, both drug treatments caused a decrease in sodium retention in relation to control animals, and thereby, an increase in sodium excretion.

In trial *A*, in addition to the simultaneous study, an integral study of sodium retention was conducted allowing comparison of the data from both methods. In both studies in trial *A*, a significant difference

as affected by furosemide, for drug and control animals *versus* time for the simultaneous and integral studies. The observed retention values shown in Fig. 1 are representative of the average retention values used to calculate the differences in per cent retention. In Table III a comparison between furosemide and hydrochlorothiazide is made. In this case, the hydrochlorothiazide-treated group were considered as the controls, and activity of furosemide in relation to hydrochlorothiazide evaluated to show the differences in potassium and sodium elimination. In trial A of both integral and differential studies, furosemide was shown to cause significantly (p = 0.01) more sodium elimination than hydrochlorothiazide.

In Table IV the differences in per cent potassium retention between drug and control therapy are given for trials A and B, and their Student t values reported. In trial B, both integral and differential studies were conducted allowing comparison of the suitability of the two methods for potassium determination. From the data in Table IV, the integral method showed statistical differences (p = 0.01) in potassium retention between furosemide and control-treated animals at all time periods except the 16-hr. observation. In the differential study, the data were significantly different (p = 0.01) at the 8 and 24-hr. time period. With hydrochlorothiazide, only in the integral study was any difference in potassium retention between control and drug-treated animals observed, and then, only at two time intervals (8 and 32 hr.). The percentages of potassium eliminated in the integral and differential study are comparable. The statistical significance of potassium elimination in the integral study and nonsignificance in the differential study may indicate limitations to the reliability of a simultaneous method. The limitations are believed to be imposed by 3 combined factors: small number of animals utilized, counting error, and the inherently

[a] Time elapsed in hours from first day administration. [b] Per cent retention hydrochlorothiazide-treated minus furosemide-treated groups. [c] Student *t* value of 2.76 reflecting a confidence level of 99% for a "one tail" test.

small amounts of potassium actually excreted as a result of drug action. Figure 2 illustrates the average per cent potassium retention for furosemide and control therapy *versus* time for both the integral and differential study.

Table V shows differences in the effect of furosemide and hydrochlorothiazide on potassium metabolism, when the hydrochlorothiazide group was considered as control animals. The integral study shows that the two drugs affect potassium elimination to a different degree, furosemide causing a significant ($p = 0.01$) elimination of potassium as compared to hydrochlorothiazide. With the differential method, no statistically significant differences are observed, although the differences in per cent potassium elimination are comparable. Here again, any difference that may exist between the diuretics has been masked.

The effect of furosemide (100 mg./Kg./day) upon sodium and potassium retention in swine is shown in Table VI. The differences in per cent retention of ^{42}K and ^{24}Na between control and drug groups at different time intervals is indicated, as well as the Student *t* values for these differences. The furosemide treatment, when compared to control treatment, caused an insignificant excretion of potassium at all time periods. The results of the study show the natriuretic effect of furosemide upon sodium excretion, with significant differences being observed at 24, 30, and 36-hr. observation periods.

The results of the swine experiment are not in complete agreement with the integral study of the kaliuretic and natriuretic properties of furosemide by Shaw, Kessler, and Christian (4). While their investigation indicated a statistically significant

difference in potassium elimination between treated and control animals and this study indicates only a trend, as previously noted, the differential method lacks the sensitivity of the integral method in determining potassium retention. However, the sodium data are consistent with their study of furosemide.

SUMMARY AND CONCLUSIONS

Using standards, a suitable method was developed which would allow simultaneous detection of ^{42}K and ^{24}Na in a composite sample by large volume liquid scintillation counting. The standard data indicate that the determination of the amount of each radionuclide, in the presence of the other, can be accomplished with an error of about 3%. In rats, a comparison of the simultaneous and integral detection methods showed both methods capable of detecting potassium elimination as affected by furosemide or hydrochlorothiazide, though the integral was the more sensitive to small differences. The simultaneous method showed no statistical differences (between the 2 drugs) in potassium elimination. The simultaneous and integral methods were equally sensitive in the detection of sodium elimination. The effect of furosemide on the rat was shown, statistically, to be more pronounced than that of hydrochlorothiazide with respect to an increased elimination of sodium. Experimentation with swine illustrated the adaptability of the simultaneous method to other species and other whole body counters.

The results of the investigation indicate that the simultaneous method for determining the kaliuretic and natriuretic properties of diuretics would be applicable to animal studies and feasible for use in clinical evaluations. The high detection sensitivity of whole body counters, in combination with the short half-lived radionuclides ^{24}Na and ^{42}K, limits whole body exposure to ionizing radiation and allows clinical evaluation with a minimal health hazard.

Phytochemical and Hypoglycemic Investigation of *Casearia esculenta*

By K. D. CHOUDHURY and N. K. BASU*

In the course of a systematic investigation of *Casearia esculenta*, the following components were isolated: a sterol, m.p. 132–134°; a substance resembling gutta-percha, m.p. 59–60°; a flavonoid compound, m.p. 255–258°; a colorless crystalline compound, neutral and water-soluble, m.p. 184°; and two resins. A reducing sugar present in the drug was identified by paper chromatography as arabinose. The hypoglycemic activity of the different fractions, both isolated and in alcoholic and aqueous extracts, has been studied.

THE ROOTS OF *Casearia esculenta* Roxb. (N. O. *Samydaceae*) are used as an antidiabetic drug in southern and southwestern India, particularly in Maharastra, by physicians who practice the Indian system of medicine known as Ayurvedha. The drug is considered to be a specific remedy for diabetes (1), and is widely used throughout Decan (2). A search of available literature (1, 3, 4) and abstracts revealed little or no scientific information concerning the evaluation of the medicinal properties of the plant. The present investigation was undertaken primarily on the basis of a preliminary report (5) which indicated the presence of hypoglycemic activity in a water-soluble crystalline body *S*, m.p. 182°, and also in two resin fractions, one of them water soluble but acid insoluble. From the available experimental data it is now evident that a water-soluble crystalline body, m.p. 184°, isolated from the roots of the plant, is responsible for the hypoglycemic activity.

EXPERIMENTAL

Source and Preparation of Material—Drug plant roots used in these investigations were received through the courtesy of Sri K. G. Gune, Ayurvedhashram Pharmacy, Ahmednagar, and authenticated by Sri Balwant Singh, Ayurvedic Garden, Banaras Hindu University, by comparison with the samples kept at the herbarium of the Ayurvedic Division, College of Medical Sciences, Banaras Hindu University. The roots were reduced to moderately fine powder.

Percentage of Extracts and Ash Determination—Suitable samples of the powdered drug were extracted successively with a series of selective solvents in a Soxhlet apparatus according to a modified Rosenthaler procedure (6). The solvents utilized and the per cent of extracts obtained with each solvent were: petroleum ether (b.p. 40°–60°), 2.55%; ether, 0.73%; benzene, 0.75%; chloroform, 0.15%; acetone, 2.66%; and alcohol, 5.34%. The determinations for ash content as recommended by the B.P. (7) afforded the following results: total ash, 3.25%; acid-insoluble ash, 0.243%; and water-soluble ash, 0.58%.

Extraction of the Drug with Benzene and Alcohol and Separation of Different Fractions (Scheme I)—Ten kilograms of the drug was completely extracted with benzene, and the extract was concentrated and ultimately dried. The residue obtained was labeled as fraction A.

The residue left after the extraction with benzene was further extracted with alcohol by percolation. The total alcoholic extract was concentrated under reduced pressure to a small volume and set aside. Some solid matter deposited from the concentrated extract and was separated from time to time. This process was continued until there was no further deposition on standing. The mixed solid was washed with a little cold alcohol and then with dry ether. It was labeled as fraction B. The ethereal washings gave positive tests for sterols and was labeled as fraction C. It was examined along with fraction A.

The alcoholic extract left after the removal of fraction B was poured in a thin stream, with constant stirring, into a large volume of water. The precipitated mass was separated, dried, and labeled as the resin. The supernatant liquid after acidification with dilute hydrochloric acid gave another precipitate which was collected and dried. This fraction was labeled as the acid-insoluble resin.

The filtrate gave positive tests for reducing sugars. A portion, labeled as fraction F, was used for the identification of the sugar.

Isolation of Sterol—*From Fraction A*—A suitable amount of fraction A was saponified with alcoholic potash and the unsaponifiable portion, after removal of alcohol, was taken up in ether. No crystalline matter separated from the ethereal extract even on prolonged storage at low temperature (10°). On addition of acetone to the ethereal extract, one yellowish body was precipitated. The precipitate gave faint tests for sterols. It was purified by repeatedly dissolving in ether and reprecipitating with the addition of acetone. After purification, this solid failed to respond to any of the tests for sterols. This was labeled as fraction K. After the removal of fraction K, only one sterol, m.p. 132–134°, could be isolated from the mother liquor.

From Fraction C—A sterol, m.p. 132–134°, separated during attempts at crystallization from

Received January 30, 1967, from the School of Pharmacy, Zaria, Northern Nigeria.

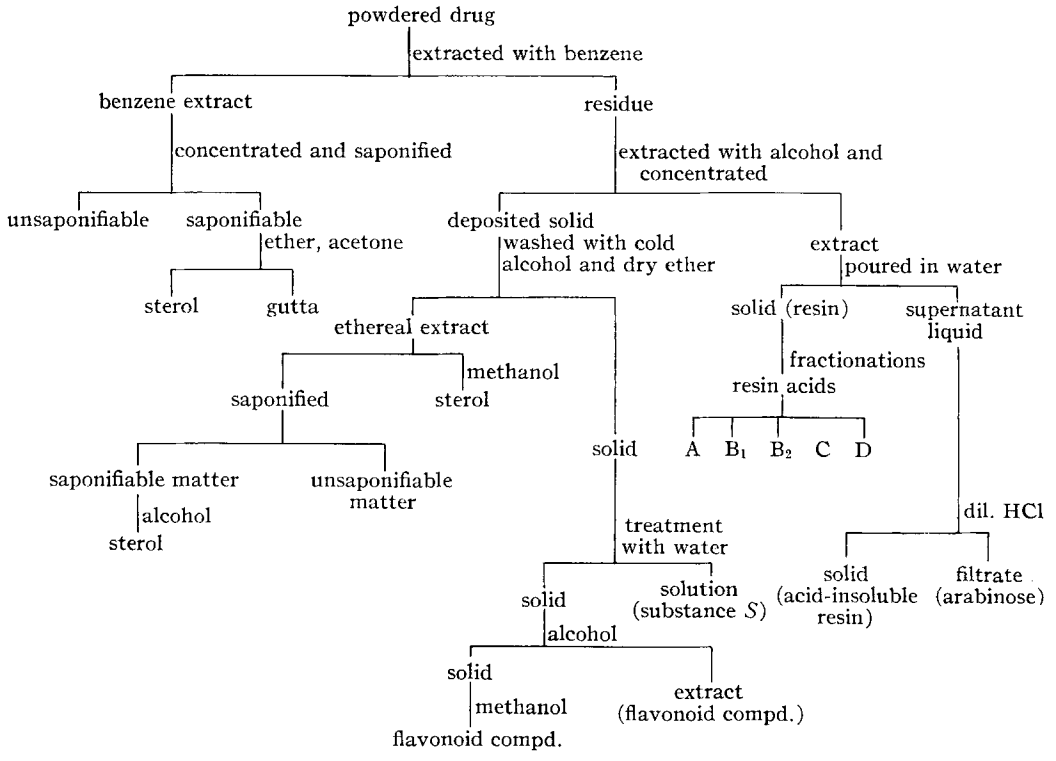
* Present address: Department of Pharmacy, Kasturba Medical College, Manipal, Mysore, India.



Scheme I

methanol and also by the process of saponification and taking up in ether and ultimate crystallization from ethanol. All the sterol fractions were found to be the same since there was no depression when mixed melting points were taken.

The following derivatives of the sterol were prepared and their melting points noted: digitonide, m.p. 202–203°; acetyl, m.p. 113–114°; and benzoyl, m.p. 113–116°.

Anal.—Calcd. for $C_{24}H_{38}O_2$: C, 80.44; H, 10.61. Found: C, 80.71; H, 10.47.

Molecular weight (Rast) using camphor as solvent.

Gutta-Like Substance—Fraction K, found during the isolation of sterol, was found to melt at 59°–60°. Elemental analysis (8) indicated the absence of nitrogen, sulfur, phosphorus, and halogens. It was classified [as per Tracey (9)] as gutta from its physical behavior and chemical tests. Since this substance did not show any hypoglycemic activity, it was not studied further.

Isolation of Substance S—Fraction B was treated with hot water. The suspension was filtered and the residue was repeatedly treated with warm water until a small volume of the filtrate did not leave anything on evaporation. The residue which did not go into solution was marked fraction P and set aside. A flavonic compound, isolated from fraction P, is described later. The mixed filtrate was concentrated to a small volume and kept for crystallization. A number of crops of crystals, m.p. 178–179°, were isolated. The crops were recrystallized separately from water and their melting points were found to lie between 182–184°. The mixed melting points of different crops did not show any depression. All the crops were, therefore, mixed together and dissolved in water and allowed to crystallize slowly. The crystals, as they appeared, were collected separately in several lots. The melting points of first and last fraction were taken and found to be 184°. When tested for hypoglycemic activity, this product was found to be active both on normal rats (Table VI) and rabbits (Table VII). The chemical constitution and antidiabetic activity of this compound, named substance *S*, (C, 39.6; H, 6.82) will be reported in a separate communication.

Isolation of Flavonoid Compound—Fraction P was found to have a silky appearance in water. It decolorized acid permanganate solution and gave positive tests for phenols with a solution of ferric chloride. Five grams of fraction P was refluxed several times with ethanol which took a small portion of it in solution. From the alcohol-soluble portion a granular body crystallized, m.p. 246–251° dec. This product turned green in a solution of ferric chloride. Light yellow needle-shaped crystals, m.p. 254–258°, with repeated crystallization were obtained from the granular body. This was labled fraction P/alcohol.

The mass left after refluxing with alcohol was refluxed several times with methanol. From the mixed methanolic extract a yellow crystalline product separated on cooling. This was separated and repeatedly crystallized from hot methanol until there was no rise in the melting point, 255–257°. This product was also found to turn green

in a solution of ferric chloride and labeled as fraction P/methanol.

Both fraction P/alcohol and P/methanol exhibited the following colors: (*a*) ferric chloride solution, green; (*b*) magnesium and HCl, orange red; (*c*) boric acid and HCl, yellow; (*d*) sodium hydroxide solution, greenish yellow; (*e*) neutral lead acetate, yellow. As the above color reactions were characteristics of flavanoids (10), the method of Gupta and Seshadri (11) for the isolation of flavanoid compounds was adopted and one crystalline yellow product, m.p. 255–258°, was isolated. This fraction was also found to respond to all the color tests mentioned above. All the three fractions were then subjected to paper chromatography, and the chromatograms were developed with various reagents (10). The same color and R_f values were obtained with all the fractions. Mixed melting points of the different fractions did not show any depression. This indicated that they were identical. Microcombustion analysis gave the following results: C, 54.02; H, 3.88. These fractions were found to be inactive when tested for hypoglycemic activity and were not further investigated.

Studies with Resin Fractions—Both the resin fractions reported above were found to lower the blood sugar level of normal albino rats (Tables III and IV). But on purification this hypoglycemic property was found to have disappeared completely from both the fractions. However, the portion that did not go into solution in ether during fractionation of the resin was found to have hypoglycemic activity (Table V). This indicated that the hypoglycemic activity might be due to adsorption of substance *S* in the crude resin fractions. On fractionation by a chemical method (12), the following resin acids were isolated from the resin: (*a*) resin acid A, m.p. 147–164° (with frothing); (*b*) resin acid B_1, m.p. 85–91° (with frothing); (*c*) resin acid B_2, m.p. 81–132° (with frothing); (*d*) resin acid C, m.p. 144–150° (with frothing); (*e*) resin acid D, m.p. 130–144° (with frothing).

Identification of Reducing Sugar—The reducing sugar present in the drug was identified as arabinose by paper chromatography (13). This was done by making separate chromatograms of a pure sample of arabinose, fraction F, and a mixture of fraction F and added arabinose. After development, each showed only one spot at the same R_f value.

Hypoglycemic Studies—Healthy albino rats of the same breed and of nearly the same weight range were selected for carrying out the experiments. They were divided into two groups: one for control and the other for the drug. Food was withdrawn 18 hr. before starting the experiments, and no food was given during the experiment. The drug was given *per os*. Blood samples were taken from the tails of the animals and blood sugar was determined by the method of Folin and Wu (14). A color comparison was made in a Lumetron photoelectric colorimeter (Lumetron model 402EF). Of all the fractions tested, only the alcoholic and aqueous extracts, two crude resin fractions, and substance *S* were found to be active, and the results

TABLE VII—CONCENTRATION OF BLOOD SUGAR AFTER A SINGLE ORAL DOSE OF SUBSTANCE *S* IN RABBITS[a]

[a] Dose, 0.5 Gm./Kg.

obtained with these fractions are given in the Tables I–VII.

From the observations recorded in the tables, it is quite evident that the hypoglycemic activity of the drug is due to substance *S* alone. Experiments to prove the antidiabetic activity of substance *S* are presently in progress.

SUMMARY

A number of fractions were isolated by a chemical method from the drug, *C. esculenta*. All of the isolated fractions were tested biologically for their hypoglycemic activity and only a few fractions, *viz.*, the two crude resin fractions and a water-soluble crystalline body *S*, showed positive results. On purification, both the resin fractions proved to be inactive, and this indicated that the activity might be due to adsorption of substance *S* in the crude resins. This was further confirmed by the fact that when the crude resin was extracted by ether the portion that did not go into solution in ether gave a positive response.

The chemical constitution and the antidiabetic activity of substance *S* will be presented in another paper.

Diffuse Reflectance Studies of Dye-Adjuvant Chemisorption

By MICHAEL BORNSTEIN, JOHN P. WALSH, BILL J. MUNDEN, and JOHN L. LACH*

A number of pharmaceutical adjuvants were screened by means of diffuse reflectance spectroscopy for possible solid–solid interaction with certified Red No. 3, Blue No. 1, and Yellow No. 5 dyes. Results indicate that a metallic or polyfunctional adsorbent molecule is necessary for these interactions. Furthermore, it was generally observed that the order of metallic adjuvant interaction with these dyes is $Mg^{2+} > Ca^{2+} > Zn^{2+} \backsim Al^{3+}$. Spectral and visual color changes, elution studies, and accelerated fading techniques support the reflectance data presented.

SEVERAL ARTICLES have recently appeared in the literature which point out drug–adjuvant interactions (1, 2) and the need for prescreening of the excipients used in the preparation of solid dosage forms. Since such interactions may be responsible for the various therapeutic discrepancies reported in related formulations, these interactions may also be of significant importance in color and drug stability.

EXPERIMENTAL

Reagents—FD&C Red No. 3 dye and aluminum lake (National Aniline), FD&C Blue No. 1 dye (National Aniline), FD&C Yellow No. 5 dye and aluminum lake (Warner-Jenkinson Mfg. Co.), acacia, aluminum hydroxide, aluminum stearate, calcium hydroxide, cellulose acetate phthalate, citric acid, lactose, magnesium citrate, magnesium hydroxide, pectin, polyethylene glycol 6000 (Carbide and Corton Chemical Corp.), starch U.S.P., titanium dioxide, zinc oxide, zinc sulfate.

Apparatus—Beckman DU spectrophotometer with a diffuse reflectance attachment, constant-temperature water bath set at 30 ± 0.5° with rotating spindles (1), assorted round amber bottles from 30 to 200 ml. with caps, Parafilm (Marathon Co.), aluminum foil (Reynolds), vacuum oven (National Appliance Co.), glass desiccator, lyophilizer (National Research Corp.) attached to a refrigeration system (Webber Refrigeration).

PROCEDURES

Equilibration Technique—The general method of studying these interactions involves equilibrating a weighed amount of adsorbent for 24 hr. with distilled water or an organic equilibration medium. After equilibration the dispersion medium is removed either by vacuum filtration followed by vacuum drying at 35° for 24 hr., by vacuum evaporation from a glass desiccator, or by freezing the aqueous media with the aid of a dry ice–methanol mixture and lyophilization for 24 hr. The particular drying method used is described under *Results and Discussion*.

Preparation of the Sample—A specified amount of pre-equilibrated dye and adsorbent (pharmaceutical adjuvant) are weighed. The powders are then placed in a suitable amber bottle and 20 ml. of the dispersion media is added. The bottle is covered with Parafilm or aluminum foil, capped, and equilibrated for 24 hr. at 30 ± 0.5° in order to effect interaction. After equilibration, one of the following three techniques is employed in order to dry the samples.

Vacuum Filtration and Drying—Used for samples with aqueous dispersion media reported in Tables I and II. The suspension is vacuum filtered after equilibration and the powder is dried in a vacuum oven at 35° for 24 hr. The resulting dry powder is then triturated, and its diffuse reflectance (DRS) measured using a magnesium carbonate reference standard.

Evaporation by Vacuum—The equilibrated solution or suspension is placed in an evaporation dish and placed in a vacuum desiccator. The organic solvent is removed at room temperature, and the resulting powder is triturated and its DRS measured.

Drying by Lyophilization—This process is used exclusively in all the samples reported in Table II. The equilibrated aqueous solution or suspension is frozen in a dry ice–methanol mixture and lyophilized for 24 hr. The resulting powder is triturated and its DRS measured.

Preparation of the Control—A specified weight of the previously equilibrated and dried adsorbent is physically mixed with an indicated amount of pre-equilibrated and dried adsorbate using a mortar and pestle. The DRS of this control is then measured using a magnesium carbonate reference standard.

SPECIAL TECHNIQUES

Washing the Sample—The dry powdered sample is placed in a 51-mm. Büchner funnel and 200 ml. of distilled water is added and removed by vacuum filtration. The resultant powder is dried and its DRS measured.

Accelerated Light Studies—The powder under study is packed into an inverted 4-cm. diameter bottle cap and placed into an Envira-Lite cabinet (Thermal Research, Inc.) which houses 10 Westinghouse F-40 CW/RFL fluorescent lamps and 4 GE lumiline No. L60 IF/T8 incandescent lamps and is

Lake + starch	100 mg.:4.00 Gm.	Dil. EtOH (1:1)	Vacuum filtration	Small change	Pink to bright yellow
Dye + lactose	200 mg.:4.00 Gm.	EtOH	Vacuum evaporation	No significant change	Orange to heterogeneous orange with dark pink crystals
Lake + CAP	100 mg.:4.00 Gm.	H_2O	Vacuum filter, wash and dry	No significant change	Yellow to yellow
Dye + PEG 6000	200 mg.:4.00 Gm.	$CHCl_3$	Vacuum evaporation	Increased reflectance	Heterogeneous light orange to orange
Dye + PEG 6000	200 mg.:4.00 Gm.	Acetone	Vacuum evaporation	No significant change	Heterogeneous light orange to deep yellow
Dye + acacia	100 mg.:4.00 Gm.	EtOH	Vacuum evaporation	Medium change	Heterogeneous light orange to intense orange
Lake + acacia	50 mg.:4.00 Gm.	EtOH	Vacuum evaporation	No significant change	Yellow to yellow
Dye + pectin	100 mg.:4.00 Gm.	Dil. EtOH (1:1)	Vacuum evaporation	Increased reflectance	Golden yellow to golden yellow

equipped with a rheostat dimmer and fan. The light intensity used throughout this study was 2,000 foot candles (f.c.) and the temperature within the cabinet was 32 ± 3°.

RESULTS AND DISCUSSION

Although it is generally acknowledged that the most common type of dye instability in pharmaceutical and cosmetic systems is due in part to light and thermal rearrangements, it is possible that some of these color changes occurring in solid dosage formulations may be due to dye–excipient interactions (1). During the past 10 years some attention has been given to color stability in pharmaceutical dosage forms (3, 4). A number of reports have appeared in the literature dealing with studies to elucidate the nature of this interaction, the effect of excipients with respect to fading, and methods employed to retard such an interaction (5–8). Since most of the reported investigations dealing with this dye–adjuvant interaction have been studied in solution, very little information is available concerning the degree of this interaction observed with diffuse reflectance techniques.

Since diffuse reflectance spectroscopy (DRS) has been shown to be a useful tool for interaction studies in the solid state (1), this technique was employed to further study dye–adjuvant interactions.

In this present study, various certified dyes were screened with a large group of adjuvants for the existence of such interactions. The dyes, FD&C Red No. 3, Blue No. 1, and Yellow No. 5, were selected either on the basis of their chemical structure, light instability, or use in pharmaceuticals. The adjuvants were chosen on the basis of the metal fraction or polyfunctional groups they contain (8) or because of their use in medicinal dosage forms.

As has been pointed out in previous communications (9–11) the adsorbate/adsorbent ratio must be carefully considered in order to observe these solid–solid interactions; if an excess of adsorbate is used, the monomolecular chemisorption occurring at the surface of the adsorbent is masked by subsequent

physical layers of the adsorbate, and the DRS spectrum approaches that of the pure dye under investigation. In this preliminary dye–adjuvant interaction study, 50 to 200 mg. of dye was used with 4.00 Gm. adjuvant samples. The controls, reported in Tables I and II, were prepared by physically mixing the dye with pre-equilibrated and vacuum dried adjuvants; the samples represent the result of equilibrating dye–adjuvant combinations in the designated equilibration media, followed by either vacuum evaporation of the solvent at room temperature or removal of the solvent by vacuum filtration, washing of this sample, and vacuum drying at about 35° for 24 hr.

An examination of the data reported in Tables I and II suggests that these dyes either undergo little interaction or that the dye–adjuvant ratio was such as to completely mask any effects due to chemisorption (unimolecular layer). The absorbance behavior of multilayers of the dye on these excipient particles becomes similar to that of the pure dye (1).

The spectral changes observed with Red No. 3 dye after equilibration with various adjuvants (see Table I) were small and correlate well with the lack of visual color changes observed. It is interesting to point out, however, that the spectral changes observed as a result of equilibrating Yellow No. 5 dye with starch or magnesium citrate did produce significant spectral and visual color changes at these high dye–adjuvant concentration ratios, suggesting chemisorption. Figure 1 illustrates this Yellow No. 5 dye–starch interaction. It is clearly seen that the absorbance and visual color change of the sample (see Table II) along with a new band formation at 315 mμ is indicative of a strong interaction. It is also interesting to note here that the interaction of the corresponding Yellow No. 5 lake with starch is much smaller, suggesting that a number of the adsorption sites are not available in the aluminum lake.

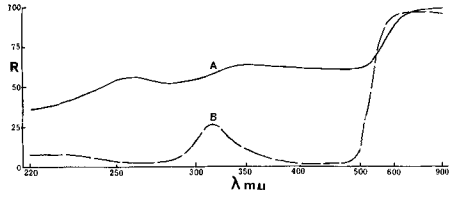

Fig. 1—DRS of FD&C Yellow No. 5 dye (100 mg.) and starch (4.00 Gm.). Key: A, *control;* B, *sample equilibrated in 30 ml. dilute ethanol (1:1).*

As has already been mentioned, spectral changes due to chemisorption are readily seen when a single layer of the dye is chemisorbed onto the surface of the adsorbent (8,9). Since the dye–adjuvant ratios employed in the initial phase of this investigation were high, these interactions were again studied, using lesser quantities of the dye. Dye concentrations of 30 mg./10.00 Gm. of adjuvant were found suitable in exhibiting this chemisorption effect.

In order that all experimental conditions be kept constant, the controls in this phase of study were prepared by separately equilibrating the dye and adjuvant in distilled water for a period of 24 hr., followed by lyophilization to remove the solvent media. The appropriate concentration of dye and adjuvant was then weighed and physically mixed by geometric dilution, and the diffuse reflectance spectrum (DRS) of this control was measured, using a magnesium carbonate reference standard. Interacted samples were prepared by placing a weighed amount of pre-lyophilized dye and adjuvant in a suitable container, adding distilled water, and equilibrating the mixture for 24 hr. This interacted sample was then lyophilized and triturated and its DRS was obtained. Although the degree of spectral change depends on both the dye and excipient under investigation, "no significant change," reported in the tables, will be defined as spectral intensity changes of 10 reflectance units (RU) or less. A "small change" will generally indicate intensity changes of 10–30 RU, whereas a "medium change" implies a spectral change of about 30–60 RU; a "large change" indicates hyperchromic changes of 60 or more reflectance units at the maximum wavelength. It is interesting to point out that the aqueous solvent serves as a dispersion medium in order to facilitate maximal interaction with the sites available. These interactions will also occur in the solid unequilibrated state in the presence of moisture (10).

Tables III, IV, and V summarize the data obtained in this study, using the structurally different certified Red No. 3, Blue No. 1, and Yellow No. 5 dyes. The spectral changes observed in these low dye concentration systems again correlate well with visual color changes observed. Typical interaction spectra of several Red No. 3–adjuvant systems are presented in Figs. 2–4. An examination of these figures certainly illustrates the high degree of interaction as evidenced by the large absorbance and other spectral differences of the equilibrated sample as compared with the control. The strength of these interactions with various adjuvants can also be demonstrated with the use of an elution technique. For example, the dye in the Red No. 3–$Al(OH)_3$ or Red No. 3–ZnO system exhibiting small or medium-sized spectral changes (Fig. 4) was readily eluted with water. In comparison, starch or $Mg(OH)_2$ interactions with this same dye, presented in Figs. 2 and 3, did not undergo significant spectral changes after the sample was washed with distilled water, indicating a stronger interaction.

It should be pointed out, however, that in spite of the fact that a dye can be readily desorbed from an excipient, indicating a relatively weaker adsorption, the interaction is nevertheless important since the color stability of the intact dosage form may be affected by this weaker interaction. In contrast, desorption of a medicinal agent from an adjuvant material is extremely important in that the therapeutic availability of this agent is directly related to this desorption phenomenon or chemical interaction.

The strength of these interactions was sometimes further correlated by subjecting the equilibrated sample to accelerated light fading conditions. For example it is seen that under these conditions, the color intensity of a Red No. 3–$Al(OH)_3$ equilibrated sample undergoes 61% increased reflectance. This change occurs at the $\lambda_{max.}$ after a 42-hr. exposure to 2,000 f.c. artificial light. On the other hand, the Red No. 3–$Mg(OH)_2$ equilibrated sample exhibits approximately 17% increased reflectance under the same conditions. This slower rate of fading or dye decomposition in the dye–$Mg(OH)_2$ system may be indicative of a stronger chemisorbed system. This is

TABLE III—FD&C RED NO. 3 DYE: DYE REACTIONS WITH PHARMACEUTICAL ADJUVANTS (CONCENTRATION: 30 mg. DYE/10.00 Gm. ADJUVANT)

Red No. 3 Dye + Adjuvant	Relative Size of Spectral Changes	Visual Color Changes (Control to Sample)	Effect of Washing Sample with 200 ml. Water	Sample Exposure to Artificial Light, 2,000 f.c.	
				42 hr.	184 hr.
$Al(OH)_3$	Small to medium change	Light pink to light pink	Eluted; spectrum approaches adjuvant	Increase of 21 RU or 61% fading[a]	Increase of 34 RU or 95% fading
$Ca(OH)_2$	Medium to large change	Light pink to pink	No elution	Increase of 16 RU or 22% fading	
$Mg(OH)_2$	Large change	Light pink to lavender	No elution	Increase of 12 RU or 17% fading	Increase of 29 RU or 41% fading
ZnO	Medium change	Faint pink to sharp pink	Eluted		
$ZnSO_4$	No significant change	Light pink to light pink			
Mg citrate	Small change	Pink to reddish-pink			
Citric acid	No significant change	Light pink to whitish pink			
Starch	Large change	Light pink to pink	No elution	Increase of 27 RU or 42% fading	Increase of 49 RU or 78% fading
Lactose	Medium change	Light pink to rosy red			Increase of 2 RU or 4% fading
Acacia	Small to medium change	Light pink to pink			

[a] % Sample fading at $\lambda_{max.} = \frac{R_{faded\ sample} - R_{sample}}{R_{control} - R_{sample}} \times 100.$

TABLE IV—FD&C BLUE NO. 1 DYE: DYE REACTIONS WITH PHARMACEUTICAL ADJUVANTS (CONCENTRATION: 30 mg. DYE/10.00 Gm. ADJUVANT)

Blue No. 1 Dye + Adjuvant	Relative Size of Spectral Changes	Visual Color Changes (Control to Sample)	Effect of Washing Sample with 200 ml. Water	Sample Exposure to 42 hr. Artificial Light at 2,000 f.c.
$Al(OH)_3$	Medium change	Powder blue to bluish-gray	Eluted	Increase of 14 RU or 31% fading
$Ca(OH)_2$	Medium change	Gray to light lavender	Eluted	Increase of 12 RU or 30% fading
$Mg(OH)_2$	Large change	Faint blue to deep blue	Little elution	Increase of 3 RU or 3% fading
ZnO	Medium to large change	Powder blue to blue	Eluted	
$ZnSO_4$	Large change	Light blue to sky blue		
Mg citrate	Large change	Light blue to dark blue-green		
Citric acid	No significant to small change	Light blue to powder blue		
Starch	Large change	Light blue to blue	Little elution	Increase of 1 RU or 1% fading
Lactose	Large change	Light blue to blue-green		
Acacia	Large change	Gray to deep blue		

TABLE V—FD&C YELLOW NO. 5 DYE: DYE REACTIONS WITH PHARMACEUTICAL ADJUVANTS (CONCENTRATION: 30 mg. DYE/10.00 Gm. ADJUVANT)

Yellow No. 5 Dye + Adjuvant	Relative Size of Spectral Changes	Visual Color Changes (Control to Sample)	Effect of Washing Sample with 200 ml. Water	Sample Exposure to 42 hr. Artificial Light at 2,000 f.c.
$Al(OH)_3$	Medium change	Off white to yellow	Eluted; spectrum approaches adjuvant	No significant change
$Ca(OH)_2$	Medium change	Off white to yellow	About $^2/_5$ eluted	Increase of 7 RU or 11% fading
$Mg(OH)_2$	Large change	Off white to golden yellow	No significant elution evident	No significant change
ZnO	Medium change	Off white to yellow	Eluted	
$ZnSO_4$	Medium change	Faint yellow to light orange-yellow		
Mg citrate	Large change	Faint yellow to canary yellow		
Citric acid	Small to medium change	Light pink to intense gold		
Starch	Large change	Faint yellow to darkish yellow	Little elution	No significant change
Lactose	Large change	White to deep yellow		
Acacia	Large change	Off white to bright yellow

clearly substantiated in the comparison of Blue No. 1 dye fading of starch and $Ca(OH)_2$ equilibrated samples presented in Figs. 5 and 6 and Table IV. These results indicate the Blue No. 1 fades about 1% in a dye–starch chemisorbed sample as compared to 30% fading in the dye–$Ca(OH)_2$ equilibrated sample, exposed to similar accelerated light conditions.

It is also interesting to note that although lactose shows comparable spectral interaction changes with the dyes to that of starch, its fading characteristics are somewhat different. For example, Fig. 7C, which represents an equilibrated Red No. 3–lactose system, shows little fading tendency even after 184-hr. exposure to artificial light at 2,000 f.c.; a Red No. 3–starch sample fades extensively under the same conditions, as illustrated in Fig. 3C. These differences show the complexity of these interactions and the need for individual dye–excipient study.

Although the structure of the dyes is quite different, suggesting different binding sites, it is nevertheless of interest to point out that the interaction obtained is dependent on both the dye and adjuvant employed. For example, Figs. 8 and 9 as well as Tables III, IV, and V illustrate that zinc sulfate reactions are markedly different with the dyes studied. Equilibration of this excipient with Red No. 3 dye, containing a sodium salt of a carboxyl group, but lacking phenylsulfonic acid functional groups,

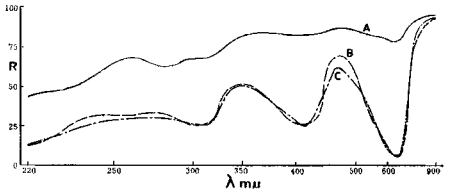

Fig. 5—DRS of FD&C Blue No. 1 (30 mg.) and starch (10.00 Gm.). Key: A, *control;* B, *sample;* C, *sample exposed to 42 hr. artificial light at 2,000 f.c.*

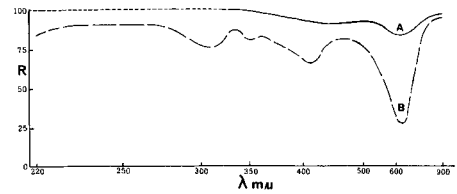

Fig. 9—DRS of FD&C Blue No. 1 dye (30 mg.) and zinc sulfate (10.00 Gm.). Key: A, *control;* B, *sample.*

found in the other two dyes under investigation, results in only very minor spectral changes, as seen in

Fig. 8. In contrast, $ZnSO_4$ does react to a large extent with Blue No. 1 dye, containing three phenylsulfonic acid groups, as well as with FD&C Yellow No. 5 which also contains a phenylsulfonic acid group, one carboxyl, and one hydroxyl functional group. These phenylsulfonic acid groups may therefore be involved in the observed chemisorption.

Furthermore, the same dye has been shown to react differently, depending on the excipient under investigation. For example, the strength of $Mg(OH)_2$, $Ca(OH)_2$, and $Al(OH)_3$ interaction with Yellow No. 5 dye is markedly different as observed in Figs. 10, 11, and 12, as well as Table V. An examination of these figures indicates that dye–$Mg(OH)_2$ equilibration facilitates a large decreased reflectance of about 74 units at the $\lambda_{max.}$ of 435 mμ as reported in Fig. 10B; the strength of this large interaction is further supported with the aid of elution studies presented in Fig. 10C. Although $Ca(OH)_2$ equilibration with this yellow dye does produce a 59 reflectance unit decrease at the $\lambda_{max.}$ of 410 mμ, seen in Fig. 11B and Table V, aqueous washing of this sample indicates that about 40% of the dye can be eluted. It is also interesting to point out that although Yellow No. 5 dye equilibration with $Al(OH)_3$ also produces a 47 reflectance unit decrease at the $\lambda_{max.}$ of 400 mμ, Fig. 12, this dye is eluted to a much greater extent from the surface of the adsorbent with aqueous washing of the sample. The above bathochromic and hyperchromic spectral changes again indicate that reactivity differences of the metallic ion present in these hydroxide adjuvants is $Mg^{2+} > Ca^{2+} > Al^{3+}$.

With regard to these interactions, although some systems may not exhibit visual color changes after equilibration, the spectral changes observed in the ultraviolet region may be significant in the photodecomposition of a particular dye.

CONCLUSION

The data presented here indicate that the "inert" materials, including starch, lactose, and acacia, do undergo significant interactions with the dyes investigated. Furthermore, various metal-containing adjuvants also chemisorb with certified dyes; the order of chemisorption capacity of the metallic adjuvants with certified dyes was as follows: $Mg^{2+} > Ca^{2+} > Zn^{2+} \backsim Al^{3+}$. These dye–adjuvant interactions may be responsible for the various color problems encountered in solid pharmaceutical formulations.

It appears that the mechanism involved in these interactions is a combination of a chelation type of interaction and one of chemisorption. This is particularly true where the excipient material does not undergo ionization. It is apparent that these solid–solid interactions are of importance, not only in drug–adjuvant studies, but also in the investigation of color and drug stability.

These studies and those previously conducted with respect to drug–excipient interactions point out the need for incompatibility studies of drug or dye–adjuvant interactions in conjunction with other considerations in the formulation of pharmaceuticals.

Effect of Preservatives on the Heat Sterilization of Sesame Oil

By ROBERT L. ROBISON* and MELVIN H. WEINSWIG†

There is little information available concerning heat sterilization of oils containing antibacterial agents. Two species of thermoresistant bacterial spores, *B. subtilis* and *B. stearothermophilus,* were used as positive controls to determine requirements for the dry heat sterilization of sesame oil containing 0.5 per cent phenol and 2 per cent benzyl alcohol. Sesame oil, polyethylene glycol (PEG), and air controls were also studied. Spores were impregnated on filter disks, dried, and sterilized in oil. Data were collected in the range of 100–160° at 0.5-hr. intervals to 2 hr. Phenol significantly reduced the sterilization requirements for *B. subtilis;* benzyl alcohol gave variable results. Controls survived higher temperatures in air than in oils. The sterilization requirements for *B. stearothermophilus* were not altered by the presence of phenol or benzyl alcohol. Sterilization in oils required higher temperatures than in air. Spores of both organisms were killed at lower temperatures in PEG than in the oils.

THE VIEW is widely held that most antibacterial agents have limited activity in anhydrous systems. Under normal conditions and within the context of the usage of preservative agents in oil vehicle injectables, there is ample evidence to support the premise that preservative agents are, indeed, ineffective if water is absent (1, 2).

Injectable grade fixed vegetable oils are normally anhydrous or contain only traces of moisture and it is unlikely that any currently acceptable parenteral preservative is of value in the usual sense unless microbial contamination is introduced into an ampul in a moist condition. The effectiveness of the preservative agent would be dependent upon its transfer from the oil to the aqueous phase where it would exert an effect if time and concentration values were adequate (3).

In an aqueous medium, the activity of antibacterial agents generally increases with rises in temperature. This increased activity is utilized in the sterilization process known as "heating with a bactericide" (4).

There is little information relating to the activity of antibacterial agents in oils at higher temperatures. This is probably due to the reported ineffectiveness of preservatives in oils which have been tested at ambient temperatures.

In reference to the sterilization of nonaqueous injections, the U.S.P. (5) states "non-aqueous injections in sealed containers may fail to be sterilized if the customary temperature and time are used, since in the absence of water vapor within the container the processing is only the equivalent of dry heat sterilization. Processing of such solutions must be accomplished by heating at higher temperatures in a dry heat sterilizer, the cycle being dependent upon the stability of the particular solution. The process should be selected only on the basis of previously demonstrated ability to sterilize representative samples of such products which have been inoculated with thermoresistant spores." The U.S.P. indicates that 2 hr. at 160° is a suitable dry heat sterilization cycle.

The requirements for the dry heat sterilization of injectable oils have not been studied extensively. Pasquale *et al.* (6) determined the time and temperature requirements for the sterilization of unpreserved vegetable oils inoculated with the spores of 3 species of aerobic bacilli and found that the requirements varied both with the species and the oils used. The maximum survival time observed was for *B. subtilis* in sesame oil and in corn oil, being 2 hr. at 150°. Perkins (7) recommends that oils be sterilized by heating for 2 hr. at 160°, the timing to start after the oil has reached full sterilization temperature. The B. P. recommends oils be sterilized by holding for 1 hr. at 150° (4).

It was the purpose of this investigation to determine if two commonly used preservatives would lower the time and temperature requirements for the dry heat sterilization of a commonly used injectable oil containing thermoresistant spores.

Received April 14, 1967, from the †College of Pharmacy, Butler University, Indianapolis, IN 46207, and the *Lilly Research Laboratories, Indianapolis, IN 46206

Accepted for publication July 17, 1967.

Presented to the Basic Pharmaceutics Section, A.PH.A. Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

Abstracted from a thesis prepared by Robert L. Robison for the Graduate School, Butler University, in partial fulfillment of Master of Science degree requirements.

The authors are indebted to the Lilly Research Laboratories for generously supplying materials and facilities for this investigation. The authors express their appreciation to Dr. H. Allisbaugh, Eli Lilly and Co., and to Mr. R. J. Russomanno, Hoffmann-LaRoche, Inc., for the spore cultures. Special gratitude is expressed to Mr. R. P. Roman and to Dr. H. Campbell, Jr., Eli Lilly and Co., for their valued advice and technical assistance.

EXPERIMENTAL

Equipment—A circulating hot air oven[1] was used for all dry heat sterilization tests. The temperature of the oil was monitored with a battery operated potentiometer[2] with copper-constantan thermocouples.

Materials—Sesame oil U.S.P.,[3] polyethylene glycol 300,[4] polyethylene glycol 400,[5] phenol reagent, and benzyl alcohol reagent.

Organisms—A preliminary series of experiments was conducted to obtain data on the dry heat resistance characteristics of five strains of nonpathogenic aerobic bacilli. Four strains of mesophilic spore formers and a thermophilic strain were evaluated.

Mesophiles—Three strains of *Bacillus subtilis* and one strain of *Bacillus cereus* were obtained from the following sources: a spore suspension of *B. subtilis* from Dr. H. Allisbaugh, Eli Lilly and Co. (HA), a lyophilized spore culture of *B. subtilis* from Mr. R. Russomanno, Hoffmann-LaRoche, Inc. (HL), a lyophilized spore culture of *B. subtilis* (ATCC 9372), and a spore suspension of *B. cereus* (ATCC 13061) from Mr. R. P. Roman, Eli Lilly and Co. The spore suspensions were used as received. The lyophilized cultures were inoculated into media to grow a suitable number of spores for the study.

Thermophile—*Bacillus stearothermophilus* was obtained by culturing a commercial autoclave control[6] which contained spores of this organism. The strain has been identified in the literature as NIH No. 7953 (8).

Growth and Harvest of Spores—*Mesophiles*—The *B. subtilis* (HL) lyophilized culture was inoculated into fluid thioglycollate medium U.S.P. (BBL) from which a 24-hr. culture was transferred to nutrient agar and held 7 days at 30–32°. The agar culture was then held at room temperature for 1 week during which sporulation became nearly complete. A spore suspension was prepared by washing off the growth with normal saline. The suspension was heated in a water bath at 80° for 15 min. to kill any vegetative cells remaining. A count by the most probable number (MPN) method (9) in fluid thioglycollate indicated 240 million viable spores per ml.

A 20-day-old fluid thioglycollate culture of *B. subtilis* (ATCC 9372) was harvested by centrifuging and resuspending three times in sterile distilled water. The suspension which contained approximately 60% spores was heated for 15 min. at 80° to kill the remaining vegetative cells. The MPN count in fluid thioglycollate was approximately 70 million viable spores per ml.

Thermophile—*B. stearothermophilus* spore strips were transferred into fluid thioglycollate and incubated for 48 hr. at 60°. The growth was harvested by centrifuging and washing three times with distilled water. The cell suspension which was comprised mostly of vegetative cells with a low percentage of spores was boiled 30 min. in a water bath. An inoculum from the heated suspension was then transferred two times in fluid thioglycollate followed each time by centrifuging, washing, and heating the cell suspension as before. The percentage of sporulation increased with each subculture and was approximately 50% on the third transfer. This procedure seemed to produce more synchronous sporulation and uniform morphology than other methods investigated and was perhaps a variant selective mechanism. Water replacement techniques (10) followed by agitation on a rotary shaker were unsuccessful as there was a marked tendency for this procedure to produce variable spore forms with low viable counts.

Preparation of Spore Disks—One-half inch filter paper disks[7] were sterilized by heating overnight at 105°. The sterile disks were then impregnated with appropriate dilutions of the spore suspensions using a 0.1-ml. capillary pipet. The disks were impregnated in a sterile enclosed stainless steel hood to prevent incidental air-borne contamination of the disks. They were then stored over silica gel in a desiccator for a minimum of 48 hr. prior to initial heat resistance studies.

Initial Resistance Studies—*Mesophiles*—Dried spore disks were placed in screw-cap bottles and heated in the preheated oven at 130° in 0.5-hr. increments to 2 hr. Disks were removed at the designated intervals and tested for growth in fluid thioglycollate medium U.S.P.

The results as shown in Table I indicated disks prepared from the *B. subtilis* (HL) and ATCC 9372 strains were the most resistant to dry heat.

Further evaluation of *B. subtilis* (HL) and *B. subtilis* ATCC 9372 indicated that the ATCC 9372 strain was somewhat more resistant. When drying was extended to 6 days the spores of ATCC 9372 survived 2 hr. at 130° while the spores of *B. subtilis* (HL) became less heat resistant. Results in tests described later show even greater resistance for the ATCC 9372 strain.

Initial Resistance Studies—*Thermophile*—The freshly harvested spore suspension of *B. stearothermophilus* was heated in a boiling water bath for 1 hr. to kill vegetative cells. The viable count by the MPN method was approximately 3,500,000 spores per ml. Dilutions of this stock suspension were made for the preparation of the disks.

A series of experiments were conducted with the spore disks to determine the proper load, the effect of drying on the resistance, and a suitable recovery medium for the spores of *B. stearothermophilus*. Since the spores of this organism are primarily used as an autoclave control, it was thought that it would also be of interest to compare its relative resistance to moist and dry heat.

Preliminary studies were conducted with disks containing approximately 50,000 spores each. In the initial experiment, the disks were dried for 2 days before testing for heat resistance and were cultured in fluid thioglycollate only. A second experiment was conducted with disks that had been dried for 6 days. Fluid thioglycollate with and without the addition of 0.1% soluble starch were used as recovery media.

TABLE III—EFFECT OF DRYING ON RESISTANCE IN DRY HEAT
(*B. stearothermophilus*, 50,000 SPORES/DISK)

Days[a] Dried	Culture Medium	Time, min. at 130°C. Dry Heat 0	15	30	45	60	75	90
2	FT[c]	2/2[b]	1/2	0/2	0/2	0/2	0/2	0/2
6	FT	2/2	2/2	1/2	0/2	0/2	0/2	0/2
	FTS[d]	2/2	2/2	2/2	0/2	0/2	0/2	0/2

[a] Dried over silica gel. [b] 2/2, number of tubes with growth/number of tubes inoculated with disks. [c] Fluid thioglycollate medium. [d] Fluid thioglycollate medium plus 0.1% soluble starch. Incubated 4 days at 60°C.

The results as shown in Tables II and III indicated that additional drying had caused a significant increase in resistance, especially to dry heat. The slight increase in recovery of dry heated spores in fluid thioglycollate containing soluble starch was not considered significant because of the very limited number of disks tested at each temperature. The initial results demonstrated that the spore was inadequate and that a heavier load should be used in subsequent studies.

The composition of the recovery medium has an important influence on the germination and outgrowth of bacterial spores and thus will affect resistance values. This is particularly so if the spores have been damaged in some way such as by heat or chemicals since damaged cells may become fastidious and require specialized media (11). It was believed the reliability of the results would be improved if additional media were evaluated for the recovery of *B. stearothermophilus*. The U.S.P calls for the use of fluid thioglycollate medium in the official sterility test; however, the literature suggests that the inclusion of soluble starch or phytone in the medium might improve the recovery of heat damaged spores of *B. stearothermophilus* (8, 12–14). The three media evaluated to determine a suitable recovery medium were: fluid thioglycollate medium, fluid thioglycollate plus 0.1% soluble starch, formulated phytone–starch medium containing phytone peptone 1.5%, trypticase peptone 1.0%, dextrose 0.5%, soluble starch 0.1%, sodium chloride 0.15%, pH adjusted to 7.2.

Disks containing approximately 100,000 spores each were used to determine the effect of the increased spore load and to compare the three media. The results, as shown in Tables IV and V, indicated greater resistance from the heavier spore load and improved recovery with the fluid thioglycollate containing soluble starch. Growth by visual inspection was essentially the same with fluid thioglycollate medium with or without starch and was somewhat greater than with the phytone–starch medium. Visible growth occurred sooner, however, with the phytone–starch medium than with either of the thioglycollate media. The recovery after dry heat was slightly greater in fluid thioglycollate with starch than in the phytone–starch medium. Both media gave appreciably better recovery than the fluid thioglycollate without starch.

The fluid thioglycollate with soluble starch also gave the best recovery after steam heat. The phytone–starch medium showed a definite tendency toward incomplete recovery after sublethal time intervals in steam heat. These results tend to support the theory that moist and dry heat kill or damage bacteria by different mechanisms (15). It has been suggested that starch has an adsorption effect on substances in the medium that repress spore germination (16).

Oil Sterilization—Dried spore disks were inserted into 10 ml. size ampuls, filled with 5 ml. oil, and flame sealed. Oil sections included 10 ampuls each of sesame oil, sesame oil containing 0.5% phenol, and sesame oil containing 2% benzyl alcohol. Controls consisted of spore disks in PEG 300 and in air. The sealed ampuls were placed into the pre-

heated oven at the designated temperature plus a 2° override to reduce the decrease in the rate of heat uptake that occurs as the temperature approaches final temperature. The controller was reset after the oil reached the designated temperature. The oil temperature was determined with a potentiometer which was connected to a thermocouple placed in an identical ampul containing 5 ml. sesame oil. The time required to reach the designated temperature (lag time) as well as the temperature during the run was monitored each time. The temperature range was from 100 to 160° in 10° increments. Ampuls were removed at 0.5, 1, 1.5, and 2 hr. after the oil reached temperature. The lag time of the oil varied only slightly from run to run, regardless of the sterilization temperature, ranging from a low of 45 min. to a high of 55 min.

Sterility Testing—Sterility tests were performed within 12 hr. of the time of sterilization. The ampuls were wiped with 5% phenol, flamed and broken open, and the oil allowed to drain. The disks were then aseptically removed with sterile-flamed tweezers, tapped lightly to remove excess oil, and transferred into fluid culture medium in 30 × 165 mm. tubes. The *B. subtilis* disks were tested in fluid thioglycollate medium U.S.P. Incubation was for 14 days at 30–32°. The *B. stearothermophilus* disks were tested in fluid thioglycollate medium containing 0.1% soluble starch. Incubation was for 4 days at 60–62°.

The tubes, which contained approximately 40 ml. of medium, were shaken vigorously by hand at the time the disks were placed on test and at periodic intervals throughout the incubation periods to disperse oil remaining on the disks and to effect transfer of the spores to the aqueous media.

RESULTS AND DISCUSSION

B. subtilis ATCC 9372—Interpretation of the results obtained with *B. subtilis* was complicated initially by a change in resistance that occurred during the approximately 5-week period in which the first series of oil tests was conducted. In the preliminary heat resistance studies, disks containing approximately 110,000 spores, which were dried for 2 days over silica gel prior to use, had a maximum resistance of 1.5 hr. at 130° in air. Disks that had been dried for 6 days were used for the initial oil sterilization at 130°. Ten disks per each time increment were included as air controls. The survival in air at this sterilization temperature was 2 hr., with nine of ten disks producing growth when cultured. Although this represented a change in resistance, the magnitude of the change was not recognized until later tests were conducted at 140°. With the first tests at 130° completed, it appeared that the preservatives had caused a decrease in the sterilization time and that the spores would survive less time in the oils or PEG 300 than in air.

As tests were conducted at the other temperatures designated for the study a rather irregular pattern of sterilization results emerged. Spores that initially survived only 1 hr. at 130° in sesame oil later survived 1 hr. at 140°. Spores that had been sterilized in 1.5 hr. at 120° in sesame oil with 2% benzyl alcohol later were not sterilized after 2 hr. at 130°. The 4 days additional drying perhaps accounted for the increased resistance first observed in air at 130°. The spore disks, however, continued to show changes in resistance which could not be related to drying of the disks as they had been stored in sealed jars after 6 days drying over silica gel.

It was noted that while sterilization in unpreserved sesame oil required 1.5 hr. at 130° and later 1.5 hr. at 140°, sterilization in sesame oil with benzyl alcohol had shown "skips" at 130° with minimal but definite survival at 140°. Repeat tests were then conducted in the range of the critical sterilization and sublethal temperatures and a quite different pattern of resistance was seen, especially as regarded the sections with benzyl alcohol in sesame oil.

The results obtained on spore disks less than 5 weeks of age are shown in Table VI. On the basis of these results alone, and relating the one survivor out of ten after 0.5 hr. at 140° to an extremely resistant spore, it would have been enticing to conclude that both the preservatives tested had a definite lowering effect on the sterilization requirements for sesame oil. Data acquired using spore disks which were aged more than 5 weeks showed that this was not the case with benzyl alcohol. The repeat tests indicated that the spores had an increased resistance to the action of benzyl alcohol but not to phenol.

The data in Table VII were extracted from all the *B. subtilis* test results without regard to the age of the spores, and represent the maximum resistance observed with each of the sterilization vehicles.

The results, although they do not help explain

why, point to a possible difference in mechanism of phenol and benzyl alcohol or to different mechanisms of spore resistance to the activity of the preservatives. It would also suggest that the resistance mechanism may be age dependent. Although there was no additional drying of the spore disks beyond 6 days, it is possible that a further loss in spore moisture content took place by equilibration with the disk material. If this hypothesis were accepted, then it could be suggested that the benzyl alcohol activity was dependent upon the moisture content of the spores whereas phenol activity was not dependent on moisture.

Additional tests were conducted at irregular intervals over a 8-month period with essentially the same findings, *i.e.*, aged spores continued to be resistant to benzyl alcohol but not to phenol.

Relation of Phenol Activity to Vehicle—Additional tests were run with another lot of sesame oil and mineral oil since earlier results indicated that phenol markedly reduced the sterilization requirements for sesame oil containing spores of *B. subtilis*. Although these tests were conducted at only limited time and temperature ranges, the results point out the significant effect of the vehicle on the resistance of the spores and the effect of the vehicle on the preservative action. The results as shown in Table VIII indicate that the resistance of the spores was about 10° greater in light mineral oil than in sesame oil and that phenol exerts less effect in mineral oil than in sesame oil. The results obtained with the second lot of sesame oil did not vary appreciably from those of the first lot.

Effect of Drying on Resistance of B. subtilis to Benzyl Alcohol—A second batch of spore disks was prepared from the original *B. subtilis* spore suspension. The MPN count on the suspension, which was

[a] Time after reaching designated temperature, dry heat. [b] 10/10, number of tubes with growth/number of tubes inoculated with disks. [c] Original lot of sesame oil. [d] A second lot of sesame oil. Fluid thioglycollate medium incubated 14 days at 30–32°C.

3 months old, was approximately 80 million per ml. and was considered to have shown no significant change. The disks were prepared to contain 200,000 spores each. They were then stored in a tightly sealed can over silica gel for 10 days, after which disks were removed and heated in sesame oil with 2% benzyl alcohol at 130° for periods of 0.5 and 1 hr. This procedure was repeated again after 20, 30, and 90 days of drying. The results in Table IX showed a similar trend to those obtained with the earlier batch (Tables VI and VII). However, the degree of maximum resistance during the 3-month drying interval was not so great as when the disks were dried only 6 days. These results did not clarify the relationship of age and degree of desiccation to resistance but they did confirm the same general pattern of increased resistance developing with time.

TABLE IX—EFFECT OF DRYING ON RESISTANCE OF *B. subtilis* SPORES IN SESAME OIL WITH 2% BENZYL ALCOHOL (200,000 SPORES/DISK)

Days Dried[a]	Time, hr. at 130°C. Dry Heat 0.5	1.0

90	6/10	5/10

[a] Dried over silica gel. [b] 2/10, number of tubes with growth/number of tubes inoculated with disks. Fluid thioglycollate medium incubated 14 days at 30–32°C.

B. stearothermophilus—Disks containing approximately 100,000 spores each were held over silica gel for 6 to 8 days and then used for the sterilization tests. As shown in Table X the maximum survival of *B. stearothermophilus* spores in air was 1.5 hr. at 130°. The maximum survival time in oil occurred in unpreserved sesame oil, being 1 hr. at 150° or 2 hr. at 140°. This increased resistance in sesame oil indicated the oil protected slightly against the effects of heat. Based on the maximum survival temperature alone, it would appear that benzyl alcohol and phenol caused a slight reduction in the sterilization requirements. Comparison of the results obtained with sublethal time intervals in the 130° and 140° temperature range, however, indicated neither 0.5% phenol nor 2% benzyl alcohol had any effect on the survival or death of the spores. In a repeat of the sterilization at 150°, there were no survivors in any of the oil sections and repeat tests at 140° did not give evidence of the preservatives having any effect. It would be tenuous, indeed, to relate any activity to the preservatives even though there was a slight increase in survival observed in the initial sterilization test of unpreserved oil at 150°. Sterilization of spores of *B. stearothermophilus* in PEG 300 occurred at significantly lower temperatures than in oil or air.

[a] Time after sesame oil reached designated temperature. Air controls not corrected for difference in lag time between oil and air. [b] 2/2, number of tubes with growth/number of tubes inoculated with disks. Fluid thioglycollate medium with 0.1% soluble starch incubated 4 days at 60°C.

Minimum Inhibitory Level of Phenol in Aqueous Media—Phenol was added to fluid thioglycollate in concentrations ranging from 1:1200 to 1:600. The tubes were then inoculated with dried spore disks of *B. subtilis* and *B. stearothermophilus* containing 110,000 and 100,000 spores, respectively. Growth of *B. subtilis* occurred with 1:1000 but not with 1:900 phenol. Growth of *B. stearothermophilus* occurred with 1:800 but not with 1:700 phenol.

The *B. subtilis* spores used in the oil sterilization study were killed at lower temperatures in oil containing phenol than in oil alone while the *B. stearothermophilus* spores were not significantly affected by phenol under the conditions of the test. The *B. stearothermophilus* was more resistant to phenol than the *B. subtilis* in aqueous media. This suggests a possible reason why phenol in oil did not reduce the sterilization requirements for *B. stearothermophilus*.

Polyethylene Glycol for Oil Sterilization Control—It has been reported that oils containing only a few spores will frequently pass the sterility test by the U.S.P. method of direct inoculation because the spores may not transfer from the oil to the aqueous medium. It has been suggested that spores be placed in a water miscible nonaqueous liquid such as polyethylene glycol (PEG) and that containers of spores in this vehicle be placed in the oven when sterilizing oils (17). After sterilization, the spore controls in the PEG are tested for sterility by the regular U.S.P. method. Since the vehicle is miscible with water, it will mix readily with the culture medium and any spores not killed will be detected. The results in this series of experiments did not substantiate that this is a satisfactory means of gauging the adequacy of an oil sterilization cycle.

One lot of PEG 300 was used throughout the initial series of oil sterilizations. Two additional lots of PEG 300 and 2 lots of PEG 400 were subsequently used in sterilization tests at 110° and 120°. PEG 300 gave results similar to those obtained in the earlier tests. PEG 400 caused nearly as great a reduction in the sterilization requirements as the PEG 300. The results in these tests confirmed that the combined effect of heat and polyethylene glycol is a marked reduction in sterilization time when compared to that in either oil or air.

SUMMARY

The spores of two thermoresistant species of nonpathogenic aerobic bacilli were heated in preserved sesame oil to determine the effect of the preservatives on the time and temperature requirements for dry heat sterilization.

B. subtilis ATCC 9372 and *B. stearothermophilus*, mesophilic and thermophilic species, respectively, were selected as test organisms. Spores of these organisms were impregnated on filter disks and heated in (*a*) sesame oil, (*b*) sesame oil with 0.5% phenol, (*c*) sesame oil with 2% benzyl alcohol, (*d*) PEG 300, and (*e*) air. Additional comparisons were made with mineral oil and PEG 400. Data were collected in the range of 100–160° in 10° increments at 0.5 hr. intervals to 2 hr.

The *B. subtilis* spores survived 2 hr. at 140° in air. The requirements for sterilization in the sesame oil and PEG 300 were lower than in air. Maximum survival time in unpreserved sesame oil was 1 hr. at 140°. The maximum survival time in sesame oil with 0.5% phenol was 2 hr. at 110°. Benzyl alcohol gave variable results which were related to an increase in resistance of the spores. It had only minimal effect against aged spores. Mineral oil required higher temperatures for sterilization than sesame oil. Phenol had less effect in mineral oil than in sesame oil.

The *B. stearothermophilus* spores survived 1.5 hr. at 130° in air. Higher temperatures were required for sterilization of the oils. There was limited survival after 1 hr. at 150° in unpreserved sesame oil. Sesame oil containing phenol and benzyl alcohol showed no survivors at 150°. Review of the survival data at sublethal temperatures as well as repeat tests indicated no significant effect from phenol or benzyl alcohol.

The spores of both organisms were killed at lower temperatures in PEG 300 than in oil. PEG 400 gave similar results.

The results of this study do not lead to any overall generalizations regarding the effect of preservatives on the heat sterilization of oils. It would appear, however, that phenol would have a wider application and would be more effective than benzyl alcohol as an injectable oil preservative.

Hydrolytic Behavior of Isoalloxazines Related to Riboflavin III

Covalent Hydration of 1,2-Dihydro-1-methyl-2-oxo-quinoxaline-3-carboxyureide

By DAVID E. GUTTMAN and THOMAS E. PLATEK

Previous studies concerned with the base-catalyzed degradation of 9-methylisoalloxazine led to the isolation of an intermediate which was reported to be an alloxan anil. The identification was based on comparing the properties of the isolated compound with those of what was thought to be authentic anil prepared by reacting *o*-methylaminoaniline with alloxan. Evidence has been obtained to indicate that an incorrect structure assignment was made and that the so-called anil is a compound which resulted from the covalent hydration of 1,2-dihydro-1-methyl-2-oxo-quinoxaline-3-carboxyureide. The hydrate is apparently formed by the addition of water across the double bond between N_4 and C_3 of the quinoxaline compound. It was found that in acid media, anhydrous and hydrated species coexisted in equilibrium while in neutral media, very little anhydrous form was detectable. The kinetics of attainment of equilibrium were studied at a number of different hydrogen-ion concentrations. Rate constants for forward and reverse reactions were determined. The influence of temperature on the rates of hydration and dehydration and on the equilibrium constant was also investigated.

RECENT PUBLICATIONS from this laboratory (1, 2) described the results of studies concerned with the base-catalyzed degradation of 9-methylisoalloxazine (I). It was reported that a white crystalline material was isolated from partially degraded solutions of the isoalloxazine and that the compound could undergo further reaction in basic solution to yield products which were identified as 1,2,3,4-tetrahydro-1-methyl-2,3-dioxoquinoxaline (II) and 1,2-dihydro-1-methyl-2-oxo-quinoxaline-3-carboxylic acid (III). The properties and behaviors of the isolated material were shown to be identical to those exhibited by a product formed by the reaction in neutral medium of alloxan and *o*-methylaminoaniline and reported in the literature (3, 4) to be the alloxan anil (IV). This report will present evidence to suggest that the compound formed as an intermediate in the base-catalyzed decomposition of 9-methylisoalloxazine and which can be synthesized by the reaction of alloxan with *o*-methylaminoaniline is not the anil (IV), as previously suggested, but rather a product (VI) which is formed through the covalent hydration of the double bond between N_4 and C_3 of 1,2-dihydro-1-methyl-2-oxo-quinoxaline-3-carboxyureide (V). Accepted for publication June 28, 1967.

Presented to the Basic Pharmaceutics Section, A.PH.A. Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

Previous paper: Wadke, D. A., and Guttman, D. E., *J. Pharm. Sci.*, **55**, 1363(1966).

King and Clark-Lewis (5, 6) and Clark-Lewis (7) have previously questioned the existence of alloxan anils such as IV. They reported that the condensation of *o*-methylaminoaniline with alloxan in neutral medium yielded a yellow crystalline compound with a characteristic spectrum which was identified as the ureide (V). That a white crystalline compound can also form under similar reaction conditions was not discussed by these authors. They did, however, refer to the work of Rudy and Majer (8) who obtained, from the reaction of 2-alkylamino-3-amino-pyridines with alloxan, two series of products, one yellow and unstable and the other colorless. The two different products were found to be interconvertible.

A number of considerations support the suggestion that the white compound in question is the covalent hydrate VI. These include: (*a*) the formation of products II and III can be readily explained on the basis of structure VI; (*b*) the compound on heating is converted to a yellow material with chromatographic and spectral characteristics of the ureide (V); (*c*) the equivalent weight of the compound, as determined by nonaqueous titration, corresponds to that of the hydrate (VI); (*d*) the ureide (V) in acidic and neutral media undergoes a rapid transformation to form a compound with spectral and chromatographic characteristics which are identical to those of the compound in question. Similarly, treatment of the latter compound with acid results in the formation of an equilibrium mixture composed of starting compound and ureide. Such facile transformations are readily explainable on the basis of a hydration–dehydration phenomenon.

The kinetics of the transformations described above were studied in some detail and, as will be seen, were found to be consistent with an acid-base catalyzed reversible covalent hydration.

RESULTS

Two different products were obtained when alloxan and *o*-methylaminoaniline were allowed to react in neutral alcoholic medium under slightly different conditions. One was the ureide (V) which is a yellow crystalline compound with the characteristic spectrum shown in Fig. 1. The other was a white crystalline compound which exhibited a much different spectrum, which is also shown in Fig. 1. This product, when heated above 100°, was converted to the ureide (V). The results of elemental analysis (C, 52.22%; H, 4.77%; N, 21.70%; O, 21.31%) were not consistent with structures IV (C, 43.6%; H, 4.10%; N, 22.8%; O, 19.5%) or VI (C, 50.0%; H, 4.58%; N, 21.20%; O, 24.2%) but were intermediate to the two possibilities. Equivalent weight determinations by nonaqueous titration yielded an average value of 265 which agreed with structure VI (theory 264). The white compound, in subsequent discussions, will be referred to as compound VI and the yellow compound as the ureide.

The spectrum of the ureide in essentially aqueous medium, buffered in the neutral range of pH, was found to rapidly change with time. The resulting spectrum appeared to be the composite of two spectra, that of the ureide and compound VI. Thin-layer chromatography showed the presence in such solutions of two components, a minor amount of ureide and a major amount of compound VI. The results suggested that an equilibrium was established between the two compounds. The differences in the spectral characteristics between the two were used to follow the kinetics of equilibration. A wavelength of 380 mμ was used for this purpose and a typical result is shown in Fig. 2. Two different data plots are contained in this figure. Decrease in absorbance as a function of time is shown by the open circles. The closed circles represent a plot of log $(A - A_\infty)$ *versus* time, where A is absorbance at time, t, and A_∞ is the constant absorbance value which was finally attained. The function $(A - A_\infty)$ reflects the concentration of ureide and the plot thus demonstrates that the rate of equilibration was first order with respect to ureide. The results of studies conducted at a number of different pH values are presented in Table I and Fig. 3. The A_∞ values shown in the table indicate that the equilibrium position was essentially independent of pH and that the equilibrium concentration of ureide was small. The plot of Fig. 3 yielded a slope of 1.03 and shows that the rate of attainment of equilibrium

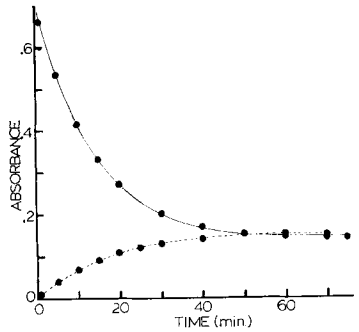

Fig. 4—A plot showing the time-dependent decrease in absorbance at 380 mμ for a 1.22 × 10^{-4} M solution of the ureide (V) (——) and the time-dependent increase in absorbance at 380 mμ for a 1.22 × 10^{-4} M solution of compound VI (– – –). The acid concentration was 0.58 N, μ = 1.0, T = 30°, and the solutions contained 2% dimethylformamide.

was first order with respect to hydroxide ion. The tabulated rate constants characterize rates of equilibration and are, therefore, sums of forward (k_f) and reverse (k_r) rate constants. The low equilibrium concentration of ureide precluded the accurate determination of an equilibrium constant and of the individual constants, k_f and k_r.

A similar transformation of the ureide, manifested by a loss of absorbance at 380 mμ, was observed in acidic media. Treatment of compound VI with acid, in contrast, resulted in a time-dependent generation of a 380 mμ absorbing species. A typical result is shown in Fig. 4 where absorbance loss of a ureide-containing system and absorbance gain of a compound VI-containing system are plotted as a function of time. It is seen that, within experimental error, the same asymptotic absorbance value was approached by the two systems. Thin-layer chromatography of equilibrated solutions confirmed the presence of two components, the ureide and compound VI. Both solutions on long standing exhibited a gradual increase in absorbance at 380 mμ. Spectrophotometric and chromatographic examination of aged solutions indicated the formation of the ketocarboxylic acid (III) which has significant absorbance at 380 mμ. The semilog plots of Fig. 5 show that the rate of equilibration was first order with respect to starting compound. The rate of attainment of equilibrium was studied at a number of different acid concentrations and from both directions. In all cases, a first-order approach to equilibrium was observed. Rate constants and A_∞ values are tabulated in Table II for systems in which the ureide was the starting material and in Table III for systems in which compound VI was the starting material. The results obtained with ureide systems are considered to be more accurate than those of the compound VI systems. A much lower concentration of ureide could be used to generate absorbance *versus* time plots. The compound VI systems were, by necessity, more concentrated and more susceptible to error because of the slow side-reaction which resulted in the formation of another compound which absorbed at 380 mμ.

It is seen from both tables that the rate of equilibration was first order with respect to the concentration of hydrogen ion, that the equilibrium absorbance value was independent of the concentration of hydrogen ion, and that at a particular concentration of hydrogen ion, essentially the same rate constant was obtained regardless of whether the starting material was ureide or compound VI.

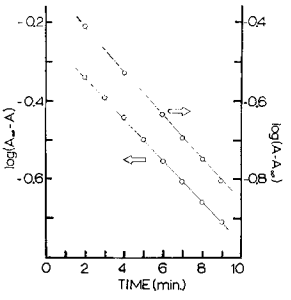

Fig. 5—A plot showing appearance (A$_\infty$ − A) of 380 mμ absorbing species in solutions of compound VI and disappearance (A − A$_\infty$) of 380 mμ absorbing species from solutions of the ureide (V). The acid concentration was 0.58 N, μ = 1.0, T = 35°. The initial concentration of VI was 6 × 10^{-4} M. The initial concentration of V was 1.22 × 10^{-4} M. The solutions contained 2% dimethylformamide.

0.98	0.630	0.209
0.58	0.620	0.120
0.195	0.620	0.0403
0.097	0.600	0.0204

[a] Temperature, 35°; μ, 1. The initial concentration of compound VI was 6.00×10^{-4} *M*. The solutions contained 4% dimethylformamide.

Equilibrium constants describing the ureide–compound VI interconversion could be calculated with reasonable accuracy from the data obtained with systems in which the ureide was the starting material. Here, the molar absorptivity of the ureide was calculated from absorbance values which were obtained by extrapolating the semilog plots to zero time. The concentration of ureide at equilibrium was then calculated from the observed A_∞ value. The concentration of compound VI was obtained by difference between initial and final concentrations of ureide. The molar absorptivity was found to be independent of temperature and to have a value of 5750 (average of 11 determinations). The kinetics of ureide transformation was studied in 0.58 *N* hydrochloric acid at three different temperatures. Rate constants and equilibrium constants are presented in Table IV. As expected an increase in temperature resulted in an increase in the equilibrium concentration of ureide. The standard enthalpy change was estimated from these data to be approximately 4 Kcal. As can be seen, temperature had a much more pronounced influence on the rate of equilibration than on the equilibrium position.

DISCUSSION

Albert and Armarego (9) in their review of covalent hydration stated, "As chemists become more aware of the circumstances in which (covalent) hydration occurs and the means for detecting it, many new examples will probably be discovered and many puzzling discrepancies solved." A hydration–dehydration equilibrium such as depicted in Scheme I does provide a logical basis for explaining behaviors which previously had indeed been puzzling. Thus the spectral changes exhibited by the ureide in aqueous medium can be explained by the addition of water across the N_4—C_3 double bond to result in a reduction in the conjugation pathway of the molecule. Similarly, the conversion by heat of the white compound to yellow ureide is logically explained by a solid-state thermal dehydration. The anomalous elemental analysis could have resulted from partial dehydration by drying, to yield a mixture of hydrated and dehydrated product. In addition, Albert (9) reported that carbinolamines formed by the hydration of C=N bonds are readily oxidized by mild oxidizing agents to form oxo compounds and he suggested mild oxidation as a test for hydration and location of added water. That the dioxo compound (II) is formed by autoxidation of compound VI is added evidence to support hydration and the postulated structure. The kinetic data are consistent with those of other systems which were recently reviewed by Perrin (10).

Although the evidence strongly supports a hydration–dehydration phenomenon, the exact nature of the species undergoing reaction is not known. It is possible, for example, that in acid media both the ureide and the corresponding hydrate are protonated and that it was protonated species which underwent transformation. Similarly, at higher pH the reacting species could have been either neutral molecules or anions derived from the ionization of the imido hydrogen. Under all of the pH conditions studied, however, it was the hydrate that was the predominant species at equilibrium.

The identification of compound VI as a covalently hydrated ureide is strongly supported by the results of this investigation. The previously proposed scheme which summarized the degradative pathway of 9-methylisoalloxazine must then be revised and such a revision is presented in Scheme II.

It is also possible that the parent isoalloxazine might, in alkaline solution, undergo an equilibration to form a finite concentration of a hydrate resulting from the addition of water across the N_{10}—C_β double bond and that this species, by attack of hydroxide ion at C_α, directly formed the hydrated ureide. Although no confirmatory evidence of this possibility has yet been obtained, studies with 3,9-dimethylisoalloxazine, which will be reported in a future publication, do support such a possibility.

EXPERIMENTAL

Materials—1,2-Dihydro-1-methyl-2-oxo-quinoxaline-3-carboxyureide (V) and the compound (VI) which is now thought to be the ureide formed by the covalent hydration of V were synthesized by methods which were previously described (1).

Thin-Layer Chromatography—Ten-microliter samples were applied on 300-μ silica gel plates and developed with a solvent system composed of chloroform–methanol–pyridine–water (180:15:1:1). After development, the plates were heated and examined under long wavelength ultraviolet light. The R_f value for the quinoxaline-3-carboxyureide was 0.90 and that for compound VI was 0.50.

Nonaqueous Titration—An accurately weighed

TABLE IV—INFLUENCE OF TEMPERATURE ON THE RATE OF EQUILIBRATION AND EQUILIBRIUM POSITION OF SYSTEMS INITIALLY CONTAINING 1.22×10^{-4} *M* UREIDE[a]

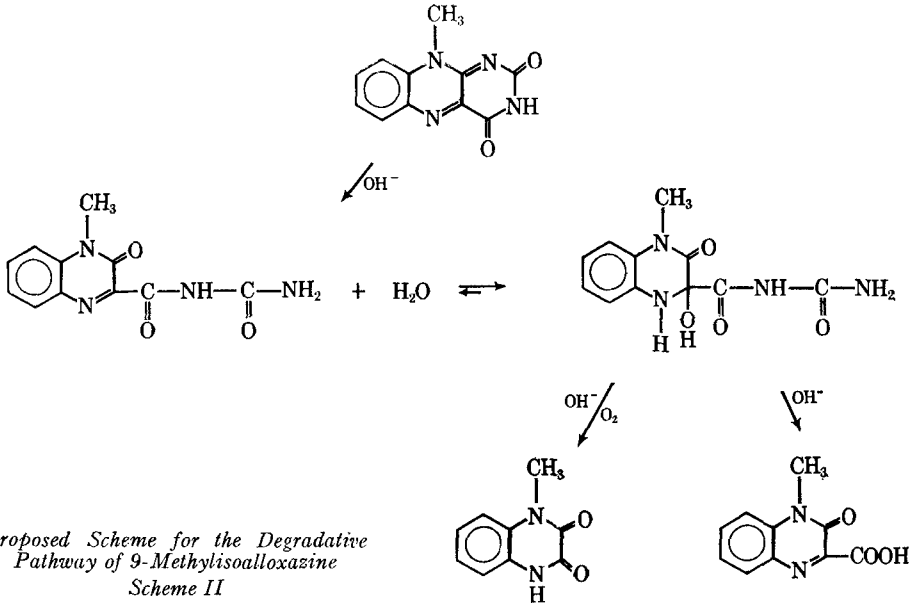
50	0.172	3.07	0.413	0.101	0.312

[a] The acid concentration was 0.58 *N* and the ionic strength was 1.0. The solutions contained 2% dimethylformamide. The equilibrium constant was calculated as the ratio (compound VI)/(ureide).



Proposed Scheme for the Degradative Pathway of 9-Methylisoalloxazine
Scheme II

sample of compound VI was dissolved in 5 ml. of dimethylformamide and titrated with 0.1 *N* sodium methoxide in methanol to a thymol blue end point.

Spectra—All spectra were obtained with a Beckman model DB recording spectrophotometer.

Kinetic Studies—Stock solution of the ureide and of compound VI were prepared in dimethylformamide. Reaction mixtures were prepared by adding an aliquot of a stock solution to a volumetric flask containing a required volume of buffer or hydrochloric acid solution and at the desired temperature. The solution contained sufficient potassium chloride to make an ionic strength of 1.0. The solution was quickly mixed and a portion introduced to a cell which was placed in the cell compartment of a Beckman model DB spectrophotometer set at a wavelength of 380 mμ and equipped with a Sargeant SR recorder. The cell compartment of the spectrophotometer was maintained at the desired temperature by circulation of constant-temperature water from a P. M. Tamson N.V. circulating bath. Absorbance *versus* time plots were traced by the recorder. Zero time was taken to be the time at which the aliquot of stock solution of reactant was introduced to the volumetric flask. Limited studies showed that, in the concentration range encountered, changes in the dimethylformamide concentration of the reaction mixture had no effect on the observed rate.

Creaming of Phosphatide Stabilized Fat Emulsions by Electrolyte Solutions

By M. S. GRAY and W. S. SINGLETON

Creaming effects of electrolytes on emulsions of cottonseed and soybean oils have been investigated. The emulsions were stabilized with egg yolk phosphatides or with soybean phosphatides of different degrees of purity. The differences in creaming of the emulsions by the electrolyte solutions apparently were due to the differences in composition or purity of the phosphatide emulsifiers, and to the differences in properties of the respective oils. Emulsions of cottonseed or soybean oils stabilized with chromatographically homogeneous lecithin creamed to a greater extent than did emulsions of the same oils stabilized with impure phosphatides. In the latter, emulsions of cottonseed oil were slightly less creamed than emulsions of soybean oil.

IN A PREVIOUS STUDY (1), the electronically counted number of particles of specific diameters in fat emulsions developed for intravenous nutrition was found to be critically dependent upon the elapsed time of dilution of the emulsion with saline electrolyte. Because of the extreme dilution required by the electronic counting method, it could not be visually established whether creaming or coalescence occurred and was the cause of the change in particle count. Recently, Le Veen *et al.* (2) have shown that when certain sera are mixed *in vitro* with a fat emulsion, creaming or complete breaking of the emulsion may occur, and ascribe this effect to a globulin. It would appear that the electrolytes of serum or plasma may be equally significant factors in emulsion stability, based on the effect noted with saline in determining particle count. It must be assumed that the protein and other components of circulating plasma to some extent "buffer" the effect of plasma electrolytes on fat emulsions; however, the creaming and breaking effects of electrolytes on certain types of emulsions is well known. Van den Temple (3) reporting on o/w emulsions of monochlorobenzene and paraffin oil, found that the chlorides of sodium, potassium, and magnesium caused coagulation and finally breaking, the rate increasing with salt concentration. The cause of the breaking, according to Van den Temple (4) and to Martin and Hermann (5) involved discharge of the double layer potential. Electrolytes may affect the rate of creaming, and van Gils and Kraay (6) found that latex was creamed in the increasing order Li > Na > K among monovalent ions, and Ba = Ca > Sr among bivalent ions. The available reports do not include the effects of electrolytes on emulsions of vegetable oils, nor on emulsions stabilized with phosphatides.

In the phenomenon of creaming, droplets of the dispersed phase of an emulsion accumulate as a "cream" layer, and the continuous phase from which the dispersed phase is withdrawn becomes clearer, with less concentration of dispersed phase than originally. The continuous phase usually remains as an emulsion. Because turbidity of an emulsion decreases with creaming, measurements of transmitted light in the clearer phase seem to be a useful method of determining cream formation, as discussed by Griffin and Behrens (7).

The present investigation reports the creaming effect of solutions of some of the electrolytes found in human plasma on emulsions of two types of vegetable oils stabilized with egg phosphatides. The mechanism of creaming as a rate function, or correlation of light transmission with any of the parameters involved in rate functions, is beyond the scope of this study.

EXPERIMENTAL MATERIALS

Emulsions—Six emulsions were used, four prepared by high pressure homogenization as described previously (8), and two commercial products. The components of the various emulsions are shown in Table I.

The egg lecithin stabilizer in SR-151 and SR-183

TABLE I—COMPONENTS OF VARIOUS EMULSIONS

Emulsion	Lipid Phase	Stabilizer
SR-151	Soybean, 20%	Egg lecithin, 1%
SR-182	Soybean, 20%	Egg phosphatide, 1.2%
SR-183	Cottonseed, 20%	Egg lecithin, 1%
SR-181	Cottonseed, 20%	Egg phosphatide, 1.2%
Emulsion *A*[a]	Soybean, 20%	Egg phosphatide, 1.2%
Emulsion *B*[b]	Cottonseed, 10%	Soybean phosphatide, 2%

[a] Intralipid, a commercial emulsion; the composition is listed on the label. [b] Lipofundin, a commercial emulsion; the composition is listed on the label.

Received April 4, 1967, from the Southern Regional Research Laboratory, Southern Utilization Research and Development Division, Agricultural Research Service, U. S. Department of Agriculture, New Orleans, LA 70119

Accepted for publication July 18, 1967.

This investigation was supported by funds from the Office of the Surgeon General, U. S. Department of the Army, Washington, D. C.

was chromatographically homogeneous (9); the egg phosphatide in SR-182 and SR-181 was not fractionated by column chromatography, and hence was less pure than the egg lecithin. The purity of the stabilizers of the commercial emulsion was not known, but when isolated from the emulsions, were nonhomogeneous, as shown by thin-layer chromatography. The isotonic aqueous phases were solutions of glycerol in all emulsions except emulsion *B* which contained sorbitol.

Electrolytes—All reagents were A. R. grade. Distilled water solutions of NaCl, KCl, $CaCl_2$, and $CaCl_2$–NaCl were made at salt concentrations of 0.25, 0.5, 1, 2, and 5%. The $CaCl_2$–NaCl solutions contained chemically equivalent weights of the two salts. A solution that simulated human plasma electrolytes was prepared with the following composition per liter: $CaCl_2$, 0.277 Gm.; KCl, 0.373 Gm.; $MgCl_2 \cdot 6H_2O$, 0.305 Gm.; $NaHCO_3$, 2.268 Gm.; $NaHPO_4 \cdot 12H_2O$, 0.358 Gm.; and NaCl, 6.546 Gm.; at pH 8.18. A fine precipitate which formed on standing was removed by filtration.

Method—Four milliliters of the respective salt solutions was mixed with 0.2 ml. of emulsion in a cell. After standing for 30 min., light transmission measurements of the solution–emulsion systems were made with a Lumetron photoelectric colorimeter, model No. 402E, operating through a constant voltage transformer and with galvanometer at direct reading. A monochromatic filter, 550 μ, was used. Under the conditions of operation, the light transmission of the freshly mixed emulsion–salt solution was 0%, after separation of the cream layer, 100%. The ratio of the per cent light transmission of a particular emulsion–salt solution after 30 min. of standing and the maximum per cent transmission of the clearer phase of a creamed emulsion was calculated. A ratio of 1.0 represents maximum creaming. Duplicate determinations of transmission were made, and the calculated results represent the average ±2%.

The transmission of the various emulsions, when diluted with distilled water, increased approximately 10–15% in 30 min. Only those increases above 15% were considered to be due to the salt solutions.

RESULTS AND DISCUSSION

The amount of creaming of the various emulsions was calculated as explained, and the calculated ratios are given in Table II. A ratio of 1.00 represents maximum creaming, and values less than 1.00 indicate some degree of creaming.

The increases in transmission of the four SR emulsions as creaming progressed, due to clearing of the dispersed phase, are plotted in Figs. 1–4. Where coincidence of data occurred, only one curve was plotted. The increases in transmission were due to decrease of dispersed phase, as electronic count of the dispersed particles (1) decreased by 400/μl./min.

Emulsions Stabilized with Homogeneous Lecithin—Emulsions SR-151 and SR-183, which were stabilized with pure lecithin but which differed in oil phase, had similar patterns of creaming with the various concentrations of salt solutions.

Upon dilution with each solution of NaCl, both emulsions were completely creamed. Results obtained with the KCl solutions were essentially similar to those obtained with NaCl.

Creaming was negligible at the lower concentrations of $CaCl_2$, with the exception of a slight amount observed in the soybean oil emulsion with the 2%

TABLE II—RATIO OF LIGHT TRANSMISSIONS OF EMULSIONS CREAMED BY VARIOUS CONCENTRATIONS OF ELECTROLYTES[a]

	Ratio of Light Transmission

solution; both emulsions were creamed by 5% solution of $CaCl_2$.

Creaming occurred in both emulsions with the 2% and 5% solutions of the mixed salts $CaCl_2$–NaCl.

Emulsions Stabilized with Crude Phosphatides—Emulsion SR-181, cottonseed oil, generally was less creamed than the soybean oil emulsion, SR-182, with all of the electrolytes.

Creaming in the two emulsions was negligible with the 0.25% and 0.5% concentrations of NaCl, but quite different with the higher concentrations. Creaming in the soybean oil emulsion increased to about the same extent as it did in the soybean oil emulsion stabilized with pure lecithin, whereas the cottonseed oil emulsion was relatively unaffected.

Similarly, the soybean oil emulsion was creamed by the higher concentrations of KCl, $CaCl_2$, and $CaCl_2$–NaCl, but the cottonseed oil emulsion was not.

Emulsions A and B—Emulsion *A* and emulsion SR-182, which are of similar composition, show similar patterns of creaming with the various concentrations of NaCl, KCl, and $CaCl_2$, except that emulsion SR-182 creamed to a greater extent with the higher concentrations of electrolytes. Emulsion SR-182 was more unstable than emulsion *A* with $CaCl_2$–NaCl.

There was little or no creaming of emulsion *B* at any of the concentrations of NaCl, KCl, and $CaCl_2$, and only a moderate amount with the concentrations of $CaCl_2$–NaCl. The oil content of emulsion *B* (10%) is less than that of the other emulsions and the phosphatide content larger, and the results may not be directly comparable with those of the other emulsions.

Plasma Electrolytes—Of the limited number of determinations with the mixture of plasma electrolytes, the soybean oil emulsion stabilized with pure lecithin was creamed, but the electrolyte had no effect on the other emulsions tested.

DISCUSSION

Creaming of the emulsions as a function of electrolyte concentration varied between emulsions of the same oil stabilized with pure lecithin and with crude phosphatide, and also between solutions of the various electrolytes. In some emulsions creaming was most complete with the 5% concentration of electrolyte; in others, with lower concentrations. In general, the amount of creaming was directly

proportional to electrolyte concentration. The inequality in creaming of the same emulsion with solutions of two different salts at identical concentrations apparently is explained by molarity of the cations (6).

The results obtained with the four SR emulsions indicated that the differences in stability of the emulsions to electrolytes apparently were due to the differences in properties of soybean and cottonseed oils, and to the differences in composition, or purity, of the stabilizers. Emulsions of cottonseed oil stabilized with chromatographically homogeneous egg lecithin or with egg phosphatides appeared to be more stable to electrolytes than were emulsions of soybean oil stabilized with the same emulsifiers. Also, emulsions of either oil stabilized with crude phosphatides were more stable to electrolytes than were emulsions stabilized with pure lecithin. The instability of the emulsions with NaCl, KCl, and $CaCl_2$ was marked with soybean oil–pure lecithin (SR-151), and was progressively less with cottonseed oil–pure lecithin (SR-183), soybean oil–phosphatide (SR-182), and cottonseed oil–phosphatide (SR-181).

Yeadon *et al.* (10) found that purified egg lecithin did not stabilize autoclaved fat emulsions in which a solution of dextrose was the aqueous phase. Zeringue *et al.* (8) produced a stable autoclaved fat emulsion stabilized with chromatographically homogeneous lecithin by substituting glycerol as the isotonic agent in the aqueous phase and adjusting the pH to 6.6–6.8. The marked instability of emulsions formulated with chromatographically homogeneous lecithin in the presence of electrolytes suggests that the electrolytes to which this type of emulsion is stable are quite limited and that salts known for their "salting out" effect bring about changes in the aqueous phase which are unfavorable to chromatographically homogeneous lecithin.

Although emulsion SR-182 and emulsion *A* were similar in composition, the egg phosphatide used in the emulsion *A* formula appeared to be nonhomogeneous, and could not be directly compared with the phosphatide in SR-182 which was quite highly purified. The greater amount of creaming of the SR-182 emulsion could be due to a difference in the composition of the two phosphatides, which lead to differences in the effects of the electrolyte solutions.

The creaming effects of the various salts with emulsion *B* were somewhat similar to those of emulsion SR-181, but differed considerably from those of the other emulsions. Emulsion *B*, although stabilized with phosphatide, differed in composition from the previously described emulsions. Soybean phosphatides were used as the stabilizer, sorbitol in place of glycerol as the isotonic phase, and a lower concentration in the oil phase, 10% cottonseed oil, as compared to 20%. The ratio of phosphatide to oil in the emulsion *B* formulation, 2.5% phosphatide to 10% oil, was considerably greater than the ratios of 1–1.2% phosphatide to 20% oil in the SR egg phosphatide-stabilized emulsions. These differences in composition may have contributed to the differences in creaming noted between emulsion *B* and SR emulsions.

It appeared that the electrolytes used caused agglomeration of the emulsions rather than coalescence. By visual inspection, cream formed in the cells and rose to the top surface. This cream could be redispersed, whereas coalescence would have resulted in free oil separation.

The relatively small amount of creaming that was observed in the phosphatide stabilized cottonseed oil emulsions essentially confirms the failure of dog blood sera to cream a similar emulsion (11). A conclusion of the latter study was that sera albumins did not complex with the fat component. It might be postulated from the present study that the sera electrolytes had but little effect on fat creaming because of the type of phosphatide used.

Mechanisms of Interphase Transport I

Theoretical Considerations of Diffusion and Interfacial Barriers in Transport of Solubilized Systems

By A. H. GOLDBERG, W. I. HIGUCHI, N. F. H. HO, and G. ZOGRAFI

Based on first principles of diffusion, equations were derived to predict transport rates of micelle-solubilized drug from its aqueous environment to an oil phase. The basic equations also take into account the possible effects of an electrical barrier between the micelle and the charged oil–water interface. These processes may be considered as being analogous to absorption of water insoluble–bile soluble drugs, and may be used to evaluate the mechanism of transport in such situations. The physical model includes the effects of the free drug-solubilized drug equilibrium, the diffusion coefficients of both free and solubilized drug, ionic strength of the aqueous medium, and the micelle size. A novel experimental approach based on the use of emulsion droplets as the "sink" is described.

MUCH RESEARCH has been carried out, particularly in the last two decades, on the mechanisms of drug absorption. These studies have led to now well-established physicochemical concepts such as the importance of the oil–water partition coefficient, and the acid-base nature of the drug.

What appears to be conspicuously absent is an attempt to study the basic diffusional processes, both theoretically and experimentally with well-defined models. Such a study should provide a unified approach for explaining some of the discrepancies in the existing qualitative theories, and also suggest new rate-determining mechanisms for drug absorption. The authors are not so naive as to think that the simple laws of physical chemistry can generally describe so complex a subject as drug absorption. What is contended, however, is that where qualitative physicochemical relationships are established or expected, it is more than worthwhile to attempt to describe them on mechanistically quantitative bases.

DISCUSSION

The present communication is related to an aspect of drug absorption that has recently attracted some interest (1–4), *viz.*, the role of micellar solubilization. The theory governing the diffusion of both the solubilized and the free drug from an aqueous environment to a lipoidal interface is presented. The various interfacial boundary conditions influencing the rate of transport between phases have been considered. In order to study the transport rate theory, a novel experimental technique, which is based on the use of micron-sized oil emulsion droplets as a lipoidal "sink," has been developed.

Past Studies on Micellar Solubilization and Drug Absorption

The earliest studies involving micellar solubilization and biological availability were concerned with the activity of germicides in soap solutions (4–6). Allawala and Riegelman (7, 8) postulated that the thermodynamic activity of the free drug is the driving force behind the effectiveness of germicides dissolved in surfactant solutions.

Based on such studies, one would expect that if a surfactant is added to a solution of a drug in a concentration high enough to exceed its CMC, the drug's thermodynamic activity would be reduced. We would, therefore, expect a decrease in rate of transport because of a reduced driving force. This was shown by Levy *et al.* (1), who measured the absorption rates of secobarbital by goldfish in the presence of polysorbate 80 solutions.

To evaluate the effect of increasing surfactant concentration on the rate of transport of a solubilized drug, Matsumoto *et al.* (2, 3) used a cellulose membrane dialysis technique. These workers mathematically derived an equation for transport, based on the laws of diffusion and the concentration of free drug. Their experimental values matched their theoretical values only when no great interaction between the drug and the surfactant was observed. The degree of interaction was independently measured, and was classified as the ratio (r) of *total drug in solution* to *free drug*. When the values of r were four or greater,[1] the rates of transport exceeded the rates predicted. They postulated that this discrepancy was due to the transport of drug directly from the micelle. In these studies, it had been initially assumed that the micelles containing drug did not contribute to the transport phenomena. Matsumoto *et al.* (2, 3) eventually considered this a possibility, but only at high r values. According to their interpretation, however, it was not due to diffusion of the micelles, but rather to the coalescence of the micelles with the membrane. What was not considered was an enhanced flux that can be attributed to the diffusion of drug-containing micelles.

Received April 14, 1967, from the College of Pharmacy, University of Michigan, Ann Arbor, MI 48104

Accepted for publication June 22, 1967.

Presented to the Basic Pharmaceutics Section, A.PH.A. Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

This investigation was supported by grant GM-13368-01 and fellowship A-F1-GM-34,237-01 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

[1] In these experiments, the r value of the drug used is about 800, at a 1% polysorbate 80 concentration.

Present Considerations

In the transport of a drug from an aqueous solubilized system to an oil phase, the flux consists of the transport of the free drug and that of the solubilized drug (9). The solubilized drug may be considered as an interaction product between the drug and the surfactant. In order for the solubilized drug to pass from the aqueous phase to the oil phase, it must diffuse to some point close to the oil, and then leave the micelle, unless the micelle itself enters the oil. The greater the drug–surfactant interaction, the greater is the role played by the drug-containing micelle in the transport process.

There are several mechanisms by which a drug can leave a micelle. In the simplest case, where a nonionic drug is solubilized by a nonionic surfactant, we postulate that it is simply diffusion from the micelle, close to the oil "sink." In the case of drug in a charged micelle approaching a charged surface, there may be a strong electrical effect, either repulsive or attractive.

To study these ideas a procedure was conceived which involves the use of micron-sized oil emulsion droplets as a sink for the drug. There are a number of advantages, both theoretical and experimental, in employing such a system instead of one involving two or more bulk phases as has been done by some investigators (10). First, even when the rates of interphase transfer are purely diffusion controlled in the external (aqueous) phase, the results are relatively insensitive to the rate of agitation of the medium over a wide range of shear rates, and the infinite-sink, steady-state mathematics may be applied to the data. This is to be expected from hydrodynamic considerations and from the theory of diffusion involving small spheres. As a result, the data may be directly evaluated with diffusion theory without invoking the empirical "effective" diffusion layer thickness ideas which have been the major cause of difficulties in past studies (10). Another advantage is that, because droplet distortion is likely to be negligible for such small droplets, it is safe to assume in most instances that surface-active agents will not alter the effective surface area of the droplets as they frequently do in the case of large interfaces. Finally, it can be shown that rate experiments with small droplets are much more sensitive to interfacial resistances. Based on the estimated diffusion layer thickness of 200 to 400 μ from the studies of Rosano *et al.* (10), experiments with sinks consisting of micron-sized oil droplets should be more than a hundred times more sensitive to interfacial resistances.

Case A—*Simple Diffusion*—For the first case to be considered, that of diffusion of a nonionic drug from a nonionic surfactant, a planar model will be presented first, and then rederived for the case of spherically symmetric transport to an oil droplet. This derivation is based solely upon the principles of diffusion. A graphical representation for the planar diffusion case is shown in Fig. 1.

If the transport rate of the drug is diffusion controlled, then the rate of uptake by the oil is equal to the rate of transport through the aqueous phase. The steady-state rate of diffusion in the aqueous phase can be denoted by:

$$G = \left(A\, D_d \frac{dC_d}{dl} + A\, D_{dm} \frac{dC_{dm}}{dl} \right) \qquad \text{(Eq. 1)}$$

Fig. 1—Illustration of the planar model of diffusion. Key: C_{dm} *= concentration of drug in the micelles;* C_d *= concentration of free drug* l *= diffusion layer thickness.*

Where G = the steady-state rate of transport through the aqueous phase to the oil droplet, A = the area, D = the diffusion coefficients,[2] and dC/dl = the concentration gradients. If the area is maintained constant, Eq. 1 can be rearranged to:

$$\frac{G}{A}\, dl = D_d\, dC_d + D_{dm}\, dC_{dm} \qquad \text{(Eq. 2)}$$

Integration from $l = 1$ to $l = 0$ gives:

$$\frac{G}{A}\, l = D_d(\Delta C_d) + D_{dm}(\Delta C_{dm}) \qquad \text{(Eq. 3)}$$

Considering the transport from an aqueous phase to an oil phase which acts as a "perfect sink," (ΔC) can be denoted as (C^b-C^s), where C^b is the bulk aqueous concentration, and C^s is the concentration of the drug very close to the oil phase. The steady-state rate of diffusion is then finally denoted by:

$$G = \frac{A}{l} \left[D_d \left(C_d^b - C_d^s \right) + D_{dm} \left(C_{dm}^b - C_{dm}^s \right) \right] \qquad \text{(Eq. 4)}$$

The integral of this rate, with respect to time, should be equal to the uptake of the drug by the oil, and is expressed as:

$$\int G dt = C_{do} V \qquad \text{(Eq. 5)}$$

where C_{do} = the concentration of the drug in the oil, and V = the volume (ml./ml.) of the oil. Differentiation of both sides of Eq. 5 then expresses the rate of change of the concentration of the drug in the oil with respect to time, and is denoted by:

$$G = V \frac{dC_{do}}{dt} \qquad \text{(Eq. 6)}$$

Substitution for G from Eq. 4 gives:

$$\frac{A}{l} \left[D_d \left(C_d^b - C_d^s \right) + D_{dm} \left(C_{dm}^b - C_{dm}^s \right) \right] = V \frac{dC_{do}}{dt} \qquad \text{(Eq. 7)}$$

[2] Subscript d = free drug; subscript dm = drug in the micelles.

There are several relationships that can be used to reduce Eq. 7 to one equation with one unknown.

It has frequently been observed (11) that above the critical micelle concentration:

$$C_{dm} = KC_dC_{saa} \quad \text{(Eq. 8)}$$

where K = the pseudoequilibrium constant relating C_{dm} to C_d, and C_{saa} = the concentration of surfactant. If we assume that this relationship holds, then the substitution of Eq. 8 into Eq. 7 gives:

$$\frac{A}{l}\left[D_d\left(\frac{C_{dm}{}^b}{KC_{saa}} - \frac{C_{dm}{}^s}{KC_{saa}}\right) + D_{dm}(C_{dm}{}^b - C_{dm}{}^s)\right] = V\frac{dC_{do}}{dt} \quad \text{(Eq. 9)}$$

If the (KC_{saa}) terms in the denominator are factored, we can then factor $(C_{dm}{}^b\text{-}C_{dm}{}^s)$ to give:

$$\frac{A}{l}\left(\frac{D_d}{KC_{saa}} + D_{dm}\right)(C_{dm}{}^b - C_{dm}{}^s) = V\frac{dC_{do}}{dt} \quad \text{(Eq. 10)}$$

We now have only three concentration terms that are unknown.

We may base the analysis on a total emulsion volume of 1 ml. Then:

$$T = C_{do}V + C_{aq.}(1 - V) \quad \text{(Eq. 11)}$$

where T = the total amount of drug present and $C_{aq.}$ = the drug concentration in the aqueous phase. However, $C_{aq.}$ can be taken as $(C_{dm}{}^b + C_d{}^b)$. Inserting this into Eq. 11 and substituting for $C_d{}^b$ from Eq. 8, we arrive at:

$$T = C_{do}V + C_{dm}{}^b\left(1 + \frac{1}{KC_{saa}}\right)(1 - V) \quad \text{(Eq. 12)}$$

Rearrangement of Eq. 12 gives:

$$C_{dm}{}^b = \frac{T - C_{do}V}{\left(1 + \frac{1}{KC_{saa}}\right)(1 - V)} \quad \text{(Eq. 13)}$$

To relate $C_{dm}{}^s$ to C_{do}, we can use the apparent partition coefficient. The true partition coefficient for a drug between oil and water is given by:

$$PC_{o/w} = \frac{C_{do}}{C_d{}^s} \quad \text{(Eq. 14)}$$

The apparent partition coefficient may be expressed as:

$$PC_{app.} = \frac{C_{do}}{C_{aq.}} = \frac{C_{do}}{C_d{}^s + C_{dm}{}^s} \quad \text{(Eq. 15)}$$

Taking the reciprocal of Eq. 15 gives:

$$\frac{1}{PC_{app.}} = \frac{1}{PC_{o/w}} + \frac{C_{dm}{}^s}{C_{do}} \quad \text{(Eq. 16)}$$

Equation 16 rearranges to:

$$C_{dm}{}^s = C_{do}\left[\frac{1}{PC_{app.}} - \frac{1}{PC_{o/w}}\right] \quad \text{(Eq. 17)}$$

Substitution of Eqs. 13 and 17 into Eq. 10 yields:

$$\frac{A}{l}\left\{\left(\frac{D_d}{KC_{saa}} + D_{dm}\right)\times\left(\frac{T - C_{do}V}{\left(1 + \frac{1}{KC_{saa}}\right)(1 - V)} - C_{do}\left[\frac{1}{PC_{app.}} - \frac{1}{PC_{o/w}}\right]\right)\right\} = V\frac{dC_{do}}{dt} \quad \text{(Eq. 18)}$$

The C_{do} terms can be factored to give:

$$\frac{A}{l}\left\{\left(\frac{D_d}{KC_{saa}} + D_{dm}\right)\times\left[\frac{T}{\left(1 + \frac{1}{KC_{saa}}\right)(1 - V)} - C_{do}\left(\frac{V}{\left(1 + \frac{1}{KC_{saa}}\right)(1 - V)} + \left(\frac{1}{PC_{app.}} - \frac{1}{PC_{o/w}}\right)\right)\right]\right\} = V\frac{dC_{do}}{dt} \quad \text{(Eq. 19)}$$

We can collect constants, and let:

$$\alpha = \frac{T}{\left(1 + \frac{1}{KC_{saa}}\right)(1 - V)} \quad \text{(Eq. 20)}$$

and

$$\beta = \frac{V}{\left(1 + \frac{1}{KC_{saa}}\right)(1 - V)} + \left(\frac{1}{PC_{app.}} - \frac{1}{PC_{o/w}}\right) \quad \text{(Eq. 21)}$$

Insertion of Eqs. 20 and 21 into Eq. 19 and rearrangement yields:

$$\frac{dC_{do}}{\alpha - \beta C_{do}} = \left(\frac{D_d}{KC_{saa}} + D_{dm}\right)\frac{A}{lV}dt \quad \text{(Eq. 22)}$$

Integration of t from 0 to t and of C_{do} from 0 to C_{do} gives:

$$\ln\left(\frac{\alpha}{\alpha - \beta C_{do}}\right) = \left(\frac{\beta A}{lV}\right)\left(\frac{D_d}{KC_{saa}} + D_{dm}\right)t \quad \text{(Eq. 23)}$$

A plot of the lefthand side of this function *versus* time should yield a straight line going through the origin, with a slope of $(\beta A/lV)\,(D_d/KC_{saa} + D_{dm})$.

If we now derive this equation for small spheres, we can graphically represent the model as in Fig. 2.

By rewriting Eq. 1 and replacing the area (A) by the area of a sphere, Eq. 1 becomes:

$$G = 4\pi r^2\left(D_d\frac{dC_d}{dr} + D_{dm}\frac{dC_{dm}}{dr}\right) \quad \text{(Eq. 24)}$$

where $\frac{dC}{dr}$ = the concentration gradient as a function of the radius. Equation 24 rearranges to:

$$\frac{dr}{r^2} = \frac{4\pi}{G}(D_d\,dC_d + D_{dm}\,dC_{dm}) \quad \text{(Eq. 25)}$$

Integration from $r = \infty$ to $r = a$, gives:

$$\frac{1}{a} = \frac{4\pi}{G}(D_d\Delta C_d + D_{dm}\Delta C_{dm}) \quad \text{(Eq. 26)}$$

or, with rearrangement and insertion of the same

concentration notations as in Eq. 4, it becomes:

$$G = 4\pi a[D_d (C_d^b - C_d^s) + D_{dm} (C_{dm}^b - C_{dm}^s)] \quad \text{(Eq. 27)}$$

The $4\pi a$ term has come from the derivation for a single sphere; however, for an emulsion that has a narrow distribution of oil droplet sizes, this can be replaced by $n4\pi a$, where n is the number of droplets. Since in a dilute, stable emulsion this term is constant with time, we can assign it the constant value A.

If we now make the same substitutions as were made for the planar case, the final equation becomes:

$$\ln\left(\frac{\alpha}{\alpha - \beta C_{do}}\right) = \frac{\beta A}{V}\left(\frac{D_d}{KC_{saa}} + D_{dm}\right) t \quad \text{(Eq. 28)}$$

The only difference between this equation and Eq. 24 for the planar model is the disappearance of (l), the size of the diffusion layer.

Equation 28 may also be rewritten to give:

$$C_{do} = \frac{\alpha}{\beta}\left\{1 - \exp.\left[-\frac{\beta A}{V}\left(\frac{D_d}{KC_{saa}} + D_{dm}\right) t\right]\right\} \quad \text{(Eq. 29)}$$

Every term, excluding C_{do}, can be independently determined. From such data, C_{do} values can be predicted for any value of time, and can be compared to the C_{do} values experimentally obtained.

There have been several assumptions made in the derivation of these equations. The first is that there exists a K between C_{dm} and C_d that holds below, as well as at saturation. It also has been assumed that the apparent partition coefficient expression correctly represents the relationship between C_{do} and C_{dm}^s. Both these assumptions can be shown to be valid with appropriate experiments.

Case B—*Electrical Effects*—The second case, that of a charged micelle diffusing to a charged lipid interface, will be presented for spheres directly. This is illustrated in Fig. 3. The steady-state rate of diffusion now has an additional term added that considers the force field of the electrical barrier. The expression for the rate becomes:

$$G = 4\pi r^2 \times \left[D_d \frac{dC_d}{dr} + D_{dm} \frac{dC_{dm}}{dr} + \frac{D_{dm}}{kT} C_{dm} \frac{dV^o}{dr}\right] \quad \text{(Eq. 30)}$$

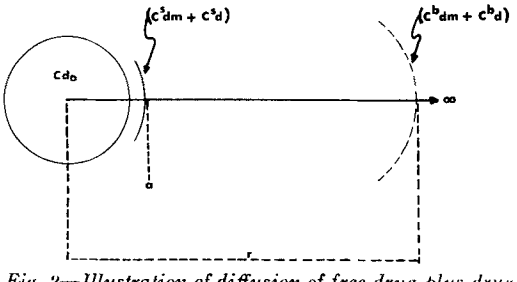

Fig. 2—Illustration of diffusion of free drug plus drug in the micelles from the aqueous phase to an oil droplet "sink." Key: C_{do} *= concentration of drug in the oil;* C^s_{dm} *= concentration of drug in the micelles, at some point* (a)*, arbitrarily close to the oil droplet;* C^b_{dm} *= concentration of drug in the micelles at an infinite distance (the bulk) from the oil droplet;* C_d *= concentration of free drug.*

The last term in the equation gives the influence of the electrical interaction upon the rate. Here V^o is the potential energy of interaction of the micelle with the charged oil–water interface. The factor, $(D_{dm}/kT)(dV^o/dr)$, is the average micellar velocity contribution due to the force. The k and T are the Boltzmann constant and the absolute temperature.

We may substitute for C_{dm} from Eq. 8 into Eq. 30. This gives:

$$G = 4\pi r^2 \left[D_d \frac{dC_d}{dr} + D_{dm}KC_d \frac{dC_{saa}}{dr} + D_{dm}KC_{saa} \frac{dC_d}{dr} + \frac{KC_dD_{dm}}{kT} C_{saa} \frac{dV^o}{dr}\right] \quad \text{(Eq. 31)}$$

Taking the case where the transport rate of the surface-active agent itself is zero, we may write:

$$C_{saa} = C^b_{saa} \exp.(-V^o/kT) \quad \text{(Eq. 32)}$$

where C^b_{saa} is the surfactant concentration at infinity. Equation 32 states that the micelle distribution obeys the usual Boltzmann distribution.

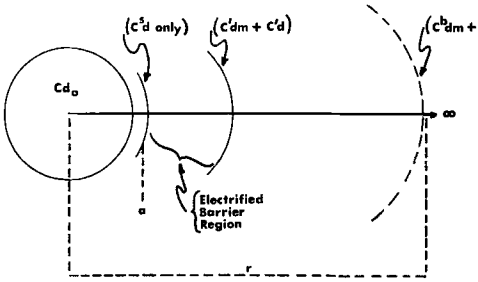

Fig. 3—Illustration of diffusion of free drug plus drug in the micelles freely diffusing to some distance from the oil droplet, where an electrical barrier permits only free drug to diffuse to some point (a)*, arbitrarily close to the oil droplet. Key:* C_{do} *= concentration of drug in the oil;* C_d *= concentration of free drug;* C_{dm} *= concentration of drug in the micelles; superscript* s *= surface,* b *= bulk, and the prime = the concentration at the start of the electrical barrier region.*

We may now substitute Eq. 32 into Eq. 31 and obtain:

$$G = 4\pi r^2 \times [D_d + D_{dm}KC^b_{saa} \exp.(-V^o/kT)] \frac{dC_d}{dr} \quad \text{(Eq. 33)}$$

This may be integrated as was done previously, C_d from C_d^s to C_d^b and r from a to ∞, to give:

$$G = \frac{4\pi (C_d^b - C_d^s)}{\int_a^\infty \frac{dr}{r^2 [D_d + D_{dm}KC^b_{saa} \exp.(-V^o/kT)]}} \quad \text{(Eq. 34)}$$

The integral in the denominator of Eq. 34 may be evaluated numerically. As it is constant with respect to time, it can be identified as the constant, γ.

As before, the drug transported from the aqueous phase to the oil phase can be represented by Eq. 5.

As was done for case A, we may substitute for G from Eq. 34 to give:

$$\int_0^t \frac{4\pi}{\gamma}(C_d^b - C_d^s)\,dt = C_{do}V \qquad \text{(Eq. 35)}$$

Differentiation of both sides gives:

$$\frac{4\pi}{\gamma}(C_d^b - C_d^s) = V\frac{dC_{do}}{dt} \qquad \text{(Eq. 36)}$$

By means of Eqs. 12, 15, and 36 we obtain the following equation:

$$\frac{4\pi}{\gamma}\left\{\frac{\text{tot.}}{(1 + KC_{saa}^b)(1 - V)} - C_{do}\times\left[\frac{V}{(1 + KC_{saa}^b)(1 - V)} + \left(\frac{1}{PC_{app.}(1 + KC_{saa}^b)}\right)\right]\right\} = V\frac{dC_{do}}{dt} \qquad \text{(Eq. 37)}$$

We can collect constants, and let:

$$\delta = \frac{\text{tot.}}{(1 + KC_{saa}^b)(1 - V)} \qquad \text{(Eq. 38)}$$

and also,

$$\epsilon = \left[\frac{V}{(1 + KC_{saa}^b)(1 - V)} + \frac{1}{PC_{app.}(1 + KC_{saa}^b)}\right] \qquad \text{(Eq. 39)}$$

If Eqs. 38 and 39 are substituted into Eq. 37, then rearranged and integrated from $t = 0$ to $t = t$, $C_{do} = 0$ to $C_{do} = C_{do}$, then we find that:

$$\ln\left(\frac{\delta}{\delta - \epsilon C_{do}}\right) = \frac{4\pi\epsilon}{\gamma V}t \qquad \text{(Eq. 40)}$$

This can be rewritten to:

$$C_{do} = \frac{\delta}{\epsilon}\left[1 - \exp.\left(-\frac{4\pi\epsilon}{\gamma V}t\right)\right] \qquad \text{(Eq. 41)}$$

Here, as in case A, all terms other than C_{do} can be independently determined and can be compared to experimentally obtained C_{do} values.

Discussion—A complete examination of models such as those discussed here requires extensive complementary studies of such parameters as K, $PC_{app.}$, D_d, D_{dm}, particle size, and a of the emulsion droplets, and the surface potential (actually the ζ-potential). Such studies are underway for several systems.

Preliminary results have been obtained on the transport rate of 2,3-bis(paramethoxyphenyl indole), a drug with very low water solubility. Isopropyl myristate was the emulsion oil phase with polysorbate 80 as the surfactant.

Figure 4 shows the comparison of experimental transport data for this system compared with theory (Eq. 29). The constants K, C_{saa}, α, and β were known from other experiments. However, only an estimate of the particle size of the emulsion and the diffusion coefficients, D_d and D_{dm}, were available. Therefore, the relatively good agreement is being regarded as tentative. A forthcoming communication (12) will present a full test.

Aside from the uncertainties in some of the parameters, the deviations between the experiments and theory in Fig. 4 are believed to be due to (*a*) neglect of the effects of the nonsteady-state diffusion, (*b*) the heterodispersity of the emulsion droplets, and (*c*) the effect of neighboring particles upon the particles in question. These factors are also being investigated, and it appears that all of these effects may be accounted for satisfactorily.

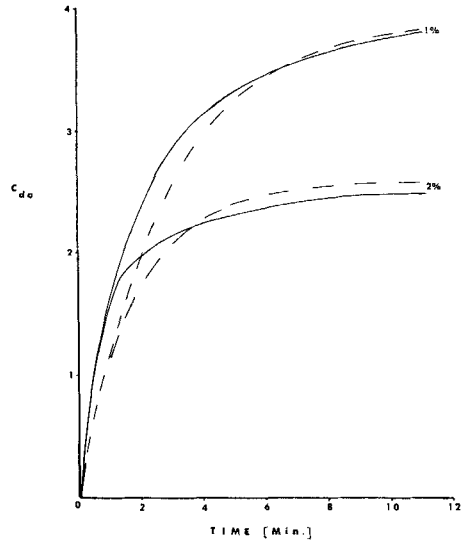

Fig. 4—Illustration of the correlation of predicted C_{do} *values to those experimentally found as a function of time. Key:* C_{do} *= concentration of drug in the oil; ——, experimental values; – – –, theoretical. The 1% and 2% refer to the concentration of polysorbate 80 present.*

Theoretical calculations of the integral in Eq. 34 have been carried out to estimate the expected electrical barrier effects upon G. The potential function, V^o, was taken to be:

$$V^o = V_A^o + V_R^o \qquad \text{(Eq. 42)}$$

where

$$V_A^o = -\frac{A}{6}\left[\frac{2a'(H + a')}{H(H + 2a')} - \ln\left(\frac{H - 2a'}{H}\right)\right] \qquad \text{(Eq. 43)}$$

is the Hamaker relation (13) for the attraction between a sphere and a plane. Here, a' is the radius of the micelle, and H is the closest distance of separation between the surface of the plane (oil droplet) and the surface of the sphere (micelle). A is the Hamaker constant, taken as 5×10^{-13} erg. V_R^o is given by:

$$V_R^o = \epsilon a'\psi_o^2 \ln\,[1 + \exp.\,(-KH)] \qquad \text{(Eq. 44)}$$

which is the electrical double layer repulsion between a sphere and a plane. ψ_o is the surface potential assumed to be the same for the micelle and the surface of the oil droplet, K is the Debye-Huckel κ, and ϵ is the dielectric constant of the medium. Equation 44 is strictly valid for the case in which $\psi_o \lesssim 25$ mv. and $a' \gg 1/K$. However, it is believed (14) to be a good approximation even for $a' \backsimeq 1/K$ and $\psi_o \backsimeq 50$ mv.

The calculations have shown that even for $\psi_o = 50$ mv., $a' = 50$ Å., and $1/K = 50$ Å., the interfacial electrical barriers may be great enough to significantly reduce G by a factor of two or more.

Ultraviolet Spectrophotometric Determination of Chlorprothixene in Biologic Specimens

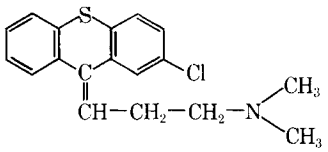
By JACK E. WALLACE

A rapid spectrophotometric method for determining chlorprothixene permits analysis of the drug in biologic specimens in the presence of its metabolites and other alkaline drugs without preliminary separation. The procedure is based upon the oxidation of chlorprothixene and its immediate metabolites to a mixture of reaction products by means of alkaline permanganate. In hexane the products have a characteristic ultraviolet absorption curve with a well-defined maximum at 233 mμ. The strong absorption at this wavelength is utilized as a basis for the analytical procedure. The method is sufficiently sensitive for the determination of chlorprothixene in urine 3 days after the ingestion of a single 50-mg. dose. Observations concerning the distribution of chlorprothixene in the rat and the excretion of the drug in man are presented.

CHLORPROTHIXENE,[1] *trans* isomer of 2-chloro-9-(13-dimethylaminopropylidene) thioxanthene, is a potent tranquilizing agent not only in acute and chronic schizophrenia but in severe psychoneuotic conditions. The chemical structure of chlorprothixene resembles that of the phenothiazines. Few methods for the determination of the drug are available in the scientific literature.

Ferrari and Toth (1) described a thin-layer chromatographic technique which identifies urinary metabolites of chlorpromazine, chlorprothixene, imipramine, and amitriptyline. Although the method is specific, it is time consuming and is not quantitative. Fluorometric procedures for determining chlorprothixene in blood and urine (2) are very sensitive, detecting 0.25-mcg. amounts of the drug, but they require the utilization of specialized analytical instruments.

Chlorprothixene strongly absorbs ultraviolet radiations, therefore, it can be determined spectrophotometrically in biologic extracts, but its strongest absorption is at 227 mμ. At that wavelength the spectral curve of the drug is often affected by background absorption and sulfoxide metabolites which induce a wide degree of variance in the ultraviolet absorbance curve, unless extensive purification of the drug extract is achieved. The method reported here is a specific spectrometric assay which requires no extensive purification procedure or no separation of unchanged drug and sulfoxides (3). The method permits a reliable evaluation of drug intake by patients treated with chlorprothixene.



Chlorprothixene

EXPERIMENTAL

Instrumentation—A Beckman DK-2A ratio recording spectrophotometer with linear presentation of the wavelength was used for the ultraviolet absorption measurements. The sample path was 10 mm. throughout. A Beckman IR-4 doublebeam infrared spectrophotometer was used for infrared spectral characterization of functional groups in the reaction products. Gas chromatographic analyses were performed by means of a Barber-Colman model 5000 gas chromatograph utilizing a 6-ft. U-shaped glass column containing 2% Carbowax 20 M on Gas-Chrom Q, 100–120 mesh. An F & M model

185 carbon-hydrogen-nitrogen analyzer was used for elemental analysis of the chlorprothixene reaction products.

Method—Ten milliliters of whole oxalated blood, serum, or gastric contents are adjusted to pH 7.0–7.5 by the addition of a dilute aqueous solution of sodium hyroxide. Ten to 50 ml. of urine or 10 Gm. of homogenized tissue specimens are adjusted to a pH of 11.0 to 12.0 with 5 *N* sodium hydroxide. The resulting solution or homogenate is shaken vigorously for 3 min. with 200 ml. of *n*-hexane (spectroanalyzed) in a 500-ml. separator. The hexane layer is placed in a graduated cylinder by filtration through Whatman No. 541 filter paper. The volume of hexane recovered is recorded, and the lost hexane is considered in the final calculations. Five milliliters of 0.5 *N* HCl is added to the filtered hexane, and this mixture is shaken for 3 min. Four milliliters of the aqueous layer is placed in a 500-ml. round-bottom flask to which are added 20 ml. of 1% $KMnO_4$ buffered at pH 12.4 with 0.4 *M* sodium triphosphate–0.4 *M* sodium hydroxide buffer, 50 ml. of *n*-hexane (spectrophotometric grade), and a Teflon-coated magnetic stirring bar. The contents of the flask are refluxed for 30 min. with constant magnetic stirring. After cooling, the *n*-hexane is separated from the aqueous permanganate layer, washed with 5 ml. of 0.5 *N* HCl, and read in the spectrophotometer at 5 mμ intervals from 220 to 340 mμ against a blank of *n*-hexane. At least three maxima should be observed. If absorption at a single wavelength is desired, it may be determined at 233 mμ. Should the *n*-hexane contain less than 2.5 mcg./ml. of chlorprothixene as the reaction product, the following concentration technique should be performed. The recovered *n*-hexane, whose total volume is recorded, is placed in a 125-ml. flask which is then attached to a rotary vacuum evaporator. The solvent is evaporated by vacuum while the flask, partially submerged, rotates in a 50° water bath. Depending on the absorbance previously observed, the residue is dissolved in 2, 4, or 8 ml. of *n*-hexane. A standard curve is prepared from aqueous solutions of the drug which have been carried through the procedure described, including the concentration technique for solutions containing small amounts of chlorprothixene.

RESULTS AND DISCUSSION

At 233 mμ a linear relationship exists between the absorbance of the reaction products and the concentration of the drug in the original sample. This relationship is demonstrated in Table I. The ultraviolet absorption spectra of chlorprothixene

TABLE I—STANDARD CURVE DATA FOR CHLORPROTHIXENE REACTION PRODUCT

Chloroprothixene in Sample, mcg./ml.	Absorbance of Reaction Product in Hexane[a]	Absorbance/ Concn.
10.0	0.84	0.084
8.0	0.67	0.084
6.0	0.50	0.083
4.0	0.33	0.083
2.0	0.16	0.080
