Supporting evidence for the 2,4-diamino structure is the moderate antifolate activity of the MTX metabolite when tested in an *in vivo* system (2), or *in vitro*, against partially purified dihydrofolate reductase from L1210 mouse leukemia cells; barring alteration of the *p*-methylaminobenzoylglutamic acid moiety, such activity is compatible with a 2,4-diamino structure but not with a 2-amino-4-hydroxy structure.

The suggestion by other workers that the MTX metabolite is 2-amino-4,7-dihydroxy-MTX was based largely on elementary analyses. The difficulties encountered in elementary analysis, however, and particularly nitrogen analysis of pteridines (6), make additional criteria obligatory before identity can be established. The additional data presented here would favor the 7-hydroxy-MTX structure over the 4,7-dihydroxy-MTX structure.

The rapid hydroxylation of MTX and other 4-amino analogs of pteroylglutamate by the hepatic aldehyde oxidase of either rabbit or guinea pig probably accounts for the very high tolerance of these species for these drugs. The resistance of the hamster to the toxicity of MTX recently demonstrated by Freireich and his co-workers (15) would suggest that the latter species also belongs to this group. On the other hand, the extremely low level of MTX-oxidizing activity of the rat and mouse hepatic aldehyde oxidases (3) correlates well with the sensitivity of the two latter species to the antifolates. The human enzyme has not been studied; however, chromatographic studies of human urine after the administration of MTX show that most of the drug is excreted unchanged (16–18);[4] in addition, clinical data suggest that man is relatively sensitive to both MTX and aminopterin. These observations support the contention that the MTX-hydroxylating properties of human hepatic aldehyde oxidase must be rather low.

SUMMARY

1. Methotrexate (MTX) is readily metabolized by rabbit liver aldehyde oxidase.

[4] Chromatographic examination of human urine 2 weeks after the administration of tritium-labeled MTX has shown the presence of a small amount of non-MTX radioactivity (17); the latter migrated more rapidly on DEAE-cellulose than did MTX, however, and thus cannot be attributed to 7-hydroxy-MTX.

2. Permanganate oxidation of the metabolite of MTX yields a simple pteridine with the properties of 2,4-diamino-7-hydroxy-6-pteridinecarboxylic acid.

3. Heating of the latter compound in 2 *N* sodium hydroxide solution at 70° leads to slow hydrolysis of the 4-amino group.

4. The nonpteridine moiety of the metabolite of MTX is identical with the nonpteridine moiety of MTX.

5. The structure 4-amino-4-deoxy-7-hydroxy-N^{10}-methylpteroylglutamic acid (7-hydroxy-MTX) is proposed for the MTX metabolite.

Statistical Analysis of Log-Dose Response Bioassay Experiments with Unequal Dose Ratios for the Standard and Unknown Preparations

By C. PHILIP COX

Well-known statistical analyses are available for the analysis of log-dose response assays when successive doses are in the same ratio for both the standard and unknown preparations. It is, however, sometimes convenient and advantageous in practice to use unequal dose ratios. Appropriate analyses are offered for such cases, analyses which reduce to the usual ones when the ratios are equal. It is seen that the operational flexibility thus permitted is obtained in return for only slightly increased computation. Four and six-point assays are discussed in detail together with a numerical example of the former. An improved method for calculating confidence interval estimates in log-dose response assays is also given.

STATISTICAL ANALYSES for log-dose response parallel line assays in which the ratios of the successively higher doses are the same for both the standard and unknown preparations are well known. (For example, see *Reference 1.*) The case to be considered here is that in which the ratios of successive doses are constant within each preparation but the constant ratio differs from one preparation to the other. Such a relaxation of the usual single constant ratio condition is occasionally desirable in practice (2) and, for example, may permit the linear response log-dose range of the standard preparation to be exploited in the presence of more uncertainty about the linear range for the unknown preparation.

It will be shown that such flexibility can be achieved with only small changes from the single ratio analyses and, in fact, the latter can be regarded as special cases of the more general analysis proposed here. This analysis has some computational advantages over the alternative based on a single log-dose transformation which gives integral dose-metameter values for one preparation but nonintegral values for the other.

SPECIFICATION AND DOSE TRANSFORMATIONS

It will be supposed that, in an $(h + k)$-point assay, the h and k doses (concentrations) of the standard and unknown preparations, respectively, are chosen so that,

$$\left.\begin{aligned} \frac{z_{Si}}{z_{Si-1}} &= D_S,\ i = 1, 2, \ldots, h \\ \text{and} \\ \frac{z_{Uj}}{z_{Uj-1}} &= D_U,\ j = 1, 2, \ldots, k \end{aligned}\right\} \quad \text{(Eq. 1)}$$

where z_{Si} and z_{Uj} are, respectively, the ith dose of the standard and the jth dose of the unknown preparation.

As usual, it will be assumed that the observed

Statistical Analysis of Log-Dose Response Bioassay Experiments with Unequal Dose Ratios for the Standard and Unknown Preparations

By C. PHILIP COX

Well-known statistical analyses are available for the analysis of log-dose response assays when successive doses are in the same ratio for both the standard and unknown preparations. It is, however, sometimes convenient and advantageous in practice to use unequal dose ratios. Appropriate analyses are offered for such cases, analyses which reduce to the usual ones when the ratios are equal. It is seen that the operational flexibility thus permitted is obtained in return for only slightly increased computation. Four and six-point assays are discussed in detail together with a numerical example of the former. An improved method for calculating confidence interval estimates in log-dose response assays is also given.

STATISTICAL ANALYSES for log-dose response parallel line assays in which the ratios of the successively higher doses are the same for both the standard and unknown preparations are well known. (For example, see *Reference 1.*) The case to be considered here is that in which the ratios of successive doses are constant within each preparation but the constant ratio differs from one preparation to the other. Such a relaxation of the usual single constant ratio condition is occasionally desirable in practice (2) and, for example, may permit the linear response log-dose range of the standard preparation to be exploited in the presence of more uncertainty about the linear range for the unknown preparation.

It will be shown that such flexibility can be achieved with only small changes from the single ratio analyses and, in fact, the latter can be regarded as special cases of the more general analysis proposed here. This analysis has some computational advantages over the alternative based on a single log-dose transformation which gives integral dose-metameter values for one preparation but nonintegral values for the other.

SPECIFICATION AND DOSE TRANSFORMATIONS

It will be supposed that, in an $(h + k)$-point assay, the h and k doses (concentrations) of the standard and unknown preparations, respectively, are chosen so that,

$$\left.\begin{aligned} \frac{z_{Si}}{z_{Si-1}} &= D_S,\ i = 1, 2, \ldots, h \\ \text{and} \\ \frac{z_{Uj}}{z_{Uj-1}} &= D_U,\ j = 1, 2, \ldots, k \end{aligned}\right\} \quad \text{(Eq. 1)}$$

where z_{Si} and z_{Uj} are, respectively, the ith dose of the standard and the jth dose of the unknown preparation.

As usual, it will be assumed that the observed

Received October 17, 1966, from the Statistical Laboratory, Iowa State University, Ames, IA 50010
Accepted for publication December 6, 1966.

The author is grateful to Dr. S. J. Folley for inspiring the solution to a problem he suggested.

responses are subject to residual variability components which are normally and independently distributed about population responses and that these are linearly related to logarithms of the doses over, at least, the dose ranges used. Then, writing

$$d_S = \log D_S \text{ and } d_U = \log D_U$$

dose transformations are defined as,

$$\left.\begin{aligned} x_S &= \frac{1}{d_S}\log(z_S/z_{S1}) \\ \text{and} \\ x_U &= \frac{1}{d_U}\log(z_U/z_{U1}) \end{aligned}\right\} \quad \text{(Eq. 2)}$$

where z_{S1} and z_{U1} are the two lowest doses. Hence, because for the ith dose, from Eq. 1,

$$z_{Si} = D_S z_{Si-1} = \ldots = D_S^{i-1} z_{S1}$$

so that,

$$x_{Si} = \frac{1}{d_S}\log(D_S^{i-1} z_{S1}/z_{S1}) = i - 1$$

it is apparent that the integral x_S values 0, 1, 2, . . . , $(h - 1)$, correspond to the z_S values z_{S1}, z_{S2}, . . . z_{Sh}, and similarly, for the unknown preparation, the second of Eq. 2 transforms the z_U values into the integral x_U values 0, 1, 2, . . ., $k - 1$.

EQUIVALENT DILUTION CONDITION AND RELATIVE POTENCY FORMULA

A dilution assay is one in which the unknown preparation acts simply as a dilution (concentration) of the standard preparation in an inert diluent. In this case if z_{ES} is a dose of the standard preparation which is equipotent to, that is, produces the same response value as a dose z_{EU} of the unknown preparation, any two such equipotent doses are connected by the equivalent dilution relationship

$$z_{ES} = \rho_p z_{EU} \quad \text{(Eq. 3)}$$

where ρ_p is the relative potency.

It is well known that, in the single dose-ratio case, this expression leads to a pair of parallel lines for the relationship between responses and log-dose values. The corresponding implication from the equivalent dilution condition based on the transformations in Eq. 2 is readily obtained as follows.

Let x_{ES} and x_{EU} denote equipotent log-dose-values so that, from Eqs. 2 and 3,

$$d_S x_{ES} - d_U x_{EU} = \log\left(\frac{z_{ES}}{z_{EU}}\right)\left(\frac{z_{U1}}{z_{S1}}\right) = \log(\rho_p z_{U1}/z_{S1}) \quad \text{(Eq. 4)}$$

and it may be noted that, if $d_S = d_U$, Eq. 4 reduces to $x_{ES} - x_{EU}$ = a constant, that is to the usual parallelism condition.

The next step is to find the relations between the parameters of the two response lines when these are such that the condition in Eq. 4 obtains. These relations will further lead to the expression from which the relative potency may be estimated.

For these suppose that population values η_S and η_U of standard and unknown preparation responses are linearly related to their corresponding x_S and x_U values by the equations:

$$\left.\begin{aligned} \eta_S &= \alpha_S + \beta_S x_S \\ \eta_U &= \alpha_U + \beta_U x_U \end{aligned}\right\} \quad \text{(Eq. 5)}$$

α_S and α_U being the intercepts, while β_S and β_U are the slopes of the lines. Then, since $\eta_S = \eta_U$ for equipotent doses,

$$\alpha_S + \beta_S x_{ES} = \alpha_U + \beta_U x_{EU}$$

and, multiplying both sides by d_S,

$$d_S\alpha_S + \beta_S d_S x_{ES} = d_S\alpha_U + \beta_U d_S x_{EU}$$

Hence, substituting for $d_S x_{ES}$ from Eq. 4 into the lefthand side,

$$d_S\alpha_S + \beta_S\{d_U x_{EU} + \log(\rho_p z_{U1}/z_{S1})\} = d_S\alpha_U + \beta_U d_S x_{EU}$$

that is,

$$d_S(\alpha_S - \alpha_U) + \beta_S\log(\rho_p z_{U1}/z_{S1}) + (\beta_S d_U - \beta_U d_S)x_{EU} = 0$$

But, for this relation to hold for all x_{EU} in the linear range, it must be an identity and hence,

$$d_S(\alpha_S - \alpha_U) + \beta_S\log(\rho_P z_{U1}/z_{S1}) = 0 \quad \text{(Eq. 6)}$$

and

$$\beta_S d_U - \beta_U d_S = 0 \quad \text{(Eq. 7)}$$

The relation in Eq. 7 is the new statement of the equivalent dilution condition and which reduces to the parallelism condition, $\beta_S = \beta_U$, when $d_S = d_U$. For the relative potency itself it is first convenient to write the condition in Eq. 7 as:

$$\frac{\beta_S}{d_S} = \frac{\beta_U}{d_U} = \beta \quad \text{(Eq. 8)}$$

Then, from Eq. 6,

$$\log(\rho_p z_{U1}/z_{S1}) = -(\alpha_S - \alpha_U)/\beta \quad \text{(Eq. 9)}$$

so that the population value of the relative potency is given by

$$\rho_p = \frac{z_{S1}}{z_{U1}}\text{ antilog}\left\{-(\alpha_S - \alpha_U)/\beta\right\}$$

and the related estimation procedure is next considered.

RELATIVE POTENCY ESTIMATE

Writing Eq. 5 in the equivalent form,

$$\eta_S = \mu_S + \beta_S(x_S - \bar{x}_S) = \mu_S + \beta d_S(x_S - \bar{x}_S)$$

$$\eta_U = \mu_U + \beta_U(x_U - \bar{x}_U) = \mu_U + \beta d_U(x_U - \bar{x}_U)$$

it follows that

$$(\alpha_S - \alpha_U) = (\mu_S - \mu_U) - \beta(d_S\bar{x}_S - d_U\bar{x}_U)$$

and hence, from Eq. 9, that

$$\log(\rho_p z_{U1}/z_{S1}) = d_S\bar{x}_S - d_U\bar{x}_U - \frac{(\mu_S - \mu_U)}{\beta} \quad \text{(Eq. 10)}$$

Conventional statistical methodology then leads to estimates of μ_S, μ_U, and β as $\bar{y}_S$, $\bar{y}_U$, and b, respectively, where

$$b = \frac{d_S\Sigma_S'xy + d_U\Sigma_U'xy}{d_S^2\Sigma_S'xx + d_U^2\Sigma_U'xx} \quad \text{(Eq. 11)}$$

in which quantities such as,

$$\Sigma_S'xy = \Sigma_S(x_S - \bar{x}_S)(y_S - \bar{y}_S) = \Sigma_S(x_S - \bar{x}_S)y_S$$

can be calculated by the usual computation formula, suffixes S and U denoting summations over the standard and test preparation values, respectively.

From Eq. 10 the relative potency estimate R is then given by

$$R = \frac{z_{S1}}{z_{U1}} \text{antilog } [d_S\bar{x}_S - d_U\bar{x}_U - (\bar{y}_S - \bar{y}_U)/b] \quad \text{(Eq. 12)}$$

Pursuance of the general case beyond this point is straightforward but likely to be of limited practical appeal; more usefully the commonly occurring cases of four and six-point assays will now be examined in detail.

FOUR-POINT LOG-DOSE RESPONSE ASSAY

Suppose that a four-point assay is carried out in a completely randomized design and that n responses are observed at each of the four preparation-dose combinations. Let S_1 and S_2 be the response totals for the lower and higher doses of the standard preparation, U_1 and U_2 being the corresponding totals for the unknown preparation. Then, as in the usual case when $d_S = d_U$, it is convenient for the analysis of variance (ANOV) and the estimation of relative potency to obtain three orthogonal contrasts between the four treatment totals.

The difference between the means for the two preparations $(\bar{y}_S - \bar{y}_U)$ is

$$\bar{y}_S - \bar{y}_U = \frac{1}{2n}(S_1 + S_2 - U_1 - U_2) = -L_p/2n \quad \text{(Eq. 13)}$$

where

$$L_p = -S_1 - S_2 + U_1 + U_2 \quad \text{(Eq. 14)}$$

is the first of the contrasts required.

The second contrast is one proportional to the regression coefficient b. In the four-point assay case the transformations in Eq. 2 lead to x-values of 0 and 1 for the upper and lower doses, respectively. Then:

$$\Sigma_S'xy = \Sigma_S(x_S - \bar{x}_S)y_S = \frac{1}{2}(-S_1 + S_2)$$

and

$$\Sigma_S'xx = \Sigma_S(x_S - \bar{x}_S)^2 = n/2$$

and similarly for unknown preparation summations. Hence, from Eq. 11,

$$b = \frac{d_S(-S_1 + S_2) + d_U(-U_1 + U_2)}{n(d_S^2 + d_U^2)} = \frac{L_r}{n(d_S^2 + d_U^2)} \quad \text{(Eq. 15)}$$

so that

$$L_r = -d_SS_1 + d_SS_2 - d_UU_1 + d_UU_2 \quad \text{(Eq. 16)}$$

will be taken as the second contrast.

The third contrast is one for testing the relevance of the model, in particular, being sensitive to departure from the equivalent dilution condition as now expressed by Eq. 8. This contrast can therefore be taken as proportional to the quantity $(d_Ub_S - d_Sb_U)$ where b_S and b_U are regression coefficients for the standard and unknown preparations taken separately. With

$$b_S = \Sigma_S'xy/\Sigma_S'xx = -(S_1 - S_2)/n$$

and

$$b_U = -(U_1 - U_2)/n$$

it follows that

$$d_Ub_S - d_Sb_U = -\frac{1}{n}(d_US_1 - d_US_2 - d_SU_1 + d_SU_2)$$

The third contrast will accordingly be taken as

$$L_d = d_US_1 - d_US_2 - d_SU_1 + d_SU_2 \quad \text{(Eq. 17)}$$

where the suffix d here denotes divergence from the condition in Eq. 8.

The statistical analysis is based on the usual assumptions that the responses are independent and normally distributed with constant variance. Accordingly, because each contrast is a linear combination of independent observations, the appropriate divisors can be found by conventional statistical procedures and it is also readily checked that the three contrasts are orthogonal. From Eqs. 14, 16, and 17 the complete scheme of contrasts together with the ANOV entries, may then be set out as in Table IA.

Defining the correction term as

$$C = (S_1 + S_2 + U_1 + U_2)^2/4n$$

the ANOV is therefore as shown in Table IB.

Model relevance may be tested by comparing the ratio of the mean squares for divergence and for within preparations and levels against the tabulated critical value, $F_c = F(1, 4n - 4, 0.05)$ say. Assuming satisfactory relevance, the point estimate of relative potency is next obtained. For this, values of $(\bar{y}_S - \bar{y}_U)$ and b can be substituted, from Eqs. 13 and 15 into Eq. 12, to give with $\bar{x}_S = \bar{x}_U = \frac{1}{2}$,

$$R = \frac{z_{S1}}{z_{U1}} \text{antilog } \frac{1}{2}\left[d_S - d_U + (d_S^2 + d_U^2)\frac{L_p}{L_r}\right] \quad \text{(Eq. 18)}$$

With the usual assumptions the only quantities subject to statistical variability are the contrasts L_p and L_r. Accordingly, an interval estimate of the relative potency can be obtained from an interval estimate for the population mean of

$$M = (d_S^2 + d_U^2)L_p/L_r \quad \text{(Eq. 19)}$$

The result due to Fieller (3, 4) for interval estimation of a ratio can be applied in this case using the method of Cox and Ruhl (5). The authors showed that r_L and r_H, the lower and upper limits, respectively, of the 95% confidence interval (for example) for the population mean of a ratio $r = L_p/L_r$ can be expressed as

$$r_L, r_H = \frac{1}{(F_r - F_c)} \times \left[rF_r \mp \sqrt{\frac{a_pF_c}{a_r}(F_p + F_r - F_c)}\right] \quad \text{(Eq. 20)}$$

where

TABLE IA—ORTHOGONAL CONTRASTS FOR AN UNEQUAL DOSE RATIO FOUR-POINT ASSAY (n RESPONSES PER DOSE)

Divergence	1	$L_d^2/2n(d_S^2 + d_U^2)$	
Within prepn. and levels	$4n - 4$	By subtraction	$s^2 = \text{s.s.}/4n - 4$
Total	$4n - 1$	$\Sigma\,(\text{response})^2 - C$ all	

$$F_c = F(1, 4n - 4, 0.05)$$

is, as previously noted, the critical F-value read from standard statistical tables, and

$$\left.\begin{aligned} F_p &= \text{the } F\text{-ratio for preparations in the ANOV} = L_p^2/a_p s^2 \\ F_r &= \text{the } F\text{-ratio for regression in the ANOV} = L_r^2/a_r s^2 \end{aligned}\right\} \quad \text{(Eq. 21)}$$

An improved method can, however, be derived as follows. From Eq. 21,

$$\frac{a_p}{a_r} = \frac{r^2 F_r}{F_p}$$

and substituting this in Eq. 20 gives

$$\begin{aligned} r_L, r_H &= \frac{1}{(F_r - F_c)} \\ &\times \left[rF_r \mp \sqrt{\frac{r^2 F_r F_c}{F_p}(F_p + F_r - F_c)} \right] \\ &= \frac{rF_r}{F_r - F_c} \\ &\times \left[1 \mp \sqrt{\frac{F_c}{F_p F_r}(F_p + F_r - F_c)} \right] \\ &= \frac{r}{\left(1 - \frac{F_c}{F_r}\right)} \\ &\times \left[1 \mp \sqrt{\frac{F_c}{F_r} + \frac{F_c}{F_p}\left(1 - \frac{F_c}{F_r}\right)} \right] \end{aligned} \quad \text{(Eq. 22)}$$

Applied in the present case the lower and upper limits, M_L and M_H, with M as defined in Eq. 19 are then, from Eq. 22,

$$\begin{aligned} M_L, M_H &= \frac{M}{\left(1 - \frac{F_c}{F_r}\right)} \\ &\times \left[1 \mp \sqrt{\frac{F_c}{F_r} + \frac{F_c}{F_p}\left(1 - \frac{F_c}{F_r}\right)} \right] \end{aligned} \quad \text{(Eq. 23)}$$

The final assay results may therefore be cited as:

$$R = \frac{z_{S1}}{z_{U1}} \text{ antilog } \frac{1}{2}(d_S - d_U + M) \quad \text{(Eq. 24)}$$

where the 95% confidence interval is defined by

$$\begin{aligned} R_L &= \frac{z_{S1}}{z_{U1}} \text{ antilog } \frac{1}{2}(d_S - d_U + M_L), \\ R_H &= \frac{z_{S1}}{z_{U1}} \text{ antilog } \frac{1}{2}(d_S - d_U + M_H) \end{aligned} \quad \text{(Eq. 25)}$$

Numerical Example—To illustrate the above method, responses from an assay (6) are used, unequal dose ratios being obtained by assuming that the upper dose of the unknown preparation was 0.9 mg. instead of 1 mg. as used in the actual experiment. The totals, each of 5 individual responses, and the doses taken for present purposes are shown in Table II.

Here then,

$$D_S = 4,\ D_U = 3.6$$

so that,

$$d_S = \log 4 = 0.6021,\ d_U = 0.5563$$

giving,

$$d_S - d_U = 0.0458,\ d_S^2 + d_U^2 = 0.6720$$

The contracts L_p, L_r, and L_d are then calculated in accordance with the scheme in Table IA as,

$$L_p = -350.1 - 213.9 + 335.8 + 240.7 = 12.5$$

$$\begin{aligned} L_r &= -d_S(S_1 - S_2) - d_U(U_1 - U_2) \\ &= (-0.6021)(136.2) - (0.5563)(95.1) \\ &= -134.9102 \end{aligned}$$

$$\begin{aligned} L_d &= d_U(S_1 - S_2) - d_S(U_1 - U_2) \\ &= (0.5563)(136.2) - (0.6021)(95.1) = 18.5083 \end{aligned}$$

With $n = 5$ the corresponding ANOV entries are then,

$$L_p^2/20 = 7.8125$$

$$L_r^2/10(d_S^2 + d_U^2) = (134.9102)^2/6.72 = 2708.4467$$

$$L_d^2/6.72 = (18.5083)^2/6.72 = 50.9758$$

TABLE II—DOSES AND RESPONSE TOTALS

	Std. Prepn., mcg./LH		Unknown Prepn., mg. Tissue	
Dose	0.6	2.4	0.25	0.9
Response total	350.1	213.9	335.8	240.7

From the original ANOV, the total corrected sum of squares was 3692.1775 so that for the present case the ANOV (in which the ratios F_p and F_r are also indicated) is as shown in Table III.

TABLE III—ANOV

Variation Source	d.f.	s.s.	m.s.	
Prepn.	1	7.8125		$F_p = 0.1351$
Regression	1	2708.4467		$F_r = 46.8517$
Divergence	1	50.9758		
Residual	16	924.9425	57.8089	
Total	19	3692.1775		

Since the mean square for divergence is less than the residual mean square relevance may be considered satisfactory. Proceeding to the estimation of relative potency, from Eq. 19,

$$\begin{aligned} M &= (d_S^2 + d_U^2)L_p/L_r \\ &= (0.6720)(12.5)/-134.9102 \\ &= -0.0623 \end{aligned}$$

so that, from Eq. 24,

$$R = \frac{0.6}{0.25} \text{ antilog } \frac{1}{2}(0.0458 - 0.0623)$$

$$= 2.36 \text{ mcg./mg.}$$

For the interval estimate F_c, from statistical tables, is $F_c = F(1, 16, 0.05) = 4.49$ or, if desired, F_c can be obtained from the t-table for 16 degrees of freedom as

$$F_c = t^2(16, 0.05) = 2.12^2 = 4.49$$

Then, with F_p and F_r from the ANOV,

$$\frac{F_c}{F_p} = \frac{4.49}{0.1351} = 33.2346$$

$$\frac{F_c}{F_r} = \frac{4.49}{46.8517} = 0.0958$$

so that, from Eq. 23,

$$\begin{aligned} M_L, M_H &= \frac{-0.0623}{0.9042} \\ &\quad \times [1 \pm \sqrt{0.0958 + (33.2346)(0.9042)}] \\ &= -0.4472, 0.3094 \end{aligned}$$

and, finally, from Eq. 25,

$$R_L, R_H = 2.4 \text{ antilog } \frac{1}{2}(0.0458 - 0.4472),$$

$$2.4 \text{ antilog } \frac{1}{2}(0.0458 + 0.3094)$$

$$= 1.51, 3.61 \text{ mcg./mg.}$$

SIX-POINT LOG-DOSE RESPONSE ASSAY

Suppose that a six-point assay is carried out using a completely randomized design and that n responses are observed at each of doses z_{S1}, $D_S z_{S1}$, $D_S^2 z_{S1}$ for the standard preparation and at doses z_{U1}, $D_U z_{U1}$, $D_U^2 z_{U1}$ for the unknown preparation. Let the respective response totals be denoted in the usual way as S_1, S_2, S_3, and U_1, U_2, U_3. Five orthogonal contrasts together with their ANOV entries can then be defined as shown in Table IV, where $d_S = \log D_S$ and $d_U = \log D_U$.

The first three contrasts are analogous to the three defined for the four-point assay while the contrasts Q_S and Q_U are sensitive to quadratic curvature in the log-dose response lines for the standard and the unknown preparations, respectively. An alternative formulation for the latter two contrasts would be to replace them by contrasts for combined and opposed curvatures Q_1 and Q_2 say, where,

$$Q_1 = Q_S + Q_U = S_1 - 2S_2 + S_3 + U_1 - 2U_2 + U_3$$

$$Q_2 = Q_S - Q_U = S_1 - 2S_2 + S_3 - U_1 + 2U_2 - U_3$$

for which the ANOV entries would be $Q_1^2/12n$ and $Q_2^2/12n$, respectively. The formulation in Table IV, however, is slightly easier to compute and provides for the relevance tests required because appreciable curvature in either response line will render the present analysis inapplicable. The ANOV is then as shown in Table V.

On the assumption that the relevance tests for divergence, curvature(S) and curvature(U) are satisfactory, the relative potency estimate is now obtained by finding appropriate quantities to substitute into Eq. 12. For the 6-point assay the transformations in Eq. 2 lead to x-values of 0, 1, and 2 for both preparations, so that $\bar{x}_S = \bar{x}_U = 1$ and

$$d_S\bar{x}_S - d_U\bar{x}_U = d_S - d_U$$

Next

$$\bar{y}_S - \bar{y}_U = \frac{1}{3n}(S_1 + S_2 + S_3 - U_1 - U_2 - U_3)$$

$$= -L_p/3n \quad \text{(Eq. 26)}$$

with L_p as defined in Table IV.

For the regression coefficient the quantities required are

$$\Sigma_S' xy = -S_1 + 0S_2 + S_3 = -S_1 + S_3$$

$$\Sigma_S' xx = 2n$$

and similarly for the unknown preparation. Hence, from Eq. 11

$$b = \frac{d_S(-S_1 + S_3) + d_U(-U_1 + U_3)}{2n(d_S^2 + d_U^2)}$$

$$= L_r/2n(d_S^2 + d_U^2) \quad \text{(Eq. 27)}$$

From Eqs. 26, 27, and 12 the relative potency estimate is then

$$R = \frac{z_{S1}}{z_{U1}} \text{ antilog } \left[d_S - d_U + \frac{2}{3}(d_S^2 + d_U^2)\frac{L_p}{L_r}\right]$$

$$= \frac{z_{S1}}{z_{U1}} \text{ antilog } [d_S - d_U + M] \quad \text{(Eq. 28)}$$

where

$$M = \frac{2}{3}(d_S^2 + d_U^2)\frac{L_p}{L_r} \quad \text{(Eq. 29)}$$

For the interval estimate M_L and M_H are calculated, using the now appropriate values, from Eq. 23 so that, for the relative potency itself the interval estimate is defined by

TABLE IV—ORTHOGONAL CONTRASTS FOR AN UNEQUAL DOSE RATIO SIX-POINT ASSAY
(*n* RESPONSES PER DOSE)

Contrast		Response Total						ANOV Sum of Sq.
		S_1	S_2	S_3	U_1	U_2	U_3	
Prepn.:	L_p	-1	-1	-1	1	1	1	$L_p^2/6n$
Regression:	L_r	$-d_S$	0	d_S	$-d_U$	0	d_U	$L_r^2/2n(d_S^2 + d_U^2)$
Divergence:	L_d	d_U	0	$-d_U$	$-d_S$	0	d_S	$L_d^2/2n(d_S^2 + d_U^2)$
Curvature (S):	Q_S	1	-2	1	0	0	0	$Q_S^2/6n$
Curvature (U):	Q_U	0	0	0	1	-2	1	$Q_U^2/6n$

$$R_L, R_H = \frac{z_{S1}}{z_{U1}} \text{ antilog } [d_S - d_U + M_L], \frac{z_{S1}}{z_{U1}} \text{ antilog } [d_S - d_U + M_H] \quad \text{(Eq. 30)}$$

CONCLUSION

For a given assay response it has been established in bioassay literature that two highly important requirements for the precision of relative potency estimations are: (*a*) the range, from the lowest to the highest dose investigated, should be as large as possible subject to linearity of the relationship between the response and the log-dose and to the requirement that responses should be normally distributed with constant variance and (*b*) the difference between the mean response of the standard and unknown preparations should be as small as possible.

Curvature (U)	1	$Q_U^2/6n$	
Residual	$6n - 6$	By subtraction	s.s./$6n-6$
Total	$6n - 1$		

In planning an assay, therefore, a basic problem is just that of using what is known about the unknown preparation to best meet these requirements. And in early stages, following perhaps some pilot investigations of log-dose response relationships, it may not be desirable to use equal spacing of log-doses for either the standard or the unknown preparations. The analyses of such general assays can be carried through quite straightforwardly using the actual log-doses instead of being based on log-dose transformations giving integral values for at least one of the two sets of log-doses. The advantages of such transformations are primarily computational so that such transformations are commonly used in relatively well-established assays. In this context the present proposals may be regarded as providing a convenient procedure for intermediate cases. It gives simple computations and allows greater flexibility in the choice of doses than is permitted by the completely canonical form which requires the same dose ratio to be used for both preparations.

Comparative Study in Man and Dog of the Absorption and Excretion of Dextroamphetamine-^{14} C Sulfate in Sustained-Release and Nonsustained-Release Dosage Forms

By EARL ROSEN, THEODORE ELLISON*, PHILIP TANNENBAUM†, SPENCER M. FREE, and ARCHER P. CROSLEY, JR.†

The absorption and excretion of dextroamphetamine-^{14}C sulfate in both sustained-release and nonsustained-release dosage forms were evaluated in identical studies in man and dog. A direct comparison of the results of these studies showed that the various dosage forms performed in a similar way in both man and dog. These results provided information on the design and evaluation of *in vivo* studies intended to indicate which preliminary sustained-release formulations merit objective human testing.

IN THE ABSENCE of an accurately measurable clinical effect, an objective way to evaluate the performance of sustained-release dosage forms in humans is to compare how a drug is absorbed and excreted from this dosage form and from the regimen it is intended to replace. There are many problems involved in conducting such studies: the need for a substantial number of humans; the need for specialized analytical techniques to measure the drug levels in body tissues; the need for knowledge not only of the statistical considerations in experimental design, but also of individual drug kinetics; and the need for professional surveillance to insure faithful adherence to dosage regimens, food and liquid intake, and a set schedule of sample collections.

Because these problems exist, only the most promising experimental formulations merit such objective human testing. So there is a need for *in vivo* animal studies that will provide data comparable to those obtained in human studies and thus indicate which preliminary formulations merit such testing.

The authors recently conducted an absorption and excretion study in humans comparing a dextroamphetamine-^{14} C sulfate pelleted sustained-release product with similarly labeled nonsustained-release regimens (1). It was necessary to tag the drug with the radioactive carbon atom because ordinary biochemical methods are not adequate to measure the low concentration of dextroamphetamine sulfate that appears in blood.

It was decided to carry out an identical study in dogs to obtain directly comparable data, reasoning that a comparison of the data would serve as a useful reference for the design and evaluation of future formulation screening studies in the dog.

This study is a report of the data on the absorption and excretion of various dosage forms of dextroamphetamine-^{14} C sulfate in both man and dog, as well as an analysis of how well these data compare with each other.

EXPERIMENTAL

Preparation of Dosage Forms—Based on human safety considerations, the highest dose of dextroamphetamine sulfate to be administered (15 mg.) was tagged with a maximum single radiation dose of 45 μc. To obviate the problems involved in uniformly mixing labeled with unlabeled drug, we chose to synthesize the labeled drug with a specific activity of approximately 3 μc./mg. The method of preparation described by Blackburn and Burghard was used (2).

The pelleted sustained-release dosage form of the labeled drug was prepared by a method similar to that reported previously by Rosen and Swintosky (3). One kilogram of medicated nonsustained-release pellets was prepared in a 12-in. coating pan located in a disposable glove-box inside a walk-in fume hood fitted with special filters. A portion (135 Gm.) of these nonsustained-release pellets was set aside and the remaining pellets were coated with a wax-fat coating. Six separate groups with approximately 7, 9, 11, 13, 15, and 17% wax-fat coating were prepared. This was done to insure that there would be sufficient spread in patterns to facilitate blending for the *in vitro* pattern of the commercial product.

The *in vitro* release patterns of the six experimental groups are shown in Table I; they were determined by the method of Souder and Ellenbogen (4).

As reported (4), the average *in vitro* pattern of 15 consecutive commercial lots of the specific 15 mg. dextroamphetamine sulfate sustained-release product we chose to simulate was 39, 62, 80, and 90% at the 0.5, 2, 4.5, and 7 hr. time intervals,

Received October 3, 1966, from the Research and Development Division, Smith Kline & French Laboratories, Philadelphia, PA 19101, and the † Section of Clinical Pharmacology, Research Institute and Department of Medicine, Presbyterian-University of Pennsylvania Medical Center, Philadelphia, PA 19104

Accepted for publication December 2, 1966.

The authors are grateful to Mr. Louis Gutzait for his technical assistance.

* Present address: Riker Laboratories, Northridge, CA 91324

respectively. In the six experimental groups it was found that the blend consisting of 25% noncoated pellets, 55% W-F3, and 20% W-F2 pellets gave a calculated pattern of 37, 57, 81, and 97% at the same time intervals.

The *in vitro* patterns of this blend before and after encapsulation are shown in Table II.

These data indicated that the *in vitro* release pattern of the experimental ^{14}C-labeled capsule closely approximated that of the commercial product.

The 5-mg. and 15-mg. nonsustained-release capsules which were used in the *in vivo* studies were prepared by filling capsules with nonsustained-release pellets of dextroamphetamine-^{14}C sulfate.

In Vivo Protocols—The following four dosage regimens of labeled drug in man and dog were compared: *A*, 15-mg. sustained-release dosage form given at 0 hr.; *B*, 15-mg. nonsustained-release dosage form given at 0 hr.; *C*, 5-mg. nonsustained-release dosage form given at 0 hr.; *D*, 5-mg. nonsustained-release dosage form given t.i.d., at 0, 4, and 8 hr.

These particular regimens were chosen because the authors wanted to determine five performance criteria: whether the sustained-release formulation provided a prompt initial dose; whether it was similar to t.i.d. administration; whether it was dissimilar to an equivalent nonsustained-release dose; whether equal doses in different dosage forms were equally effective in making the drug available for absorption; and whether there was any significant variability among subjects receiving the various regimens.

The earlier study in humans utilized 16 subjects in a crossover sequence; the study plan is shown in Table III.

Radiation safety considerations precluded the giving of each subject all four dosage regimens. Instead, each subject received two regimens, one week apart. Because four subjects were studied at one time, all four regimens were given on each day of the study. All possible combinations and permutations were covered in the first three groups, so the authors utilized the last group to repeat the most significant direct comparisons—that of *A* with *D*, and *B* with *C*.

The plan for the dog study is shown in Table IV. Eight female purebred beagle dogs ranging in weight from 9 to 11 Kg. were used in this study. They were given no food after 4:30 p.m. the day prior to dosing and the prescribed dosage regimen was administered, with no fluid, starting at 10 a.m. the next morning. The animals were then fed and watered 3.5 hr. after receiving the drug. Each animal received all four dosage regimens.

Blood Sampling—Human blood specimens were collected at 0.5, 1, 2, 3, 4, 6, 8, 12, 24, 32, and 48 hr. To accomplish this with a minimum of discomfort to the subject, the first seven specimens were collected through an indwelling anticoagulated venous needle system, as illustrated in Fig. 1. Before each collection, 5 ml. of blood was aspirated into a syringe; this flushed the system with fresh venous blood. Then the syringe was isolated from the system and the required 10-ml. specimen was collected through a heparin vacuum tube inserted in the stopcock. When the specimen had been withdrawn, the system was again flushed with the anticoagulant-blood mixture by returning 5 ml. to the subject. The plasma was removed from each blood sample and frozen until assayed.

Stopcock is then closed to await next collection.*

Blood samples from the dog were taken using a 5-ml. heparinized vacuum tube, and the time periods were the same as those in the human study. These plasmas were also separated and frozen until assayed.

Urine Sampling—Urine was collected from all humans for 48 hr. following ingestion of the drug. The collection intervals were 0–3, 3–6, 6–9, 9–12, 12–24, 24–32, and 32–48 hr. Aliquots of these samples were frozen until assayed.

Urine was collected from the dogs by catheterization at the same time intervals as those in the human study, and these samples were also stored frozen until assayed.

Analysis of the Specimens—Samples of plasma and urine ranging from 0.2 to 0.5 ml. were placed in a liquid scintillation counting solution with the following formula: dimethyl POPOP [2,2-*p*-phenylenebis(5-phenyloxazole)], 50 mg.; PPO (2,5-diphenyloxazole), 7-Gm.; naphthalene, 80 Gm.; toluene, 400 ml.; *p*-dioxane, 400 ml.; diluted to a total of 1000 ml. with absolute alcohol.

The samples were counted using a Tri-Carb[1] liquid scintillation spectrometer, and all measurements were corrected for background, quench, and dilution. The efficiency of the counter was approximately 50%.

RESULTS AND DISCUSSION

The human data have been reported previously (1), but because they are an integral part of this comparative study, they are repeated here. In this regard, note that two minor errors were found after reporting these data and, although they in no way alter the original interpretation, they have been corrected in Fig. 2 (ordinate scale) and Table V (*0–48 hr. data column*).

Plasma Data—The radioactivity appearing in the plasma of the humans following the administration of the four dosage regimens is shown in Fig. 2.

[1] Model 314-DC, Packard Instrument Co., Inc., La-Grange, Ill.

Because of the low order of radioactivity, the average plasma data are reported as counts per minute per milliliter. Of course, the authors were measuring the levels of radioactivity not only from the parent compound but also from its metabolites.

The 15-mg. sustained-release dosage form and the 5-mg. capsule given at 0, 4, and 8 hr. produced roughly similar curves, but the sustained-release preparation showed a higher level during most of the first 8 to 10 hr. after administration, with none of the "staircase" effect or 12-hr. peaking seen with the t.i.d. regimen. The 15-mg. nonsustained-release dosage form gave different results. It showed a high peak at 2 hr. that was maintained for at least 8 hr.; this plot paralleled the one for the 5-mg. capsule given once, but at a proportionately higher level.

The radioactivity appearing in the plasma of dogs following the administration of the four regimens is shown in Fig. 3.

Although the plots for the 15-mg. sustained-release dosage form were very similar in man and dog, the plots for the 5-mg. capsule given t.i.d. differed. In the dogs, this plot showed a rapid rise after the first two doses but, unexpectedly, there was no rise after the third dose. And there was no peak at the 12th hr., causing a plateau from the 6th to the 12th hr.

The 15-mg. nonsustained-release dose showed a peak at 2 hr. that was maintained until the 4th hr.; then the level started to drop. As in the human study, this plot paralleled that of the 5-mg. capsule given once, but at a proportionately higher level.

Urine Data—The urinary excretion plots for the humans are shown in Fig. 4; those for the dogs are shown in Fig. 5. Although the excretion values are expressed as milligrams of drug to which the ^{14}C is equivalent, as mentioned before, the radioactivity reflects not only the parent compound but also its metabolites.

The urinary findings in man and dog were consistent with the plasma findings. The 15-mg.

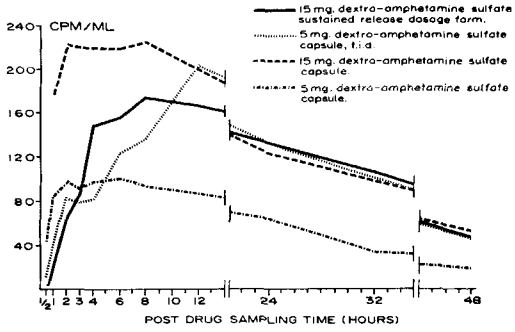

Fig. 2—Adjusted average human plasma levels. Each line represents eight subjects per regimen in a balanced incomplete block crossover design.

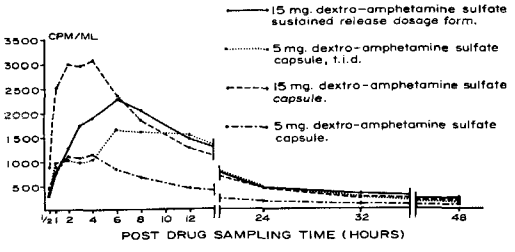

Fig. 3—Adjusted average dog plasma levels. Each line represents eight dogs per regimen.

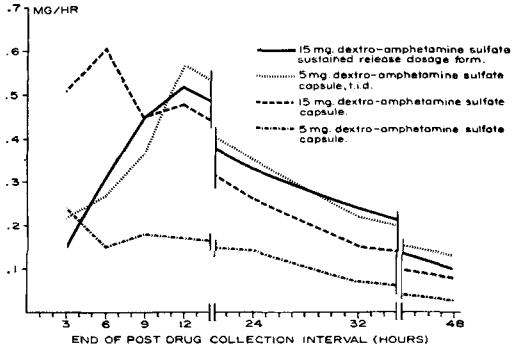

Fig. 4—Adjusted average human urinary excretion rates. Radioactive counts are expressed as average milligrams of dextroamphetamine sulfate per collection interval divided by the number of hours in each interval

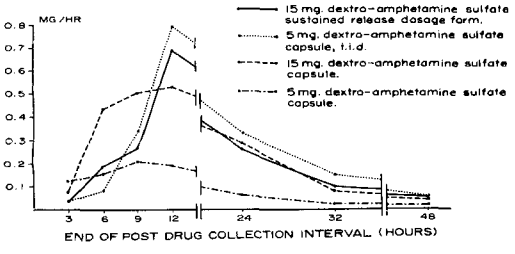

Fig. 5—Adjusted average dog urinary excretion rates. Radioactive counts are expressed as average milligrams of dextroamphetamine sulfate per collection interval divided by the number of hours in each interval.

sustained-release dosage form gave a curve similar to that of the 5-mg. capsule given three times a day. And, just as the plasma data for the 3–10-hr. period showed more drug being absorbed from the sustained-release dosage form, so the urinary data showed that during this same period the excretion was greater from the sustained-release form than from the t.i.d. regimen. The plots of the 15 and 5-mg. plain capsules again paralleled each other at proportionate levels.

The cumulative urinary excretion data for the humans are shown in Table V. These data indicated that in the first 12 hr. following administration of the drug, the sustained-release and t.i.d. regimens made approximately the same amount of drug available for absorption. On the other hand, the 5-mg. capsule given once made significantly less of the drug available and the 15-mg. capsule given once made significantly more of the drug available. Cumulative urinary excretion data for the 24th hr. through to the 48th hr. showed that the three 15-mg. regimens made the same amount of drug available for absorption. Almost proportionately equivalent amounts were made available from the 5-mg. single dose.

TABLE V—ADJUSTED AVERAGE[a] URINE RECOVERIES IN HUMANS, mg. OF DEXTROAMPHETAMINE SULFATE EQUIVALENT

Dosage Form	Collection Interval, hr. 0–12	0–24	0–48
5-mg. capsule	2.18	3.90	4.89

5-mg. capsule, three times each day	4.32	8.48	12.30
15-mg. capsule	6.14	9.31	11.86

[a] Each figure is the average for eight humans. [b] No figure included in a brace is significantly different from any other figure included in that brace ($P < 0.05$).

The cumulative urinary excretion data for the dogs are shown in Table VI. In the 0–12 hr. interval, the three highest and three lowest values were not significantly different from each other; only the extreme values showed a significant difference. And, as in the human study, the data in this interval for the sustained-release and t.i.d. regimens showed excellent agreement. It should be noted that although both humans and dogs excreted similar amounts after the 5-mg. acute dose, the dogs excreted less than the humans after the three 15-mg. regimens. It is assumed that this finding is related to the lower total absorption seen in the dogs. All three 15-mg. regimens again made the same amount of drug available by the 24th hr., and through to the 48th hr., with significantly less drug excreted from the 5-mg. single dose.

Although the most valid way to compare drug availability from various dosage forms is to compare cumulative urinary recovery data, plotting plasma data is also informative. When the authors plotted plasma level *versus* time, the area under the 15-mg. acute dose plot was significantly greater than the area under the 15-mg. sustained-release plot or the 5-mg. t.i.d. plot, but the urinary recoveries for all three regimens were similar. And this was true for both man and dog. To explain this apparent paradox,

we assume that the 15-mg. acute dose did not achieve distribution equilibrium during the early time periods.

TABLE VI—ADJUSTED AVERAGE[a] URINE RECOVERIES IN DOGS, mg. OF DEXTROAMPHETAMINE SULFATE EQUIVALENT

Dosage Form	Collection Interval, hr. 0–12	0–24	0–48
5-mg. capsule	2.02[b]	2.74	3.23
15-mg. sustained-release capsule	3.50[b]	6.62[b]	8.28[b]
5-mg. capsule, three times each day	3.77[b]	7.71[b]	9.76[b]
15-mg. capsule	4.62	9.76	9.33

[a] Each figure is the average for eight dogs. [b] No figure included in a brace is significantly different from any other figure in that brace ($P < 0.05$).

Coefficient of Variation Data—Table VII shows the coefficient of variation for the first 8 blood specimens and for the cumulative urine collections in the human study; Table VIII shows these data for the animal study.

In both humans and animals, these data indicated that there was a relationship between the variation at any particular time and the average recovery result at that time, with low intrinsic values showing the highest degree of variation. At most data points, the three 15-mg. regimens showed equivalent variability; in other words, the variability was related to the average ^{14}C recovered at each sampling time or collection interval, and not to the dosage forms studied.

The design of the experiments provided internal checks of its validity by including dose response relationships. In man and dog, the 15 and 5-mg. plain capsules gave plasma and urine plots that paralleled each other at proportionate levels; this fact validated our methodology.

SUMMARY

The study in man and dog was undertaken to determine certain performance criteria for four dosage forms of dextroamphetamine-^{14}C sulfate. The experimental data indicated the following conclusions.

1. In man and dog, the initial 3-hr. portions of the plasma plots for the sustained-release dosage form, the t.i.d. regimen, and the 5-mg. single dose were similar. Therefore, the sustained-release formulation did provide a prompt initial dose.

2. In man and dog, the plasma and urine plots for the sustained-release dosage form and the t.i.d. regimen were similar.

3. In man and dog, the plasma and urine plots for the sustained-release dosage form and the 15-mg. plain capsule were dissimilar.

4. In man and dog, the sustained-release dosage form made as much drug available for absorption as the other two 15-mg. regimens.

5. In man and dog, the variation in plasma and urine data is not greater with the sustained-release dosage form than with the t.i.d. regimen.

Because the preceding five statements can be applied to both man and dog, this example study serves to promote confidence in the selection of sustained-release formulations worthy of objective human testing based on comparative dosage form performance criteria obtained in the dog.

Effect of Urea on Solubility

Role of Water Structure

By STUART FELDMAN and MILO GIBALDI

The solubilities of benzoic and salicylic acid in aqueous urea, methylurea, and 1,3-dimethylurea solutions were studied. From a thermodynamic transfer model, the free energy, enthalpy, and entropy of solution were determined. By virtue of the fact that the solubilization process was nearly athermal and by the magnitude of the free energy and entropy values obtained, it was concluded that the enhanced solubilization of benzoic and salicylic acid in urea and alkylurea solutions did not involve complexation. The effect of urea on water structure and hydrophobic bonding was considered. By examination of the literature and analysis of the data obtained from this investigation it was proposed that urea, methylurea, and 1,3-dimethylurea solubilized benzoic and salicylic acids by "breaking up" water clusters surrounding the nonpolar molecule, increasing the entropy of the system, and producing a "driving" force for the solubilization. It was found that the alkyl substituted ureas, methyl- and 1,3-dimethylurea, produced a greater increase in solubility than urea, with 1,3-dimethylurea having the greater effect upon the solubility of the aromatic acids. It was noted that the urea and the alkylureas had the greatest solubilization effect on the more hydrophobic molecule, salicylic acid. A discussion of the solubilizing effect of urea on the aromatic acids is presented.

IT HAS BEEN reported that the presence of urea increases the water solubility of benzoic and the hydroxybenzoic acids (1, 2). Bolton (1) and Altwein *et al.* (2) studied the effect of urea on the solubilization of benzoic and salicylic acids. Altwein and co-workers (2) concluded that the interaction of urea with salicylic acid was a complex interaction but was definitely a "complexation" even though "urea possesses low complexing ability."

Bolton (1) termed the "interaction" of urea with salicylic and benzoic acids a complexation and calculated approximate stability constants (K_s), on the basis of a 1:1 interaction, of 0.2 for the urea–benzoic acid system and 0.3 for the urea–salicylic acid system.

These values are considerably lower than stability constant values of complexations which have been reported in the literature (3). Literature values have ranged from about $K_{1:1} = 2.0$ for salicylic acid and substituted amides to $K_{1:1} = 44$ for the complexation between salicylic acid and caffeine (3). Benzoic acid has yielded corresponding values for similar interactions (3).

The unusual thermodynamic data reported for urea–benzoic acid and urea–salicylic acid raises some doubt as to the mechanism of this solubilization. It was therefore of interest to consider the phenomenon in terms of the general properties of urea solutions. To appreciate fully the complex properties of aqueous solutions of urea, a discussion of water structure is in order.

THEORETICAL ASPECTS

Water Structure and the Effect of Urea—Water, as ice, exists in an open structure consisting of tetrahedral hydrogen bonds between water molecules in three dimensions (4). When ice melts there still remains a high degree of hydrogen bonding in the resulting liquid. The hydrogen bonded water molecules take the form of "clusters" which are nearly spherical in shape (4). Therefore, there exist in liquid water two types of water molecules: (*a*) the free or unbonded water molecule; and (*b*) the clusters of hydrogen bonded water.

When nonpolar solutes dissolve in water, they increase the ordering of water molecules around them (5). It was from this model that the concept of "icebergs" or water molecule clusters, forming about nonpolar solutes, was evolved. Essentially, the nonpolar solute becomes associated with the tetrahedral water molecules and becomes its fifth neighbor through van der Waals interactions. The water cluster forms a partial cage around the hydrocarbon. Since there is greater stability in this penta-coordinated state, more molecules will occupy lower energy levels, promoting more hydrogen bonding and an ordering effect on the solvent (4). This process is known as *hydrophobic hydration* and is accompanied by a small decrease in enthalpy, a large decrease in entropy, and a resulting large positive free energy of the system.

An opposite effect is achieved when nonpolar moieties or residues associate in the presence of water. This phenomenon is termed *hydrophobic bonding*. The formation of the hydrophobic bond will involve a decrease in the ordering of the system since the "ice-like" regions between the nonpolar residues become partially melted as the residues come together. Therefore, there will be an increase in the entropy of the system, a small positive enthalpy, and a free energy of from -0.2 to -1.5 Kcal./mole. Hydrophobic bonding, from a mechanistic point of view, actually places a limitation on the solubility of nonpolar compounds in water. The hydrophobic interaction, which is "driven" by entropic contributions, would tend to "pull"

hydrocarbons out of solution, and is responsible for the low water solubility manifested by nonpolar compounds.

It is widely held that urea has the ability to reduce hydrophobic bonding (5–7). This effect has been ascribed to the unusual capacity of urea for "breaking up" the icebergs in liquid water. Urea becomes associated with the structured water by hydrogen bonding and takes an active part in the formation of a more open "lattice" structure (8). The increase in entropy gained by "disruption" of water structure by urea makes the association of nonpolar molecules by hydrophobic bonding thermodynamically less favorable, and there is an increase in water solubility of the nonpolar compound.

Mukerjee and Ghosh (6) have shown that urea effectively reduces the degree of self-association of methylene blue in aqueous solution, thereby increasing its water solubility. Katayama *et al.* (9) showed the effect of urea on the aqueous solubility of a series of azo-dyes. They noted that urea had a more pronounced effect on the solubility of those compounds having the larger "hydrophobic surface."

Abu-Hamdiyyah (8) proposed that urea participated in the formation of "mixed" clusters in aqueous solution. The "mixed" clusters were found to be less thermally stable than pure water clusters, indicating a higher enthalpy in the aqueous urea solutions and an entropic driving force for the spontaneous transfer of nonpolar solutes from pure water to aqueous urea solutions (10). The increase in entropy was attributed to the "increase in the number of available cavities or interstices for the solute molecules in aqueous urea solutions."

Abu-Hamdiyyah (8) also predicted, on the basis of the above conclusions, the effect of alkyl-substituted ureas on the strength of the hydrophobic bond. He stated that (*a*) an alkylurea derivative would have a decreased ability to hydrogen bond with water compared to the ability of urea itself, thereby decreasing the ability of the urea derivative to participate in cluster formation, and (*b*) the alkyl groups themselves could only be accommodated in the cavities produced in the aqueous solution, resulting in a decrease in the number of cavities available for the nonpolar compound. He concluded that alkyl substituted ureas would have a minimal effect on hydrophobic bonding as compared to urea.

Thermodynamic Considerations—When considering the process where a compound is transferred from water to urea solution, the following equation may be written (5, 9):

compd. in water (mole fraction N_0) $\rightarrow$
compd. in urea solution (mole fraction N) (Eq. 1)

The ratio of the mole fractions N/N_0, may be considered as a partitioning ratio since it involves the distribution of the compound between two phases, the water phase and the urea solution phase.

In this case the free energy of partitioning (ΔF) may be determined from the following expression (9):

$$\Delta F = -2.3\,RT \log (N/N_0) \qquad \text{(Eq. 2)}$$

The enthalpy of partitioning (ΔH) can be determined from the following relationship, which represents a modification of the van't Hoff equation (9, 11):

$$\frac{d \ln (N/N_0)}{dT} = \frac{\Delta H}{RT^2} \qquad \text{(Eq. 3)}$$

Rearranging to solve for ΔH;

$$\Delta H = -2.3R\,[d \log (N/N_0)/d(1/T)] \qquad \text{(Eq. 4)}$$

From this equation it can be seen that a plot of log (N/N_0) *versus* $1/T$ for each urea concentration would result in a straight line with a slope equal to $-\Delta H/2.3R$, providing ΔH remains reasonably constant over the temperature range studied. The change in entropy (ΔS) associated with this process can be determined by use of the following equation (9):

$$\Delta S = \frac{\Delta H - \Delta F}{T} \qquad \text{(Eq. 5)}$$

EXPERIMENTAL

Materials—The benzoic acid (m.p. 122°), salicylic acid (m.p. 159°), and urea (m.p. 132°) used in this study were Fisher certified reagent grade. Methylurea (m.p. 101°) and 1,3-dimethylurea (m.p. 107°) were obtained from Eastman Kodak. The purity of each drug was determined by melting point analysis and determination of ultraviolet spectra.

Assay Procedures—Beer's law plots were obtained for benzoic and salicylic acid by diluting aliquot portions of standard solutions of each drug with 0.1 *N* HCl–anhydrous methanol (1:10) solution.

Absorbance was determined by means of a Beckman DB recording spectrophotometer at the 272 mμ peak for benzoic acid and the 304 mμ peak for salicylic acid. Absorbance *versus* concentration plots were then constructed, and the slope was determined by the method of least squares.

Possible interference with the assay procedure was determined by adding various quantities of 3 *M* urea or urea derivative to known concentrations of each drug. No shifts in absorbance maxima and no alterations in absorbance values were noted.

Solubility Determinations—Initial solubility studies were conducted according to the methods of Altwein *et al.* (2). After encountering significant experimental difficulties, which are discussed in a subsequent section of this report, the following methodology was adopted.

The quantity of urea, methylurea, or 1,3-dimethylurea needed to produce a given volume of 3 *M* solution was carefully weighed out on a Mettler balance (model H15). The urea was then dissolved in a minimum amount of water. The pH of the solution was adjusted to pH 1 with concentrated HCl to suppress ionization of the acid species. All pH measurements were recorded by means of a Beckman Zeromatic pH meter. The solution was then transferred to a suitable volumetric flask and brought to volume with 0.1 *N* HCl.

Solutions of urea or urea derivative ranging from 0 to 3 *M*, at half-molar intervals, were prepared in 25-mm. screw cap culture tubes, by adding an appropriate amount of 3 *M* urea solution and sufficient 0.1 *N* HCl to bring the total volume to 10 ml.

A sufficient amount of drug (benzoic acid, 0.5 Gm.; salicylic acid, 0.6 Gm.) was added to each tube to insure an excess at equilibrium. The

mouth of each tube was covered with aluminum foil and capped to prevent evaporation.

The samples were equilibrated in a Metabolyte water bath shaker[1] at temperatures of 30°, 33°, 40°, and 45° and in a Gyrotory incubator shaker model G-25[1] at 37° for periods not less than 12 or more than 18 hr. Equilibrium was determined by repetitive sampling.

Before the tubes were to be sampled, the shaker was turned off to allow the excess solid material to settle. The liquid was then filtered through a Millipore[2] filter (0.45 μ pore size) to insure that no solid particles were present in the sample. To eliminate any variation due to a temperature differential, the filtration and sampling equipment were maintained at the same temperature as that of the equilibrium study.

One milliliter of sample was withdrawn from the filtrate and was diluted to 10 ml. with acidified methanol (1 ml. 0.1 *N* HCl to 100 ml. anhydrous methanol). All subsequent dilutions were made with 0.1 *N* HCl–acidified methanol (1:10). The absorbance of each solution was determined and the drug concentration was calculated from the absorbance values by use of the Beer's law plots.

RESULTS AND DISCUSSION

The initial solubility studies, using the method of Altwein *et al.* (2), involved equilibrating the drug in stock solutions of urea prepared in 0.1 *N* HCl. However, this approach led to a number of unusual findings. The pH values of 1 to 5 *M* urea solutions prepared in this manner were then checked to determine whether a substantial difference in pH existed between samples. Values ranged from pH 1.45 in 1 *M* urea to pH 2.40 at a 5 *M* urea concentration. The increase in pH of 0.1 *N* HCl solution as a function of urea concentration is apparently due to the presence of impurities in the urea, since urea itself is too weak a base to produce these effects. Bull *et al.* (12) have reported that even recrystallized urea contains small amounts of ammonium cyanate present in sufficient quantity to elevate the pH of HCl solutions. The effect of increasing pH on the solubility of benzoic and salicylic acids is quite significant in view of the fact that the greater the degree of ionization, the greater the solubility.

The procedures described under *Experimental* were adopted to overcome these difficulties. At each urea concentration, sufficient HCl was added to insure that essentially all the benzoic or salicylic acid in solution existed in the undissociated form. Under these experimental conditions little degradation of urea will occur (13). In addition, the ionic strength of these solutions was sufficiently high so that the small ionic contamination in the urea sample should have little effect on the solubility data.

Each drug was equilibrated with urea and methylurea at 30°, 37°, and 45° and with 1,3-dimethylurea at 30°. The N/N_0 ratios were determined from the base solubility of each drug (N_0) and the corresponding solubility in urea (N) solution. The solubility curves in mg./ml. of drug *versus* molarity of urea for each drug and urea derivative at the temperatures studied are represented by Figs. 1–4. Solubility data are also tabulated in Tables I and II. It can be seen from the graphs that the solubility of benzoic and salicylic acid is a linear function of urea concentration. The plots of solubility of drug *versus* moles of urea derivative for methylurea show curvature. Similar plots were observed for 1,3-dimethylurea at 30°. In each case the solubility of both drugs is increased significantly

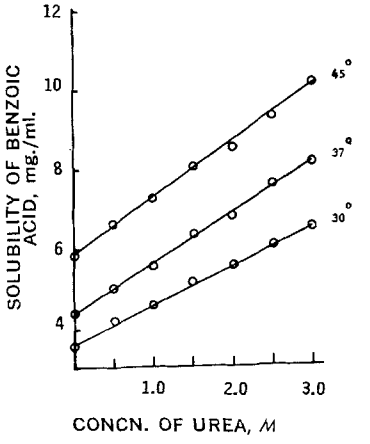

Fig. 1—Solubility of benzoic acid as a function of urea concentration.

[2] Millipore Filter Corp., Bedford, Mass.

by the addition of urea or urea derivative to the aqueous solutions. For each drug the order of effectiveness of the urea derivatives as solubilizers decreased in the following manner: 1,3-dimethylurea > methylurea > urea. Comparative solubility plots of benzoic and salicylic acid at 30° as a function of urea derivative are presented in Figs. 5 and 6.

To determine the enthalpic contribution to the dissolution process, log N/N_0 values of salicylic and benzoic acid for each concentration of urea and methylurea between 0.5 and 3.0 M were plotted *versus* $1/T$. The slope of each plot was determined by the method of least squares and the ΔH calculated. The change in enthalpy was found to be exceedingly small, in the order of ±100 cal. The random nature of the results, however, prevented a definitive statement as to whether the process was endothermic, exothermic, or athermal. The variation in ΔH from concentration to concentration showed no trend and appeared to involve a random error.

In an attempt to refine the data, solubility determinations of each drug were carried out in 2 M solutions of urea and methylurea at 33° and 41°,

and in 2 *M* 1,3-dimethylurea at 33°, 37°, 41°, and 45°. It was anticipated that a total of five temperature data points for each drug in each urea solution would clarify the extent of enthalpic contribution. Unfortunately, this was not the case. The ΔH values closely approximated zero, but the degree of inherent error prevented assignment of a positive or negative sign to the enthalpic component.

Further analysis of the data indicated that the method used for determining ΔH values was considerably more sensitive than the experimental procedures. The following illustration may serve to clarify the problem. Assume that the N/N_0 ratios for a particular experimental condition at 30° and 45° were 1.50 and 1.53, respectively. Further assuming that the N/N_0 ratio is really constant, these data would be in error to the extent of 1.5%. However, when the N/N_0 ratios are converted to logarithms the error is increased to approximately 4.5%. The 1.5% deviation (which is a reasonable approximation of experimental error) and the corresponding 4.5% deviation in the log of N/N_0 yields a ΔH of approximately −255 cal./mole, rather than zero.

The failure to refine the data by no means negates the value of determining the thermodynamic parameter, albeit an approximation. The methods employed were sufficiently sensitive to permit the conclusion that the enthalpic component was indeed small, certainly no greater than ±100 cal., and to a first approximation considered as zero.

The type of complexation most frequently described in the pharmaceutical literature involves the formation of a hydrogen bond (11). The enthalpy for the formation of a hydrogen bond is between 3 and 5 Kcal./mole (14), well above the small ΔH's noted in this investigation. Furthermore, it has been reported (15) that the strength of the hydrogen bond formed by urea molecules is of the same order of magnitude as those bonds formed by water. Therefore, even if urea formed hydrogen bonds with the benzoic or salicylic acid molecule, the strength of the bond would be about the same as the hydrogen bond formed between water and the drug molecule, and there should be no significant increase in solubility of the drug in aqueous urea solutions.

The free energies (ΔF) for the solubilization process have also been computed and are reported in Tables III and IV. They are small negative values similar to values reported by Katayama (9) and others (10, 15), who have solubilized nonpolar solutes in urea solutions. The negative sign is indicative of the spontaneity of the process.

Bolton (1), relying on complexation theory to explain the interaction of urea and salicylic acid, calculated apparent stability constants for the process. The magnitude of these constants, however, would yield a positive ΔF indicating a nonspontaneous process, which is clearly not the case. Moreover, the free energy values obtained in this investigation also tend to rule out a complexation mechanism in that the ΔF values of complexation are usually in the 2–5 Kcal./mole range (3, 16).

Since salicylic acid and benzoic acid do not appear to be solubilized by urea *via* a complexation mechanism, the possibility remains that urea is in some way "disrupting" water structure and thereby bringing about an increase in the solubility of the aromatic acids.

The solubility of benzoic and salicylic acid in water is due largely to the presence of polar groups on the aromatic ring. Water can solvate the benzoic or salicylic acid molecule through dipole interaction forces, particularly hydrogen bond formation. Thus, benzoic acid has a higher water solubility than salicylic acid. The latter, by forming intramolecular hydrogen bonds, presents a more "hydrophobic surface" to the solvent. When benzoic or salicylic acid is placed in water two interactions are possible.

The first possibility is that there is an interaction between the polar group on the aromatic nucleus and the water clusters. This hydrogen bonding between the polar group on the acid molecule and the water clusters would tend to break the clusters of hydrogen bonded water molecules and replace them partially with hydrogen bonds between the polar portion of the aromatic acid and the free water molecules. This interaction would tend to increase the solubility of the drug molecule through the negative ΔH values produced by hydrogen bond formation and the positive ΔS values brought about by the break up of water clusters.

The second possible point of interaction is between the nonpolar or hydrophobic portion of the drug molecule and the water clusters. The interaction comes about through van der Waal's forces and results in a hydrophobic hydration of the nonpolar molecule. An interaction of this type would tend to be a limiting factor in the solubility of the compound because of the large negative entropies and positive free energies which result. As noted previously, extensive hydrophobic hydration produces a situation where hydrophobic bonding between drug molecules and the resulting limitation on solubility would be energetically favored.

Therefore, the degree of solubility of benzoic or

salicylic acid in pure water would depend upon the relative magnitudes of the hydrophobic surface of each molecule. Since salicylic acid, by virtue of its intramolecular bonding, has the larger hydrophobic surface and can, therefore, demonstrate self-interaction to a greater extent by hydrophobic bonding, it should (based on the above consideration) have a lower water solubility than benzoic acid. This is, of course, the case.

Since urea effectively breaks up the clusters of hydrogen bonded water molecules in aqueous solution resulting in an increase in the entropy of the system, there would be less entropy to be gained by the hydrophobic bonding between the relatively nonpolar benzoic or salicylic acid molecules. Since formation of the hydrophobic bond has been decreased, there is a resulting increase in water solubility of the drug molecule.

If this mechanism is correct, then urea should have a greater effect upon the more hydrophobic molecule. A comparison of N/N_0 values reveals that salicylic acid, the more hydrophobic molecule, is solubilized by urea to a greater extent than the less hydrophobic benzoic acid molecule.

The effect of the alkyl substituted ureas, methylurea and 1,3-dimethylurea, on the solubility of benzoic and salicylic acid raises a number of interesting considerations. Based on Abu-Hamdiyyah's theory (8), the substituted ureas should have less of an effect on hydrophobic bonding than unsubstituted urea. This, in turn, would result in less solubilization of drug molecules by the alkylurea derivatives. The results of this study clearly show the opposite effect. Methylurea and 1,3-dimethylurea were more effective in solubilizing benzoic and salicyclic acid than urea, with 1,3-dimethylurea having the greatest effect. The values of log N/N_0 for 2 *M* 1,3-dimethylurea with both aromatic acids at various temperatures showed that ΔH was extremely small but slightly positive, and ΔF was negative (approximately −700 to −900 cal./mole). These values indicate the solubility increase was entropic in origin as was the case with unsubstituted urea.

These findings, however, should not be construed as a criticism of Abu-Hamdiyyah's model because the present experimental system is different from the system considered in the model. Considering the basicity of urea, and particularly the alkyl ureas, it is reasonable to conclude that at pH 1, there is present significant amounts of the conjugate acids of the ureas. While there exists a likelihood that these solutions have the same structure as aqueous solutions of nonionic ureas, this fact is yet to be experimentally demonstrated.

Photochemical Formation of Hydrogen Peroxide in White Lotion U.S.P.

By EARL P. GUTH and Z. MANSOUR

White lotion U.S.P. produces hydrogen peroxide when it is irradiated with ultraviolet radiation or with natural sunlight. The amount of hydrogen peroxide formed during irradiation is sufficient to oxidize the sulfide ion to sulfate. When cholesterol is added and the product irradiated, the β-hydroxyl group on the cholesterol molecule is oxidized.

WHITE LOTION is a widely used external preparation in which insoluble compounds of zinc are present. It has been used for the topical treatment of a number of dermatologic diseases. The lotion was proposed for the American Recipe Book in 1912 (1). It became official in the U.S.P. XV and U.S.P. XVI with the following formula:

Zinc sulfate	40 Gm.
Sulfurated potash	40 Gm.
Purified water, a sufficient quantity to make	1000 ml.

"Dissolve the zinc sulfate and sulfurated potash separately, each in 450 ml. of purified water, and filter each solution. Add slowly the sulfurated solution with constant stirring. Then add the required amount of purified water, and mix.

"Note: Prepare the Lotion freshly and shake thoroughly before dispensing."

The mode of action of white lotion is attributed to be astringent and protective (2). The principal activity is associated with the sulfur content (3), and at one time the presence of residual hydrogen sulfide in the lotion was considered to be the important reason for preparing the lotion freshly.

DISCUSSION

A number of papers on the catalytic production of hydrogen peroxide by irradiation of zinc oxide in aqueous medium have appeared (4–13) since 1944. All these studies showed that zinc oxide catalyzed the production of hydrogen peroxide when exposed to light in the presence of water and air, the rate of production being influenced by the kind of light and temperature. Since this is a catalytic process, the production of peroxide would continue indefinitely as long as all components of the system were present. The source of ultraviolet light used in this study was a Dazor floating fixture ultraviolet lamp model No. U-58, equipped with a General Electric UA-3, 360-w. quartz photochemical lamp. The radiant energy is greatest at 2537 Å., 3131 Å., and 3564 Å. Irradiations were also done by exposing samples directly to sunlight.

Received April 26, 1966, from the College of Pharmacy, Ohio State University, Columbus, OH 43210

Accepted for publication December 29, 1966.

Presented to the Basic Pharmaceutics Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

Samples for irradiation were placed in 600-ml. beakers. These were placed in a water bath situated on a six-plate magnetic stirrer. The U.V. lamp was suspended 30 cm. over the surface of the sample, and the entire assembly was enclosed in an aluminum box. Irradiation time was 30 min. in all cases unless otherwise noted.

Since sulfurated potash is a complex and variable mixture of potassium polysulfides and potassium thiosulfate depending on the particular batch and age of the product, and since zinc sulfate undergoes dissociation in water to give hydronium, sulfate, and zinc ions, a number of chemical reactions are possible. The extent of any one of these reactions can be affected by concentration and temperature of the system.

Possible reactions:

$$\text{sulfurated potash in water} \rightleftharpoons K^+, S^{=}, S_x^{=}, S_2O_3^{=}, OH^-$$

$$S_2O_3^{=} + 2H^+ \rightleftharpoons SO_2 + H_2O + S$$

$$SO_2 + 2H_2S \rightleftharpoons 3S + 2H_2O$$

$$S^{=} + Zn^{++} \rightleftharpoons ZnS$$

$$xS + Zn^{++} \rightleftharpoons ZnS_x \text{ (where } x \text{ is mostly 2 or 3)}$$

$$SO_4^{=} + 2K^+ \rightleftharpoons K_2SO_4$$

$$S_2O_3^{=} + Zn^{++} \rightleftharpoons ZnS_2O_3$$

The formation of zinc hydroxide in an acid medium of zinc sulfate solution occurs as follows:

$$[Zn(OH_2)_6]^{++} + H_2O \rightleftharpoons [Zn(OH_2)_5(OH)]^+ + H_3O^+$$

hexa-aquo zinc (II)

$$[Zn(OH_2)_5(OH)]^+ + H_2O \rightleftharpoons [Zn(OH_2)_4(OH)_2]^0 + H_3O^+$$

(zinc hydroxide)

The OH^- ions in the sulfated potash shift both reactions to the right forming zinc hydroxide.

In view of these considerations, white lotion was restudied to evaluate the following: (*a*) composition of the soluble phase of the lotion, (*b*) composition of the insoluble phase of the lotion, (*c*) the effect of order of mixing on the composition of the two phases, (*d*) the effect of temperature on the composition, (*e*) the production of hydrogen peroxide by catalytic action of zinc hydroxide, (*f*) the effect of hydrogen peroxide on the components of the lotion, (*g*) the effect of aging lotion, (*h*) the effect of hydrogen peroxide on additives such as cholesterol.

EXPERIMENTAL

Qualitative Analysis of the Fresh Lotion

Soluble Phase—*Potassium*—This was determined by cobaltinitrite solution: a finely divided yellow to orange-yellow precipitate was obtained.

Thiosulfate, Sulfate, Sulfite, and Zinc—The U.S.P. tests for these ions were applied. The presence of sulfate and thiosulfate ions was confirmed. No sulfite ion was detected.

Hydrogen Sulfide—Van Itallie reagent (14) (freshly prepared solution of *p*-diazobenezensulfonic acid) was added to the filtrate of the freshly prepared lotion (pH 7.3). No coloration occurred (reaction negative).

Insoluble Phase—*Sulfides*—This test depends on the ability of sulfides to facilitate the reaction between equal quantities of 0.2 *N* aqueous solution of iodine and 0.2 *N* sodium azide solution. A violent evolution of nitrogen occurs in this reaction. The washed precipitate obtained by filtration of white lotion gave a positive test for sulfides.

Zinc Hydroxide—The gelatinous precipitate of zinc hydroxide is amphoteric and dissolves in alkalies to form the complex ion $[Zn(OH)_4]^=$. The identification of zinc hydroxide was done by treating the insoluble phase with dilute ammonium hydroxide solution. The sample is filtered and the filtrate neutralized with acid. A white precipitate indicated zinc hydroxide (reaction positive).

Quantitative Analysis—A quantitative analysis was run on the washed and dried precipitate obtained from the lotion. The dried precipitate was extracted with carbon disulfide, filtered, and the solvent evaporated. The free sulfur was determined by a gravimetric or a volumetric procedure depending on the amount of the extracted sulfur obtained (15–17).

Sulfides were determined by Kolthoff's method (18) for insoluble sulfides as modified for polysulfides (19). Zinc was determined by the U.S.P. XVI method (20).

Table I gives percentage composition of dried precipitate from three differently prepared lotions. Each entry is the average of seven determinations.

Ultraviolet and sunlight irradiations were performed on suspensions made by resuspending the washed precipitate of the lotion in 40 ml. of water. The amounts of precipitate represented 25 and 5 ml. of lotion, respectively. After irradiation, both the filtrate and the precipitate were analyzed. Results are shown in Table II.

According to Goudah (9), increasing the zinc oxide irradiated in the aqueous system increases the peroxide formed but not in a linear relationship. In this work, irradiations were performed in identical containers, for the same period of time, stirred at the same speed, and placed in the same circulating water bath. The samples representing 25 ml. of lotion showed sulfite and zinc ions, free sulfur, zinc oxide, and no free hydrogen peroxide. The samples representing 5 ml. of lotion show the presence of sulfate and no zinc sulfides. It is concluded from these results that in the 25-ml. sample, the amount of hydrogen peroxide produced in the 30 min. of irradiation was insufficient to oxidize the larger amount of sulfides present in the 25-ml. samples. The 5-ml. sample, however, did produce sufficient peroxide in the 30 min. of irradiation to completely oxidize the sulfides to sulfates. This is probably due to the fact that in the irradiation of the sample under the conditions used, the exposure of zinc oxide to light in the 25-ml. samples was not proportionally greater than the zinc oxide in the 5-ml. samples. This is a reasonable conclusion since the area of the exposure was identical in all samples.

Table III lists the amount of peroxide present after irradiation of different amounts of washed precipitate resuspended in 40 ml. of water. The amount of residual peroxide detected showed an increase with the decrease of the amount of precipitate irradiation.

The iodometric method of Kolthoff (21), as modified by Chari and Qureshi (12), was utilized for the quantitative determination of hydrogen peroxide.

To the aqueous suspension made from the washed precipitate of 5 ml. of lotion, 200 mg. of cholesterol dissolved in 5 ml. of ethanol was added. The mixture was irradiated for 4 hr. in the sunlight, or

TABLE I—PERCENTAGE COMPOSITION (W/W) OF DRIED PRECIPITATE FROM THREE DIFFERENTLY PREPARED LOTIONS

Lotion[a]	Contents, % w/w in the Dry Precipitate: Free Sulfur	Zinc Oxide	Zinc Sulfides[b]	Sulfides' Sulfur

30 min. under the ultraviolet light, with continuous stirring. The samples were then extracted with chloroform, the extract condensed under vacuum to 10 ml., dried in a desiccator, and analyzed by infrared spectroscopy. A sample of cholesterol, ethanol, and water was treated in the same manner. In addition, the precipitate suspension with cholesterol was placed in the dark. The entire process was repeated using samples made of 5 ml. of the entire lotion.

Infrared spectra are shown in Figs. 1, 2, 3, 4, and 5. Finally, the effect of aging white lotion was determined by storing the lotion in clean glass bottles at room temperature, and samples analyzed at intervals. Results are shown in Table IV.

RESULTS

The results of this study show that white lotion U.S.P. XVI is a mixture of several insoluble and soluble materials and that the percentage composition of each of these materials is not significantly affected by the order of mixing or alteration of the temperature of the reactants. The composition of the precipitate of freshly prepared lotion appears to contain approximately 4.5% of free sulfur, 45–48% of zinc oxide, and 47–49% of zinc sulfides. The zinc sulfides represent sulfur to the extent of 35 to 36% of the precipitate.

When the precipitate is separated and washed with distilled water, then resuspended in distilled water and subjected to irradiation by ultraviolet light, considerable alteration occurs. When 25 ml. of lotion is used the filtrate shows, after irradiation, sulfite and zinc ions. When 5 ml. of lotion is irradiated for the same time, the filtrate shows the presence of sulfate and zinc ions, and hydrogen peroxide, while the precipitate shows the absence of sulfide ions.

These changes show that the peroxide oxidizes the sulfide to sulfite and finally to sulfate and only after this reaction is completed is it possible to show the presence of hydrogen peroxide. Table III shows the results of peroxide formation from increasing amounts of resuspended precipitate when irradiated by ultraviolet light for 30 min., and by sunlight for 4 hr. These values show that the amounts of peroxide produced by the two light sources are approximately the same for the time periods used. This also indicates that these reactions may occur when white lotion is applied to the skin.

The existence of cholesterol on the skin, and the probability of its being a precursor of 7-dehydro-

60	29.60	45.2	25.20	12.30

cholesterol (provitamin D_3) suggested the determination of the effect of irradiation of cholesterol in the presence of the white lotion. The results represented in the infrared spectra of cholesterol before and after irradiation show oxidation of cholesterol when irradiated in the presence of both the resuspended washed precipitate and in the entire white lotion.

The characteristic absorption band of the hydroxyl group of cholesterol is seen at 3600^{-1} or 2.75 μ wavelength in the infrared spectra of cholesterol and in that of cholesterol extracted from a nonirradiated sample. A band is noted at 1075 cm.$^{-1}$ due to the presence of a secondary alcohol (Figs. 2 and 3). These respective characteristic absorption bands disappear in the I.R. spectra of cholesterol extracted from the precipitate and from entire lotion samples after ultraviolet irradiation (30 min.) or sunlight irradiation (4 hr.) (Figs. 3, 4, and 5). A new absorption band appears in these spectra in the region of 6 μ or 1750 cm.$^{-1}$. This band is ascribed to the vibrations of carbonyl function C=O, and is found in about the same region as in ketones and aldehydes. The irradiation of cholesterol alone under the above condition does not produce any changes in the absorption peaks of the I. R. spectra. The results obtained are in agreement with previous work by Guth and Goudah (9).

The findings of this study suggest further investigation of the effect of the peroxide produced by white lotion on the sterols in the skin.

The results on the effect of aging on the white lotion showed an increase in the free sulfur content and a decrease in sulfides' sulfur as shown in Fig. 6. The physical stability of white lotion is affected only slightly on aging. Colloidal sulfur particles seem to aggregate and the components of the precipitate do not remain uniformly distributed, but since no caking or flocculation is noted, the lotion is readily redispersed into a uniform mixture when the container is shaken.

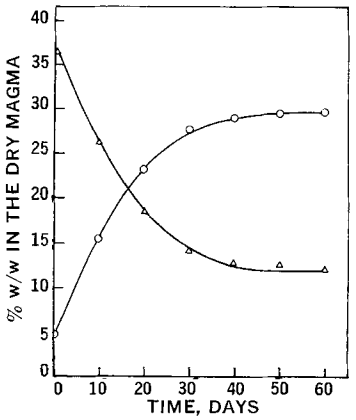

Fig. 6—Effect of aging on white lotion. Key: O, free sulfur; △, sulfides' sulfur.

It seems that the freshly prepared lotion was reported beneficial in acne and other dermatologic diseases due to its high content of insoluble sulfides. It appears from this study that there may be merit in requiring a freshly prepared lotion, since the effectiveness of white lotion could in part be associated with the gradual release of colloidal sulfur.

SUMMARY

1. White lotion U.S.P. contains zinc mono and polysulfides, zinc hydroxide, and free sulfur all suspended in an aqueous medium containing sulfate, thiosulfate, and potassium ions.

2. Zinc oxide catalyzed hydrogen peroxide is formed in white lotion when irradiated by ultraviolet and sunlight. The peroxide so formed is very active in oxidizing sulfides to sulfites and then to sulfates.

3. When cholesterol is present, β-hydroxyl group is oxidized.

4. On aging, there is a marked increase in free sulfur in the lotion.

Irreversible Enzyme Inhibitors LXIX

Candidate Active-Site-Directed Irreversible Inhibitors of Dihydrofolic Reductase III. Bromoacyl Derivatives of 5-(*p*-Aminophenoxypropyl)-2,4,6-triaminopyrimidines

By B. R. BAKER and DANIEL V. SANTI

5-(*p*-Aminophenoxypropyl)-2,4,6-triaminopyrimidine (XIV*d*) was synthesized by alkylation of malononitrile by 3-bromopropyl *p*-nitrophenyl ether (X*b*), followed by ring closure with guanidine and catalytic reduction of the nitro group. Selective haloacylation of the aromatic amino group of XIV*b* was accomplished by protonation of the triaminopyrimidine moiety of XIV*d* with acetic acid. Treatment with the anhydrides of bromoacetic acid, *p*-bromoacetamidophenylbutyric acid, and *N*-bromoacetyl-β-alanine gave the pure bromoacyl derivatives, XIV*e*, *i*, and *j*. These three compounds were good reversible inhibitors of dihydrofolic reductase, but failed to show irreversible inhibition; these failures are attributed to the phenoxypropyl group of the inhibitors (XIV) being complexed with a hydrophobic region on the enzyme—a region not apt to have groups that could form a covalent bond.

PRIOR TO THE discovery of a strong hydrophobic bonding region on dihydrofolic reductase (1) with its conformational requirements (2–6) and the possible pyrimidine rotomers that could bind to the enzyme (5–9), more than 30 candidate compounds were synthesized and evaluated as active-site-directed irreversible inhibitors (5, 10) of this enzyme with negative results. By proper utilization of the hydrophobic region, successful active-site-directed irreversible inhibitors (I–III) were found (11, 12). By complexing the hydrophobic region by a 5-phenylbutyl group—as in the pyrimidines, I and II (11)—or by 6-phenyl as in III (12), the remaining aralkyl group then projected into a hydrophilic region on the enzyme and could covalently link a nucleophilic group on the enzyme.

DISCUSSION

The first candidate active-site-directed irreversible inhibitor successfully synthesized in this laboratory was IV; the latter was a good reversible inhibitor of dihydrofolic reductase, but gave no inactivation of the enzyme. Subsequent work on hydrophobic bonding to dihydrofolic reductase (1–9) allowed a suitable rationalization for this failure; the 5-side chain of IV was most probably complexed in a hydrophobic region and, therefore, was not likely to be juxtaposed to a nucleophilic region on the enzyme. The synthesis of inhibitors such as IV was accomplished only after a number of false starts; this successful synthesis of IV paved the way for the ultimate synthesis and enzymic evaluation of the successful candidate inhibitors (I–III) (11, 12).

Since the anilinopropyl pyrimidinol (VII*a*) was a reasonably good inhibitor of dihydrofolic reductase (13, 14), the related *p*-bromoacetamidoanilinopropyl pyrimidinol (VII*e*) was selected as a candidate active-site-directed irreversible inhibitor (5, 10) for dihydrofolic reductase, and its synthesis was undertaken. The various reactions following are outlined in Scheme I. The first general route developed to structures of type VII was the reductive condensation of an arylamine (VI) with the pyrimidine-5-propionaldehyde (V) (13, 15). The condensation failed to give VII*b* with the more weakly basic *p*-nitroaniline (VI*b*). The required intermediate (VII*b*) was synthesized by the second general route starting the *N*-(*p*-nitrophenyl)-*p*-toluenesulfonamide *via* VIII*b* and IX*b* (16). Re-

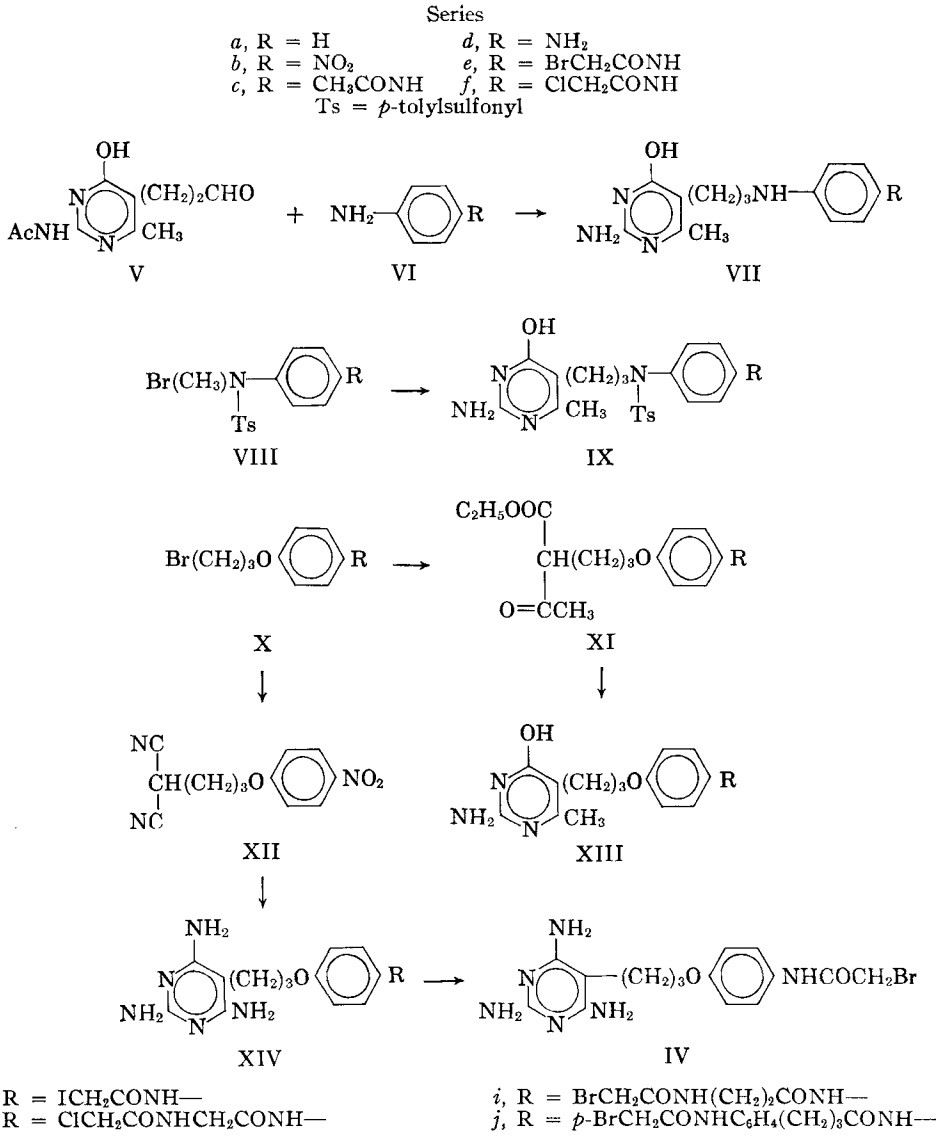
Previous paper of this series see *Reference 12*.



Scheme I

duction of the nitro group of VII*b* to the substituted *p*-phenylenediamine (VII*d*) or preparation of VII*d* from the *p*-acetamidoanilinopropyl pyrimidinol (VII*c*) in this and the corresponding 6-phenyl series (17) appeared to be intractable due to the instability of the *p*-phenylenediamine moiety.

Since the anilinopropyl group of VII*a* can be replaced with phenoxypropyl (XIII*a*) with no change in binding to the enzyme (18) and since the *p*-anisidine is much more stable than *p*-phenylenediamine, the synthesis of XIII*b* was investigated. The latter was readily synthesized from *p*-nitrophenyl 3-bromopropyl ether (X*b*) by alkylation of ethyl acetoacetate to XI*b* followed by ring closure with guanidine to XIII*b*. Such a synthesis has considerable latitude in variation of the 4- and 6-substituents of the pyrimidine ring. Therefore, the 2,4,6-triaminopyrimidine ring system bearing a 5-(*p*-nitrophenoxypropyl) group (XIV*b*) was selected for study with the extra consideration that 2,4,6-triaminopyrimidines are better reversible inhibitors of dihydrofolic reductase than the corresponding 2-amino-6-methyl-4-pyrimidinols (1, 5, 19).

Alkylation of malononitrile with the bromopropyl phenyl ether (X*b*) gave a crude product (XII) which was condensed with guanidine in ethanol to give the triaminopyrimidine (XIV*b*) in 51% over-all yield; this product contained some minor impurities (by TLC) that could not be removed. Since XIV*b* was rather intractable, it was reduced catalytically to XIV*d* with a Raney nickel catalyst; the anisidine derivative (XIV*d*) was readily purified in 56% yield.

Methods were then developed for selective halo-

acylation of the polyfunctional XIV*d* to give derivatives of type XIV*e–j* where only the aromatic amino group has become acylated. The first studies in this laboratory on selective acylation of aminophenyl groups attached to an aminopyrimidine were performed on XIV*d*. Although the methods developed for selective bromoacylation of these aminopyrimidines have been collected in one paper (20) to indicate the scope and limitations of the reaction, the background work was performed on XIV*d* and will be reported here.

It was reasoned that the greatest selectivity in acylation of the aromatic amino group of XIV*d* would occur if the more strongly basic triaminopyrimidine moiety could be protonated throughout the experiment. Such a procedure would be more difficult with an acid chloride than with an anhydride, since the evolved hydrogen chloride would be more difficult to keep neutralized at acid pH than the organic acid evolved from an anhydride. The first acylation was performed with chloroacetic anhydride on XIV*d* in acetone containing excess aqueous 5% acetic acid; within 10 min. precipitation occurred. By use of excess chloroacetic anhydride to overcome partial aqueous hydrolysis of the anhydride, the reaction was carried to completion. The salt that separated appeared to be a mixture of monoacetate and monochloroacetate. Upon warming the mixture, the salt redissolved; the solution was added to excess aqueous potassium carbonate, then the isolated free base of XIV*f* was converted to the acetate salt; when dried without heating, this material gave combustion values for a diacetate salt. Extended drying at 100° gave varying amounts of acetate in the salt. Attempts to convert XIV*f* to the iodo derivative (XIVg) with sodium iodide in acetone containing glacial acetic acid were unsuccessful, the products seeming to be unstable.

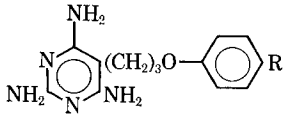
Similarly, the anhydride of chloroacetylglycine could be used to form XIV*h*—isolated as an acetate salt. However, with bromoacetic anhydride, the product (XIV*e* = IV) could not be treated with aqueous potassium carbonate since some of the bromoacetyl group hydrolyzed to hydroxyacetyl. Therefore, a different set of criteria and a different isolation had to be devised, namely (*a*) the Bratton-Marshall test (13, 15, 21) for aromatic amines was negative; (*b*) thin-layer chromatography showed the presence of a single spot that gave a positive *p*-nitrobenzylpyridine test for active halogen (22, 23); (*c*) ultraviolet spectra were essentially unchanged showing that an amino group on the pyrimidine had not become acylated (24).

Treatment of XIV*d* in 2:1 acetone–10% acetic acid at 0° with 2–3 equivalents of bromoacetic anhydride resulted in a salt of the product (XIV*e* = IV) separating from solution. Since this salt was probably a mixture of acetate salt and bromoacetate salt and since IV could not be converted to the free base without decomposition, the acetate salt of IV was directly converted to the salt of a stronger acid such as hydrobromic or sulfuric acid; either a monohydrobromide or dihydrobromide of IV could be prepared, depending upon the conditions (20).

Similarly, the use of the anhydrides of *N*-bromoacetyl-β-alanine and *p*-bromoacetamidophenylbutyric acid (20) gave XIV*i* and *j*, respectively, isolated as their acetate and sulfate salts, respectively.

Enzymatic Evaluation—Table I lists the results on reversible and irreversible inhibition of dihydrofolic reductase with the bromoacyl derivatives of structure IV or XIV. All three compounds are better reversible inhibitors than the 4-pyrimidinol (II). However, when incubated at a concentration sufficient to convert 50% of the enzyme to the reversible complex (E · · · I), the bromoacyl derivatives of structure IV or XIV failed to show any inactivation in 1 hr. at 37°. In contrast, the 5-phenylbutyl-6-(*p*-bromoacetamidophenylbutyl)-4-pyrimidinol (II) showed 50% inactivation in 18 min. (11). These results are believed to be due to the 5-phenoxypropyl group of XIV being complexed to a hydrophobic region on the enzyme where there are not apt to be any polar nucleophilic groups.

TABLE I—INHIBITION OF DIHYDROFOLIC REDUCTASE BY



Compd.	R	Reversible[a] μM Concn. for 50% Inhibition	Reversible[a] Estimated $Ki \times 10^6$ M[c]	Irreversible[b] μM Concn.	Irreversible[b] % EI[d]	Irreversible[b] Time, min.	Irreversible[b] % Inactivation

				10	20	25	43

[a] The dihydrofolic reductase was a 45–90% ammonium sulfate fraction from pigeon liver that was prepared and assayed with 6 μ*M* dihydrofolate and 12 μ*M* TPNH in 0.05 *M* Tris buffer (pH 7.4) containing 10 m*M* mercaptoethanol, as previously described (14). [b] Dihydrofolic reductase was incubated with the inhibitor at 37° in 0.05 *M* Tris buffer (pH 7.4) containing *no* mercaptoethanol and *no* TPNH, but diluted with 10% of its volume with *N*,*N*-dimethylformamide in which the inhibitor had been dissolved; in each case an enzyme control was run that showed 0–4% inactivation (22). [c] Estimated from $Ki = I \times Km/S$ where I = inhibitor concentration giving 50% inhibition (5, 25); this equation is valid since $S = 6\ Km > 4\ Km$. [d] Calculated from $[EI] = [Et]/[1 + Ki/I]$, where $[Et]$ = the concentration of total active enzyme and $[EI]$ = fraction of Et reversibly complexed by I (5, 26). [e] Data from *Reference 11*.

EXPERIMENTAL

Melting points were taken in capillary tubes on a Mel-Temp block and those below 230° are corrected. Infrared spectra were determined in KBr pellet, unless otherwise indicated, with a Perkin-Elmer 137B recording spectrophotometer. Ultraviolet spectra were taken in water, unless otherwise indicated, with a Perkin-Elmer 202 spectrophotometer. Thin-layer chromatograms (TLC) were run on Brinkmann Silica Gel GF, and spots were detected by visual examination under ultraviolet light.

3-Bromopropyl p-Nitrophenyl Ether (Xb)—To a well stirred solution of 120 Gm. (0.60 mole) of 1,3-dibromopropane in 75 ml. of dimethylsulfoxide was added 29.4 Gm. (0.15 mole) of sodium *p*-nitrophenolate dihydrate. After 1 hr. the mixture had formed a jell; it was heated on a steam bath for 30 min., then spin-evaporated *in vacuo* at 100°. The residue was partitioned between 750 ml. of benzene and 500 ml. of water. The organic layer was washed successively with five 500-ml. portions of water, two 500-ml. portions of 0.5 *N* aqueous sodium hydroxide, then once more with water. The benzene layer was spin-evaporated *in vacuo;* the last traces of higher boiling materials were removed at 100° at 1 mm. The oily residue was crystallized from ethanol. The product was collected on a filter and washed with petroleum ether (b.p. 30–60°) until the washings were colorless; yield, 26.0 Gm. (67%), m.p. 52–54°; this product was suitable for further transformations even though TLC with petroleum ether (b.p. 60–110°)–benzene (1:1) showed it was only about 90% pure. Recrystallization from petroleum ether (b.p. 60–110°) gave yellow crystals, m.p. 57–58°. [Lit. m.p. 58–59° (27).]

2-Amino-6-methyl-5-(p-nitrophenoxypropyl)-4-pyrimidinol (XIIIb)—A mixture of 70 ml. of *tert*-butyl alcohol, 3.90 Gm. (0.03 mole) of ethyl acetoacetate, and 0.72 Gm. (0.03 mole) of sodium hydride as a 56.5% suspension in mineral oil was magnetically stirred until hydrogen evolution was complete. After the addition of 5.2 Gm. (0.02 mole) of X*b*, the mixture was gently refluxed for 24 hr. protected from moisture. Acidified with glacial acetic acid, the mixture was spin-evaporated *in vacuo* finally at about 1 mm. to remove ethyl acetoacetate. The oily residue was dissolved in about 50 ml. of chloroform and washed with water. After being dried with magnesium sulfate, the solution was evaporated *in vacuo* to give crude XI*b* as an oil; yield, 5.7 Gm. of an oily residue containing some mineral oil.

A part (3.12 Gm., 10 mmoles) of the residual XI*b* and 0.99 Gm. (5 mmoles) of guanidine carbonate in 20 ml. of *tert*-butyl alcohol was gently refluxed with magnetic stirring for 48 hr. The cooled mixture was filtered and the product washed with 25 ml. of hot ethanol. The crude product was dissolved in about 15 ml. of hot 1 *N* aqueous sodium hydroxide. The hot solution was clarified by filtration, then acidified to about pH 5 with 3 *N* aqueous hydrochloric acid. After being cooled to 0°, the mixture was filtered and the product was recrystallized from 2-methoxyethanol–water; yield, 1.26 Gm. (42% based on X*b*) of light yellow crystals, m.p. 260–261° dec. $\nu_{max.}$ 3400–3100 (broad, NH); 1640, 1600, 1590 (NH, C=O, C=C, C=N); 1525, 1320 (NO_2); 1255 (C—O—C); 750, 720, 690 cm.$^{-1}$ (p-C_6H_4).

Anal.—Calcd. for $C_{14}H_{16}N_4O_4$: C, 55.3; H, 5.30; N, 18.4. Found: C, 55.1; H, 5.43; N, 18.6.

5-(p-Nitrophenoxypropyl)-2,4,6-triaminopyrimidine (XIVb)—To a magnetically stirred mixture of 5 ml. of dimethylsulfoxide and 0.24 Gm. (10 mmoles) of sodium hydride as a 56.5% dispersion in mineral oil was added 0.72 Gm. (11 mmoles) of malononitrile in 2 ml. of dimethylsulfoxide over a period of about 5 min. with cooling in a water bath. When hydrogen evolution was complete, a solution of 2.6 Gm. (10 mmoles) of X*b* in 4 ml. of dimethylsulfoxide was added. After 10 min. at ambient temperature, the mixture was heated at 75° for 30 min., then poured into 50 ml. of benzene. The mixture was washed with three 50-ml. portions of water, then spin-evaporated *in vacuo*. To the residual XII*b* was added a filtered solution of 1.05 Gm. (11 mmoles) of guanidine hydrochloride and 0.595 Gm. (11 mmoles) of sodium methoxide in 10 ml. of absolute ethanol. After being refluxed with magnetic stirring for 3 hr. protected from moisture, the mixture was cooled. The amorphous product was collected on a filter and washed with 100 ml. of hot ethanol in portions; yield, 1.57 Gm. (51%), m.p. >250°. $\nu_{max.}$ 3450, 3390, 3200 (NH); 1660, 1620–1575 (broad) (NH, C=C, C=N, NO_2); 1335 (NO_2); 757, 720, 690 cm.$^{-1}$ (p-C_6H_4). $\lambda_{max.}$ (pH 1): 284, 320 mμ; (pH 13): 278, 320 mμ.

TLC in ethanol showed one major spot and several minor spots; no suitable purification method could be found, but the reduction product (XIV*d*) could be purified.

5-(p-Aminophenoxypropyl)-2,4,6-triaminopyrimidine (XIVd)—A mixture of 7.6 Gm. (0.025 mole) of crude XIV*b*, 200 ml. of 70% aqueous ethanol, and about 15 Gm. of Raney nickel was shaken with hydrogen at 2–3 Atm. until reduction was complete (4 hr.). The mixture was filtered through a pad of diatomaceous earth[1] then spin-evaporated *in vacuo*. The oily residue readily crystallized on trituration with ethanol. Two recrystallizations from ethanol afforded 3.9 Gm. (56%) of buff-colored crystals, m.p. 179–180°; the compound moved as a single spot on TLC in ethanol. $\lambda_{max.}$ (pH 1): 283 mμ (ϵ 18,400); (H_2O): 279 mμ (ϵ 12,600); (pH 13): 277 mμ (ϵ 12,400). $\nu_{max.}$ 3500, 3400, 3150 (NH); 1650–1575 (broad) (NH, C=C, C=N); 1240 (C—O—C); no nitro band near 1340 cm.$^{-1}$.

Anal.—Calcd. for $C_{13}H_{18}N_6O$: C, 56.9; H, 6.62; N, 30.7. Found: C, 56.7; H, 6.62; N, 30.9.

5-(p-Chloroacetamidophenoxypropyl)-2,4,6-triaminopyrimidine (XIVf)—To a magnetically stirred solution of 822 mg. (3 mmoles) of XIV*d* in 12 ml. of acetone and 12 ml. of 5% aqueous acetic acid cooled in an ice bath was added a solution of 1.026 Gm. (6 mmoles) of chloroacetic anhydride in 6 ml. of acetone. The mixture was stirred at ambient temperature for 2 hr., then the separated solid was redissolved by warming. The solution was poured into 60 ml. of 5% potassium carbonate previously cooled to 0°. The product was collected on a filter and washed with 25 ml. of cold water, then dried. The dry XIV*f* free base was dissolved in a small volume of glacial acetic acid, then slowly precipitated by dropwise addition of ethyl acetate.

[1] Marketed as Celite by Johns-Manville Corp., New York, N. Y.

The *diacetate* salt was collected, washed with ethyl acetate and ether, then dried at room temperature *in vacuo;* yield, 1004 mg. (71%), m.p. 144–146° dec. $\lambda_{max.}$ (pH 1): 284 mμ; (pH 13): 276 mμ. $\nu_{max.}$ 3500, 3400, 3300–3150 (NH); 1670 (amide I); 1640–1610 (C=C, C=N); 1570 cm.$^{-1}$ (amide II). TLC in chloroform–ethanol (5:3) showed one spot.

Anal.—Calcd. for $C_{15}H_{19}ClN_6O_2 \cdot 2CH_3COOH$: C, 48.5; H, 5.78; N, 17.8. Found: C, 48.7; H, 5.94; N, 17.6.

When dried at 100° in high vacuum to constant weight, the analysis indicated that most of the diacetate had been converted to the free base; the m.p. had now changed to >200° dec.

Anal.—Calcd. for $C_{15}H_{19}ClN_6O_2$: C, 51.6; H, 5.43; O, 10.8. Found: C, 50.9; H, 5.64; O, 10.8.

N-Bromoacetyl-β-alanine—To a magnetically stirred solution of 4.56 Gm. (0.05 mole) of β-alanine and 2.81 Gm. (0.05 mole) of potassium hydroxide in 15 ml. of water cooled in an ice–salt bath was added, in five portions (5 min. apart), 5.25 ml. (0.06 mole) of bromoacetyl bromide; immediately after each portion of bromoacetyl bromide was added in five portions 25 ml. of 2.8 *N* aqueous potassium carbonate. After being stirred an additional 1 hr. at −5 to 0°, the solution was acidified to about pH 3 with 12 *N* aqueous hydrochloric acid, then extracted with ethyl acetate (3 × 75 ml.). The combined extracts were washed with 75 ml. of water, dried with magnesium sulfate, then spin-evaporated *in vacuo*. The residue was leached with hot petroleum ether (b.p. 60–110°) (2 × 50 ml.), then crystallized from chloroform at −20°; yield, 4.07 Gm. (40%), m.p. 71–77°. Two more recrystallizations from chloroform at −20° gave 2.44 Gm. (23%) of white crystals, m.p. 83–84°. $\nu_{max.}^{Nujol}$ 3300 (amide NH); 1700 (carboxyl C=O); 1640 (amide I); 1550 cm.$^{-1}$ (amide II).

Anal.—Calcd. for $C_5H_8BrNO_3$: C, 28.6; H, 3.82; N, 6.70. Found: C, 28.4; H, 3.84; N, 6.55.

No effort was made to obtain optimum yields.

5-[(p-Chloroacetylglycylamido)phenoxypropyl]-2,-4,6-triaminopyrimidine (XIVh) Acetate—To a magnetically stirred solution of 1.516 Gm. (10 mmoles) of *N*-chloroacetylglycine in 30 ml. of reagent ethyl acetate cooled in an ice bath was added 1.236 Gm. (6 mmoles) of *N,N*-dicyclohexylcarbodiimide. After being stirred 2 hr. at ambient temperature, the mixture was filtered and the dicyclohexylurea was washed with two 10-ml. portions of ethyl acetate. The combined filtrate and washings were spin-evaporated *in vacuo* (bath 25°) to about 10 ml. Addition of about 35 ml. of petroleum ether (b.p. 30–60°) gave 0.896 Gm. (67%) of *N*-chloroacetylglycine anhydride that was not further purified and had $\nu_{max.}$ 3300 (NH); 1825, 1760 (anhydride C=O); 1675 (amide I); 1550 cm.$^{-1}$ (amide II).

Reaction of XIV*d* with an excess of this anhydride as described for the preparation of XIV*f* gave 56% of product after recrystallization from glacial acetic acid–ethyl acetate and drying at 100° *in vacuo* for 24 hr. After being dried at 100° in high vacuum, it showed no definite m.p., but gradually decomposed over 200°. $\lambda_{max.}$ (pH 1): 284 mμ; (pH 13): 276 mμ. $\nu_{max.}$ 3500–3200 (NH); 1780 (amide I); 1660–1600 (NH, C=C, C=N); 1560 cm.$^{-1}$ (amide II). TLC in chloroform–ethanol (5:3) showed a single spot.

Anal.—Calcd. for $C_{17}H_{22}ClN_7O_3 \cdot {}^1/_2CH_3COOH$: C, 49.3; H, 5.50; N, 22.4; O, 14.6. Found: C, 49.2; H, 5.54; N, 22.4; O, 13.7.

5-[(p-Bromoacetyl-β-alaninamido)phenoxypropyl]-2,4,6-triaminopyrimidine (XIVi) Diacetate—To a magnetically stirred solution of 274 mg. (1 mmole) of XIV*d* in 6 ml. of acetone and 2 ml. of 10% aqueous acetic acid cooled in an ice bath was added 643 mg. (1.6 mmoles) of *N*-bromoacetyl-β-alanine anhydride (prepared as described for the anhydride of chloroacetylglycine in tetrahydrofuran as solvent). After 1 hr. at 0°, during which time a salt of XIV*i* separated, the mixture was filtered, and the product was washed with acetone. The product was recrystallized from glacial acetic acid by addition of ethyl acetate; yield, 485 mg. (83%), m.p. 158–161°. A second recrystallization gave 395 mg. (68%), m.p. 160–162°. $\lambda_{max.}$ (pH 1): 284 mμ; (pH 13): 276 mμ. $\nu_{max.}$ 3500–3200 (NH); 1680–1600 (amide I, C=C, C=N); 1570 cm.$^{-1}$ (amide II). The compound traveled as a single spot on TLC in chloroform–ethanol (5:3); the spot gave a negative Bratton-Marshall test and a positive *p*-nitrobenzylpyridine test (20). For analysis the compound was dried at room temperature in high vacuum.

Anal.—Calcd. for $C_{18}H_{24}BrN_7O_3 \cdot 2CH_3COOH$: C, 45.1; H, 5.50; Br, 13.6. Found: C, 45.1; H, 5.65; Br, 13.9.

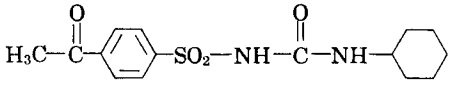
Qualitative and Quantitative Tests for Acetohexamide

By EDWARD F. SALIM* and W. W. HILTY†

Provisional, unofficial monographs are developed by the Drug Standards Laboratory, in cooperation with the manufacturers of the drug concerned, for publication in the *Journal of Pharmaceutical Sciences*. The ready availability of this information affords discriminating medical and pharmaceutical practitioners with an added basis for confidence in the quality of new drug products generally, and of those covered by the monographs particularly. Such monographs will appear on drugs representing new chemical entities for which suitable identity tests and assay procedures are not available in the published literature. The purity and assay limits reported for the drugs and their dosage forms are based on observations made on samples representative of commercial production and are considered to be reasonable within expected analytical and manufacturing variation.

1 - [(*p* - ACETYLPHENYL)SULFONYL] - 3 - CYCLOHEXYLUREA; $C_{15}H_{20}N_2O_4S$; mol. wt. 324.40. The structural formula of acetohexamide may be represented as:



Physical Properties—Acetohexamide occurs as a practically odorless, white, crystalline powder, m.p 184–189° (U.S.P. class Ia). It is practically insoluble in water and in ether, and slightly soluble in alcohol and in chloroform. It is soluble in pyridine and in dilute solutions of alkali hydroxides.

Identity Tests—A 1 in 100,000 solution of acetohexamide in 0.01 *N* sodium hydroxide exhibits an ultraviolet absorbance maximum at about 249 mμ [absorptivity (*a*) about 43]. The spectrum is shown in Fig. 1.

The infrared spectrum of a 0.5% dispersion of acetohexamide in potassium bromide, in a disk of about 0.82 mm. thickness, is shown in Fig. 2.

Dissolve about 100 mg. of 2,4-dinitrophenylhydrazine in 1 ml. of sulfuric acid and cautiously add 5 ml. of alcohol. Cool, filter if necessary to obtain a clear solution, add 5 ml. of a solution of acetohexamide in hot alcohol (1 in 200), and warm on a steam bath: an orangish yellow precipitate is formed.

Purity Tests—Dry about 1 Gm. of acetohexamide, accurately weighed, at 105° for 3 hr.: it loses not more than 1% of its weight.

Char about 1 Gm. of acetohexamide, accurately weighed, cool the residue, add 1 ml. of sulfuric acid, heat cautiously until evolution of sulfur trioxide ceases, ignite, cool, and weigh: the residue does not exceed 0.1%.

Determine the heavy metals content of acetohexamide by the U.S.P. heavy metals test, method II: the heavy metals limit for acetohexamide is 20 p.p.m.

Assay—Transfer about 300 mg. of acetohexamide, accurately weighed, to a 125-ml. conical flask, and dissolve in 40 ml. of dimethylformamide. Add 5 drops of thymol blue T.S., and titrate with 0.1 *N* sodium methoxide, using a magnetic stirrer and

taking precautions against absorption of atmospheric carbon dioxide. Perform a blank determination, and make any necessary correction. Each milliliter of 0.1 *N* sodium methoxide is equivalent to 32.44 mg. of $C_{15}H_{20}N_2O_4S$. The amount of acetohexamide found is not less than 97% and not more than 101%, calculated on the dried basis.

DOSAGE FORMS OF ACETOHEXAMIDE

Acetohexamide Tablets

Identity Tests—The final solution prepared from the tablet sample in the *Assay* exhibits an absorbance maximum and minimum at the same wavelengths as the acetohexamide standard solution.

Assay—Weigh and finely powder not less than 20 acetohexamide tablets. Weigh accurately a portion of the powder, equivalent to about 500 mg. of acetohexamide, and transfer to a 100-ml. volumetric flask. Add about 60 ml. of 0.1 *N* sodium hydroxide and shake for 30 min. Dilute to volume with water, and mix. Filter the solution, discarding the first portion of filtrate, and transfer 20.0 ml. into a 125-ml. separator. Add 2 ml. of diluted hydrochloric acid and extract with four 40-ml. portions of chloroform, filtering each portion through chloroform-washed paper into a 200-ml. volumetric flask. Make to volume with chloroform, and mix. Pipet 20.0 ml. of this solution into a suitable beaker and evaporate to dryness on a steam bath. Transfer the residue quantitatively, with the aid of 0.1 *N* sodium hydroxide, into a 100-ml. volumetric flask, add alkaline solution to volume, and mix. Dilute 10.0 ml. of this solution to 100.0 ml. with water, and mix. Concomitantly determine the absorbance of this solution and of a standard solution of acetohexamide, in the same medium, at a concentration of about 10 mcg./ml., in 1-cm. cells, at the maximum at about 249 mμ, with a suitable spectrophotometer, using 0.01 *N* sodium hydroxide as the blank. Calculate the quantity, in milligrams, of $C_{15}H_{20}N_2O_4S$ in the portion of tablets taken by the formula $50C \times (A_u/A_s)$, in which C is the exact concentration of the standard solution, in micrograms per milliliter, A_u is the absorbance of the sample solution, and A_s is the absorbance of the acetohexamide standard solution. The amount of acetohexamide found is not less than 90.0% and not more than 110.0% of the labeled amount.

DISCUSSION

U.S.P. and N.F. terminology for solubility, melting range, reagents, *etc.*, has been used wherever feasible.

Acetohexamide[1] is an oral hypoglycemic agent effective in the treatment and management of selected patients with stable diabetes mellitus. The reduction of blood sugar levels by sulfonylurea drugs is achieved primarily by stimulating the release of endogenous insulin and secondarily by inhibition of glucose formation from liver glycogen.

Identity Tests—The qualitative tests included for acetohexamide provide suitable differentiation from official sulfonylurea compounds. The ultraviolet absorption maximum of acetohexamide in alkaline solution is exhibited at about 249 mμ as compared to 230 and 228 mμ for chlorpropamide and tolbutamide, respectively, in the same medium. The formation of the hydrazone derivative with acetohexamide which does not occur with chlorpropamide nor tolbutamide constitutes a rapid distinctive test.

Quantitative Tests—The nonaqueous titration of acetohexamide with sodium methoxide using thymol blue T.S. gave an average value of 100.2 ± 0.5%.[2] Satisfactory recoveries can be obtained by dissolving acetohexamide in a known excess of 0.1 *N* sodium hydroxide and back titration of the excess base with 0.1 *N* hydrochloric acid using phenolphthalein T.S. Neutralized alcohol is added prior to the back titration to retard precipitation of acetohexamide at the end point. Spectrophotometric analyses of commercial tablets labeled to contain 250 and 500 mg. of acetohexamide gave average values of 102.2 ± 0.7%[2] and 100.6 ± 0.4%[2] of the labeled amounts, respectively.

Assay of Methotrexate in the Presence of Its Decomposition Products and Other Folic Acid Analogs

By JOSEPH F. GALLELLI and GLENN YOKOYAMA

Extensive studies with the folic acid antagonist methotrexate in cancer chemotherapy prompted the development of an assay for methotrexate in the presence of its decomposition products and other folic acid analogs. This was accomplished by quantitative chromatographic separation and spectrophotometric analysis of intact methotrexate and its decomposition products. Methotrexate U.S.P. samples were assayed and found to be at best approximately 90 per cent pure.

THE PRESENT U.S.P. method of assay for methotrexate (4-amino-N^{10}-methylpteroylglutamic acid) is based solely on the characteristic ultraviolet absorption of the compound. However, spectrophotometric studies of this type are subject to several limitations. Methotrexate is known to be contaminated with its decomposition products and other closely related folic acid analogs, often differing by as little as one functional group. The similarity of the ultraviolet absorption characteristics of methotrexate, its decomposition products, and other folic acid analogs requires that some type of quantitative separation and purification technique be utilized prior to a spectrophotometric assay of the intact methotrexate in the ultraviolet region.

Although paper chromatography (1) has been used for the separation and identification of closely related derivatives of pteroylglutamic acid, it is not suitable for purification and resolution of folic acid analogs on the preparative scale of milligram or gram quantities. Furthermore, compounds in the folic acid series have been reported (2, 3) to be degraded when subjected to variations of paper chromatography due to photolytic breakdown and transformation due to extreme pH changes.

Column chromatography of proteins on a cellulose anion exchange adsorbent has been described by Sober and Peterson (4). Mixtures of proteins were separated using gradients of pH and salt concentrations for elution. Heinrich *et al.* (5) have employed a strongly basic anion-exchange resin[1] for the resolution of mixtures of certain folic acid analogs.

Oliverio (6) applied diethylaminoethyl (DEAE) cellulose and linear gradient elution by means of phosphate buffers to separate folic acid analogs in milligram quantities. The present study involved an adaptation of this method. A specific method of assay was developed for methotrexate in the presence of its decomposition products and other folic acid analogs, utilizing in part modified techniques and methods of separation and purification.

EXPERIMENTAL

Reagents—Methotrexate[2] U.S.P., m.p. 182–189°, and sodium methotrexate for injection,[3] 50 mg. methotrexate per vial. One of the decomposition products of methotrexate, N^{10}-methylpteroylglutamic acid, had m.p. 224–228°. Stock solutions of 0.1 *M* and 0.4 *M* ammonium bicarbonate were prepared and adjusted to pH 8.3 with ammonium hydroxide U.S.P. Diethylaminoethyl (DEAE) cellulose,[4] 0.75 meq./Gm., was passed through a 100-mesh screen and prepared batch-wise by successive washings with 1 *N* sodium hydroxide, water, 1 *N* hydrochloric acid, water, until pH 5.6 to 6.5. The cellulose was finally washed with 0.1 *M* ammonia–ammonium bicarbonate buffer until pH was approximately 8.3 and then stored in the refrigerator. All other chemicals used were of reagent grade.

Apparatus—A Gilson Medical Electronics (GME) volumetric fractionator model V 15-square[5] was used for fractionations. The eluent was monitored by a GME ultraviolet absorption meter, model UV-265 1F[5] and transmittance recorded on a Texas Rectilinear recording milliammeter.[6] A Sigmamotor pump[7] was employed to monitor rates of approximately 2 ml. per minute. Borosilicate glass containers, 1-cm. inner diameter and 25-cm. in length, held the cellulose adsorbent. A Beckman DU spectrophotometer was used for spectrophotometric determinations.

Chromatographic Separation Procedure—A dilute suspension of the washed DEAE cellulose in 0.1 *M* ammonia–ammonium bicarbonate buffer was added to a column and packed by gradually increasing air

pressure from 2 to 10 p.s.i. Five milliliters of a sample solution representing theoretically 5 mg. of methotrexate in 0.1 *M* ammonia–ammonium bicarbonate buffer was allowed to run slowly into the prepared column of washed DEAE cellulose. The methotrexate is separated from its decomposition products and other folic acid analogs by a linear gradient with pH 8.3 ammonia–ammonium bicarbonate buffer of increasing molarity. The mixing chamber contained 500 ml. of 0.1 *M* ammonia–ammonium bicarbonate buffer, and the reservoir contained 500 ml. of 0.4 *M* ammonia–ammonium bicarbonate buffer. The column was attached *via* polyethylene tubing to the automatic fraction collector. The transmittance of the eluent was continually monitored by a 265 mμ ultraviolet light source and per cent transmittance plotted on a rectilinear recorder. Five-milliliter fractions were collected at the rate of 2 ml. per minute. All chromatographic operations were carried out at room temperature in subdued light to protect the sample from any possible photochemical effects. The peak tubes, as indicated by the per cent transmittance on the chromatogram, were then pooled and the ultraviolet absorption spectrum (230 to 340 mμ) of each peak was measured on a Beckman DU spectrophotometer.

Determination of the Purity of Methotrexate—The sample solution of 1 mg. methotrexate per ml. before fractionation was diluted to 1 mg. per 100 ml. with ammonia–ammonium bicarbonate buffer, pH 8.3, and its absorbance at a wavelength of 302 mμ was recorded on a Beckman DU spectrophotometer. The sample solution was then fractionated as described under *Chromatographic Separation Procedure*. The major peak (methotrexate) tubes were pooled, and a dilution to a theoretical 1 mg./100 ml. solution was prepared and its absorbance recorded at a wavelength of 302 mμ on a spectrophotometer. The purity of methotrexate was determined by calculating the per cent of its absorbance at a wavelength of 302 mμ recovered following chromatographic separation. Further confirmation of the purity of the methotrexate peak was obtained by taking the pooled fractionated solution from the major peak (methotrexate) and refractionating it by first concentrating the methotrexate fractions *via* freeze-drying, followed by reloading on a fresh column utilizing the chromatographic separation procedure previously described.

Identification of the Decomposition Products—In addition to the major peak (methotrexate) on the chromatogram (Fig. 1), three other peaks were obtained. The tubes of each peak were pooled and the ultraviolet absorption spectra (230 to 340 mμ) were recorded on a Beckman DU spectrophotometer. (See Fig. 2.) The identities of the single peaks were then obtained by comparing the ultraviolet curve with that of the authentic sample.

RESULTS AND DISCUSSION

Chromatographic separation of methotrexate U.S.P. is shown in Fig. 1, in which the per cent transmittance has been plotted against the volume of ammonia–ammonium bicarbonate buffer (eluent). Figure 1 shows, in addition to the major peak (methotrexate), the transmittance of three other peaks. These indicated that contaminants or hydrolysis products were present in the methotrexate U.S.P. sample. The hydrolysis products appearing as peaks 1, 2, and 4 on the chromatogram all absorbed at the wavelength of maximum absorbance, about 302 mμ, for methotrexate (see Fig. 2) and accounted for approximately 10% of the methotrexate sample. When the methotrexate fraction was collected, freeze-dried, reconstituted, and refractionated, none of the possible decomposition products showed up in the chromatogram seen in Fig. 3.

The spectrum of the major decomposition product of methotrexate U.S.P. was identical to an authentic sample of N^{10}-methylpteroylglutamic acid. This hydrolysis product appearing as the last peak (No. 4) on the chromatogram accounts for approximately one-half of the total impurities. The molar ab-

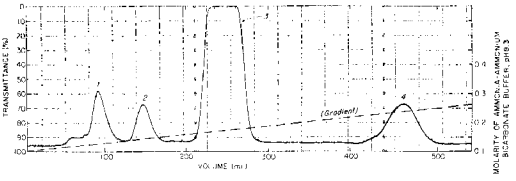

Fig. 1—Chromatogram of methotrexate U.S.P. from DEAE ion-exchange column by linear gradient elution from 0.1 M *to 0.4* M *ammonia–ammonium bicarbonate buffer, pH 8.3. Gradient is represented by dashed line.*

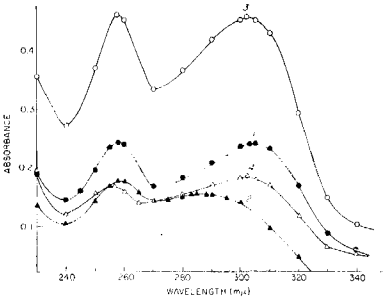

Fig. 2—Ultraviolet spectra of peaks 1, 2, 3, and 4 obtained from chromatographed methotrexate U.S.P. in ammonia–ammonium bicarbonate buffer, pH 8.3. Key: ○, peak 3 (methotrexate); ●, peak 1; △, peak 4 (N^{10}-methylpteroylglutamic acid); ▲, peak 2.

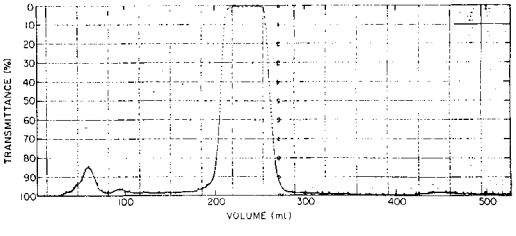

Fig. 3—Chromatogram of refractionated methotrexate U.S.P. from DEAE ion-exchange column by linear gradient elution with ammonia–ammonium bicarbonate buffer, pH 8.3.

sorptivity of N^{10}-methylpteroylglutamic acid was determined, at a wavelength of 302 mμ, and found to be the same as that of the parent methotrexate compound. The molar absorptivities of the unidentified first and second peaks were assumed because of their spectral characteristics of pteroyls to be essentially the same as that of the parent methotrexate compound. It should be noted that molar absorptivity values have been reported in the literature (7, 8) for analogs of pteroyl and pteroylglutamic compounds and found to be approximately the same as that for methotrexate at a wavelength of 302 mμ in alkaline media.

Specificity of Assay for Intact Methotrexate—The present U.S.P. XVII method of assay for methotrexate consists of determining and comparing the absorbance of both the solution of an unknown sample and a standard solution of a U.S.P. methotrexate reference substance (theoretically 100% methotrexate) at the wavelength of maximum absorbance at about 306 mμ with a suitable spectrophotometer using 0.1 *N* hydrochloric acid as the blank. This method is unsatisfactory for distinguishing intact drug from decomposition products, because all decomposition products isolated were shown (see Fig. 2) to absorb at the wavelength of maximum absorbance at about 302 mμ for methotrexate.

The quantitative chromatographic separation of a solution of a methotrexate sample followed by the determination of the absorbance of the methotrexate fraction at a wavelength of 302 mμ on a suitable spectrophotometer does provide a specific method of assay for the intact drug in the presence of its decomposition products and other folic acid analogs. Also, the assay method is such that it might not require the use of a U.S.P. methotrexate reference substance as employed in the U.S.P.

Calculation of Intact Methotrexate—The following formula would permit calculation of per cent intact methotrexate (% IM) on an anhydrous basis at a wavelength of 302 mμ in a 0.1 *M* ammonia–ammonium bicarbonate buffer, pH 8.3:

$$\% \text{ IM} = (A_u/A_s)\,(100 - \% \text{ water})$$

where A_u is the absorbance of the methotrexate solution after chromatographic separation, and A_s is the absorbance of the methotrexate solution before chromatographic separation. The absorptivity (a) of pure or intact methotrexate at a wavelength of 302 mμ in 0.1 *M* ammonia–ammonium bicarbonate buffer, pH 8.3, was calculated in terms of anhydrous methotrexate and found to be 53.9. The above formula can be further expressed as

$$\% \text{ IM} = \frac{(A_u)\,(10)\,(d)}{53.9\,(W_s)}$$

where A_u = absorbance of the chromatographed methotrexate solution whose fractions made up to 100 ml. are diluted to a theoretical 1 mg. methotrexate per 100 ml. solution, d = dilution factor required to dilute the methotrexate fractions made up to 100 ml. to a theoretical 1 mg. methotrexate per 100 ml. solution, and W_s = weight, in grams, of methotrexate sample put on the column.

SUMMARY

A chromatographic separation followed by a spectrophotometric method of analysis is reported for the determination of methotrexate in the presence of its products of hydrolytic decomposition and other folic acid analogs.

All methotrexate samples assayed were found to be at best approximately 90% pure methotrexate.

Recommendation is made for revision of the present U.S.P. method of assay for methotrexate to the one discussed in this paper.

Improved Method of Assay of Pyrvinium Pamoate and Its Official Preparations

By H. D. BECKSTEAD and S. J. SMITH

A simple, rapid, and reliable assay procedure for pyrvinium pamoate and its official preparations using 80 per cent acetic acid solutions and absorption measurement at 508 mμ is presented. Results with this method are found to be more precise and can be obtained with greater facility than with the U.S.P. method. In addition a thin-layer chromatography system using Silica Gel G and dioxane–water (3:1), for the identification of pyrvinium base is described.

THE ASSAY procedure described in the "United States Pharmacopeia" XVII (1) for pyrvinium pamoate {6-dimethylamino-2-[2-(2,5-dimethyl-1-phenyl-3-pyrrolyl)vinyl]-1-methylquinolinium 4,4′-methylenebis[3-hydroxy-2-naphthoate]} specifies the use of low actinic glassware and minimal exposure to light of the sample being analyzed. In the revised method of assay of the bulk drug (2) the use of sodium hydroxide in methoxyethanol has been deleted since this was found to depress the absorbance of solutions.

Analysis of oral suspensions and tablets containing pyrvinium pamoate requires (in addition to protecting the sample from unnecessary exposure to bright light) the use of a rather involved partition chromatography system [both phases of chloroform–hexane–water–methoxyethanol–acetic acid (30:20:10:10:1) on acid washed siliceous earth].

In this laboratory, results from analyses of official preparations of pyrvinium pamoate were found to be closely coupled to the rate of column elution. A maximum elution rate of 4 ml./min., as specified in the U.S.P., gave results with very low values and broad analytical ranges (Table I). When the elution rate was held at a maximum of 3 ml./min. (elution time: 30 to 35 min.) reasonable results were obtained. However, when duplicate samples of U.S.P. reference standard pyrvinium pamoate were eluted through columns on each of 3 consecutive days, a broad analytical range was obtained while standard deviations between days varied from 1.53 to 2.45.

This apparent sensitivity of the official method to variation in elution rates (and perhaps variation in column density), together with the resulting imprecision and inaccuracy, led to the search for a more satisfactory assay procedure.

The only other method of assay of pyrvinium pamoate apparent in the literature is that described by Alves, who used absorption measurement in dimethylformamide (DMF) and acetic acid solutions (3). In this paper a simple, rapid, and reliable spectrophotometric assay procedure for pyrvinium pamoate and its preparations employing 80% acetic acid solutions is reported.

Received June 9, 1966, from the Research Laboratories, Food and Drug Directorate, Ottawa, Ontario, Canada.

Accepted for publication November 14, 1966.

The authors thank Dr. L. Levi and Dr. W. N. French for their comments and Dr. D. F. Bray and Mr. J. M. Airth for their statistical evaluations.

EXPERIMENTAL

Light absorption measurements in stability studies were made using a Beckman model DK2 and in assays a Beckman model DU spectrophotometer. Both were calibrated previously by means of a mercury source.

Solvents—Reagent grade DMF, acetic acid, dimethylsulfoxide, and methoxyethanol were used as supplied. Technical grade formamide was distilled (b.p. 97–99°/14 mm. Hg) before use.

Stability Studies—Ten micrograms per milliliter solutions of pyrvinium pamoate (U.S.P. reference standard) in the various solvents were prepared and their absorbances recorded at suitable time intervals.

Assay Procedure—*U.S.P.*—Pyrvinium pamoate: assay according to the official revised procedure (2). Oral suspension and tablets: assay as described in the U.S.P. (1) observing either the maximum elution rate of 4 ml./min. or 3 ml./min.

Proposed Method—Standard solution: accurately weigh 10 mg. of U.S.P. reference standard pyrvinium pamoate and transfer to a 10-ml. volumetric flask. Add approximately 5 ml. of 80% acetic acid, shake mechanically for 5 min., make up to volume, and mix. Dilute 1.0 ml. of this solution to 100 ml. in a volumetric flask with 80% acetic acid.

Pyrvinium pamoate: prepare as described for the standard solution.

Oral suspension: into a 100-ml. volumetric flask weigh by difference 0.7 Gm. oral suspension. Add 50 ml. 80% acetic acid, shake mechanically for 5 min., make up to volume, and mix. Dilute 10 ml. of this solution to 100 ml. with 80% acetic acid in a volumetric flask.

Tablets: determine the average weight of 20 tablets. Powder 5 tablets and transfer an aliquot equivalent to about 50 mg. pyrvinium base to a 100-ml. volumetric flask. Add 50 ml. 80% acetic acid, shake mechanically for 5 min., make up to volume, mix, and filter through Whatman No. 1 paper, or equivalent. Pipet 1 ml. of the filtrate into a 100-ml. volumetric flask and dilute to volume with 80% acetic acid.

Measure the absorbance of all solutions at 508 mμ on a suitable instrument using 80% acetic acid as a blank.

[d] Superceded procedure for powder. [e] Revised procedure for powder. [f] Corresponding in composition to a commercial preparation.

Calculations—For pyrvinium pamoate:

$$\frac{A \times \text{wt. of ref.}}{B \times \text{wt. of sample taken}} \times 100 = \% \text{ (w/w) pyrvinium pamoate} \quad \text{(Eq. 1)}$$

For the oral suspension:

$$\frac{A \times SG \times 0.6644}{B \times \text{wt. of sample taken}} \times 100 = \% \text{ (w/v) pyrvinium base} \quad \text{(Eq. 2)}$$

For tablets:

$$\frac{A \times 100 \times \text{av. wt./tablet (Gm.)} \times 0.6644}{B \times \text{wt. of sample taken (Gm.)} \times \text{labeled wt. (mg.)}} \times 100 = \% \text{ (w/w) pyrvinium base/tablet} \quad \text{(Eq. 3)}$$

where

A = absorbance of sample solution,
B = absorbance of standard solution,
SG = specific gravity of the suspension,
0.6644 = ratio of the formula weight or pyrvinium base to one-half of the molecular weight of pyrvinium pamoate (the pamoate moiety being dibasic).

Thin-Layer Chromatography

Plates—Prepare plates with standard equipment for thin-layer chromatography (*cf. Reference 4*). To obtain five plates 20 × 20 cm., mix 25 Gm. of Silica Gel G (Merck) with 50 ml. of 0.5 *N* NaOH. Apply the slurry to plates (layer thickness about 250 μ), air dry, and activate within 1 hr. of use by heating at 110° for 20 min.

Solvent System—1,4-Dioxane–water (3:1 v/v).

Spray Reagents—(*a*) Mix 20 ml. of 10% w/v aqueous $FeCl_3$ and 10 ml. 5% w/v aqueous $K_3Fe(CN)_6$ with 70 ml. water. (*b*) Prepare 2 *N* HCl.

Preparation of Samples—Dissolve sufficient bulk drug, suspension, or powdered tablet in methoxyethanol to give a concentration of about 1 mg./ml. pyrvinium pamoate. If the solution is turbid, filter or centrifuge it before spotting.

Chromatographic Procedure—Equilibrate a suitable jar with the chromatographic solvent. Spot 5 μl. of solutions being examined next to a similar amount of U.S.P. reference pyrvinium pamoate. Insert the plate in the chromatographic jar and allow the solvent to rise to a height of 15 cm. (about 2 hr.). Air dry plates and view under shortwave U.V. light or treat with spray (*a*) followed by spray (*b*).

RESULTS AND DISCUSSION

The revised assay of pyrvinium pamoate has deleted the use of sodium hydroxide in the methoxyethanol. Figures 1 and 2 clearly indicate the deleterious effects of this base. Furthermore, the figures indicate that the degradative effects of the base are greatly in excess of breakdown due to actinic activity, since the sample curves obtained for solutions stored in both low actinic and normal glassware are superimposable (Figs. 1 and 2). The deleterious activity of sodium hydroxide is further demonstrated when the lower analytical results from the now-superseded procedure for pyrvinium pamoate powder (1) are compared with data obtained from the revised method (2) (Table I).

The use of heat recommended to aid solution of

pyrvinium pamoate may reduce the accuracy of the official method of assay due to possible breakdown of the drug. Furthermore, analyses of oral suspensions and tablets require that aliquots of material subjected to assay be adsorbed on chromatographic support prior to transfer to the column. Each of these factors increases the exposure of the sample to light and introduces the possibility of error. A major factor causing variability in assay results employing the chromatographic column was found to be variation in the rate of column elution. Elution of the column at a maximum rate of 4 ml./min. as specified in the U.S.P. gave results which were, in all cases, below U.S.P. limits and exhibited broad analytical ranges (Table I). In all analyses pink material was noted to remain on the column. However, when the elution rate was kept at a maximum of only 3 ml./min. (elution time: 30–35 min.), results and standard deviations were found to be reasonable (Table I).

Relatively minor variations in elution rates, and perhaps also in the density of the column packing, may have given rise to relatively broad ranges in the U.S.P. assay results. This can be inferred from the data obtained when duplicate samples of U.S.P. reference material were chromatographed in a uniform manner on 3 consecutive days. Standard deviations between pairs of results were 1.82, 1.53, and 2.45. The six results examined *in toto* had a standard deviation of 3.49. The variation in absorbance of the eluates was the equivalent of an analytical range of 9.29%. Thus in addition to variation within the sample itself inconsistencies are even obtained with the reference standard using the official method.

To find a suitable medium for the assay of pyrvinium pamoate, the stability of the drug in 80% acetic acid, DMF, dimethylsulfoxide, and methoxyethanol in low actinic and normal glassware was determined (Figs. 1 and 2). Solutions kept in low actinic glassware were found to be quite stable, in all cases exhibiting at least 97% of the original absorption at 508 mμ after 60 min. Solutions stored in normal glassware were somewhat less stable (Fig. 2), showing a rapid initial decrease in absorption and thereafter their absorbances remaining fairly constant. No satisfactory absorption curve could be obtained with formamide solutions of the drug, although the trend of readings appeared to indicate that the order of stability was very similar to that in solvents listed above.

Concomitant with these studies, assays of pyrvinium pamoate and its preparations were carried out in both low actinic and normal glassware employing the five solvent systems listed in Table I. Results obtained are shown therein. As anticipated, low actinic glassware always afforded more reliable results than normal glassware. With formamide and also with dimethylsulfoxide solutions, satisfactory results could not be obtained. Assays were calculated as shown under *Experimental*, and for consistency all figures in Table I have been quoted as per cent of labeled claim. To conform with the U.S.P. procedure, values quoted for the suspension (Eq. 2; Table I) should be divided by 100 to read grams per 100 ml.

The data in Table I indicate that results from analyses carried out in dimethylsulfoxide and formamide (powder only) gave the highest values.

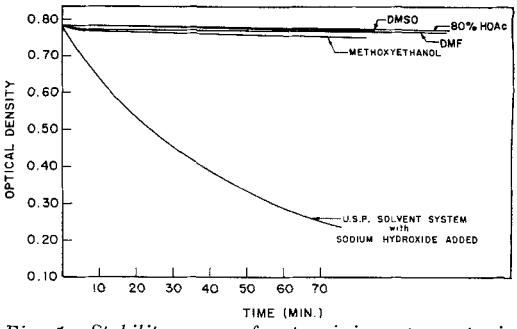

Fig. 1—Stability curves for pyrvinium pamoate in low actinic glassware.

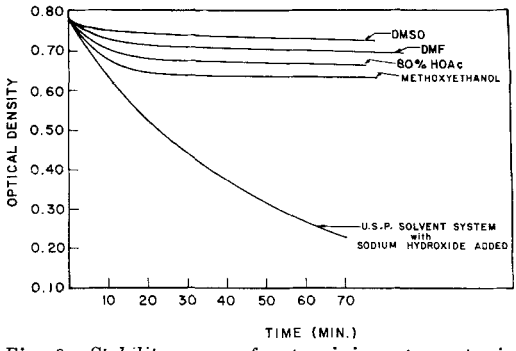

Fig. 2—Stability curves for pyrvinium pamoate in normal glassware.

In addition, results from both of these methods exhibited, in some instances, large standard deviations. Analyses based on the use of both 80% acetic acid and DMF in low actinic glassware showed consistently smaller experimental ranges and smaller standard deviations (probability <0.05) than analyses based on the other systems. These ranges were also smaller than those obtained from assays using 80% acetic acid and DMF in normal glassware. There is little difference in the variability between 80% acetic acid and DMF solvent systems when low actinic glassware (aluminum foil wrapped around the volumetric flask suffices) is employed. However, the greater stability of pyrvinium pamoate in acetic acid solution compared to DMF solution (Fig. 1), coupled with the more general availability, lower toxicity, and lower cost of acetic acid, leads to the proposal of the acetic acid solvent system as the medium of choice for the assay of pyrvinium pamoate and its preparations.

Most of the preparations of pyrvinium pamoate examined did not completely dissolve in methoxyethanol. In addition, when some brands were brought into contact with the solvent, a copious precipitate was formed which appeared to adsorb pyrvinium pamoate, thus making it difficult to obtain homogeneous aliquots for subsequent chromatography. This source of error was eliminated by the use of 80% acetic acid in which all excipients were found to be completely soluble.

To confirm the accuracy of the proposed method a simulated tablet as well as a suspension was prepared and assayed according to the new method.

The values shown in Table I are per cent recovery. These results appear to confirm that the proposed method is both accurate and precise. In addition to its greater precision, it is also much faster than the official method; about 8 min. compared with near 40 min. in the latter.

Thin-layer chromatographic examination of official dosage forms of pyrvinium pamoate and a U.S.P. reference standard indicated that the drug consists of a number of components. Pyrvinium pamoate contained in official preparations separated into two major red spots at R_f 0.33 and 0.44 and a minor red spot at R_f 0.50. Upon spraying, these spots stained intense blue, while pamoic acid, previously visible only by fluorescence at R_f 0.50, stained light blue. U.S.P. reference standard pyrvinium pamoate was found to contain all of the above components as well as another minor red constituent, staining intense blue, at R_f 0.15. Pamoic acid could be separated from the red material also appearing at R_f 0.50 by using 0.1 *N* NaOH instead of 0.5 *N* NaOH in preparing the chromatographic plates (new R_f of pamoic acid: 0.69).

The occurrence of a greater number of red spots than expected, on the basis of two isomeric configurations of the compound, should not be attributed to the degradative effect of sodium hydroxide in the aqueous system since, for example, chromatography with chloroform–ethanol (7:3) on neutral Silica Gel G (Merck), although giving very poor separation, clearly indicated three red constituents in commercial and four such components in U.S.P. reference standard pyrvinium pamoate. These compositional characteristics of the drug will be examined further.

Analysis of Combinations Containing Phenylephrine in Liquid Dosage Forms

By K. O. MONTGOMERY, P. V. JENNINGS, and M. H. WEINSWIG

A method is presented for the isolation, separation, and determination of phenylephrine, an antitussive, and an antihistamine in commercial products containing the combination. All three compounds are extracted with strong cation exchange resin AG 50W-X4. The phenylephrine is eluted from the resin bed with 8.0 *N* phosphoric acid. The antitussive is then eluted with 1.0 *N* hydrochloric acid in 60 per cent methanol in water. Finally the antihistamine is eluted with 3.5 *N* hydrochloric acid in 40 per cent methanol in water. The compounds are determined by subjecting the eluates to ultraviolet spectrophotometry. The method is used successfully on several commercial products.

THE ASSAY of complex formulations containing several active ingredients is usually a difficult and time-consuming problem. This is especially true if the active ingredients are similar in their chemical and physical properties. Ion-exchange chromatography was selected as the method of choice for this assay because of its ability to isolate completely the cationic active ingredients from the inactive ingredients, and separate these active ingredients by selective elution. Each ingredient was then quantitatively eluted in a form suitable for determination by ultraviolet spectrophotometry.

Ion-exchange chromatography has been used extensively to accomplish difficult separations of inorganic ions. Hofer (1) used an ion-exchange resin[1] to absorb calcium and magnesium from tissue extracts. Magnesium was then eluted with 2 *N* hydrochloric acid and calcium was eluted with 3 *N* hydrochloric acid. Grasselly (2) used anion-exchange resins to separate iron, aluminum, manganese, calcium, and magnesium. Pollard (3) separated magnesium, strontium, barium, and calcium on the ion-exchange resin[1] utilizing a gradient elution technique. Pitstick and associates (4) separated magnesium, cobalt, zinc, copper, and iron with anion-exchange resins.

Most of the references to organic separations utilize a simple adsorption–elution technique to separate anions or cations from neutral components. Wang and Hunter (5) assayed 11 different alkaloids separately by adsorbing them on an ion-exchange resin,[2] eluting with glacial acetic acid, and titrating the eluate with perchloric acid.

Morphine has been separated from the nonphenolic alkaloids of opium utilizing ion exchange (6). Blake and associates (7, 8) applied tech-

niques similar to those used in inorganic separation to determine active ingredients in pharmaceuticals.

The combinations of compounds considered in this paper have been studied by several groups. Schriftman and Shultz (9) used paper electrophoresis for their separation and measured spot size on a densitometer to determine the active ingredients. Thin-layer chromatography has also been used with spot size measurement (10). Hyatt (11, 12) has proposed the use of partition columns to separate the active ingredients. Three columns are used and the separated compounds determined spectrophotometrically.

EXPERIMENTAL

Apparatus—Glass column 20 cm. × 1 cm. with a stopcock made of Teflon and containing a built-in needle valve for control of flow rate; the column is also fitted with a reservoir with a capacity of 250 ml.

A suitable recording ultraviolet spectrophotometer such as a Beckman DK-2A or Spectronic 505 which records in absorbance units.

Reagents—Cationic exchange resin AG 50W-X4, 100–200 mesh, hydrogen form, available from Bio-Rad Laboratories, Richmond, Calif. Enough resin, about 3 Gm., is added in the form of an aqueous slurry to the glass column; the resin bed is rinsed with water.

Phosphoric acid, 8.0 *N* in water; hydrochloric acid, 0.05 *N* in 50% methanol in water; hydrochloric acid, 1.0 *N* in 60% methanol in water; hydrochloric acid, 3.5 *N* in 40% methanol in water.

Standard Solutions—Prepare the following standard solutions using U.S.P., N.F., or other suitable reference standards. (*a*) Phenylephrine hydrochloride 10 mg./250 ml.; 8.0 *N* phosphoric acid in water. (*b*) Phenylephrine hydrochloride, 20 mg./250 ml.; 8.0 *N* phosphoric acid in water. (*c*) Codeine phosphate, 20 mg./200 ml.; 1.0 *N* hydrochloric acid in 60% methanol in water. (*d*) Dextromethorphan hydrobromide, 30 mg. in 200 ml.; 1.0 *N* hydrochloric acid in 60% methanol in water. (*e*) Chlorpheniramine maleate, 4 mg./200 ml.; 3.5 *N* hydrochloric acid in 40% methanol in water. (*f*) Promethazine hydrochloride, 10 mg./200 ml.; 3.5 *N* hydrochloric acid in 40% methanol in water.

Sample Treatment—Use 10-ml. samples of preparations *A*,[3] *B*,[4] and *C*.[5] For preparations *D*,[6] *E*,[7] and *F*[8] use 20-ml. samples. Pipet the sample into the reservoir, rinse the pipet with distilled water, and add to the reservoir.

Add distilled water to the sample to make the volume approximately 100 ml. and mix well. Allow this sample solution to flow through the resin bed at the rate of 2–3 ml./min. Wash the column by adding 100 ml. of distilled water to the reservoir and allow it to flow through the resin at the rate of 5 ml./min.

Traces of aromatic amines from flavors or coloring agents are removed by allowing 50 ml. of 0.05 *N* hydrochloric acid in 50% methanol in water to flow through the column at 5 ml./min.

Position a 250-ml. volumetric flask under the column and add 240 ml. of 8.0 *N* phosphoric acid to the reservoir. Allow this to flow through the column at the rate of 2 ml./min. The eluate volume is adjusted with 8.0 *N* phosphoric acid. This eluate contains the phenylephrine.

Position a 200-ml. volumetric flask under the column and add 190 ml. of 1.0 *N* hydrochloric acid in 60% methanol in water to the reservoir. Allow this to flow through the resin at 3 ml./min. Adjust the eluate volume with 1.0 *N* hydrochloric acid in 60% methanol in water. This eluate contains the antitussive.

Position another 200-ml. volumetric flask under the column and add 190 ml. 3.5 *N* hydrochloric acid in 50% methanol in water to the reservoir. Allow this to flow through the resin at the rate of 4 ml./min. Adjust the eluate volume with 3.5 *N* hydrochloric acid in 40% methanol in water. This eluate contains the antihistamine.

For re-use the column is washed with 100 ml. of distilled water.

Determinations—Record the ultraviolet spectra of the sample eluates and the standard solutions using a suitable spectrophotometer. Absorbance units should be used. Using the base line technique, determine the absorbances for each sample and standard at the particular maximum. Calculate the amounts of each compound present in each sample from the values obtained for the standard solutions.

DISCUSSION AND RESULTS

Standard solutions, when subjected to the above procedures, gave the results shown in Table I. These results are derived from ten determinations for each compound. These data indicate that the method is accurate to within 1% of the true values and is reproducible to ±1.5% at 95% confidence limits. The data for the analyses of marketed products are shown in Table II.

A slightly raised base line was noted with some products where a small portion of the coloring agent was held and eluted with the sample. This did not cause any problem since the base line technique was used in the calculations.

When the maleate salt of a compound is used for a standard, there is a small difference in the base line caused by ultraviolet absorbance of the maleic acid radical. This also is overcome for the most part by the use of the base line technique.

One deviation from the described procedures was necessary for preparation *E*. Since terpin hydrate is precipitated on dilution with water, the sample dilution prior to column application and the washing of the column were performed using 50% methanol in water instead of distilled water.

In products containing acetaminophen, a small amount of *p*-aminophenol is usually present which could interfere with the analysis of phenylephrine. This is effectively removed during the rinse using

B	Phenylephrine HCl	5	98.8
	Dextromethorphan HBr	15	98.1
	Chlorpheniramine maleate	2	100.2
C	Phenylephrine HCl	10	100.85
	Codeine phosphate	10	100.82
	Chlorpheniramine maleate	2	101.65

0.05 *N* hydrochloric acid in 50% methanol in water.

One product, preparation *B*, actually contained four amines as active ingredients: phenylephrine, dextromethorphan, chlorpheniramine, and phenylpropanolamine. The last compound does not have a significant ultraviolet absorbance and therefore was outside the scope of this study. However, because of its lack of ultraviolet absorbance character, it did not interfere with the assay for the other active ingredients.

To demonstrate the characteristics of this method of assay, a mixture of phenylephrine, codeine, and chlorpheniramine standards was sorbed onto a column and eluted according to the previously described scheme. The eluate from the column was monitored utilizing a flow-through cell in an ultraviolet spectrophotometer. A strip chart recorder was connected to the spectrophotometer to record absorbance *versus* volume of eluate. (Fig. 1.) This chart shows a complete and concise separation of the three compounds.

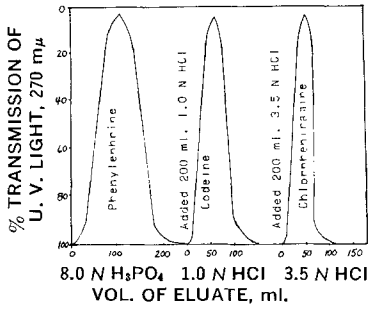

Fig. 1—Graph of per cent transmission of column eluate vs. *volume.*

SUMMARY

A method of assay for liquid dosage forms containing the combination of phenylephrine, an antitussive, and an antihistamine in a single product has been presented. The procedures have been used successfully on commonly available products with accurate and reproducible results.

Effects of 5-Fluorotryptophan on the Biosynthesis of Ergot Alkaloids by *Claviceps purpurea*

By W. A. SKINNER, J. J. MORRIS, and J. V. STEVENSON

The possibility of incorporation of 5-fluorotryptophan into ergot alkaloids by *Claviceps purpurea* PRL 1565 was explored utilizing randomly tritiated material. Very little radioactivity was found in the alkaloid fraction, most of it residing either in the mycelium or in the base-soluble fraction which would contain unchanged 5-fluorotryptophan. Thin-layer chromatography allowed the isolation of an alkaloid containing radioactivity, but fluoride analysis using neutron activation indicated the absence of fluorine in the molecule. It was concluded that 5-fluorotryptophan was not incorporated into the ergot alkaloids produced by *C. purpurea* PRL 1565.

THE BIOSYNTHESIS of ergot alkaloids has been the subject of many studies (1–5), primarily with regard to the elucidation of the pathway followed and identification of precursors. Tryptophan is known to be actively incorporated into the ergot or clavine alkaloids by certain strains of *Claviceps*. However, except for two studies, ring-substituted tryptophans have not been investigated as precursors of the ergot nucleus. Arcamone *et al.* (6) investigated the effect of 4-,5- or 6-methyltryptophans on the ergot alkaloid production by *Claviceps paspali* Stevens and Hall in submerged culture. They concluded on the basis of comparison of chromatography of the products isolated from the media containing the 5- or 6-methyltryptophans with that containing tryptophan that no incorporation of the methyltryptophans had occurred. Further evidence cited for this was comparison of the infrared spectra of hydrazides of the *dl*-isolysergic acid obtained from the culture containing the 5- or 6-methyltryptophans with that of an authentic sample of the unsubstituted derivative. However, one would expect only small differences between the chromatographic behavior and infrared spectra of ring methyl substituted isolysergic acid amides and hydrazides and the nonring substituted analogs. The added 4-methyltryptophan inhibited alkaloid production, while the 5- and 6-methyl substituted tryptophans allowed production of alkaloids greater than the control without the addition of the tryptophans. This increase in alkaloid production could be due either to incorporation or enzyme induction.

The other study of the effect of substituted tryptophans in *Claviceps* on alkaloid production was conducted by Floss and Mothes (7) using a saprophytic culture of *Claviceps*-Stammes SD 58. These workers investigated the effects of 4-, 5-, 6-, and 7-methyltryptophans and 5-fluorotryptophan on alkaloid yield. The methyl ring-substituted tryptophans were all found to increase alkaloid production somewhat with the 5- and 6-isomers giving the greatest increase. A marked reduction in alkaloid yield was obtained with the addition of 5-fluorotryptophan but no incorporation data were obtained. The incorporation into elymoclavine of tritium marked 5- and 7-methyltryptophans was studied. No appreciable incorporation into elymoclavine was obtained, and the authors concluded that the increases in alkaloid production obtained with these ring methyl derivatives were due to enzyme induction.

In these laboratories, the authors have also been interested in whether ring-substituted tryptophans could be incorporated into ergot alkaloids as a possible biosynthetic method for the preparation of new ring-substituted ergot derivatives. The results of studies using randomly tritium-labeled 5-fluorotryptophan in submerged cultures of *Claviceps purpurea* PRL 1565 are reported.

METHODS

Two strains of *C. purpurea*, initially obtained from Dr. W. A. Taber, were used for experiments. Strain 1565 was found to give the highest yields of alkaloids when grown on a modified Abe medium plus yeast extract and glucose and strain 1578 when grown on Abe's medium plus ammonium succinate and a 19:1 mixture of galactose and glucose. The extraction procedure used was that of Vining and Taber (8). By using ergometrine as a control, the efficiency was determined to be satisfactory. Alkaloid content was ascertained by the van Urk method using ergometrine as a standard. The maximum alkaloid production was attained in 20–50 days. Addition of L-tryptophan, either just before the time of peak alkaloid production or earlier in the growth period, resulted in increased alkaloid production.

Investigation of various silica gel GF thin-layer chromatographic systems using authentic ergot and clavine alkaloids indicated that the two solvent systems, benzene–ethanol (2:1) and ethyl acetate–dimethylformamide–95% ethanol (10:1:1), were sufficient to separate most of the alkaloids of interest. Alkaloids could be detected under ultraviolet light or by spraying with *p*-dimethylaminobenzaldehyde reagent. In both solvent systems 5-fluorotryptophan and 5-fluorotryptamine stayed at the origin. In butanol–acetic acid–water (10:1:1), 5-fluorotryptophan has an R_f of 0.4.

[a] Added on day 24 (1.5 mg. with specific activity of 2.46×10^7 d.p.m./mg.). [b] In addition to labeled 5-FT added on day 24, L-tryptophan added at time of inoculation to yield final concentration of 0.1%. [c] Added on day 6 (1.1 mg. with specific activity of 2.46×10^7 d.p.m./mg.). [d] Added on day 4 (1.3 mg. with specific activity of 2.34×10^7 d.p.m./mg.).

RESULTS

5-Fluorotryptophan (K and K Chemical Co.) was identified by its melting point and infrared absorption spectrum and randomly tritiated at the New England Nuclear Co. by the Wilzbach technique of exposure of 375 mg. at 250 mm. pressure to 3 c. of tritium at 27° for 2 weeks. The labile tritium was removed by dissolving the material in 95% ethanol and by removal of the solvent *in vacuo*. This material was purified by crystallization from isopropanol–water to yield material whose infrared absorption spectrum and thin-layer behavior in butanol–acetic acid–water (10:1:1) and in *n*-propanol–concentrated ammonium hydroxide (70:30), R_f 0.5, agreed with that of authentic material. This purified material, which also showed no change in specific activity upon recrystallization, was added to submerged cultures of *C. purpurea* PRL 1565 and alkaloidal yields were determined colorimetrically by using van Urk reagent (Table I). In some experiments L-tryptophan was added at the time of inoculation and the labeled 5-fluorotryptophan was added later.

TABLE II—DISTRIBUTION OF RADIOACTIVITY IN EXTRACTS FROM *C. purpurea* PRL 1565

Expt.	% of Counts Basic Extract	Neutral Extract	Acidic Extract	Mycelium
33	20	8.2	5.0	66.8
36	33.6	0.8	3.0	62.6
39	10.6	7.5	7.7	74.2

TABLE III—THIN-LAYER CHROMATOGRAPHY OF ALKALOIDS FROM *C. purpurea* PRL 1565 AND STANDARD ALKALOIDS

Alkaloid Extract	Ethyl Acetate–Dimethylformamide–95% Ethanol (10:1:1) Orig., 0.55, 0.90	Benzene–Ethanol (2:1) Orig., 0.60, 0.90
Chanoclavine	0.05	0.06
Ergonovine	0.17	0.20
Agroclavine	0.40	0.44
Ergosine	0.54	0.48
Ergotamine	0.55	0.65
Ergocristine	0.58	0.70
Ergocryptine	0.60	0.75
Ergocornine	0.68	0.70
Ergocristinine	0.75	0.70
Ergotaminine	0.90	0.85

Distribution of the radioactivity among extracts from the various experiments is shown in Table II. Each per cent represents the average of results from four separate flasks.

Investigation of the thin-layer behavior (silica gel GF) of the acidic extracts after basification with ammonium hydroxide and extraction of the alkaloids with $CHCl_3$ and ether gave results as seen in Table III when compared to authentic samples of ergot and clavine alkaloids. These R_f values are averages of a large number of determinations.

The spots were all detected by their fluorescence and all but the origin spots were van Urk positive. The alkaloid at 0.55 in ethyl acetate–dimethylformamide–95% ethanol and 0.60 in benzene–ethanol corresponds most closely to ergotamine. The alkaloid at 0.90 corresponds most closely to ergotaminine.

The alkaloid mixture isolated from experiment 39 (Table II) was put on a thick-layer silica gel GF plate and developed with ethyl acetate–dimethylformamide–95% ethanol (10:1:1). The plate was sectioned to separate the fluorescent spots at the origin, 0.55 and 0.90 and the silica gel was extracted, first with methanol, then with chloroform. The combined extracts were dried *in vacuo* and counted in a scintillation counter. The products had the following counts: origin (8,040 c.p.m.), 0.55 (92,300 c.p.m.), and 0.90 (6,390 c.p.m.). Nonfluorescent sections between these zones had only background counts.

The van Urk positive radioactive material at 0.55 was isolated from a silica gel H plate by removal of the zone of ultraviolet absorption and extraction with methanol. The methanol was removed *in vacuo* and the sample submitted along with a control sample to General Atomic Division of General Dynamics, San Diego, Calif., for fluoride analysis by neutron activation. The results were 1.1 ± 0.2 mcg. F for the blank and 0.7 ± 0.3 mcg. F for the alkaloid extract.

DISCUSSION

5-Fluorotryptophan was found to somewhat inhibit production of ergot alkaloids from *C. purpurea* PR 1565 when added early after inoculation, agreeing with the results that Floss and Mothes found on clavine alkaloid yields using *Claviceps*-Stammes SD 58. However, when the 5-fluorotryptophan was added on the day 24 after inoculation, the alkaloid yields were increased.

The distribution of radioactivity after addition of

randomly tritiated 5-fluorotryptophan to *C. purpurea* PRL 1565 was found to be largely in the mycelium and the basic extract which would contain unincorporated labeled 5-fluorotryptophan. In the alkaloid containing extract, the majority of the radioactivity was found to be concentrated in the thin-layer chromatographic spot at R_f 0.55 when developed with ethyl acetate–dimethylformamide–95% ethanol (10:1:1). The low yields of alkaloids produced by the organism prevented conventional fluoride analyses on them. The sensitivity of neutron activation analysis for fluoride was useful in indicating the absence of fluorine in the radioactive, van Urk positive material. The conclusion is that 5-fluorotryptophan was not incorporated into the ergot alkaloids by *C. purpurea* PRL 1565. Two possible explanations could account for the radioactivity of the alkaloid at R_f 0.55: tritium exchange between the tritiated 5-fluorotryptophan and tryptophan or enzymatic reduction of the 5-fluoro group followed by incorporation of the tryptophan. Doubly labeled 5-fluorotryptophan with a better alkaloid producing organism would be required to distinguish between these explanations.

Gastrointestinal Irritant Effect of Glycerin as Compared with Sorbitol and Propylene Glycol in Rats and Dogs

By R. STAPLES, A. MISHER, and J. WARDELL, JR.

Effects of glycerin, sorbitol, and propylene glycol on the gastrointestinal mucosa were compared in rats and dogs. At equivalent, undiluted doses (ml./Kg.) in both species glycerin was more irritating than sorbitol, and propylene glycol was the least irritating of the three compounds studied. The types of irritant effects observed were qualitatively similar, and the degree of severity was dose-dependent in both species. Studies in rats showed that irritation produced by any of the three compounds was reduced by dilution of the dose.

GLYCERIN is a fairly common component of liquid pharmaceutical vehicles. However, there is little definitive information in the literature on its gastrointestinal effects. Johnson *et al.* (1) reported that ingestion of 30 ml. (approximately 0.6 ml./Kg.) of 95% glycerin with orange juice three times daily for 50 days by 14 normal humans produced no consistent changes in body weight or temperature and no overt pharmacological effects. The daily number and consistency of stools was unaffected by the quantities of glycerin fed. Subjectively, four subjects (29%) reported an occasional "sensation of warmth" in the stomach after ingestion, especially in the rare instance when glycerin was taken on an empty stomach. No enterogastric examinations were done, however, to assess gastrointestinal effects directly. These same investigators noted "no ill effects" in 11 fasted rats which received single oral doses of glycerin ranging from 7 to 18 Gm./Kg. (5.6 to 14.3 ml./Kg.). Arnschnik (2) cited "no illness" in dogs after single oral doses of glycerin up to 8 Gm./Kg. (6.3 ml./Kg.). However, at 11 Gm./Kg. orally (8.7 ml./Kg.), the same investigator reported "intestinal disturbances" and vomiting. Kobert (3) and Sollmann (4) stated that repeated ingestion of large doses of glycerin lead to a chronic inflammation of the gastrointestinal tract in man. Deichmann's review of the pharmacology of glycerin (5, 6) cited Kobert's report (3) of the accidental ingestion of 300 Gm. (about 238 ml.) of glycerin by a 2-year-old child who lost consciousness but recovered following stomach lavage. Drill (7) noted that oral administration of 100 to 300 ml. of undiluted glycerin has caused "severe symptoms" in humans, whereas the same amount diluted or mixed with food produces "little or no effect." Sroka (8), in a patient given "more than 100 grams orally" while being treated for kidney stones, observed dizziness, drowsiness, violent headache, bloody diarrhea, and kidney pains (differing from the orginal kidney pains).

The purpose of this study was twofold: (*a*) to compare the gastrointestinal irritation liability of glycerin with that of sorbitol (in aqueous solution) and propylene glycol, two other commonly used constituents of oral liquid pharmaceutical preparations; and (*b*) to determine the effect of water dilution on the gastrointestinal irritant potential of these three compounds.

METHODS

Female Charles River rats, weighing 150 to 210 Gm., and adult mongrel dogs of either sex, weighing 8.9 to 16.0 Kg., were used. The rats were housed five per cage, and the dogs caged individually, in rooms maintained at 74° F. The compounds studied (glycerin, sorbitol, and propylene glycol) were administered by stomach tube, three times

[a] Sorbitol, 90% w/v in distilled water is sorbitol solution U.S.P.

daily (at 10 a.m., 1 p.m., and 4 p.m.), for 3 days. Food and water were withheld during the dosing period (from 8:30 a.m. to 4:30 p.m.) on each day but were available *ad libitum* at all other times.[1] All animals were observed for overt effects following each dose. The animals were sacrificed about 1 hr. after the second dose on the third day (after having received 8 doses). Rats were killed by a blow on the head; dogs received a lethal intravenous dose of a veterinary euthanasia agent.[2] Following sacrifice, the stomach and attached portion of the duodenum (about one-third the entire duodenal segment) of each animal were removed carefully and rinsed in tepid water. The stomach was cut along its greater curvature from cardiac sphincter through the pylorus, and the duodenum was cut longitudinally by extending the incision. The mucosal surface was examined grossly and irritated areas were observed under a binocular microscope.

The degree of irritation was graded according to the following descriptions, arranged progressively from least to most severe: *normal*, appearance of mucosa same as in water-treated controls; *slight hyperemia*, slight reddening of mucosa; *severe hyperemia*, deep reddening of mucosa; *petechial hemorrhage*, hyperemia and pinpoint submucosal hemorrhages; *erosion*, mucosal erosion with associated severe hyperemia and hemorrhage.

RESULTS AND DISCUSSION

The results of this study in rats (Table I) and dogs (Table II) clearly indicate that at equivalent undiluted oral doses glycerin was more irritating to the gastrointestinal tract than either sorbitol or propylene glycol. Chronic dosing (t.i.d. for 8 doses) in both species with glycerin at doses up to 3.00 ml./Kg. produced hyperemia, petechial hemorrhages, and erosions. These effects may be due to the hygroscopicity of the compound which, in high concentration, is somewhat dehydrating and irritating to exposed tissue (9). In contrast, undiluted sorbitol solution U.S.P. was far less irritating than equivalent doses of glycerin, and propylene glycol was relatively innocuous. Gastrointestinal irritation following oral administration of undiluted glycerin has been cited in the literature. The doses used, however, were in the toxic range. Deichmann (6) reported an acute irritation of the entire gastrointestinal tract in rats receiving lethal oral doses of undiluted glycerin. The previously cited "severe symptoms" in humans (3, 7, 8) were produced by doses in the lethal range since Dreisbach (10) estimated the fatal oral undiluted dose in humans to be 100 Gm. of glycerin (79.4 ml.). The highest dose used in the present study, 3.00 ml./Kg. of undiluted glycerin, was sublethal, and was about one-seventh of the reported oral LD_{50} in rats (11).

Thus, the irritating properties of undiluted glycerin have been observed in two species at doses below that required to produce overt toxicity.

According to Drill (7), the gastrointestinal irritating potential of glycerin in humans was reduced by dilution of the dose. Johnson, Carlson, and Johnson (1) reported a similar observation in rats and dogs. Results of the present study in rats confirm these earlier investigations. Rather severe irritation was produced by 3.00 ml./Kg. of undiluted glycerin; but when the same dose was given as 80%, 60%, 40%, or 20% dilutions in distilled water, the irritation was reduced as the concentration was decreased. Similar results were obtained with both sorbitol and propylene glycol, although the initial irritation produced by either compound undiluted was less than that produced by glycerin. It appeared that irritation was reduced to minimal

[1] Rats received Purina rat chow. Dogs received 1 lb. of Red Heart dog food daily.

TABLE II—GASTROINTESTINAL IRRITATING EFFECTS OF GLYCERIN, SORBITOL, AND PROPYLENE GLYCOL AFTER ORAL ADMINISTRATION t.i.d. FOR 8 DOSES TO DOGS

Compd.	Dose, ml./Kg.	Dog No.	Description of Stomach and Duodenum
Glycerin	0.75	1	Appeared "normal."
	1.50	2	All mucosa severely hyperemic with widespread petechial hemorrhages.
	3.00	3	All stomach mucosa slightly to severely hyperemic with several localized areas of petechial hemorrhages; duodenal mucosa mostly "normal" with scattered hyperemic areas.
		4	Several localized severely hyperemic areas containing several small erosions; duodenum appeared "normal."
Sorbitol[a] soln.	0.75	5	Appeared "normal."
	1.50	6	Most of stomach slightly to severely hyperemic; duodenum appeared "normal."
	3.00	7	Appeared "normal."
Propylene glycol	0.75	8	Appeared "normal."
	1.50	9	All stomach mucosa slightly hyperemic; duodenum "normal" except for several small, localized slightly hyperemic areas.
	3.00	10	Appeared "normal."
Distilled water—controls	3.00	11	Appeared "normal."

[a] 0.75 ml./Kg. of sorbitol solution U.S.P. = 0.675 Gm./Kg., as sorbitol. 1.50 ml./Kg. of sorbitol solution U.S.P. = 1.35 Gm./Kg., as sorbitol. 3.00 ml./Kg. of sorbitol solution U.S.P. = 2.70 Gm./Kg., as sorbitol.

levels: (*a*) when 3.00 ml./Kg. of glycerin was administered in a concentration of under 40% v/v; and (*b*) when 3.00 Gm./Kg. of sorbitol was administered at concentrations of 45% w/v, or less. Propylene glycol, even undiluted, produced only minimal irritation.

These studies in rats and dogs have shown that repeated oral administrations of high concentrations of glycerin are irritating to the gastrointestinal mucosa. This effect might be a factor for consideration in the development of vehicles for liquid pharmaceutical preparations intended for repeated administration to humans. The results suggest that additional investigations in man would be desirable to establish the possible clinical significance of our observations in animals.

SUMMARY

In this study, undiluted glycerin, administered orally to rats and dogs, produced gastrointestinal irritation to a much greater degree than did either sorbitol or propylene glycol. The degree of severity of the irritant effect of each compound was dose-dependent in both species and was reduced in rats by dilution of the dose.

Structure Elucidation and Chemistry of *Catharanthus* Alkaloids II. Isolation and Partial Structure of Catharine, a Dimeric Indole Alkaloid from *C. lanceus* and *C. roseus*

By DONALD J. ABRAHAM, NORMAN R. FARNSWORTH, RALPH N. BLOMSTER, and ROBERT E. RHODES

A continuing study of *Catharanthus lanceus* alkaloid fractions, in a search for new antineoplastic alkaloids, has led to the isolation of catharine, a dimeric indole alkaloid found previously only in the related *C. roseus*. High resolution mass spectrometric measurements have shown that catharine has the formula $C_{46}H_{54}N_4O_{10}$ and is made up of a vindoline moiety and an alkaloid moiety with a molecular formula of $C_{21}H_{23}N_2O_4$.

PREVIOUS STUDIES in these laboratories on *Catharanthus lanceus* have led to the isolation of the monomeric alkaloids lanceine (1), tetrahydroalstonine (2), ajmalicine (3), and yohimbine (4), which were previously reported from this plant by Janot *et al.* (5–7). In addition, monomeric alkaloids previously unreported from this plant, but reported present in related genera or species, were found to be vinosidine (1), perivine (4), perimivine (3), pericalline (tabernoschizine, apparicine, gomezine) (3), vindoline (4), and lochnerinine (2). Three new and hitherto unreported monomeric alkaloids, catha-lanceine (3), pericyclivine (8), and periformyline (2, 9), were similarly isolated in the authors' studies. On the other hand, only one dimeric alkaloid, leurosine (4), had been encountered in this investigation of *C. lanceus* alkaloids. This alkaloid was previously isolated from *C. roseus* by Svoboda *et al.* (10), and has been subsequently shown to be highly active against the P-1534 leukemia in DBA/2 mice (11–13).

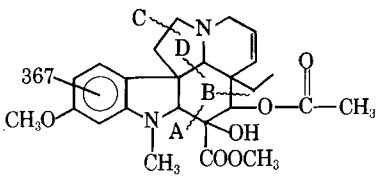
A continued investigation of alkaloid fractions obtained from *C. lanceus* has resulted in the isolation of a second dimeric alkaloid, catharine, from this plant. The isolation, characterization, and partial structure elucidation of this alkaloid is reported here.

EXPERIMENTAL

Isolation of Catharine.—In a previous paper the authors investigated the leaf alkaloid (A_1) fraction from *C. lanceus* and isolated the alkaloids tetrahydroalstonine, lochnerinine, and a new alkaloid periformyline (2). The structure for periformyline was subsequently shown by us to be $N_{(b)}$-formyl perivine, the first example of an $N_{(b)}$-substituted formyl iodole alkaloid to be found in nature (9). Additional studies on this leaf (A_1) fraction have resulted in the isolation of catharine, previously isolated only by Svoboda *et al.* from *C. roseus* (14).

Work-up of the chloroform eluted fractions 175–181 from the column chromatographic separation of the (A_1) alkaloids (100 Gm.), as previously described (Table I), resulted in the formation of 0.730 Gm. of crystals from benzene after several weeks of refrigeration. Recrystallization of these fine crystals from methanol–anhydrous ether afforded an analytical sample of catharine, m.p. 257–258° dec. A mixed melting point with reference to catharine showed no depression,[1] and an infrared absorption spectrum (Fig. 1) was superimposible with that of a reference sample, as was that of a comparison ultraviolet absorption spectrum. The molecular weight of catharine, as determined by mass spectrometry, was found to be 822.

Partial Structure Elucidation of Catharine.—The mass spectrum[2] of catharine showed major peaks at *m/e* 822, 763, 735, 733, 622, 555, 554, 158, 144, 136, 135, 130, 122, 121, 108, and 107. From the above data it became apparent that vindoline made up one-half of this dimeric alkaloid. If one considers the partial structure (I) for catharine, the mass spectral data can be interpreted reasonably. The 367 in I



I

represents the molecular weight of the other half of the dimeric alkaloid. The *m/e* 763 peak represents a loss of 59 mass units, or a carbomethoxy group. Previous mass spectral degradations of vindoline (16, 17) are also evident here. The *m/e* 822 to *m/e* 662 (II) transition (Scheme I), with loss of 160 mass units, indicates ABD cleavage to give the fragment II*a*. A strong metastable ion for this transition is observed at *m*/e* 533.1. The *m/e* 554 peak can possibly be represented as the following ion (III) (Scheme II), from cleavage at E in II, which is similar to that basic ion formed by vindoline at *m/e* 188. The *m/e* 282 (IV) to *m/e* 222 (V) transition has a weak metastable ion at *m/e** 174.8 and is pictured as similar to that particular degradation in vindoline (Scheme III).

Other characteristic vindoline peaks (17) are at *m/e* 135 (VI) and *m/e* 107 (VII)[3] with a metastable

[1] Although the literature (11, 14) states 271–275° as the m.p. for catharine, an authentic sample, found to be homogeneous when examined by thin-layer chromatography using three different solvent systems (15), and supplied by G. H. Svoboda, gave m.p. 257–258° dec.

[2] The AEI MS 9 high resolution mass spectrometer was used in this work.

[3] These structures are designated in *Reference 16* as the open chain analogs, *i.e.*,

[a] All fractions collected were 1000 ml. [b] All fractions collected were alkaloidal.

peak at *m/e** 84.8, and at *m/e* 122 (VIII), resulting from B,C,D cleavage (Scheme IV).

High resolution mass spectrometry measurements on several of these peaks showed them to be in agreement with the postulated formulas (Table II). However, the site of the attachment of the 367 group to vindoline has not as yet been determined.

Some possible molecular formulas for catharine are listed in Table III and it can be seen from high resolution data that the formula for catharine is in agreement with $C_{46}H_{54}N_4O_{10}$.

If $C_{46}H_{54}N_4O_{10}$ is the correct molecular formula for catharine, it follows that with the vindoline moiety having a molecular formula of $C_{25}H_{31}N_2O_6$, then the other half of the dimer has the formula $C_{21}H_{23}N_2O_4$. The authors are at present investigating the nature of this second half of the dimer.

Preliminary results on the acid cleavage of catharine show desacetylvindoline, by thin-layer chromatography, to be one of the products. This would be expected, and attempts are in progress to isolate the cleavage products and rigorously establish their structures.

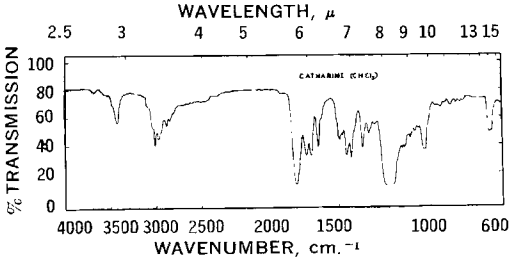

Fig. 1.—Infrared spectrum of catharine.

It was previously reported (14) by other workers, that the formula of catharine was $C_{46}H_{52}N_4O_9 \cdot CH_3OH$; however, they only reported an elemental analysis as their proof for the proposed structure. Their first elemental analysis of catharine is also in agreement with our proposed formula of $C_{46}H_{54}N_4O_{10}$.[4]

Simultaneous Determination of Ethanol and Chloroform in Liquid Cough Preparations by Gas Chromatography

By HORACE P. WARRINGTON, JR., and JOHN M. LENNON

A gas chromatographic procedure using a styrene-divinylbenzene polymer as column-packing material is described. The use of this column allows for the complete separation and simultaneous determination of ethanol and chloroform contained in liquid cough preparations.

THE WIDESPREAD current use of gas chromatography for the quantitative measurement of ethanol (1) and of chloroform (2) suggests that this approach would be desirable in the analytical examination of formulations containing both substances. In practice, however, important difficulties arise. The volume ratio of ethanol to chloroform is always large (*e.g.*, 20 to 1). Response of a flame ionization detector is approximately 10 times greater to ethanol than it is to chloroform. With column materials available until recently, separation characteristics were such that chloroform showed up on the chromatogram as a very small peak on the tail of the ethanol peak. The contribution of ethanol peak tail area to the area under the chloroform peak was large enough to result in poor precision for the chloroform estimation. Recently, Hollis (3) introduced the use of a styrene-divinylbenzene polymer as a column-packing material. This material gives excellent separations of low molecular weight compounds with a minimum of tailing and permits column temperature programming with very low column bleed. A column packed with a styrene-divinylbenzene polymer[1] shows a complete separation of ethanol and chloroform. It has been found possible to measure 0.5% chloroform and 10% ethanol accurately and simultaneously in a cough syrup which also contains dextromethorphan hydrobromide, chlorpheniramine maleate, phenylephrine hydrochloride, glyceryl guaiacolate, glucose, and common preservative, sweetening, coloring, and flavoring agents.

EXPERIMENTAL

An F and M model 609 instrument was set up as described in Fig. 1 with a glass wool plug inserted in the injection port. The column was a 6-mm. o.d. glass tube 4 ft. long packed with 80 to 120-mesh styrene-divinylbenzene polymer.

An ethanol–chloroform standard solution was prepared by accurately weighing 10.5 ml. of absolute ethanol and 0.55 ml. of chloroform into about 20 ml. of distilled water contained in a 100-ml. volumetric flask. The mixture was made to volume with distilled water and thoroughly mixed. An isopropanol–*n*-butanol internal standard solution was prepared by accurately weighing 11 ml. of isopropanol and 0.1 ml. of *n*-butanol into about 20 ml. of distilled water in a 100-ml. volumetric flask. This mixture was made to volume with distilled water and thoroughly mixed.

Detector response calibration factors were determined from a chromatogram obtained from a 3-μl. injection of a solution prepared by mixing 10.0 ml. of the isopropanol–*n*-butanol internal standard solution and 10.0 ml. of the ethanol–chloroform standard solution. The ethanol peak area was compared to the isopropanol peak area, and the chloroform peak area was compared to the *n*-butanol peak area. In the cough preparation already described, the amounts of chloroform and ethanol were determined from a chromatogram of a 3-μl. aliquot of a mixture of 10.0 ml. of the cough syrup and 10.0 ml. of the isopropanol–*n*-butanol internal standard solution.

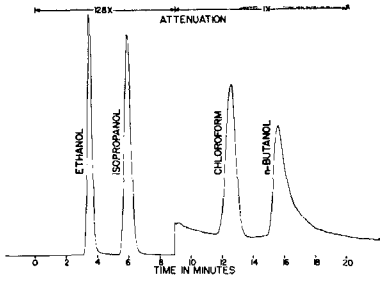

Fig. 1—Chromatogram of detector response calibration solution. Column temperature: 125° isothermally for 3 min., then programmed to 150° at a rate of 2.3° per minute. Injection port temperature = 125°. Helium carrier gas flow rate = 40 ml. per minute. Range = 10. Detector = flame ionization.

DISCUSSION

The glass wool plug in the injection port retains sugars and other high boiling components. At injection port temperatures greater than 125°, spurious peaks are observed which presumably originate from the thermal decomposition of components. Results using this assay for determining the amounts of chloroform and ethanol in various cough medicines are shown in Table I.

Effects of Sex Hormones on the Duration of Drug Action in Mice

By T. GESSNER, M. ACARA, J. A. BAKER, and L. L. EDELMAN

An altered drug response is induced in mice following pretreatment not only with repeated doses, but even after a single dose, of a sex hormone. Testosterone pretreatment produces a biphasic effect on the duration of action of hexobarbital, prolonging the action initially and shortening the action in 4–8 days after the pretreatment. The early action of testosterone appears to be associated with an effect on the hypnotic property of a drug, since both hexobarbital and barbital sleep times are prolonged while the duration of action of the muscle relaxant chlorzoxazone remains unaffected. The long-term pretreatment with testosterone leads to a shorter duration of action of drugs that are deactivated by detoxification, notably hexobarbital and chlorzoxazone, but has no effect on the duration of hypnosis produced by barbital, a drug which is predominantly eliminated unchanged.

THERE IS increasing evidence that steroids are endogenous substrates of drug-metabolizing enzymes in mammals (1–8). Such a relationship between the drug and steroid metabolism could be of great consequence for drug therapy in man. In animals the evidence for the above interrelationship consists of two kinds of data. On one hand, compounds which have been known for some time to stimulate drug-metabolizing enzymes (2, 3) have been found more recently to be effective in stimulating steroid metabolism *via* hydroxylation (1, 4–7). On the other hand, sex hormones exert a marked effect on drug-metabolizing enzymes in the rat (8, 9). This latter phenomenon is seen both as an inherent sex difference in the susceptibility to drugs (female rats sleep four times longer than male rats after the same dose of hexobarbital), and as a virtual obliteration of such a sex difference through pretreatment of male rats with estrogens or of female rats with androgens (1, 8, 9). Similar experiments with sex hormones in mice and guinea pigs have been unsuccessful (8, 9).

It seemed important to the authors that if the relationship between drug- and steroid hormone-metabolizing enzymes is applicable to mammalian species in general, sex hormones should have an effect on the duration of drug action in species other than rats, though such effects might be more subtle, and hence less readily discernible. The authors re-examined the effect in mice.

EXPERIMENTAL

Animal Treatment—Swiss Webster mice of ICR strain from Blue Spruce Farms were used for the experiments. The mice weighed 18–26 Gm. on arrival and were maintained on commercial chow diet and water *ad libitum*. Each animal was used only once. Animals were randomly assigned to either a test or the corresponding control group. Both groups were treated similarly in all respects, except that the control mice received injections of the vehicle (corn oil) in place of the hormone solution.

In the study of the effects of chronic sex hormone pretreatment the hormone in corn oil solution was administered subcutaneously every other day for a period of 1 week or longer, as stated. Female mice were thus treated either with 4 doses of 10 mg./Kg. of ethinyl estradiol in an 8-day period, or with 8 doses of 20 mg./Kg. of testosterone acetate in a 16-day period. Male mice were treated with 7 doses of 25 mg./Kg. of diethylstilbestrol in a 14-day period. Chlorzoxazone and hexobarbital assays were performed 24 hr. after the last injection of the hormone.

In the study of the development of an altered drug response due to pretreatment with only a single dose of a sex hormone, assays were carried out using chlorzoxazone,[1] hexobarbital, and barbital at 0 hr., 24 hr., 96 hr. (4 days), and 192 hr. (8 days) after the hormone pretreatment. In the special case of the 0-hr. pretreatment the hormone in corn oil was injected intraperitoneally immediately before the assay drug; in all other cases the injections were subcutaneous. In all experiments corn oil was administered to control mice on a schedule identical with that used for the corresponding test animals.

Drug Assays—The duration of drug action was assayed by means of the following drugs at the given dosages: chlorzoxazone[2] (150 mg./Kg.), hexobarbital[3] (150 mg./Kg. unless otherwise stated), barbital[4] (250 mg./Kg.). The compounds were administered as sodium salts in isotonic saline. The duration of drug effect (the chlorzoxazone prostration time and the hexobarbital or barbital sleep time) was determined by noting the time interval during which the righting reflex was lost.

Where direct comparisons were made between assays with different agents (hexobarbital, chlorzoxazone, or barbital), control and test mice were randomly selected for assay with either agent and the assays were performed contemporaneously under identical conditions. The statistical significance of the observed differences (the P value) was determined by use of the tailed t test except where the F test showed the variance ratio itself to be significant. In the latter event Wilcoxon's two-tailed Rank test was employed (10).[5]

RESULTS AND DISCUSSION

The results (Table I) show that the duration of drug action is significantly changed after chronic pretreatment of mice with an estrogen (diethylstilbestrol or ethinyl estradiol) or with an androgen (testosterone acetate). Estrogen treatment leads to the prolongation of drug action in both male and female mice; conversely, androgen treatment leads to a shorter duration of drug action.

M	7	None[b]			Hexobarbital	56.5 ± 7.1	

[a] Number of animals. [b] All control animals received injections of the vehicle (corn oil) on a schedule identical to that used for the corresponding tests. [c] During the pretreatment period the indicated dose of the sex hormone was administered every 48 hr. [d] Single-tailed *t* test.

It is interesting that female mice do not appear to have an inherently greater susceptibility to hexobarbital than male mice (Table I, hexobarbital control groups). In fact, the trend appears reversed but the observed difference in the sleep times is not statistically significant ($P < 0.06$). However, a highly significant sex difference ($P < 0.001$) is apparent in the duration of action of chlorzoxazone; female mice exhibit chlorzoxazone prostration times twice as long as those of the males.

The results of the sex hormone pretreatment are amenable to two interpretations. First, it could be argued that a period of chronic hormone pretreatment is necessary for the sought effect on drug action to become manifest. Second, the possibility exists that a single administration of hormone is sufficient, but that a certain length of time has to elapse before the process initiated by this hormone injection (in effect, the first injection of a chronic pretreatment regimen) results in an observable effect. In order to distinguish between these two possibilities, the authors injected female mice with a single high dose of testosterone acetate and carried out the duration of drug effect assays after various time intervals. As shown in Table II, the authors found a significant decrease in the duration of action of chlorzoxazone and of hexobarbital 192 hr. after a single injection of a dose of either 140 mg./Kg. or 46 mg./Kg. of testosterone.

Many compounds which stimulate drug metabolism when long-term pretreatment is employed are found to be inhibitors of drug-metabolizing enzymes both *in vivo* and *in vitro* (2, 11, 12). Accordingly, such compounds are seen to have a biphasic effect on the duration of action of drugs which are subject to inactivation through rapid metabolism. In order to test whether testosterone pretreatment can elicit a biphasic effect on the duration of drug action the authors carried out a series of duration of drug effect assays immediately after the hormone administration (0 hr. pretreatment, Table II). The results show that indeed such a short-term pretreatment with either testosterone or testosterone acetate produces a prolongation of the hypnotic action of barbiturates, but that this occurs irrespective of whether the barbiturate is one which is extensively metabolized, *i.e.*, hexobarbital (13), or one which is hardly metabolized at all, *i.e.*, barbital (14). Moreover, the identical pretreatment has no effect on the duration of the paralysis produced by chlorzoxazone, a drug which is inactivated mainly by metabolism (15). These results therefore suggest that the observed longer duration of action of barbiturates is mainly unrelated to an effect of testosterone on drug-metabolizing enzymes, but rather is associated with a potentiating effect on the hypnotic action. In this latter respect, the report of Selye (16) on the anesthetic property of testosterone in partially hepatectomized rats is noteworthy.

Novick *et al.* (17) have reported that daily pretreatment of mice with testosterone for 4–5 days resulted in a prolongation of hexobarbital sleep time in these animals, whereas we found that long-term testosterone pretreatment shortens the duration of drug action (Tables I and II). In the experiments of Novick *et al.*, high levels of circulating testosterone would be expected to be present at the time of the sleep-time assay, since, in contrast to our experiments, these workers administered the last injection of the hormone only 1-hr. before the hexobarbital assay. In such circumstances testosterone could extend the duration of hexobarbital action, not only by any possible inhibition of the drug-metabolizing enzyme (Novick *et al.* report somewhat decreased microsomal metabolism in the livers of testosterone pretreated mice) but also by a direct potentiation of the hypnotic action of the barbiturate.

The authors conclude that testosterone exerts a biphasic effect on the hypnotic action of hexobarbital. The prolongation of hexobarbital sleep time in the initial period following pretreatment with the hormone appears to be mainly unrelated to an effect on drug metabolism, but instead seems to involve potentiation or synergism of the hypnotic property of the drug, as is evidenced by the fact that hypnosis due to barbital is affected similarly. On the other hand, the shorter duration of drug action after long-term pretreatment with testosterone is probably associated with a stimulation of drug-metabolizing enzymes. This is indicated by the fact that an 8-day (192 hr.) pretreatment with testosterone has no effect on the barbital sleep time, but foreshortens the duration of action of the two drugs that are extensively metabolized, hexobarbital and chlorzoxazone.

TABLE II—TIME COURSE OF DEVELOPMENT OF AN ALTERED DRUG RESPONSE IN FEMALE MICE PRETREATED WITH A SINGLE DOSE OF AN ANDROGEN

	Pretreatment			Duration of Drug Effect		
N^a	Hormone	Dose, mg./Kg.	Length, hr.	Assay Drug	Time, min.	P

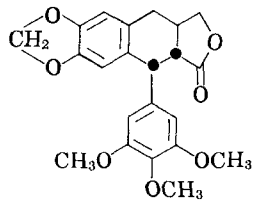
Tumor Inhibitors XIX. Desoxypodophyllotoxin, the Cytotoxic Principle of *Libocedrus decurrens*

By S. MORRIS KUPCHAN, RICHARD J. HEMINGWAY, and JANE C. HEMINGWAY

An alcoholic extract of *Libocedrus decurrens* Torr. was found to show significant inhibitory activity when tested *in vitro* against cells derived from human carcinoma of the nasopharynx (KB). Systematic fractionation of the extract led to the isolation and characterization of desoxypodophyllotoxin as the active principle.

In the course of continuing search for tumor inhibitors from plant sources, an alcoholic extract of *Libocedrus decurrens* Torr.[1] (*Pinaceae*) was found to have significant inhibitory activity against cells derived from human carcinoma of the nasopharynx in tissue culture (KB).[2] Consequently, a systematic study aimed at isolation of the KB-inhibitory principle of *L. decurrens* Torr. was undertaken. The preliminary fractionation of the alcohol extract is summarized in Scheme I. Fraction H material, dissolved in chloroform, was subjected to chromatography on silicic acid, whereupon the total activity was eluted in the first yellow band using chloroform as eluant. Further careful rechromatography on silicic acid, collecting fractions which were analyzed by thin-layer chromatography, led to the isolation of desoxypodophyllotoxin (I) from the fraction eluted with 10% chloroform in benzene. The assay data are reported in Table I. Evaluation of the tissue culture assay results by the CCNSC is such that a material is considered active if the ED_{50} (dose inhibiting growth to 50% of control growth) equals or is less than 1 mcg./ml. The fractions containing desoxypodophyllotoxin were found to show the highest cytotoxicity. The results indicate that desoxypodophyllotoxin is the major cytotoxic principle of the extract of *L. decurrens* Torr.[3]



I

EXPERIMENTAL

Melting points were determined on a Hoover Uni-Melt capillary melting point apparatus. Infrared spectra were determined in chloroform solution on a Beckman IR5A infrared spectrophotometer. The petroleum ether used was Skellysolve B, b.p. 60–68°. Evaporations were carried out at temperatures less than 40°.

Extraction and Preliminary Fractionation of L. decurrens—Coarsely ground leaves and stems of *L. decurrens* (500 Gm.) were twice extracted continuously with 95% ethanol for 5 hr., and the ethanol extract was concentrated under water pump pressure to a thick dark syrup (A, 142 Gm.). A portion of the extract (96 Gm.) was partitioned between water (1.5 L.) and chloroform (2.5 L.), and the two solutions were evaporated under reduced pressure (B, 59 Gm., and D, 27 Gm., respectively) and the insolubles (C, 8.1 Gm.) collected separately. The chloroform solubles, except a small assay sample (50 mg.), were partitioned between petroleum ether (1 L.) and 10% aqueous methanol (750 ml.) and the two solutions were evaporated under reduced pressure (E, 9.0 Gm., and F, 15.0 Gm., respectively). The 10% aqueous methanol solubles were dissolved in methanol (250 ml.) and treated with a saturated methanol solution of neutral lead acetate until no more precipitate formed. The precipitate was removed by centrifuging and washed with methanol before suspending in methanol and bubbling in hydrogen sulfide. The lead sulfide was filtered after regeneration had been completed and the filtrate was evaporated to a gummy residue (G, 1.94 Gm.). The supernatant liquid from lead acetate precipitation was also treated with hydrogen sulfide, and the lead sulfide was filtered off and the solvent evaporated (H, 11.9 Gm.).

Isolation of Desoxypodophyllotoxin—A larger batch of fraction H (151 Gm.) was prepared from the crude extract (1.5 Kg.) and a portion (57.9 Gm.) was dissolved in chloroform and added to a column of silicic acid (2.6 Kg.). The column was eluted with chloroform until the first orange-yellow band was collected (I, 16.445 Gm.) and the remaining material was stripped with methanol (J, 36.0 Gm.).

A portion of the active fraction I (5.6 Gm.), was dissolved in benzene, added to a column of silicic acid (80 Gm.) packed in benzene, and chromatographed using 10% chloroform in benzene as solvent. Fractions were collected and examined by thin-layer chromatography on silica gel using chloroform as solvent and ceric sulfate (3% in 3 *N* sulfuric acid) spray reagent. The fractions richest in desoxypodophyllotoxin were combined, evaporated to dryness (533 mg.), and crystallized from ethanol. The colorless crystalline product (K, 195 mg.) was characterized as desoxypodophyl-

Molecular Weight of the Antifungal Antibiotic Saramycetin

By JOEL KIRSCHBAUM and A. ASZALOS

The molecular weight of the antibiotic saramycetin was determined as 2100 by two ultracentrifugal methods: (*a*) approach to sedimentation equilibrium and (*b*) combination of the zero concentration diffusion constant ($D_{20} = 34 \times 10^{-7}$ cm.^{2} sec.$^{-1}$) with the zero concentration sedimentation constant ($S_{20}, w = 1.2 \times 10^{-13}$ cm. sec.$^{-1}$). At concentrations above 5 mg./ml. saramycetin associates, forming aggregates with a molecular weight of 55,000.

THE MOLECULAR weight of the antifungal agent saramycetin had been previously reported by Baudet and Cherbuliez (1) to be 14,000 daltons on the basis of sedimentation and diffusion constant measurements. Evidence will be presented in this paper that saramycetin is capable of molecular association and that the apparent molecular weight is dependent on polarity of solvent and solute concentration.

EXPERIMENTAL

Molecular weights were measured by the Archibald (2) approach to sedimentation equilibrium method. One to 0.1% solutions, in 12-mm. interference cells, were centrifuged in an An-D rotor at 22°. Concentration gradients were formed at speeds ranging from 8766 to 42,040 r.p.m. using the schlieren optical system with a phase bar angle of 75°. The concentration gradient was evaluated using Engelberg's modification (3), at the meniscus and cell bottom from photographs recorded on Kodak metallographic plates magnified tenfold on a Nikon magnifier. Total solute concentration was measured with a synthetic boundary centerpiece in an interference cell centrifuged at 29,500 r.p.m.

Sedimentation coefficients for saramycetin solutions with concentrations from 10 mg./ml. to 1.25 mg./ml. were measured in a 4°, 12-mm. cell centrifuged in an An-D rotor at 42,040 r.p.m. For solutions with concentrations of 1.25 mg./ml. to 0.313 mg./ml., the sedimentation coefficients were evaluated from schlieren peaks produced with the aid of a 12-mm. synthetic boundary centerpiece in an interference cell, rotated at speeds to 42,040 r.p.m.

Diffusion constants were evaluated in the analytical ultracentrifuge (4), at 22°, using a synthetic boundary centerpiece and the schlieren optical system. Solute concentrations were from 10 mg./ml. to 0.313 mg./ml. The first image was recorded at two-thirds of the final speed of 42,040 r.p.m. or 29,500 r.p.m. This first image was considered to be recorded at zero time for the diffusion constant calculations.

Partial specific volume was determined at 20° in a 1-ml. pycnometer.

RESULTS AND DISCUSSION

As the concentration of saramycetin is diminished from a concentration of 10 mg./ml. to 0.313 mg./ml. in 0.2 *M* NaCl–0.02 *M* phosphate buffer, pH 6.85, the sedimentation coefficient (*s*) first increases and then decreases (Fig. 1). Two *S* values at infinite dilution can be calculated by extrapolating to zero solute concentration both the positively sloping and negatively sloping regions of the curve. At the higher concentrations of saramycetin (10 mg./ml. to 5 mg./ml.) $S_{20}, w = 5.28 \times 10^{-13}$ cm. sec.$^{-1}$ and at concentrations of saramycetin below 2.5 mg./ml., $S_{20}, w = 1.2 \times 10^{-13}$ cm. sec.$^{-1}$. The *S* value found for saramycetin depends then on the solute concentration in 0.2 *M* NaCl–0.02 *M* phosphate buffer.

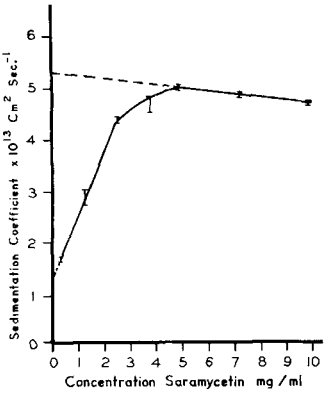

Fig. 1—Dependence of sedimentation coefficient of saramycetin on the concentration of saramycetin in 0.2 M *NaCl–0.02* M *phosphate buffer, pH 6.85.*

Measurements of the diffusion constant also give two values dependent on saramycetin concentration. At the higher saramycetin concentrations, $D_{20} = 6.0 \times 10^{-7}$ cm.^{2} sec.$^{-1}$ and at the lower concentrations, $D_{20} = 34 \times 10^{-7}$ cm.^{2} sec.$^{-1}$, extrapolating to zero concentration.

The partial specific volume, $\bar{V}$, was found to be 0.58, and agrees with the value of 0.60 ± 0.05 published by Baudet and Cherbuliez.

By combining the *S* and *D* data (5) from each concentration range, two molecular weights have been calculated: 55,000 for the 10 to 5 mg./ml. solute concentration and 2100 for the 2.5 to 0.313 mg./ml. concentration range. Acid titration yields an equivalent weight of 2200. This evidence suggests that 2100 represents the true molecular weight. In this solvent system, if it can be assumed that the mass action law is valid, the monomer concentration term in an equilibrium gradient expression would have an exponent of about 25.

Further evidence for aggregate formation is summarized in Table I, which gives the molecular weight of saramycetin in various solvents.

Approach to equilibrium sedimentation (6) yielded a molecular weight of 54,000 ± 2000 daltons at the meniscus and cell bottom for a 1% solution of saramycetin dissolved in any of the following buffers: 1 *M* acetate buffer, pH 4.05; 0.2 *M* NaCl–0.02 *M* phosphate buffer, pH 6.85; 2 *M* NH_4OH–2 *M* NH_4Cl, pH 9.4; or an isotonic solvent containing the inorganic cations and anions found in human serum.

TABLE I—MOLECULAR WEIGHT OF 1% SARAMYCETIN SOLUTIONS IN VARIOUS SOLVENTS AS DETERMINED BY APPROACH TO EQUILIBRIUM SEDIMENTATION

Solvent	Mol. Wt.
1 *M* acetate buffer, pH 4.05	55,000 ± 2,000
0.2 *M* NaCl–0.02 *M* phosphate buffer, pH 6.85	56,000 ± 2,000
2 *M* NH_4OH–2 *M* NH_4Cl buffer, pH 9.4	55,000 ± 2,000
Isotonic phosphate buffer containing K^+, Na^+, Ca^{++}, Mg^{++}, Cl^-, and $SO_4^=$	54,000 ± 2,000
0.68 *M* borate buffer, pH 8.6	6,000–20,000
8 *M* urea in NaCl–phosphate buffer	7,000 ± 1,000
90% ethanol (95%)–10% NaCl–phosphate buffer	2,100 ± 100

Sedimentation of 1% saramycetin in 8 *M* urea–NaCl–phosphate buffer diminished the apparent molecular weight to 7000 ± 1000 daltons, indicating a disruption of the aggregate.

Borate buffer, pH 8.6, 0.68 *M*, also affected the aggregate molecular weight with several components found with uncorrected molecular weights of from 6000 to 20,000 daltons.

By diminishing the concentration of the phosphate–NaCl buffer to concentrations of $^1/_{100}$ of the original, a molecular weight of 5500 ± 1000 daltons was found ($S = 1.37 \times 10^{-13}$ cm. sec.$^{-1}$). The physical effect of diluting the buffer is to diminish the apparent molecular weight of the saramycetin aggregate. The *in vitro* microbiological activity of 0.1% saramycetin solutions varied inversely with the ionic strength of the buffer (7). This indicates that the biological effect of using a more dilute buffer is to increase the *in vitro* antifungal activity of saramycetin solutions.

In summary, saramycetin, molecular weight 2100, may form aggregates in solution. The molecular weight of these aggregates may range upward to 55,000 depending on the solvent and on electrolyte ionic strength.

Mathematics of the Three-Phase *In Vitro* Absorption Models

Sir:

Several reports on three-phase models for drug absorption have recently appeared in the literature (1–3). However, it appears that volume terms should be included in the rate equations as well as in the equilibrium equations to obtain more meaningful values for the transfer rates. In these models, the drug (usually weakly basic or weakly acidic) is transferred from an aqueous buffer (*A*) of a pH found in the alimentary tract, through a water immiscible organic phase (*B*) acting as the "membrane," to a buffer of blood pH (*C*). Assuming that only the unionized drug is soluble in the organic phase, then the equilibrium concentrations (C_A, C_B, C_C) can be expressed in the equations derived below in terms of the initial concentration of the drug (a_0), the true distribution coefficient of the drug between the organic layer and water (D), the pH's of the buffers (pH_A and pH_C), the pKa of the drug, and the volumes of the phases (V_A, V_B, and V_C).

For a monobasic acid

$$C_B = \frac{a_0 D}{1 + 10^{pH_A - pK_A} + \frac{V_C}{V_A}(1 + 10^{pH_C - pK_A}) + \frac{V_B D}{V_A}}$$

$$C_A = \frac{C_B}{D}(1 + 10^{pH_A - pK_A})$$

$$C_C = \frac{C_B}{D}(1 + 10^{pH_C - pK_A})$$

For a mono-acidic base

$$C_B = \frac{a_0 D}{1 + 10^{pK_A - pH_A} + \frac{V_C}{V_A}(1 + 10^{pK_A - pH_C}) + \frac{V_B D}{V_A}}$$

$$C_A = \frac{C_B}{D}(1 + 10^{pK_A - pH_A})$$

$$C_C = \frac{C_B}{D}(1 + 10^{pK_A - pH_C})$$

In the kinetics of the three-phase distribution

TABLE I—MOLECULAR WEIGHT OF 1% SARAMYCETIN SOLUTIONS IN VARIOUS SOLVENTS AS DETERMINED BY APPROACH TO EQUILIBRIUM SEDIMENTATION

Solvent	Mol. Wt.
1 *M* acetate buffer, pH 4.05	55,000 ± 2,000
0.2 *M* NaCl–0.02 *M* phosphate buffer, pH 6.85	56,000 ± 2,000
2 *M* NH_4OH–2 *M* NH_4Cl buffer, pH 9.4	55,000 ± 2,000
Isotonic phosphate buffer containing K^+, Na^+, Ca^{++}, Mg^{++}, Cl^-, and $SO_4^=$	54,000 ± 2,000
0.68 *M* borate buffer, pH 8.6	6,000–20,000
8 *M* urea in NaCl–phosphate buffer	7,000 ± 1,000
90% ethanol (95%)–10% NaCl–phosphate buffer	2,100 ± 100

Sedimentation of 1% saramycetin in 8 *M* urea–NaCl–phosphate buffer diminished the apparent molecular weight to 7000 ± 1000 daltons, indicating a disruption of the aggregate.

Borate buffer, pH 8.6, 0.68 *M*, also affected the aggregate molecular weight with several components found with uncorrected molecular weights of from 6000 to 20,000 daltons.

By diminishing the concentration of the phosphate–NaCl buffer to concentrations of $^1/_{100}$ of the original, a molecular weight of 5500 ± 1000 daltons was found ($S = 1.37 \times 10^{-13}$ cm. sec.$^{-1}$). The physical effect of diluting the buffer is to diminish the apparent molecular weight of the saramycetin aggregate. The *in vitro* microbiological activity of 0.1% saramycetin solutions varied inversely with the ionic strength of the buffer (7). This indicates that the biological effect of using a more dilute buffer is to increase the *in vitro* antifungal activity of saramycetin solutions.

In summary, saramycetin, molecular weight 2100, may form aggregates in solution. The molecular weight of these aggregates may range upward to 55,000 depending on the solvent and on electrolyte ionic strength.

Mathematics of the Three-Phase *In Vitro* Absorption Models

Sir:

Several reports on three-phase models for drug absorption have recently appeared in the literature (1–3). However, it appears that volume terms should be included in the rate equations as well as in the equilibrium equations to obtain more meaningful values for the transfer rates. In these models, the drug (usually weakly basic or weakly acidic) is transferred from an aqueous buffer (*A*) of a pH found in the alimentary tract, through a water immiscible organic phase (*B*) acting as the "membrane," to a buffer of blood pH (*C*). Assuming that only the unionized drug is soluble in the organic phase, then the equilibrium concentrations (C_A, C_B, C_C) can be expressed in the equations derived below in terms of the initial concentration of the drug (a_0), the true distribution coefficient of the drug between the organic layer and water (D), the pH's of the buffers (pH_A and pH_C), the pKa of the drug, and the volumes of the phases (V_A, V_B, and V_C).

For a monobasic acid

$$C_B = \frac{a_0 D}{1 + 10^{pH_A - pK_A} + \frac{V_C}{V_A}(1 + 10^{pH_C - pK_A}) + \frac{V_B D}{V_A}}$$

$$C_A = \frac{C_B}{D}(1 + 10^{pH_A - pK_A})$$

$$C_C = \frac{C_B}{D}(1 + 10^{pH_C - pK_A})$$

For a mono-acidic base

$$C_B = \frac{a_0 D}{1 + 10^{pK_A - pH_A} + \frac{V_C}{V_A}(1 + 10^{pK_A - pH_C}) + \frac{V_B D}{V_A}}$$

$$C_A = \frac{C_B}{D}(1 + 10^{pK_A - pH_A})$$

$$C_C = \frac{C_B}{D}(1 + 10^{pK_A - pH_C})$$

In the kinetics of the three-phase distribution

experiment, volume terms should be included to obtain a mass balance. Consider the transfers

$$A \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} B \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} C$$

then

$$V_A \frac{dA}{dt} = -V_A k_1 A + V_B k_{-1} B$$

$$V_B \frac{dB}{dt} = V_A k_1 A - V_B k_{-1} B - V_B k_2 B + V_C k_{-2} C$$

$$V_C \frac{dC}{dt} = V_B k_2 B - V_C k_{-2} C$$

where A, B, C are the concentrations in the three compartments at any instant. These equations are perfectly general and all transfers in the three-phase model should obey them.

Estimates of the values of the transfer constants k_1, k_{-1}, k_2, and k_{-2} can be obtained with or without the aid of a computer. These transfer constants are dependent on the pH of the solutions, the pKa of the drug, the true distribution coefficient, and the interfacial area, but not on the volumes of the phases. Often several of the terms are negligible (substitution in the equilibrium equations given above will aid in predicting this), so simplifying solution of the equations. The simplest case observed (3) and the one possibly nearest to an *in vivo* absorption situation is the transfer of a weakly acidic drug from a buffer of low pH, in which ionization is negligible, through an organic solvent, in which the drug is much more soluble than the unionized entity is in water, to a buffer of pH 7.4 ("blood"), in which the drug is fully ionized. In this case the back reactions are negligible and if $V_A = V_C$ then on integration we have

$$A = a_0 e^{-k_1 t}$$

$$B = \frac{V_A}{V_B} \frac{a_0 k_1}{k_2 - V_A k_1 / V_B} \left(e^{-V_A k_1 t / V_B} - e^{-k_2 t}\right)$$

$$C = a_0 \left[1 - \frac{1}{k_2 - V_A k_1 / V_B} \left(k_2 e^{-k_1 t} - k_1 e^{-k_2 t} - \frac{V_A}{V_B} k_1 e^{-k_1 t} + k_1 e^{-V_A k_1 t / V_B}\right)\right]$$

Many of the other special cases for this type of transfer have been reported by Doluisio and Swintosky (2); here the authors have a different approach, avoiding the use of volumes in the differential equations. However, if these equations are integrated and/or used in the comparison of theoretical with experimental data, then volume terms must be introduced at some stage.

Review Article

Applications of Thin-Layer Chromatography in Pharmaceutical Analyses

By J. P. COMER and I. COMER

THIS REVIEW is a humble effort toward providing a guide to the literature for those pharmaceutical analysts who are not specialists in thin-layer chromatography (TLC), but who are using TLC as one of the many analytical techniques available today. Data on adsorbents, solvent systems, and R_f values are presented so that this review may be used as an intermediate reference between the textbooks and the original journals when they are not conveniently available.

Unfortunately, many good references listed in the abstracting journals were not available to the authors. Because of the repetitive nature of TLC publications, data in the articles omitted will probably appear in future papers. Some classes of compounds, such as amino acids, lipids, and carbohydrates, have been omitted for the sake of brevity. Most of the references reviewed were subsequent to 1959 and for alkaloids, steroids, and vitamins after 1963. Only the first author's name is mentioned in the text but full credit is given to all authors under *References*.

REVIEWS

The popularity of TLC by virtue of its simplicity and economy has produced a large number of general reviews (about 80) since 1960. Most of these were short articles designed for the introduction of the technique. Publication of the texts by Stahl (1), Bobbitt (2), Randerath (3), and Truter (4) consolidated many of the facts and generalizations available from the earlier literature.

Gänshirt's (5) publication summarized some of the earlier work on separation and identification of drug formulations by TLC in his laboratory.

Publications on pharmaceuticals previous to 1960 are included in reviews by Stahl (6,7) in 1961 with sections on pharmaceuticals, steroids, and vitamins. Wollish (8) listed 8 references on pharmaceuticals and showed construction details for an applicator, plate holder, and storage cabinet. Demole (9) gave a general review (French) with 61 references including some alkaloids and vitamins. Teijgeler (10) in 1962 presented a review (Dutch) with 132 references outlining the history, advantages over other forms of chromatography, principles, and reference to six publications on quantitative analyses. The compounds were categorized in terms convenient to the pharmaceutical analysts. Teijgeler (11) brought his review up to date with 64 additional references tabulated according to his original scheme. The book edited by Stahl published in German in 1962 and translated in 1965 (1) is the most convenient starting place for review of the earlier literature, and it is recommended for all analysts active in TLC. It includes chapters by experts in their fields.

A paper by Giacobazzi (12) includes 36 references of pharmaceutical interest. Heft-

Received from the Control Division, Eli Lilly and Co., Indianapolis, IN 46206

mann's comprehensive bibliography (13) included literature from December 1961 through December 1963 on column, paper, and thin-layer chromatography for many classes of compounds and 30 references specifically for pharmaceuticals.

Russel's (14) review (English) is a very good condensed general outline of TLC particularly in reference to types of development. It could be used as a guide for a short course for the introduction of analysts to the techniques of TLC. No attempts were made by Russel for the classification of compounds.

Zarnack (15) published a similar paper (German) designed for the teaching and practice of drug analyses. Solvent systems and examples are given for analgesics, antipeptics, purines, sulfonamides, and alkaloids with 67 references through 1963.

In a section of a book on biochemical analysis, Mangold (16) presented another condensed summary (90 pages) of the techniques of TLC. No attempt to list classes of compounds was made by the authors. A table of common reagents for detection was shown on page 410. An elutropic series was listed on page 422, and a very good section on means of quantitation was included. A table of increasing affinity of functional groups and adsorption power of adsorbents was shown. In other tables, material and solvents were listed for adsorption, ion exchange, partition, and reversed phase partition TLC. The section was concluded with a very convenient list of manufacturers of TLC apparatus and 87 references.

Coombe (17) gave a brief summary (two pages) on the application of quantitative TLC to pharmaceutical analyses.

Heftmann's (18) bibliography in 1966 with 2,329 references covering TLC, paper, and column chromatography (December 1963–December 1965) gave TLC separate discussion on technique and application to classes of compounds. About 90 references were listed for pharmaceuticals and a separate listing made for steroids, vitamins, and antibiotics. Heftmann's review, even though not specific for TLC nor pharmaceutically oriented, is the best starting point for a literature survey of recent publications. Unfortunately, the only way to find data on specific compounds is to read the whole section on that class and then look up the original references cited. Another survey by Teijgeler (19) added 243 references to his earlier paper.

Special bibliographies furnished by suppliers of apparatus and chemicals are available particularly since the introduction of precoated plates and sheets. One of these by Baitsholt (20) includes sections on pharmaceuticals.

EXPLANATION OF TABLES

There has been much written on the merits of and the factors influencing R_f values. In fact, this itself has been the subject of several publications (21–23). Active workers in the field know that observing a fresh TLC plate or suitable reproduction of such tells much more than observing a table in regard to size of spots, shape, tailing, *etc.* A summary of data using reproduction of plates is not practical in a review article such as this. The original R_f values or averages of ranges of values are listed in the tables. The reference for each publication is listed first. The alphabetical designation for solvent system refers to the list of solvents at the bottom of the table.

An "X" was used to show that the R_f value was not reported or was unavailable to the authors when this review was written.

The compounds are generally listed alphabetically, except when other arrangements make interpretation more convenient. Nomenclature presented the usual problems (24) of various trade names in different languages. Classification of the drugs under the general headings was by convenience and according to type of articles in which the work was reported. These lists certainly should not be used as a therapeutic or pharmacological index.

Some duplication, ambiguity, and inaccuracies are undoubtedly present; but workers active in the specific fields will recognize the various names. The adsorbents are designated by a number which refers to the list in Table I.

TABLE I—ADSORBENTS

1, Silica gel (with or without $CaSO_4$)
2, Silica gel with 0.1 *M* NaOH
3, Silica gel with 0.1 *M* KOH
4, Silica gel with 0.1 *M* $KHSO_4$
5, Silica Gel HF254
6, Silica Gel GF
7, Silica gel with rice starch
8, Silica gel with kieselguhr (1:1)
9, Silica gel with $AgNO_3$
10, Silica gel with EDTA
11, Silica gel with NaEDTA
12, Silica gel with $ZnCO_3$ (1:1)
13, Aluminum oxide (with or without $CaSO_4$)
14, Basic aluminum oxide
15, Silica gel + PEG 200
16, Aluminum oxide with $ZnCO_3$ (1:1)
17, Cellulose
18, Cellulose-MN300
19, Kieselguhr
20, Kieselguhr with formamide
21, Carbon
22, Carbon with acid
23, Polyamide powder

[a] *A*, ethyl acetate–*N*,*N*-dimethylformamide–ethanol (130:19:1); *B*, benzene-*N*,*N*-dimethylformamide (13:2); *C*, $CHCl_3$–ethyl ether–water (175:25:50); *D*, $CHCl_3$–ethyl ether–water (3:1:1); *E*, ethyl acetate–*n*-heptane–Et_2NH (250:300:1); *F*, $CHCl_3$–MeOH (9:1); *G*, C_6H_6–acetone–ether–10% NH_3 (4:6:1:0.3); *H*, C_6H_6–acetone–ether–25% NH_3 (4:6:1:0.3); *I*, $CHCl_3$–acetone–Et_2NH (50:40:10); *J*, $CHCl_3$–Et_2NH (90:10); *K*, cyclohexane–$CHCl_3$–Et_2NH (50:40:10); *L*, cyclohexane–Et_2NH (90:10); *M*, C_6H_6–ethyl acetate–Et_2NH (70:20:10); *N*, $CHCl_3$; *O*, cyclohexane–$CHCl_3$ (30:70) + 0.05% diethylamine (3 drops); *P*, CH_3OH.

The descriptions of the means of visualization are included in the text. Usually if good separation is obtained, detection is not a problem since there are many means and reagents available, such as I_2 vapor, H_2SO_4, $KMnO_4$, U.V. and fluorescence, and bioautograph. Analysts usually improvise means of detection suitable for their specific problems.

ALKALOIDS

One of the many papers on the separation and identification of alkaloids was an early report by Waldi (25) in 1961. A total of 54 alkaloids were studied using various solvent systems and silica gel or alumina as the adsorbent. The chapter by Waldi in Stahl's book (*Reference 1*, page 279), the chapter on TLC in Stolman's book (26), and the chapters in the book by Marini-Bettolo (*Reference 22*, pages 144, 149, 155) survey the early literature. This review will mention some pertinent studies reported after 1963.

Hydrogenated ergot alkaloids were separated by Hohmann (27) on cellulose powder impregnated with formamide (Table II). The alkaloids were detected by irradiating with a low pressure Hg burner giving a yellow-green fluorescent zone. The method also separated the nonhydrogenated alkaloids which appeared as blue fluorescent zones.

McLaughlin (28) developed a method for the identification and determination of ergot alkaloids. The solvents shown in Table II were chosen from 111 solvent systems studied. Regression analyses for data obtained by a quantitative determination of the eluted alkaloid by reaction with *p*-dimethylaminobenzaldehyde (PDAB) was tabulated.

A TLC procedure using silica gel and C_6H_6–$CHCl_3$–EtOH (2:4:1) was used by Ziner (29) for the quantitative evaluation of the stability of ergot alkaloids in aqueous preparations with the PDAB reaction.

The separation of ergot alkaloids from pharmaceuticals by Sahli (30) was accomplished on silica gel plates using $CHCl_3$–95% EtOH (9:1) as solvent. The plates were examined under U.V. light and the spots were then determined fluorimetrically using blank zones for comparison.

French (31) used TLC for the determination of identity and purity of ergot alkaloids and other active components present in pharmaceutical dosage forms.

Wasicky (33) used microscope slides as a support for silica gel and a small chromatographic chamber with butanol containing 10% acetic acid and saturated with water as the solvent for opium alkaloids. Spots were detected with PDAB reagent.

Brochmann-Hanssen (34) observed the TLC zones (Table III) under U.V. light, then sprayed

the chromatogram with potassium iodoplatinate. Ikram (35) used modified Dragendorff's spray reagent after TLC (Table III) for the identification of opiates obtained in narcotic seizures. Eight solvent systems were studied by Steele (36) for the same purpose on 26 compounds.

A table of reactions of some opium alkaloids and acetylated derivatives with ten reagents and U.V. after separation in MeOH–$CHCl_3$–NH_3 23% (85:15: 0.7) was prepared by Vignoli (37). Continuing a series on TLC without binding agents, Schwarz (38) tabulated R_f values for 19 alkaloids in nine systems including ethylmorphine and codeine. Some of these systems were applied to the separation of mixtures in tablets, extracts, and tinctures.

A method for the separation and the U.V., I.R., and color test identification of acetyl codeine from illicit heroin was described in detail by Nakamura (39). Pfeifer (40) thoroughly studied and tabulated the R_f values of alkaloids of the genus *Papaver* on Silica Gel G with benzene–acetone–methanol (7:2:1) and alumina with heptane–$CHCl_3$–ether (4:5:1). The R_f values of 22 opium alkaloids and 22 rauwolfia alkaloids in $CHCl_3$–acetone–Et_2NH (5:4:1) and chloroform–cyclohexane–Et_2NH (7:2:1) systems along with the fluorescence color and color with iodoplatinate were tested by Kaess (41). Other TLC studies on opium alkaloids are mentioned under *Analgesics and Antipyretics.*

The TLC of cinchona alkaloids (Table IV) was studied intensively by Suszko-Purzycka (45–48) and Steele (36) and also was included in the recent work of Fike (42). The detection of zones was by modified Dragendorff reagent

[a] *A*, benzene–acetone–ether–10% NH_3 (4:6:1:0.3); *B*, benzene–acetone–ether–25% NH_3 (4:6:1:0.3); *C*, $CHCl_3$–MeOH–diethylamine (50:50:1); *D*, $CHCl_3$–MeOH–diethylamine (80:20:1); *E*, $CHCl_3$–acetone–diethylamine (50:40:10); *F*, $CHCl_3$–diethylamine (90:10); *G*, cyclohexane–$CHCl_3$–diethylamine (50:40:10); *H*, cyclohexane–diethylamine (90:10); *I*, benzene–ethyl acetate–diethylamine (70:20:10); *J*, $CHCl_3$; *K*, cyclohexane–$CHCl_3$ (30:70) + 0.05% diethylamine (3 drops); *L*, CH_3OH; *M*, cyclohexane–benzene–diethylamine (75:15:10); *N*, acetone; *O*, 95% EtOH.

and U.V. Rauwolfia alkaloids reported by Ikram (35), Waldi (25), and Zarnack (32) are recorded in Table V. A single tablet assay of reserpine developed by Weaver (49) used Silica Gel G with an acetone–$CHCl_3$ (3:10) solvent. Quantitation was obtained by a comparison of the size

and intensity of the PDAB spots to the standard.

Tropane alkaloids reported by Fike (42), Cuven (50), Zarnack (32), French (31), and Waldi (25) are given in Table VI. Detection was made by modified Dragendorff reagent or iodoplatinate. Kaess (51) reacted a 2% solution of the alkaloid with a few drops of 1 *N* KOH in a sealed capillary tube for 1 hr. before TLC.

Atropine was estimated by Ikram (52) in tropane alkaloids by TLC on alumina with MeOH. The eluted atropine zone in acid was back titrated with base with a relative error of 2%.

Chen (53) separated strychnine and brucine on alumina using as a solvent benzene–ethyl acetate (1:2). The strychnine was eluted from the

chromatogram and determined by polarography. The differentiation of *Vinca rosea* alkaloids by TLC (Table VII) has been reported by Jakovljevic (54) with ceric ammonium sulfate in phosphoric acid as the reagent. The same reagent was used by Farnsworth (55) for a study on *Catharanthus* alkaloids shown in Table VII. In a study by Cone (56), the R_f values of 26 vinca alkaloids were obtained. Some of the veratrum alkaloids were resolved by cyclohexane–EtOH (17:3) on Silica Gel HF254 by Zeitler (57) and observed under U.V. after treatment with trichloroacetic acid and heat.

ANALGESICS-ANTIPYRETICS

The early work of Gänshirt (5) was the beginning of many articles on the separation of acetylsalicylic acid, phenacetin, and caffeine. These components from extracts of tablets and suppositories were identified by U.V., potassium ferricyanide, and with chlorine, HCl, and then NH_3. His system was later used for a laboratory experiment in teaching pharmaceutical analysis by Conners (58). Simple equipment for coating onto microslides and spray applicators were described. The authors stated: "Despite this simplification the procedures described are entirely practical for serious analytical and research use." This was a very conservative statement, for these "simple" techniques have been used to solve many age-old problems such as the measurement of *p*-chloroacetanilide and acetanilide in phenacetin (59–61) by U.V. and permanganate and for the determination of

salicylic acid in acetylsalicylic acid by reflectance spectroscopy following TLC by Frodyma (62).

Gänshirt (63) also published a table showing reaction of seven common analgesics with reagents already mentioned plus $AgNO_3$–NH_3, Cl_2 + benzidine, I_2, and rhodamine B. Gänshirt (64) reported the accuracy and relative standard deviation results from quantitative TLC for caffeine was 113% ± 12%, amidopyrine as 98.6% ± 5%, and phenacetin as 100% ± 27% from ten replicates. Sarsunova (65) gave solvent systems of choice for the separation of various combinations of acetylsalicylic acid, phenacetin, amidopyrine, caffeine, and quinine. Bailey (66) was able to measure 0.05% or less of salicylsalicylic acid (SSA) in salicylic acid (SA) by U.V. at 310 mμ following TLC. Verification was obtained by the shifting of maxima of SSA to 345 mμ in acid alcohol while SA remained at 310 mμ. Shelly (67) extracted TLC to detect *p*-hydroxyisophthalic acid in SA. Mule (68) applied TLC along with gas chromatography and U.V. spectrophotometry for the identification of analgesics in human urine, plasma, and tissue homogenates. The data on R_f values were organized by Mule according to chemical families and offer a good reference for toxicological studies. Some of these data from the latter authors are presented in Table VIII. Fike (42) gave a comprehensive list of 140 drugs including some analgesics with a separate table for 112 basic drugs and 28 phenothiazines. Five solvent systems were used and a correlation of structure and R_f values discussed. (See Table III.)

ANTIBIOTICS

Nicolaus (74) published one of the early papers on antibiotics using agar containing triphenyltetrazolium for microbiological detection of zones.

[b] Adjusted to pH 3.7 with PO_4 buffer.

Experimental details were given for preparation of the TLC plates of Silica Gel G with buffers pH 6.85, 4.5, and 2.2, and the agar inoculation with *Sarcina lutea* for rifomycin, *Bacillus subtilis* for tetracycline, and *Staphylococcus aureus* for penicillin. After cooling, another layer of agar was applied to protect the tetrazolium from the air. Preliminary chilling before incubation allowed the antibiotics to diffuse through the agar. They found that sensitivity of TLC was 10 times greater than paper chromatography, with detection limits of 0.1 mcg. chemically and 0.001 mcg. microbiologically. Fischer (75) used iodine–azide solution for detecting 1–2 mcg. including a white and a yellow spot for some penicillins. Only the single component R_f values are reported in Table IX.

Nussbaumer (76) studied the effect of 40 tablet excipients on the identification of penicillins and found most of them were removed by TLC. A penicillin V spot (77) was removed for measurement at 276 mμ after separation, on silica gel plus rice starch, from phenoxyacetic acid and 20 possible tablet excipients.

Brodasky (78) used acid and neutral carbon black for TLC of neomycin A, B, and C followed by agar diffusion inoculated with *Bacillus pumilus*. Bromophenol blue spray 15 min. after 5% $KMnO_4$ was found by Akita (79) to lower the detection limit for antibiotics over $KMnO_4$ alone. The acid oxidation products produce blue or greenish colors which lasted for 1 month. Tyrocidin and gramicidin (80) were observed on Silica Gel G by U.V. and reaction with *o*-tolidine in AcOH after treatment with Cl_2. Sprays of $SbCl_3$ 50% in AcOH and H_2SO_4, and fluorescence under 350 mμ intensified by NH_4OH or NaOH identified three tetracyclines for Sonanini (81) on regular and circular TLC. Kapadia (82) also used circular TLC for the same compounds. EDTA was incorporated into Silica Gel G to prevent iron from forming complexes with the tetracyclines. A regular TLC plate was inverted over a Petri dish containing the development solvent. A roll of filter paper served as the wick. Ferric chloride and fluorescence were the means of visualization.

Nine basic water-soluble antibiotics were separated on MN cellulose by Ito (83) with oxidized nitroprusside and ninhydrin used for visualization. Actinomycins were separated by Cassani (84) into C and F groups (Table IX). Other systems isolated C_1, C_2, C_3, F, and F_3 portions. Erythromycins were detected on Silica Gel G with phosphomolybdic acid by Anderson (85) and 0.05 mcg. of erythromycin by *Streptococcus lactis* on agar using a reprint from 0.5 mm. Al_2O_3 by Meyers (86). Preliminary treatment of streptomycin and dihydrostreptomycin with phenylhydrazine allowed the separation of these two antibiotics (87). Streptomycin yields 2 spots and dihydrostreptomycin one spot following the reaction and subsequent TLC. The spots of these two antibiotics were removed (88), centrifuged with PO_4 buffer pH 7.9, and the supernatant used for microbiological assay with *B. subtilis*. The procedure was recommended for the control of injectables of streptomycin. The degradation of bacitracin was followed by TLC by Nussbaumer (89) with the spots detected by U.V. and ninhydrin. The microbiological inactivity of the new spot confirmed the technique. Other quantitative TLC work by Foppiano (90) on neomycin was based on its ribose moiety determined with orcinol–ferric chloride–AcOH reagent. Assays after TLC invariably were lower (0.5 to 13%) than before chromatography. The variation of the TLC method was no greater than an official method. Circular TLC with silica gel and disodium EDTA of degradation products in tetracycline using NH_3 and U.V. for detection was reported by Rustici (91).

Dragendorff's reagent detected 2 mcg. spots after TLC of mono-, di-, and triacetyl derivatives of oleandomycin by Gantes (92). Kline (93) used a paint sprayer to coat silica gel and kieselguhr TLC plates with agar inoculated with *B. subtilis* or *S. lutea*. Sensitivities were 0.1 mcg. for streptomycin, 0.25 mcg. for tylosin and erythromycin, and 0.005 units for penicillin.

ANTIHISTAMINICS

Antihistamine compounds have been considered along with tranquilizers by Cochin (95). The phenothiazine derivatives respond to reagents described later under *Psychotropic Drugs*. In a quantititative study, Morrison (96) used ceric sulfate (5%) as a reagent and measured the area of the spot by comparison to a plastic sheet imprinted with circles and ellipses of known area. A formula was used for calculating the concentration of unknown drugs with accuracies for concentrations of 25–50 mcg. of about 3%. Thirty replicates on six different capsule preparations gave recoveries from 94.3–104.5% of label with relative standard deviations 5.8 to 11.4%. Fike (97) used three solvent systems and two spray reagents (Dragendorff and 1% solution ammonium vanadate in H_2SO_4) to identify all but six of 30 antihistamines.

BARBITURATES

The analyses of the barbiturates and related compounds has received exhaustive and often repetitive attention from many authors. Most of the work was designed for the identification of barbiturates in blood, urine, and tissue samples [Cochin (98), Walker (99), Bogan (100), Eberhardt (101), Shellard (102), Petzold (103)]. Stolman's book (26) is an excellent starting reference for separation on Silica Gel G using the most popular system of $CHCl_3$–acetone (9:1). (Designated *A* in Table XI.) Pretreatment of the barbiturates by H_2SO_4 on the plate by Petzold (103) allowed separation of five common (U.S.) drugs. The same technique was suggested later by Walker (99) following earlier use of this on paper chromatography. Qualitative analyses in pharmaceuticals have received less attention. Phenobarbital was identified in a suppository

containing amidopyrine and quinine by Kraus (104) using benzene–96% ethanol (37:3) on silica gel–$CaSO_4$ (4:1) and other barbiturates by Shellard (102) in galenicals and tablets using diisopropyl ether–$CHCl_3$ (1:1) on Silica Gel G. Sahli (105) was able to separate 15 compounds using three systems, *A*, *F*, *G*, in Table XI. Using a system similar to *H*, Table XI, Kiger (106) differentiated 23 barbiturates on silica gel.

Many detection reagents are available. Mercurous salts gave grey, black, and white colors [Sahli (105), Kraus (104), Stolman (26)]. Cobalt nitrate, then NH_3 vapor, formed a deep blue color (102). Different colors of fluorescence were recorded (101) at 254 and 366 mμ with and without $HgNO_3$. Silver acetate–diphenylcarbazone gave purple colors (103). Permanganate was used to differentiate unsaturated substituents (98) by the yellow colors produced.

CARDIAC GLYCOSIDES AND CARDENOLIDES

The section on cardiac glycosides by Waldi in Stahl's book (1) described the evolution of the work on TLC of the cardiac glycosides. Stahl (108) was able to separate most of these compounds on silica gel. Chloramine–trichloroacetic acid reagent and U.V. were used for visualization.

Mixtures of scillarin and digitoxin were resolved on silica gel and identified by Steinegger and van der Walt (109) with $SbCl_3$. Reichelt (110), using silica gel without binder inactivated with water or acetic acid, observed separation of many of the cardenolides in water saturated by the reagent benzene–alcohol (3:1) reported by Stahl (108).

Duncan (111) was able to postulate possible success of scale up from TLC to column chromatography by the R_f found on material from *Pachycarpus concolor*. Bobbitt (2) discussed in detail Duncan's formula of

$$r = \frac{a}{b + 0.1a}$$

where a and b are the R_f values of the fast and slow moving substance, and pointed out that even though r is greater than 1, good column separation may not be obtained.

Faucennet (112) reported a greater sensitivity on TLC than paper chromatography for cardenolides of digitalis with H_3PO_4–Br_2 reagent. Sonanini (113) chose previously mentioned reagents for observing several compounds separated on kieselguhr impregnated with formamide. Momose (114) introduced 1,3,5-trinitrobenzene 0.1% in DMF–5% aqueous Na_2CO_3 as a reagent to produce orange-red spots with oleandrin, digitoxin, digoxin, and ouabain.

Commercial K-strophanthin analyses by Lukas (115) revealed four components on silica gel with a BuOH–MeOH–formamide (17:2:1) system.

Corona (116) identified five components of K-strophanthin on Silica Gel G and observed another unidentified spot using $CHCl_3$–AcOH–MeOH (85:2:13) solvent.

CENTRAL STIMULANTS

Many reports of other central stimulants such as the sympathomimetic amines are included in review articles previously discussed. Stolman's book (26) shows tables taken from literature for several of these compounds.

Noirfalise's (117) comprehensive paper on central stimulants tabulated responses of many of these compounds to U.V., $KMnO_4$, Dragendorff, iodoplatinate, PDAB, $HClO_4$–KNO_3–$FeCl_3$, and furfural–H_2SO_4. Beckett (118) found multiple spots formed when the amines were treated with trichloroacetic acid in the solvent system used but not with the same system without the acid on cellulose powder (Table XII). Some of the primary amines and their *N*-methyl derivatives are included in Fike's (42) discussion on correlation of structure to R_f. The identification by Troup (119) of the degradation products of phenylephrine in tablet formulations containing aspirin were accomplished by TLC and detection with diazotized *p*-nitroaniline.

Catecholamines and their metabolites were assayed quantitatively following TLC by de Potter (120). Fluorimetric measurement of the eluted spots indicated recoveries of 97–100% for norepinephrine, epinephrine, and metanephrine.

CRUDE DRUGS AND EXTRACTS

The use of TLC in pharmacognosy is a field of its own. Analysts in this work have taken advantage of the simplicity and utility of TLC for the identification of tinctures, fluid extracts, and powdered extracts. It is used routinely in the authors' laboratory for the identification of about 40 such preparations (121). A partial summary of the literature is shown in Table XIII.

DIURETICS

Margasinski (131) applied TLC before and after hydrolysis of benzothiadiazine derivatives to obtain separation on Al_2O_3 with visualization by PDAB. Without the buffer in the ethyl acetate solvent, Adam (132) separated most of these and other compounds of the same series and observed them under U.V. at 250 mμ. (Table XIV.)

[a] *A*, ethyl acetate, pH 6.7–7.2, with NH_4OH; *B*, ethyl acetate; *C*, ethyl acetate–C_6H_6 (80:20). [b] After hydrolyses.

DYES, EXCIPIENTS, FLAVORS, AND PRESERVATIVES

Although TLC offers a very fast method for separation of dyes, the comprehensive summary of paper chromatography of dyes (133) should be consulted before attacking a complicated dye mixture problem with TLC.

Gasparic (134) listed 87 dyes separated on Al_2O_3 with benzene, and Synodinos (135) separated 7 FD&C dyes on $CaCO_3$ with BuOH–EtOH–water (2:1:1) + 10% NH_3. Stahl's book (1) offers a guide to other systems.

The excipients in pharmaceuticals pose the greatest problems and are the least mentioned in the literature. Those working in stability assays of creams, ointments, and suppositories have experienced many frustrations by the obscuration of good TLC by the smearing action of PEG's, surfactants, flavors, and preservatives, particularly when attempting to observe minor amounts of degradation products. There are a few publications which may offer guidance in these types of problems. Mannitol and sorbitol were separated using isopropanol–0.1 *N* boric acid (85:15) (136). Breithurd (137) dissolved PEG's in methylene chloride. The 2% solutions were applied to silica gel plates and developed with acetone–NH_4OH 20% (85:15).

Vakhtina (138) used alumina with $CHCl_3$–EtOH (98:2) for glycols with molecular weights up to 2000. Thoma (139) found that $CHCl_3$–MeOH–H_2O (3:25:12) would separate the stearates of PEG. Hartsaw (140) studied several excipients with some common systems and general means of visualization (Table XV).

[a] *A*, cyclohexane–acetone (40:50); *B*, $CHCl_3$–EtOH (9:1); *C*, $CHCl_3$–EtOH–heptane (1:1:1); *D*, cyclohexane–$CHCl_2$–AcOH (40:50:10); *E*, MeOH–benzene–AcOH (8:45:4); *F*, ethyl acetate–MeOH–AcOH (80:10:10); *G*, MeOH–acetone–triethanolamine (50:50:1.5); *H*, cyclohexane–acetone–Et_2NH (70:20:10); *I*, $CHCl_3$–Et_2NH (9:1); *J*, BuOH–5 *N* NH_4OH–MeOH (60:20:20). [b] Where no R_f value listed, the compound remained at point of application or it gave no reaction to reagents. [c] Two zones formed. [d] U.V. [e] I_2. [f] $KMnO_4$. [g] H_2SO_4 sprayed over $KMnO_4$.

For the partial resolution of nine preservatives Copius-Peereboom (141) used cellulose plates with a 20 cm. solvent travel. (Table XVI.) By using two developments on silica gel, Gossele (142) was able to separate these preservatives on a 20 × 20-cm. plate with temperature control below 22°. All of the compounds were observed under 366 mμ with a fluorescent indicator present, but other color reagents were used for additional differentiation.

Pinson (143) identified and determined four of the same compounds in codeine syrups and other syrups containing carboxymethylcellulose.

Antioxidants in vitamin A were detected after TLC by phosphomolybdic acid and ammonia vapor (144). Attaway (145) studied 60 flavor esters on silica gel using benzene or trifluorotrichloroethane–methylene chloride solvents and 5% vanillin in 96% H_2SO_4 reagent.

[a] *A*, cyclohexane–benzene–Et_2NH (75:15:10); *B*, MeOH; *C*, acetone; *D*, 95% EtOH; *E*, benzene; *F*, benzene–EtOH (98:2); *G*, benzene–EtOH (95:5); *H*, benzene–EtOH (90:10); *I*, benzene–EtOH (80:20); *J*, $CHCl_3$; *K*, $CHCl_3$–EtOH (99:1); *L*, $CHCl_3$–BuOH (98:2); *M*, $CHCl_3$–acetone (1:1); *N*, ether; *O*, ether–pet. ether (1:1); *P*, benzene–acetone–NH_4OH (80:20:1).

LOCAL ANESTHETICS

A major contribution in the TLC of local anesthetics was made by Sarsunova (146). He recommended specific systems for pairs of compounds, including local anesthetics in a large group of drugs. Iodine and Dragendorff were effective reagents for these compounds (Table XVII). Fuwa (147), in a series of drug analyses by TLC, included 14 local anesthetics along with a study of hypnotics and anthelmintics. Other compounds were separated in BuOH–AcOH–H_2O (5:1:4) on silica gel (148).

ORAL HYPOGLYCEMIC DRUGS

In a series of papers on drug analyses Reisch (149) reported on the resolution of carbutamide, chlorpropamide, and tolbutamide with visualization by ninhydrin spray. Neidlein's (150) work included hypoglycemic compounds with other sulfonamides.

Strickland (151) studied the above compounds plus acetohexamide and phenformin HCl in six solvent systems. The R_f values cited in Table XVIII for his work (151) are the average of 50 measurements.

PSYCHOTROPIC DRUGS

In an early report on chromatography by paper, electrophoresis, and thin layer of phenothiazine drugs, Mellinger (152) found silica gel thin layer "by far, the best procedure for any phenothiazine drug." A comprehensive study of solvent systems was reported on 23 compounds (Table XIX). Fluorescence under 263 mμ gave a sensitive means of detection, but in the presence of acids, decomposition was evident. Light protected tanks were used for chromatography in acid systems. Various colors were obtained with 40% H_2SO_4. Addition of ferric salts or PDAB to the H_2SO_4 or a palladium chloride reagent gave no additional differentiation. Paulus (153) also observed a better color differentiation with H_2SO_4–EtOH 10% than with Dragendorff, $KMnO_4$, H_2O_2, and KNO_3 solutions. Margasinski (154) added iodoplatinate, H_2SO_4 16% + 1 ml. formalin to the list of color reagents. Adank (155) pointed out the utility of analyses of trace contaminants by TLC.

Continued ⟶

Imipramine HCl[1] was found to contain eight impurities with a composite total of less than 0.2%. Pharmacological evidence was obtained to show that the impurities would not cause unfavorable side effects at the low concentration present.

Cochin (95) in the development of methods for phenothiazine in body fluids preferred H_2SO_4 for color differentiation on 26 compounds including the sulfoxide metabolic products. Noirfalise (156) tried cellulose as an adsorbent and used I_2 vapor visualization in addition to others listed. Rusiecki (157) found the same problems with decomposition during exposure to light. With proper protection TLC was recommended for quality control of ampuls and suppositories for possible degradation products.

Heyndrickx (158) separated meprobamate from sulfathiazole for subsequent colorimetric assay. Hynie (159) used benzidine–KI reagent for meprobamate and metabolites in urine. Rusiecki (160) extracted chlorpromazine from decomposition products (157) and eluted TLC plates with MeOH for assay at 268 mμ. Noirfalise (161) continued

[1] Marketed as Tofranil by Geigy Pharmaceuticals, Ardsley, N. Y.

the series of papers on phenothiazine compounds and showed tables for color reaction with various compounds.

Reaction of psychotropic drugs on TLC with bromine and bromine + aniline were recorded by Clarke (162). Additional R_f values for phenothiazines on silica gel with a $CHCl_3$–EtOH (70:30) system were given by Moza (163).

STEROIDS

The section on steroids by Waldi in Stahl's book (1) followed by a series (13 pages) by Neher in Marini-Bettolo's book (22) on TLC of steroids and by Cavina and Vicari in Marini-Bettolo's book (22) on the qualitative and quantitative analyses of natural and synthetic corticosteroids by TLC (14 pages) covered the literature through 1962–1963. These authors all gave excellent details on techniques, reagents, and listings for specific separation. Heftmann's (167) article on TLC of steroids in chromatographic reviews (13 pages, 180 references) again surveyed earlier work and extended the review

through mid 1964. Stevens (168) covered a similar period (4 pages) with a more selective bibliography. Tschesche wrote a chapter (13 pages) in another book (169) on the same subject.

To bring the literature up to date from 1964 through 1965 is beyond the scope of this review. For example, there were at least 20 publications on the TLC of estrogens and androgens in urine.

Some publications (1964–1966) have been selected for the TLC of pure steroid compounds. They are listed in Table XX. A mass of R_f values and correlations with structure are available in these publications. Many of the means of visualization and solvent systems are listed in these references. Some articles on assay of steroids in pharmaceuticals during the same period are mentioned in the subsequent paragraphs.

Bican-Fister (180) applied a chloroform dilution of oil solutions of progesterone and testosterone to Silica Gel HF254. Development in cyclohexane–ether (8:2) and removal of U.V. absorbing spots permitted the quantitative assay of these compounds by the INH reaction with 98% recovery and relative standard deviation of about 3.6%. Cavina (181), with added sophistication, used continuous elution with petroleum ether–ethyl ether–AcOH (70:30:1 or 50:50:1) to separate testosterone propionate, progesterone, 19-nortestosterone propionate, and estradiol cyclopentylpropionate from oily solutions. The steroid spots were eluted with $CHCl_3$, evaporated, and dissolved in EtOH for measurement in U.V. from 225–250 mμ or by INH reaction. Recoveries of 95–99.4% were obtained. The U.V. method was found to be more precise than the INH reagent. Bennett (182) successfully separated some closely related steroids by an improved continuous development technique on 50 × 200 × 0.25-mm. Silica Gel G plates.

3-β-Hydroxy-Δ^5-steroids (13 compd. and 6 estrogens)	(178)
Δ^5-3-β-Hydroxysteroids (8 compd.)	(179)

Methyltestosterone and three related compounds were extracted from tablets and capsules with acetone and from liquids with $CHCl_3$ for subsequent TLC by Castren (183). After development in benzene–ethyl acetate (7:3), the methyltestosterone 2,4-dinitrophenylhydrazone was determined colorimetrically with accuracy of ± 5%.

Jacobsohn (184) photographed the H_2SO_4 color reaction zones of TLC plates of estrone, estradiol, and estriol, irradiated by U.V. The densities of spots were measured in a Photovolt densitometer and quantitative relationships of densities and concentrations were established.

Jensen (185) used TLC to study the stability of steroid ophthalmic solutions. $CHCl_3$ extracts of the solutions were evaporated and applied to Silica Gel G plates. Fluprednisolone (R_f 0.12) and the acetate (R_f 0.50) zones were removed and determined by blue tetrazolium to within ±2%. Comer (186) compared the results of the tetrazolium determination and a TLC scintillation method for measurement of the stability of ^{14}C-labeled fluorandrenolone cream. Jakovljevic (187) used TLC to verify a column chromatographic method for the same steroid. Tishler (188) separated the reaction products of the determination of methandrostenolone with MeOH–HCl solution and was able to postulate reaction mechanisms.

Schultz (189) applied TLC on silica gel, using (90:10) benzene–ether for development solvent, for the determination of 17α-ethynylestradiol-3-methyl ether (R_f 0.32) in the presence of 19-nortestosterone and 6-chloro-6-dehydro-17α-acetoxyprogesterone in tablets. The steroid zone was removed and measured at 278 mμ with accuracy of 95.5–98.5%.

Various colors formed initially, finally, and the colors in U.V. (366 mμ) with 50% H_2SO_4 spray and then heat at 78° were recorded (190) for 141 compounds.

SULFONAMIDES

Wollish (8) used the separation of five sulfonamides as examples in a review of advances in TLC in 1961. Klein (191) and Kho (192) used two-step systems for separation with diazotization for detection of N^1-substituted and bromocresol purple for the N^4-substituted sulfonamides. Bican-Fister (193) used alkaline coupling with betanaphthol after diazotization to detect 0.25 mcg. amounts after separation and the Bratton-Marshall reagent for quantitation after elution. In another study by Bican-Fister (194) the quantitative data showed a relative standard devia-

tion of about 4%. Tablets were extracted with 70% EtOH–NH_3 and the extract applied in three 3-μl. portions to Silica Gel G. Suppositories were extracted with petroleum ether–water–NH_3 and the aqueous layer applied to Silica Gel G. Suspensions were shaken with EtOH–NH_3 and centrifuged. The solution was applied to the TLC plates as in tablets. Pastor (195,196) separated and identified 11 sulfonamides.

Karpitschka (197) found better separation when EtOH in the Wollish system was replaced by butanol and a wedged-shaped adsorbent used.

Sarsunova (198) screened 13 systems for several components and made a table for the most useful systems for separation of specific pairs of sulfonamides. They used $CHCl_3$–EtOH (100:8) for separation of sulfathiazole, sulfadimidine, and sulfacetamide. For quantitative assay the tablets were extracted with acetone–ethanol and applied to Al_2O_3. After separation, the spots were located with I_2 vapor and removed with a vacuum filter, and the sulfonamides measured at 270 and 290 mμ. The relative standard deviations of 2.5%, 4.1%, and 3.2% were obtained for the three components with six replicates.

There have been so many solvent systems tried (see Table XXI) that it is difficult to find a new one. Even so, publications are still appearing with new combinations and color reagents. Other means of detection are 2% vanillin in acetic acid (199), coupling with dimethyl α-naphthylamine after nitrous acid (196) and 3% ninhydrin in BuOH (200). Other studies on TLC of sulfonamides include those of Poethke (201), Wehrli (202), Lin (203), and Fogg (204).

VITAMINS

A convenient starting point for a survey on TLC of vitamins is the chapter on vitamins in Stahl's book (1). Recent reviews by Katsui (205–207) on techniques, plates, adsorbents, solvent systems, and spray reagents, followed by reviews on fat-soluble and water-soluble vitamins, brought the literature up to date in 1964. This review will attempt to cover some of the work since that time.

Castren (208) was able to separate vitamins A, D, and E in multivitamin preparations after alkaline hydrolysis on silica gel. Oxidation products of vitamin A appeared on TLC of old preparations. Quantitative analyses of vitamins A and E by the linear relationship of area of spots, observed by U.V. or phosphomolybdic acid, to concentration were possible. Various components of vitamin A were observed on alumina (209) by fluorescence in U.V. Varma (210) studied the separation of vitamin A and related compounds in six systems and used one of these systems (*F* in Table XXII) for nonsaponifiable fractions of a liquid multivitamin sample to identify anhydrovitamin A, retrovitamin A alcohol, and vitamin A alcohol. John (211) observed the same compounds after TLC under U.V. and listed blue, green, or yellow colors formed with $SbCl_3$. Silica Gel G treated with PEG 200 was used (212) for the separation of vitamin A alcohol, D_2,D_3, and β-tocopherol.

David (213) used cellulose and other adsorbents and several solvent systems other than *O* in Table XXIII for TLC of thiamine and nitrates. A $Fe(CN)_3$ reagent was used for visualization.

Vorobéva (214) was able to separate vitamin B_{12}, factor B, and factor III on silica gel contain-

ing gypsum and NaCN. Combustion of the organic material in a furnace allowed the detection of cobalt with β-nitroso-α-naphthol. The amount of cobalt could be determined from the eluted spots at 367 and 420 mμ.

Using basic alumina, Popova (215) separated additional analogs with a detection limit of 0.5 mcg. apparently based on the color of the compounds. The procedure was applicable to the control of the purity of concentrates of commercial preparations. The same authors (216) obtained improved separations on neutral alumina using NH_4OH to form cobalichromes.

Sasaki (217) found that cellulose MN300 gave good resolution of cyanocobalamin, hydroxycobalamin, and three coenzymes.

Chen (218) showed that fluorescent dyes sprayed on TLC plates of tuna oil gave less sensitivity to vitamin D_2, D_3, ergosterol, and 7-dehydrocholesterol than heating with H_2SO_4, but permitted a degree of qualitative differentiation. Pasalis (219) incorporated $AgNO_3$ and rhodamine into silica gel to separate some saturated and unsaturated esters of D_2 and D_3. Parekh (220) used TLC for the purification of ^{3}H-vitamin D_3 until all the U.V. fluorescent by-products were removed (Table XXIV). A quantitative assay of vitamin D in a pharmaceutical preparation was made possible by Heaysman (221) with wedges removed from the side of silica gel plates to form an elongated area for sample application and formation of concentric arcs following solvent development. Removal of the area containing vitamin D and subsequent rechromatography produced zones measured by the area of color found with H_2SO_4. The range found from eight tablet (800 units) assays was 700–920 units. The system of cyclohexane–ether (4:1) did not differentiate vitamins D_2 and D_3.

The TLC of tocopherols has been studied extensively and reported in recent publications. Skinner (222, 223) tabulated melting points, R_f, and spray reagents for many phenolic compounds related to tocopherols and their oxidation products and Sturm (224) published a quantitative determination of individual tocopherols. Peanut oils from various sources were assayed spectrophotometrically with bathophenanthroline–$FeCl_3$ after saponification and TLC. The average recovery of α-tocopherol was 93.2% ± standard deviation of 6.85%. Schmandke (225) obtained separation of α, γ, and δ-tocopherol on Al_2O_3–$ZnCO_3$ (3:1) plate with $CHCl_3$ as the solvent.

rect measurement instrumentation or the tedious nature of removal of adsorbent containing the desired compounds are the major disadvantages of quantitative TLC. This is probably the technology in TLC that will receive the most advances in the next few years. Table XXVI lists references on the application of radioactive tracers and TLC for analyses. This combination offers some exciting possibilities in the development of pharmaceutical assays, especially in the evaluation of stability.

Use of Activation Analysis in Problems of Drug Control

By LEON M. REYNOLDS*, WAYNE V. KESSLER, JOHN E. CHRISTIAN, and PAUL L. ZIEMER

Two major problems in drug control are the manufacture of counterfeit drugs and the diversion of legitimate drugs into illegal underground channels of distribution. In this study the use of neutron activation analysis was investigated for identification of the source of a drug product by analysis of certain trace elements added to it during manufacture, or by analysis of natural trace elements or contaminants already present. The usefulness of added trace elements was found to depend on the levels of natural contaminants. A level too high of the latter would require the addition of larger amounts of additives than physiological considerations permit. Thus, each drug product should be considered individually, after first establishing its natural contaminant content. Samples of dextroamphetamine tablets and capsules from five manufacturers, along with common tablet and capsule ingredients, were analyzed for natural contaminants. In the group, 17 elements were detected in amounts of less than 1 part per billion to over 0.1 per cent. The contaminants present in the tablets and capsules from the five manufacturers indicated each product was readily distinguishable from the others.

THE INTRODUCTION of new classes of drugs, particularly barbiturates, tranquilizers, amphetamines, and more recently the hallucinogens, has created new and difficult problems of control for law enforcement agencies. The widespread abuse of these new products has been well documented in popular periodicals. The Food and Drug Administration (FDA) has estimated that half the barbiturates and amphetamines produced legally in the United States are diverted into illicit systems of distribution (1). This diversion is possible largely through pilferage and the smuggling of exported products back into the country (2). Legislation in the form of the Drug Abuse Control Amendments of 1965, enforced by the FDA, provides for safeguards in the distribution of depressant and stimulant drugs. A second aspect of the control problem is the small scale practice of drug counterfeiting, in which clandestinely manufactured imitations of brand name products are merchandised in normal channels (3).

Any aids in product source identification will obviously be of material assistance in the enforcement program. The present work explores various aspects of product source identification through the use of neutron activation analysis (NAA). One approach is to arbitrarily introduce minute quantities of trace elements, having no effect on drug quality, which will show up at any future time under NAA. Another approach is to investigate contaminants already present in the drugs in the hope of their proving distinctive with respect to origin.

According to Robinson (4), pharmaceutical manufacturers have long added small quantities of harmless substances to products for identification purposes. Such tracers, usually detected spectrographically, are considered by both manufacturer and the FDA to be trade secrets. The present study shows NAA to be a promising alternate tracer detection technique, with the additional prospect that natural contaminants of a product may also be used as a means of source identification. Others have reached similar conclusions. Pro (5) reports that he has suggested to the FDA a list of possible elements as markers.

NAA is a sensitive, powerful analytical tool, effective for about two-thirds of the elements. Activation is ordinarily carried out by placing the sample in a nuclear reactor, where the large quantities of thermal neutrons present create radioactive nuclides through an (n, γ) nuclear reaction. Analysis is achieved by measuring the radioactivity of the product nuclides after a radiochemical separation procedure, or by direct γ ray spectrometry, with a scintillation detector and multichannel analyzer. This work makes use of the latter. Basic principles and applications of NAA are amply described in the litera-

Received December 9, 1966, from the Bionucleonics Department, School of Pharmacy and Pharmacal Sciences, Purdue University, Lafayette, IN 47907

ture. Four recent reference books (6–9) list hundreds of applications in a variety of disciplines, but surprisingly few in the pharmaceutical sciences.

Using direct γ ray spectrometry without radiochemical separation, several investigators have presented evidence indicating the possibility that sources of phenobarbital and pethidine hydrochloride (10), moonshine whiskey (11), meprobamate and heroin (12), and raw opium (13) are readily distinguishable on the basis of the presence and relative concentration of trace elements. Schlesinger *et al.* (12) also report a private communication from Dr. V. P. Guinn saying that his group had used these techniques successfully with amphetamine tablets.

With these same techniques, Tuckerman *et al.* (14) have identified 13 trace elements in samples of 40 drugs and drug ingredients, in concentrations of 0.01 mcg./Gm. to 5%.

The arbitrary addition of tracers is applicable to a variety of drug products. The studies reported here, however, are concerned entirely with dextroamphetamine sulfate tablets and capsules, and diluents commonly employed in tablet and capsule manufacture.

EXPERIMENTAL

Systems of Additives—Minute quantities of trace elements could be added to drugs during manufacture either as a single element or in groups. The number of elements having the desired properties is quite limited and, if used singly, the list would be quickly exhausted. Consequently, group or multicomponent systems would be required if a large number of separate distinguishable tags was desired. It is believed that, if differentiation is to be based on quantitative measurement of the amounts of the additives present, such measurements could only have validity if expressed in relation to some internal standard included as an additive. Thus, it was decided to investigate a four-component system in which one of the components serves merely as a standard, against which the other three are varied and measured.

The amounts of additives to be used will depend on the quantities needed to override the radioactivity produced by natural contaminants in the drug product. It was essential, therefore, to determine the levels of natural contaminants. The second phase of this study was devoted to that end.

Selection of Additives—The basic equation for neutron activation is (15)

$$A_m = \frac{m\sigma f\phi N_0}{A}(1 - e^{-\lambda t_r}) \qquad \text{(Eq. 1)}$$

where A_m is the activity of the sample of mass m, σ the thermal neutron activation cross-section, f the fractional isotopic abundance, ϕ the thermal neutron flux, N_0 Avogadro's number, A the atomic weight, λ the radioactive decay constant, and t_r the time of irradiation. Criteria for the selection of an additive which follow from Eq. 1 are high natural isotopic abundance, high neutron activation cross section, and short half-life (but not shorter than about 30 min. to allow reasonable time for counting). Additional criteria used were a high γ ray yield per disintegration, a reasonably simple γ ray spectrum, freedom from energy overlap with other radionuclides of other additives, freedom from interfering activities of other isotopes of the nuclide selected as an additive, availability in the form of a fine, nonhygroscopic powder, availability as a chemical compound in which the other constituents do not appreciably activate under neutron bombardment, absence as a natural contaminant at least in comparable quantities, nontoxicity, and reasonable availability and cost.

Results of the survey of elements are shown in Table I. The sensitivity values were calculated using Eq. 1 plus application of the γ ray yield factor. The asterisk in the last column indicates whether the spectrum is complex, due either to the presence of a large number of γ ray peaks or to multiple activities from the various isotopes present in the element.

TABLE I—POSSIBLE IDENTIFYING MARKERS

Nuclide	Abundance, %[a]	Activation Cross-Section, Barns[a]	Half-Life[a]	γ Ray Yield/ Dis.[b]	Peak Energy, Mev.[c]	Sensitivity, mcg.[d]	Complex Spectrum[a, c]

^{197}Au	100	96	2.7 day	0.98	0.41	20	

[a] From Koch (6). [b] From Strominger *et al.* (16). [c] From Heath (18). [d] Amount of element required for a 10-min. irradiation at a 10^{10} neutron flux to produce immediately 100 counts/sec at 100% counting efficiency. [e] Not known.

In selecting nuclides from Table I for a four-component system, several opposing factors must be considered. Manganese and copper have the desired properties, but are already known to be present to some extent in drugs (14). Arsenic might be thought unsuitable, even at submicrogram levels, because of its toxicity. Iodine has an undesirably short half-life for many experimental arrangements, and a photopeak overlapping that of gold, preventing their simultaneous use. The samarium peak overlaps that of dysprosium. Based on these considerations, the major portion of this work was done with the seven additives listed in Table II.

Sample Preparation—Samples for irradiation were prepared in the form of fine, dry powders sealed in plastic containers. Since quantities of an additive required for irradiation and counting were much less than 1 mg., a dilution technique was required to provide samples of known weight. Lactose powder was found to be sufficiently inert under activation to serve as the basic diluent, although, as Table VI shows, mannitol would have been preferred, had the fact been known at the time. Stock mixes of the seven additives in lactose were prepared in concentrations ranging from 0.01% for Dy_2O_3 to 2% for La_2O_3. Geometric dilutions were carried out with a spatula on a pill tile, with a mixing period of 10 min. after each successive blending of equal portions. After blending on the pill tile was complete, the mixture was transferred to a 22-ml. glass vial, where it was further agitated for 30 min.

The first stock mixes prepared exhibited a variation in specific activity under neutron activation, as shown in Table III by Au stock mixes A and B, and by Cu stock mix A. Although first thought to be due to inadequate mixing, this variability turned out to be related to the fineness of the additive powders. In the case of Au, mixes A and B were prepared from purchased powder, passed through a 100-mesh screen, with mix B being more thoroughly mixed than A. Mix C was passed through a 100-mesh screen. The CuO powder was used as purchased in mix A, and further subdivided with a mortar and pestle before preparing mix B. The La_2O_3 powder as purchased was noticeably finer than the other oxides, as Table III indicates.

Both Lucite and polyethylene vials were used for the irradiations. Because both showed slight Mn and Na contamination, samples were transferred to other vials before counting. To facilitate transfer, the sample was usually encased in a plastic film.[1] This was done by centering the weighed powder on a 3-in. disk of the film, gathering up the edges and twisting, and then holding the twisted portion about 2 mm. from a heated soldering pencil until fused.

Activation and Analysis—For the investigation of the scheme of additives, the Purdue University reactor (with an available flux of about 2×10^{10} thermal neutrons/cm.^{2}/sec.) was used. Studies on the natural contaminants were carried out, using a flux of about 5×10^{12}, in the CP-5 reactor at Argonne National Laboratory. Neutron flux values were determined by use of gold foil or gold powder flux monitors, along with calibration of the counting assembly using a calibrated ^{137}Cs source. The duration of all irradiations except the last, which was 105.6 hr., was 10 or 30 min. Counting was begun as soon as possible after removal from the reactor (about 1 hr. for the Purdue reactor and 3 hr. for the CP-5). Counting was delayed 1 week after the long irradiation, to permit decay of the ^{24}Na.

The counting system consisted of a NaI(Tl) crystal mounted in a commercial steel shield[2] having 6-in. walls and inside dimensions of 20 × 20 × 36 in. The detector output was fed into a 400-channel analyzer.[3] Readout was by a high speed printer,[4] writing at 5 channels/sec. Two different detectors were used. All measurements on the additives were made with a 2-in. well crystal. All spectra of natural contaminants were collected with a 4 × 4-in. crystal.

Spectra of single photopeaks of the additives were analyzed by summing the counts in the seven central channels and dividing by the count accumulation time, the exponential decay factor, and the additive weight. The result was the specific activity at the end of irradiation. In a mixture of radionuclides, this calculation was carried out only on the outermost peak. The peak was then removed by instrumental stripping, with previously prepared standards (8, 14), before analysis of the next lower energy peak. Thus, for each component of the mixture, the specific activity, corrected for decay, was determined. Studies of 14 mixtures resulted in the data contained in Table II.

Gold was selected as the internal standard against which the other three components were varied and

TABLE II—EXPERIMENTAL DETERMINATION OF MARKER SENSITIVITIES[a]

Additive	Radionuclide Marker	Specific Activity, Relative to Au[b]
MnO_2	^{56}Mn	1.38
CuO	^{64}Cu	0.437
La_2O_3	^{140}La	0.14[c]
Eu_2O_3	^{152m}Eu	4.01
Sm_2O_3	^{153}Sm	1.22
Dy_2O_3	^{165}Dy	69
Au	^{198}Au	1

[a] A 2-in. diameter × 2-in. thick well detector was used. [b] The specific activity of Au was 4.12×10^5 counts/min./mg. of Au, for a 30-min. irradiation at a flux of approximately 2.1×10^{10} neutrons/cm.^{2}/sec. Counting rate was based on a seven-channel peak, corrected for decay, at 5 kev/channel. [c] A 15-channel peak was used.

TABLE III—UNIFORMITY OF STOCK MIXES

Stock Mix (in Lactose)		Replicates Analyzed, No.	Specific Activity— Coeff. of Variation, %	Activity— Range, % of Mean
0.25% Au	A	6	9.7	43
	B	6	9.3	28
	C	7	2.2	5.3
1.0% CuO	A	8	7.3	21
	B	8	1.7	6.1
2.0% La_2O_3		8	1.4	4.8

measured. Reasons for the choice were its high sensitivity, single sharp photopeak, intermediate photopeak energy value, and longer half-life. For ^{165}Dy the X-ray peak was used since it predominated, but because of its low energy an analyzer resolution of 5 kev/channel was required.

Mix Combinations—In order to prove the efficacy of a four-component system, mix combinations of additives were prepared and further diluted with lactose, to simulate a batch of drug product. Samples were then taken for irradiation and measurement. It was considered desirable to determine the amount of change in any amount or level necessary for it to be positively identifiable as "different." Or, stated in another way, it was desirable to determine the number of distinguishable tags possible through varying the amounts of additives over an order of magnitude relative to Au. Results of measurements on the first three mix combinations are shown in Fig. 1. The solid lines represent the expected activities relative to Au, based on data similar to those in Table II. The data points show results obtained from actual measurement. The levels shown in Fig. 1 were selected to approximate an interval of $\sqrt{2}$ between levels. Each dot corresponds to a sample of the mix combination.

Difficulty in maintaining the intended level was encountered only with ^{56}Mn. This was found to be the result of a particle size too large in the MnO_2 powder, which was composed of hard granules as purchased and had to be subdivided before dilution.

Determination of Natural Contaminants—Eight samples of dextroamphetamine sulfate tablets and capsules from five manufacturers, along with 10 ingredients commonly used in amphetamine and other drug products, were irradiated in the Argonne CP-5 reactor. Each material was analyzed following two 30-min. and one 105.6-hr. irradiations. Samples approximately 100 mg. in size were sealed by heat in $^2/_5$ dr. polyethylene vials for the short irradiations, and quartz ampuls for the long one. Samples were weighed after counting.

Identification of contaminants was based on determination of the peak energy and half-life, with both being required. γ Ray spectrum catalogs of Crouthamel (17), and particularly Heath (18), were helpful here. Data reduction was carried out as for the additives, though subtraction of the adjacent continuum was usually necessary to determine the seven-channel-peak counting rate.

Standards were prepared and irradiated along with the unknowns, when their need became apparent from the previous irradiation. Amounts of contaminants present were determined by the comparator method described by Lyon (8). The radionuclides ^{46}Sc, ^{51}Cr, ^{59}Fe, ^{60}Co, ^{65}Zn, ^{122}Sb, ^{124}Sb, and ^{233}Pa have longer half-lives and were detected only after the long irradiation. Amounts of these elements present were calculated by an absolute method using Eq. 1, and published data on cross sections (6) and decay schemes (16). To relate photopeak counting rates to sample disintegration rates, it was necessary to determine the counting efficiency of the detector system. This was done in the following manner.

A calibrated ^{137}Cs source with a γ ray emission of 4.95×10^5 γ rays/min. was prepared. A count of this source immediately gave the counting efficiency for the energy 0.66 Mev. The values for other energies were calculated from absolute detection efficiencies and peak-to-total ratios published by Heath (18). Values of counting efficiency as a function of energy for three different detectors are plotted in Fig. 2. Data points on the 2-in. well crystal were established by direct experimental comparison to the other two crystals. The validity of the absolute method is supported by the cross checks shown in the data in Table IV.

[a] Entries are in mcg./Gm. or per cent where designated. [b] Coded designation of lot numbers. Lot numbers were greatly different numerically, indicating lots manufactured at greatly differing times. [c] In every instance 64-day ^{85}Sr was also observed. [d] In every instance 60-day ^{124}Sb was also observed.

Application of Eq. 1 to contamination concentration determinations required measurement of the neutron flux for the long irradiation. This was done by six different determinations using La, Au, and Mn standards in two different irradiations, yielding as the result $(5.5 \pm 0.8) \times 10^{12}$ neutrons/cm.^{2}/sec.

Contaminants in Dextroamphetamine Tablets and Capsules—Contaminants observed in the dextroamphetamine sulfate tablets and capsules are shown in Table V. Polaroid photographs of samples of the spectra providing the data for Table V are shown in Fig. 3. Spectra of tablets from four different manufacturing sources, taken after a 30-min. irradiation and a 6-hr. waiting period, show the presence of only ^{24}Na, ^{56}Mn, and ^{87m}Sr, but in widely varying amounts. The longer lived nuclides are observable only with longer data collection times after the shorter ones have decayed. This effect is illustrated further with the capsules in Fig. 4, where *A* shows only the presence of ^{24}Na, ^{56}Mn, and ^{64}Cu. In *B*, the peak at 0.55 Mev. shows the presence of ^{82}Br in one manufacturer's product, but not in the other. In *C*, both sources show ^{65}Zn and ^{124}Sb, but ^{47}Ca is apparent in only the samples from manufacturer No. 4.

Contaminants in Drug Ingredients—Table VI shows contaminants present in a selection of nine commonly used tablet ingredients, and also in a commercial sample of pure dextroamphetamine sulfate crystals. Sodium was the one element found in all cases, but was present in a wide range of concentrations. Because the dextroamphetamine sulfate crystals were supplied by manufacturer No. 4, one might expect the same trace elements to appear in the tablets and capsules of manufacturer No. 4. That several do not is attributed to the fact that, because of sample sizes, the detection sensitivity for the pure dextroamphetamine sulfate sample is enhanced by a factor of about 50 over that of the tablets and capsules.

RESULTS AND CONCLUSIONS

Requirements for Additives—The experimental work has demonstrated that a four-component system of additives to provide product identification will work insofar as activation and counting techniques are concerned. In applying any such system to a particular drug product, the factor determining the amount of additives required will obviously be the principal activities produced by natural contaminants. For dextroamphetamine tablets, these activities would be due to Sr, Mn, and Na. Using a seven-channel-peak from a 4-in. detector at 10 kev/channel, the sensitivity ratios between ^{198}Au and ^{24}Na, ^{56}Mn, and ^{87m}Sr were 19, 0.16, and 29, respectively. If, in a four-component system, one assumes that Au used as an internal standard would need to produce a peak at least as large as that of any natural contaminants, when measured after a delay of the order of 3 hr., the Au concentrations required to match those of Na, Mn, and Sr for the tablets of Table V would be 13, 7, and 11 mcg./Gm., respectively. Such concentrations are unlikely to be granted official approval. A gain by a factor of 5–10 would be possible with an alternate approach using Sm_2O_3, Eu_2O_3, and CuO, together with Au, comprising the mixture, then waiting about 10 hr. until most of the ^{56}Mn and ^{87m}Sr had decayed, and removing the ^{24}Na by instrumental stripping. It is evident that

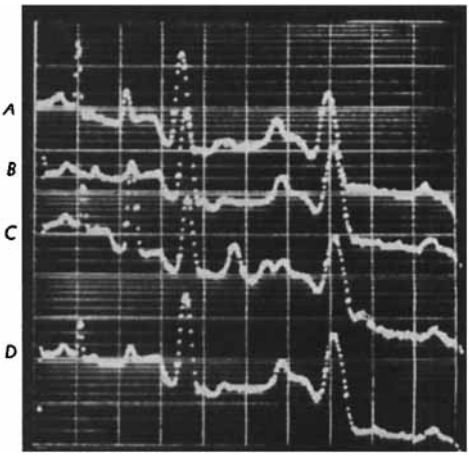

Fig. 3—Spectra of dextroamphetamine sulfate tablets from four manufacturers. Thirty-minute irradiation followed by 6-hr. decay; 0–4 Mev.; vertically displaced for clarity; scale of vertical axis is logarithmic. each drug product must be considered individually in designing a system of identifying additives, after first establishing the levels of natural contaminants.

Eu_2O_3 is suitable as an additive component, but only if irradiation time is in the range of 1 hr. or less, and assay made within about 10 hr. Though the spectrum is very complex, only the 9.3-hr. activity of ^{152m}Eu appears at first.

The number of separate identifiable tags possible under a four-component system also depends on how much the measurements are affected by natural contaminant activity. In a situation where one could use an arrangement such as shown in Fig. 1, 8^3 combinations are possible, if one includes the zero level. Not enough combinations were tried to be certain that all 512 combinations would be dis-

tinguishable; but it is evident that, with care, most could be used.

Single component additives have a distinct advantage. Quantitative differences would not be involved; only detection would be required for identification purposes, and far smaller amounts could be used. Table VI shows natural levels of Au of less than 1 part per billion were easily identified. Similar values would apply to other additives of comparable sensitivity.

Contaminants Detected—These results are generally consistent with those of Tuckerman *et al.* (14). In analyzing a somewhat different group of materials, the following additional trace elements were found: Cr, Fe, Zn, Sr, La, Eu, and Au. In the two compounds common to both studies, namely magnesium stearate and talc, these samples contained the same trace elements as those of Tuckerman, and in the same general levels; but other contaminants were also observed, as seen in Table VI.

Contaminants for Source Identification—Examination of Table V shows the six dextroamphetamine sulfate products from the five different manufacturers to be clearly and readily distinguishable from each other, on the basis of contaminants present and their relative concentrations. On the other hand, the three different lots of manufacturer No. 4, though apparently widely spaced in time, are so similar as to be indistinguishable. These results, then, provide further supporting evidence that natural contaminants may offer a means of determining the specific manufacturing source of amphetamine drug samples.

Determination of Vitamin D in the Presence of Vitamin A by Cylindrical Thin-Layer Chromatography

By KENJIRO HIRAYAMA and KENZO INOUE

Vitamin A alcohol in vitamin D_2 preparations is converted to retinene by passage through a column of manganese dioxide, inactivated with acetone containing water, and eluted with the mixed solvent of acetone and petroleum ether (1:4). This eluate is used for cylindrical thin-layer chromatography (CTLC). The sample is applied to the thin layer under a stream of nitrogen gas, and the chromatogram is developed with chloroform. With this proposed procedure, no decomposition of vitamin D_2 took place and the recovery of vitamin D_2 from a vitamin A–D_2 preparation was about 97–102 per cent compared to untreated vitamin D_2.

THE FOLLOWING three points seem to be unresolved in the determination of vitamin D in pharmaceutical preparations using thin-layer chromatography (TLC).

(*a*) With commonly used adsorbents and developing solvents in TLC, vitamin A interferes with the isolation of vitamin D, due to the similarity of the R_f values of both vitamins. It is necessary, therefore, to convert vitamin A to substances that have R_f values different from that of vitamin D_2. In their earlier studies Barua and Rao (1) converted vitamin A to anhydrovitamin A with 0.033 *N* ethanolic hydrogen chloride. Later the same authors (2) reported its conversion to retinene on a column of precipitated manganese dioxide.

(*b*) Partial decomposition of vitamin D_2 occurs within a few minutes on a dry silica gel layer, but it is stable as long as the solvent is present. Therefore, if the ordinary thin-layer plate is used, it should be absolutely essential in the quantitative assay to place the plate in the developing chamber immediately after applying the sample solution—before the solvent (*e.g.*, petroleum ether) evaporates (3). However, this seems to be impossible in practice, since the solvent will evaporate during successive application on a single plate.

(*c*) To minimize errors and avoid concentration of sample extracts, it is very desirable that a large amount of sample solution be applied to the thin layer.

In the present paper, the conversion of vitamin A to retinene by a column of manganese dioxide according to Barua's method was studied in detail. Satisfactory results were obtained with the use of a new method of inactivating manganese dioxide so that the conversion of vitamin A to retinene was complete without alteration or adsorption of vitamin D_2.

Received October 11, 1966, from the Shonan Plant, Takeda Chemical Industries, Ltd., Fujisawa City, Japan.

Accepted for publication December 8, 1966.

The authors thank Mr. M. Iwanaga, for his advice and Mr. K. Hiruma for his cooperation in this work.

To apply a large amount (more than 1 ml.) of the sample solution and to prevent any decomposition of vitamin D_2 while applying the sample solution to the thin layer, a new apparatus was used for quantitative TLC. It was found that by using this apparatus and introducing nitrogen gas while applying the sample solution, no decomposition of vitamin D_2 took place.

After developing with chloroform, the vitamin D_2 zone is located between two visible yellow bands of vitamin A oxidation products. The use of an ultraviolet light is unnecessary.

The adsorbent between these two yellowish bands is scraped off while still damp with solvent (chloroform), and immediately eluted with ethyl ether. After evaporation of the ether, the residue is dissolved in ethylene dichloride for color development with antimony trichloride reagent (U.S.P. XVII).

EXPERIMENTAL

Apparatus—The cylindrical thin-layer chromatographic apparatus was previously described (4).

Reagents—Manganese dioxide, JIS 1st grade or extra pure; silica gel, Wakogel B-5 for TLC or Kieselgel G for TLC; calciferol, U.S.P. grade; antimony trichloride reagent, U.S.P. XVII vitamin D assay color reagent.

Other reagents (petroleum ether, acetone, chloroform, methanol, ethyl ether, ethylene dichloride, anhydrous sodium sulfate) were JIS special grade or guaranteed reagent.

Method—*Extraction*—To a convenient weight of the sample,[1] at least 0.1 Gm., equivalent to not less than 0.5 mg. (20,000 I.U.) of vitamin D_2, 20–30 ml. of water is added, and the fat-soluble materials (vitamin D_2 and A also included) are extracted with three 30-ml. portions of petroleum ether. If there is emulsifying agent in the sample, addition of acetone may be helpful for separation of the two phases.

The combined extracts are washed with water and dried over anhydrous sodium sulfate. The dry extract is evaporated under reduced pressure to

[1] This sample should contain enough vitamin A to provide the two yellowish pilot bands; add about 1000 I.U. of vitamin A alcohol, if necessary.

approximately 20 ml., transferred to a 25-ml. volumetric flask, and brought to volume with acetone.

Oxidation—*Preparation of the Column*—A column (1 cm. inside diameter) 3 cm. in height with manganese dioxide is prepared by mixing two different mesh sizes (equal parts by weight below 105 μ and 105–210 μ). The column is washed with 2 ml. of acetone containing 3% water, and then with two 1-ml. portions of acetone–petroleum ether (1:4).

Oxidation—Ten milliliters of the above dried extracted solution is transferred to the column and allowed to pass through dropwise. When all the solution has passed through, the column is washed with five 3-ml. portions of acetone–petroleum ether (1:4). During this procedure it is necessary to keep the solvent on the column. Collect the eluates in the same receiver and bring to 25 ml. with petroleum ether. This is the sample solution.

For samples of low vitamin D content (50–250 mcg.), the entire dried extract is evaporated almost to dryness and the residue transferred with acetone–petroleum ether (1:4) to the oxidation column. The eluate is evaporated under reduced pressure until free of solvent, the last few milliliters being removed in a current of nitrogen. The residue is redissolved accurately for cylindrical thin-layer chromatography.

Cylindrical Thin-Layer Chromatography (CTLC)—A volume (V_p ml.) of sample solution of at least 1.00 ml., equivalent to not less than 50 mcg., and preferably more than 2.00 ml., equivalent to a maximum of 100 mcg. of vitamin D_2, is pipeted into the thin-layer cylinder and allowed to exude to the outer thin layer. (Fig. 1.)

During the course of this procedure, nitrogen gas is introduced from the inlet (Fig. 2, a). In this experiment, "partial volume method" (see Fig. 2) is adopted for applying the sample solution.

Extraction from the Adsorbent—Immediately after development with chloroform, the colorless portion of the thin layer between the two yellowish ring bands (oxidation products of vitamin A alcohol), is scraped off with a flat spatula while rotating the thin-layer cylinder into a small flask containing a small amount of ethyl ether.[2]

The suspensions are vigorously shaken and rapidly filtered through a dry filter or centrifuged. This procedure is repeated using four or five 5-ml. portions of ethyl ether. Each filtrate or supernatant is collected in a 25-ml. volumetric flask and brought to volume with ether.

Determination of Vitamin D_2—An aliquot of the ether extract is pipeted into the test tube and the solvent perfectly evaporated to dryness *in vacuo* and with the aid of stream of nitrogen gas. The residue is redissolved in 3.0 ml. of ethylene dichloride, and the color is developed by mixing 3 ml. of antimony trichloride reagent. The absorbance is measured (A_{T500}) at 500 mμ 90 sec. after adding the reagent, and A_{T550} at 550 mμ after 120 sec.

RESULTS AND DISCUSSION

Stability of Vitamin D_2 Coloration with $SbCl_3$—In general, the absorbance at 500 and 550 mμ is measured 45 and 90 sec., respectively, after adding the reagent. But in this experiment the variation of absorbance with the time lapse from 45 to 120 sec. was very small (Fig. 3). Therefore, the A_{500} and A_{550} were measured after 90 and 120 sec., respectively, using the Zero method spectrophotometer.

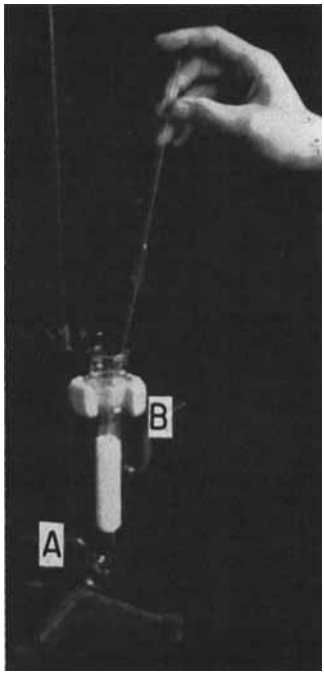

Fig. 1—Application of the sample solution to thin-layer cylinder.

Oxidation by Manganese Dioxide—The oxidation of vitamin A alcohol to retinene by manganese dioxide has been reported by Ball *et al.* (5) and Henbest *et al.* (6). These reports do not refer to the mesh size of the MnO_2. In the report of Barua *et al.*, precipitated MnO_2 was used, but the preparation and activation method was not described in detail.

In this experiment, investigation of mesh size and the inactivation method of MnO_2 are described.

Recovery Experiments with Pure Vitamin D_2 from the MnO_2 Column—A solution of vitamin D_2 in petroleum ether (equivalent to about 0.1 mg.) was pipeted into the prepared columns which contain various mesh sizes and heights of MnO_2 and was eluted with 20 ml. of each eluting solvent. In this procedure it is essential that the column never run dry; the moment the surface of the eluting solvent has dropped to the top of the column, fresh eluting solvent must be added. The eluate was collected in a 25-ml. volumetric flask and brought to volume with eluting solvent.

An aliquot of this solution equivalent to about 15 mcg. of vitamin D_2 was pipeted into the test tube and the vitamin D_2 determined as described above to obtain A_{T500} and A_{T550}. The A_{S500} and A_{S550} are determined for the D_2 solution (in petroleum ether) without passing through the MnO_2 column.

The recovery of vitamin D_2 from the MnO_2 was calculated from the following equation:

$$\text{recovery } (\%) = \frac{A_{T500} - A_{T550}}{A_{S500} - A_{S550}} \times 100$$

The results are shown in Table I.

[2] The most suitable solvents for extraction according to the literature are petroleum ether, ethyl ether, and chloroform. In this experiment ethyl ether was used.

The recovery experiments show (Table I) that vitamin D_2 was adsorbed on the column and cannot be eluted with *n*-pentane or petroleum ether as suggested in the literature (2).

Using the same procedure (1.5-cm. column of small mesh MnO_2), the inactivation of MnO_2 with water and eluting solvent was studied. The results are shown in Table II.

The recovery experiment shows (Table II) that vitamin D_2 is adsorbed firmly on the column of MnO_2 small mesh size, that the inactivation process with acetone containing water is necessary, and that the mixed solvent of acetone–petroleum ether (1:4) is superior to petroleum ether alone.

In the case of MnO_2 large mesh size, using the same procedure, the results are shown in Tables III and IV. The data in Table III are from untreated MnO_2, and the data in Table IV are those from inactivated MnO_2.

From the comparison of data in Tables III and IV, it is necessary to inactivate MnO_2. Inactivation method *A* is no different from *B* (*cf.* $\bar{A} = 99.13$; $\bar{B} = 99.27\%$). Washing method *A* is little different from *B* (*cf.* $\bar{A} = 99.47$; $\bar{B} = 98.93\%$). The results show that a little petroleum ether, used for washing the remaining acetone in the column, is superior to the excess; therefore, acetone–petroleum ether (1:4) should be used as the washing solvent.

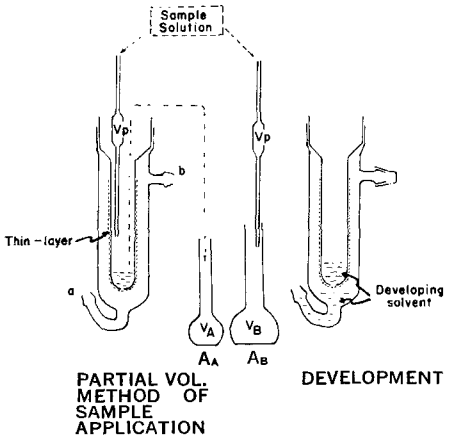

Fig. 2—Cylindrical thin-layer chromatography. The outside of inner cylinder (like a test tube), the bottom of which has a small hole (about 1 mm. in diameter) used for exuding the sample solution and developing solvent from the inside to outside, is covered with a thin layer of adsorbent. The sample solution is pipeted into the thin-layer cylinder and it exudes to the outer thin layer automatically. Thus, the sample makes the ring band around the bottom. The size of the ring band is regulated with the stream of introducing gas. In this case, if the gas flows very rapidly, the hole becomes plugged but if the gas flow is suitably regulated, the sample does not plug. The optional amount of sample solution (in this case the whole of solution exuding is total volume method) has exuded to the outer thin layer, then the remaining solution is removed, quantitatively diluted to a volume, and a color developed (or directly measured at suitable wavelength) for both solutions (original and diluted). The volume of the sample solution exuded to the outer thin layer is then calculated by difference.

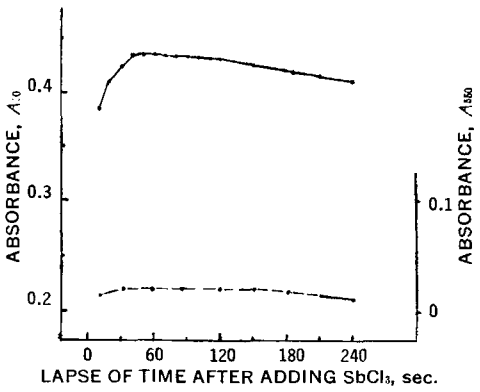

Fig. 3—Stabilities of vitamin D_2 color developed with $SbCl_3$. Key: top curve, A_{500}; bottom curve, A_{550}.

TABLE I—RECOVERY OF VITAMIN D_2 FROM MnO_2 COLUMN

MnO_2 Mfgr.	MnO_2 Mesh Size, μ	MnO_2 Ht., cm.	Eluting Solvent	Recovery, %

B	Below 105; 105–210 (1:1)	1.5	*n*-Pentane	16.5
B	Below 105; 105–210 (1:1)	3.0	Pet. ether	0

TABLE II—RECOVERY OF VITAMIN D_2 FROM INACTIVATED MnO_2 (Below 105 μ) COLUMN (1.5 cm. HEIGHT) USING VARIOUS ELUTING SOLVENTS

Inactivation of MnO_2	Eluting Solvent	Recovery, %
1% water[a]	Pet. ether	0
5% water[a]	Pet. ether	30.3
No water	EtOH–pet. ether (1:9)	10.2
No water	EtOH–pet. ether (1:4)	10.7
No water	Acetone–pet. ether (1:9)	15.2
No water	Acetone–pet. ether (1:4)	44.1
No water	Acetone–pet. ether (3:7)	18.5
Acetone, 1 ml.	Pet. ether	17.5
Acetone, 1% water[b], 1 ml.	Acetone–pet. ether (1:4)	56.5
Acetone, 3% water, 1 ml.	Acetone–pet. ether (1:4)	59.5
Acetone, 5% water, 1 ml.	Acetone–pet. ether (1:4)	74.9
...	Ethyl ether	2.5

[a] Inactivation method with water: to 10 Gm. of MnO_2 in 30 ml. of petroleum ether, add 0.1 ml. or 0.5 ml. of water and vigorously shake for about 30 min. [b] Inactivation method with acetone containing 1–5% water: pour 1 ml. of acetone containing 1, 3, or 5% water into the MnO_2 columns soaked in petroleum ether.

In Tables I–IV, vitamin D_2 in petroleum ether is used. Results for vitamin D_2 in acetone–petroleum ether (1:4) using the column of below 105 μ: 105–210 μ (1:1) MnO_2, inactivation method *A*, and washing with two 1-ml. portions of acetone–petroleum ether (1:4), are shown in Table V. The only difference here is that the vitamin D was placed on the column in the acetone–petroleum ether (1:4) solution. The results are no different from those in Table IV.

Stability of Vitamin D_2 in Eluting Solvent—To vitamin D_2 in petroleum ether was added the eluting solvent which had passed through the column of MnO_2. This mixed solution was allowed to stand for various periods of time and the color developed by using the same procedure described above. The results are shown in Table VI.

After allowing to stand for 3 hr., an aliquot of each of the vitamin D_2 solutions *1–6* was evaporated to about 0.3 ml. and analyzed by TLC. Spots other than vitamin D_2 were not detected on the plate. The results show that the vitamin D_2 was not altered in these eluting solvents.

Oxidation of Vitamin A Alcohol by MnO_2—Vitamin A alcohol (about 5000–10,000 I.U.) in petroleum ether was poured into the column of MnO_2 with or without inactivation, and the eluate was evaporated to about 1 ml. under nitrogen gas. This concentrated solution was used for micro TLC[3] to determine the completeness of vitamin A alcohol oxidation. The results are shown in Table VII.

The results show that under the conditions for good recovery of vitamin D_2, almost all vitamin A alcohol is converted to retinene so that little vitamin A alcohol is detected on the thin layer.

The chromatogram of vitamin A and D_2 passing through the column of MnO_2 inactivated with 2 ml. of acetone containing 3% water is shown in Fig. 4. (Table VIII.)

Determination of Vitamin D_2 in the Presence of Vitamin A by CTLC—*CTLC of Vitamin D_2 Alone*—The vitamin D_2 in petroleum ether solution (about 50 mcg./ml.) (V_p ml.) was pipeted into the thin-layer cylinder and the vitamin D_2 was isolated according to the described procedure. The absorbance A_c was obtained (when dilution was V_c).

For an evaluation of the volume (V) of vitamin D_2 solution exuding through a hole to the outer thin layer, aliquots of V_A and V_B solutions (see Fig. 2) were evaluated with antimony trichloride and A_A, A_B were obtained.

Recovery (R) of vitamin D_2 from the thin layer against no treatment of vitamin D_2 was calculated by:

$$R(\%) = \frac{A_C \times V_C \times V_p}{A_B \times V_B \times V} \times 100 \quad \text{(Eq. 1)}$$

Equation 2 (volume determination) was combined with Eq. 1 to obtain Eq. 3

$$V(\text{ml.}) = \left(1 - \frac{A_A \times V_A}{A_B \times V_B}\right) \times V_p \quad \text{(Eq. 2)}$$

$$R(\%) = \frac{A_C \times V_C}{A_B \times V_B - A_A \times V_A} \times 100 \quad \text{(Eq. 3)}$$

The results are shown in Table IX.

The results show that if nitrogen gas was introduced using CTLC, decomposition of vitamin D_2 did not occur during the application of the sample solution to the thin layer.

Determination of Vitamin D_2 in Vitamin A and D_2 Emulsion by CTLC—To vitamin A emulsion containing gum arabic, vitamin D_2 in petroleum ether was added. Water and acetone were added and the vitamins A and D_2 extracted according to the method described.

For evaluation of the volume (V) of the sample extract solution exuding through a hole to the outer thin layer, absorbances of V_A and V_B solutions were measured spectrophotometrically at 328 mμ[4] and

TABLE III—RECOVERY OF VITAMIN D_2 FROM UNTREATED MnO_2[a]

[4] The wavelength 328 mμ is the maximum of vitamin A palmitate. In this experiment, to avoid isomerization of vitamin D_2, the hydrolysis was not adopted for extraction of vitamin D_2 from the sample. Therefore, only vitamin A alcohol which existed in vitamin A palmitate was converted to retinene by MnO_2 and almost all vitamin A ester remained unchanged.

A_A and A_B were obtained, respectively. The volume (V) of the sample extracting solution exuded was calculated from Eq. 2.

The recoveries of vitamin D_2 from vitamin A and D_2 emulsion against untreated vitamin D_2 (standard) are shown in Table X.

These experiments show that the recoveries of vitamin D_2 from vitamin A–D_2 emulsion are excellent with the proposed procedure.

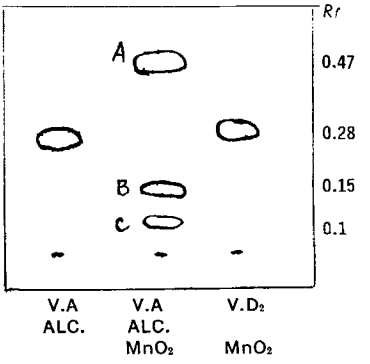

Fig. 4—Thin-layer chromatogram of oxidation products of vitamin A alcohol by MnO_2.

SUMMARY

It was found that vitamin D_2 was adsorbed on untreated MnO_2 and was not eluted with petroleum ether or pentane. Good recovery of the vitamin D_2 was obtained from water–acetone inactivated MnO_2 with an eluant of acetone in petroleum ether (1:4). Thus results were satisfactory.

Vitamin A alcohol having an R_f value similar to vitamin D_2 (R_f 0.28) was oxidized with inactivated MnO_2 on TLC into three yellowish bands which have R_f values of 0.47, 0.15, and 0.10.

Vitamin D_2 was located between the two yellowish bands which have R_f values of 0.47 and 0.15. It is unnecessary to use U.V. light to locate the bands.

By means of a cylindrical thin-layer chromatograph (4) with the introduction of nitrogen gas during the application of sample solution, the partial decomposition of vitamin D_2 was prevented.

With this technique it was found that the application of more than 1 ml. of sample solution, thus minimizing this source of error, was achieved without damaging the thin layer.

Method for the Evaluation of Antihidrotic Substances in the Anesthetized Cat

By R. S. ALPHIN, DALE SAUNDERS, and JOHN W. WARD

An improved method using newly designed equipment is described for the evaluation of antihidrotic substances in the anesthetized cat. The substances to be tested were applied locally on the foot pads. The effect on the sweating induced by the administration of a pharmacological agent such as pilocarpine was then observed by recording changes in the moisture content of air passed at a constant flow over the foot pads. The method as described gave consistent and reproducible results with a substance known to produce antihidrotic effects.

FROM A SEARCH of the literature, there appear to be few methods available for investigating the pharmacological activity of substances on sweating in laboratory animals. Kuno (1) was among the first to use the moisture produced by the sweat glands as a measurement of sweating in man. The method had limitations since changes in sweat secretion could only be observed for a period of 5 min. Adams *et al.* (2) have

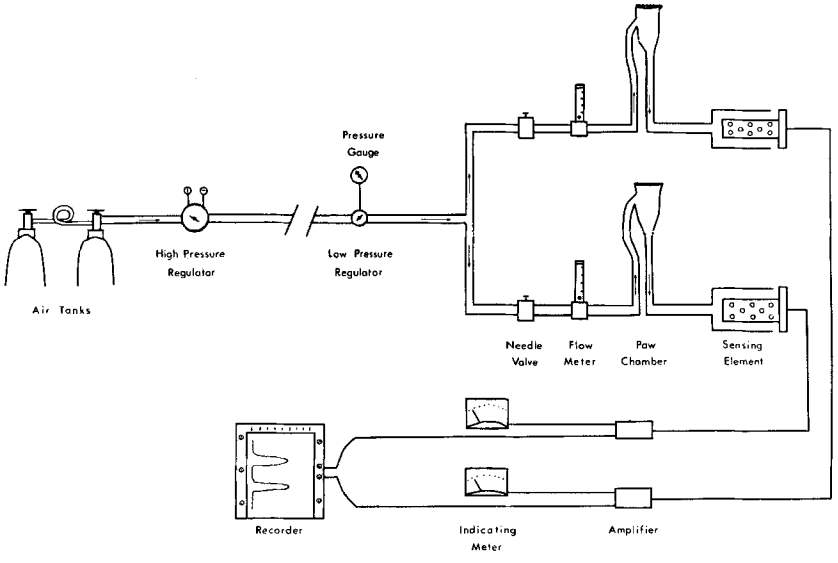

Fig. 1—Diagram illustrating the sweating rate measuring system. The sensing elements were partially enclosed to prevent accumulation of dust and other foreign material in the room air.

described the measurement of evaporative water loss by a thermal conductivity cell. Nakayama and Takagi (3) used, instead of the absorption of water as Kuno had done previously, a sensitive resistance hygrometer which enabled them to make a continuous recording of sweating. Bullard (4) later described a modification of the method used by Nakayama and Takagi for studies in man. The purpose of this report is to describe a method for the study of sweating, especially in cats. The method is a modification of the one described by Bullard (4) and which has been adapted for animal use. In principle, when air of any known low relative humidity is passed at a fixed and appropriate rate over the foot pads of cats, the change in the water content of the air is dependent upon the sweating rate.

MATERIALS AND METHODS

The sweating rate measuring system is shown diagrammatically in Fig. 1. The air (less than 5% relative humidity) supplied by storage tanks was reduced in pressure by high and low pressure regulators and fed into two separate flowmeters. By the use of needle valves at the flowmeters, the air flow could be adjusted and maintained at any desired rate. The air flow selected to be used in all of the experiments was 0.5 L./min. The air passed into a specially designed glass chamber which contained one of the cat's paws. The small chambers were not only designed to provide minimal air volume, but also large enough to permit the use of larger cats. The chamber dimensions were approximately 7 cm. in length and had an inside diameter of 4 cm. The air inlet and exit openings were 6 mm. inside diameter. The position of the paw was always such that the air inlet opening was opposite the foot pad surface. The cat's paw entered into the chamber through a small opening made in a rubber dam which was used to close the open end of the chamber. It was imperative that the position of the paw did not interfere with its blood circulation. This was accomplished by using a very flexible rubber dam with various size holes for entrance of the paw and to avoid inhibiting or occluding the local circulation. To insure that there was uniformity in distribution of air in the "paw chamber," the position of the paws inside the chambers was as nearly the same as possible. Figure 2 shows a close-up view of the cat's paw inside the chamber. After the air had passed over the foot pads at a known flow rate, it then passed into the humidity sensing elements (Hygrodynamics, Inc., Silver Spring, Md.). The principle of the sensing element is based on the ability of a hygroscopic film to change its

Fig. 2—The position of the cat's paws within the chambers. The small polyethylene cannula in the lower right was used for the intravenous injections via jugular vein.

Fig. 3—The entire system showing the cat; paws enclosed in the small glass containers.

electrical resistance instantly with microchanges in the relative humidity. The resistance change is then measured in terms of electric current flowing through the element and is indicated and recorded by suitable instruments. The hygroscopic film used in the sensing element is lithium chloride. The wide-range sensing element used is capable of detecting humidity changes in the range of 5 to 40%. The Hygrodynamics humidity indicator (catalog No. 15-3000) serves several purposes, that of an a.c. voltage source to the sensing elements, a meter showing the electrical current changes, and a d.c. signal source for recording purposes. The humidity changes may be visually recorded from the indicator meter. However, it is much simpler and less time consuming to use a suitable recording instrument. A Moseley (model 7100A) two pen strip chart recorder was used to record the results reported here. Each humidity sensing element contained a thermistor for temperature measurement. The elements were supplied with a graph of correction factors to be used between −40° and 120°F. The correction factors were added to or subtracted from the humidities read from the calibration curves depending upon the temperature at the level of the sensor. As the air flow rates are known, it may also be desirable to express the data as the amount of water vapor evaporated from a measured paw surface area per unit time. Lawton *et al.* (5) have used the following expression to determine the sweating rates:

$$\text{sweating rate (mg./min.)} = \text{air flow (L./min.)} \times \frac{\Delta RH}{100} \times \text{density of sat. steam (mg./L.)}$$

The entire system used for measuring the sweating response is shown in Fig. 3. The housing for the humidity sensing elements, flow and pressure regulators, amplifiers and meters was designed and made in the machine shop of these research laboratories. A heat lamp was installed, since it has been our experience that a more pronounced sweating response is obtained when heat is applied. The heat lamp consisted of a 125 w. infrared bulb contained in a reflector. It was placed about 18 in. directly above the animal's abdomen and remained in that position throughout the entire experiment. The heat lamp alone in this position never elicited a significant sweating response.

The pharmacological substances to be tested were dissolved in water at various concentrations. They were then applied (0.1–0.2 ml.) directly on the foot pads of the anesthetized (sodium phenobarbital, 125 mg./Kg. i.p.) cat by use of an applicator stick. The material was then allowed to dry before the paw was placed into the glass chamber. Another paw, enclosed in a separate chamber, served as a

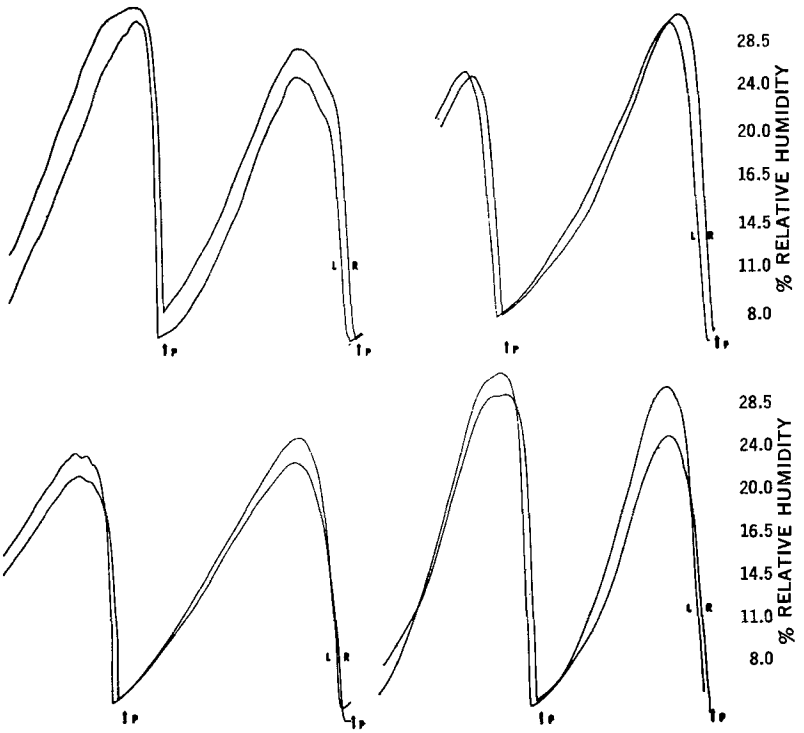

Fig. 4—Control sweating responses to the intravenous administration of pilocarpine (0.1 mg./Kg.) in four cats. The graphs read from right to left. The arrows indicate the time of pilocarpine injections. The time interval between the two injections was approximately 2 hr. Key: top right, cat No. 192-66; top left, cat No. 162-66; bottom right, cat No. 233-66; bottom left, cat No. 198-66.

control. Sweating was induced by the administration of pilocarpine hydrochloride (0.1 mg./Kg.) *via* a jugular vein previously cannulated with P.E. 50 tubing.

The duration of action produced by various substances can also be determined using this method simply by increasing the length of time between application and the injections of pilocarpine.

RESULTS

Figure 4 shows the sweating responses obtained in four cats following the intravenous administration of pilocarpine. In control experiments, the difference in sweating response between the two paws never varied more than 4 to 5%. This small difference made it possible to determine the effect of various substances, when applied topically, on the sweating response. The response to pilocarpine in the majority of tests has been consistent and reproducible over a period of about 5 to 6 hr. Whenever the time has been extended to 8 and 10 hr., the pilocarpine response may be diminished. This diminution in the response may be noted even though the body fluid lost through sweating and salivation is replaced during the entire experiment by the intravenous infusion of normal saline.

To illustrate that the system is capable of detecting differences in sweating rates, the effects of a commercially available aluminum salt preparation,[1] applied as previously described, are shown in Fig. 5. The aluminum salt preparation was applied 3–5 hr. prior to the injections of pilocarpine. It can be seen that the maximum relative humidity provided by the control paw was between 30 and 36%, whereas the treated paw showed values of between 12 and 15% following two injections of pilocarpine. Upon further extending the time between application and the injection of pilocarpine, the effect was greatly diminished or could no longer be demonstrated.

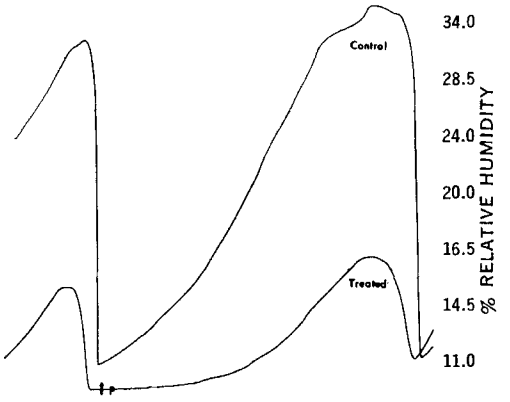

Fig. 5—The sweating response obtained after the local application to one foot pad of a commercial aluminum salt preparation 3–5 hr. prior to pilocarpine. The graph reads from right to left. The arrows indicate the time of the pilocarpine injections (0.1 mg./Kg. i.v.). Time interval between pilocarpine injections was approximately 2.5 hr. (cat No. 250-66.)

DISCUSSION

There have been few methods reported in the literature suitable for the rapid evaluation of pharmacological substances on sweating in laboratory animals. The adapted method of resistance hygrometry reported in this study makes it practical to investigate a relatively large number of such substances in anesthetized cats. The same general method has also been used in this laboratory to study the sweating response in dogs. The duration of the antihidrotic effects of a substance may be easily determined simply by varying the time between application and the injections of pilocarpine.

The choice of the anesthetic agent used is important in sweating rate studies involving cats. The longer-acting barbiturates are the most desirable since additional drug is usually avoided during the experiment. In most experiments involving the use of supplemental doses of a shorter-acting agent, there was an initial increase in the sweating response. The reason for the increased sweating rate following barbiturate administration is not clearly understood.

The sweating rate measuring system described is readily adaptable for the measurement of sweating produced under a variety of environmental conditions. Finger tip sweating in man has also been determined by this method.

Effect of Diester Type Plasticizers on the Differential Thermal Spectrum of a Polyvinyl Chloride System

By R. K. O'LEARY, J. FOY, W. L. GUESS, and J. AUTIAN

One of the most successful formulated plastics for medical and paramedical applications is the polyvinyl chloride (PVC) family. A variety of excellent properties is possible by incorporating other agents such as plasticizers into PVC. Plasticized systems are currently being used for flexible tubings, blood bags, various types of catheters, and protective materials. Because of the lack of published information on the effects of plasticizers on the thermal spectra of PVC and the paucity of data on this polymer using differential thermal analysis, a study was initiated to note what effects a group of plasticizers would have on the thermal behavior of formulated PVC systems. A group of diester plasticizers was used to note how each member of the series would influence the depolymerization process. Results of this study suggest a method of predicting whether a plasticizer will increase or decrease the tendency of the polymer to degrade.

THE RAPID increase in the use of polymeric materials to replace glass, rubber, and metals is very evident by observing the multitude of plastic products now in use in medicine and paramedical applications. Advancements in plastic technology have brought forth certain polymeric materials which require the introduction of an appreciable quantity of plasticizers to impart specific desired physicochemical and mechanical properties. Polyvinyl chloride, cellulose acetate, polyvinyl acetate, and nitrocellulose are a few examples of plastic materials which may contain one or more plasticizers.

In medical practice the plasticized polyvinyl chloride (PVC) has been and is currently being used widely for the construction of blood bags, tubings, devices for the administration of drug products, as collection devices for body fluids, and as storage containers for one or more products. This widespread acceptance of PVC has required much scrutiny in selecting plasticizers which will produce the desired processing and performance characteristics in the finished medical product. It is also understood that the plasticizers should be nontoxic when used for a medical application which might have contact with tissue or with a product to be administered to a patient (1, 2).

The addition of a plasticizer to polyvinyl chloride reduces the glass transition temperature (T_g) and thereby imparts various degrees of softness and flexibility. Since polyvinyl chloride materials must also contain a stabilizer to prevent or hinder degradation of the material during processing, it was felt that the various plasticizers might have different effects on influencing the stability of the plastic when thermal conditions are imposed. Few reports of a quantitative nature, however, have appeared in the literature in regard to the role of the plasticizer as a stabilizing agent in polyvinyl chloride. For this reason a study was undertaken to assess the relative heat stabilizing properties of a group of plasticizers on polyvinyl chloride when exposed to thermal treatments using differential thermal analysis (DTA).

EXPERIMENTAL

Materials and Apparatus—(*a*) Polyvinyl chloride.[1]

(*b*) Plasticizers: dimethyl phthalate, dibutyl phthalate, dioctyl phthalate, ditridecyl phthalate (W. R. Grace & Co., Hatco Chemical Division, Fords, N. J.), dioctyl adipate, didecyl adipate (Eastman Chemical Products, Inc., Kingsport, Tenn.), dihexyl azelate, dioctyl azelate (Emery Industries, Inc., Cincinnati, Ohio), dibutyl sebacate, dioctyl sebacate (Reichhold Chemical Co., Deecy Products Division, Cambridge, Mass.), dibenzyl sebacate, dibutyl suberate, dibutyl dodecanedioate (Wallace & Tiernan, Inc., Harchem Division, Belleville, N. J.), trioctyl trimellitate (Rubber Corporation of America, Hicksville, N. Y.), and trioctyl phosphate (Monsanto Co., St. Louis, Mo.).

(*c*) Stabilizer: a barium-cadmium carboxylate type stabilizer.[2]

(*d*) Polyvinyl chloride films: the films of the polymer are prepared by the plastisol fusion technique, *i.e.*, a colloidal dispersion of a high molecular weight vinyl chloride resin in the desired plasticizer is heated until all the plasticizer in the liquid phase is absorbed into a fused polymer. The loss of separate phases and interfacial boundaries produces a translucent plastic with a high tensile strength.

[2] Advastab BC-100 S-1, Advance Division, Carlisle Chemical Works, Inc., New Brunswick, N. J.

The formulation used in this study was: 100 Gm. PVC, 60 Gm. plasticizer, and 1.5 Gm. stabilizer.

The particular PCV[1] was chosen because its molecular weight is high enough to prohibit undue solvation by the plasticizer at normal temperatures, though assuring proper solvation at increased temperatures. Lower molecular weight resins were avoided because they are solvated at room temperatures such that the swelling resin particles raise the volume concentration of solid phase and the plastisol becomes an unworkable plastigel. The barium-cadmium carboxylate type was chosen as the stabilizer system for this study because it provides excellent heat and light stabilization in closed mold plastisol processing. Prior to molding the formulation, the plasticizer and stabilizer were placed in a Hobart model K45 mixer,[3] and the vinyl chloride resin added slowly until a uniform dispersion was produced (approximately 45 min. to 1 hr.). The formulations were stored for 24 hr. to achieve partial deaeration and then poured into preheated (165°) 40-mil thick molds and processed on a Dake press model 44–325[4] for 3.5 min. at 35,000 lb. pressure. The molds were then cooled to 120° and the films removed. All the formulations were conditioned 48 hr. at 22° and 50% relative humidity.

(*e*) Differential thermal analysis apparatus: the apparatus consists of a controlled atmosphere differential thermal analyzer with a quick cool furnace model F-1DF and two L&N Speedomax H strip chart recorders. This instrument is manufactured and described by Robert L. Stone Co., Austin, Tex. (3, 4).

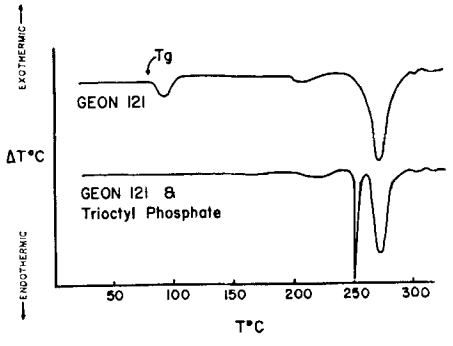

Fig. 1—DTA thermograms of plasticized and unplasticized polyvinyl chloride.

Effect of a Group of Plasticizers on the Dehydrohalogenation of PVC—One-milligram samples of each of the PVC formulas were run in the differential thermal analysis apparatus at a heating rate of 6.0°/min., using highly calcined, 80 mesh Al_2O_3 as the inert reference. Nitrogen was used as the dynamic gas in order that purely thermal effects might be distinguished from the oxidative transitions which will occur in an air atmosphere. In each instance four determinations were made for each plastic formula to insure the reliability of the results. Figure 1 illustrates the thermograms for an unplasticized PVC and for a plasticized PVC (trioctyl phosphate). As may be noted from the unplasticized PVC, a main glass transition temperature is apparent at 86.0° and a small depolymerization temperature occurs at 200.6°. No glass transition temperatures were noted for the plasticized resins in the temperature range studied (ambient to 300°). Figure 1 also reveals that in the plasticized PVC, the plasticizer (trioctyl phosphate) apparently "boils" off the plastic immediately prior to the dehydrohalogenation. None of the other plasticized resins followed this trend.

From each of the thermograms, the following information was derived: (*a*) the temperature of onset of dehydrohalogenation, (*b*) the peak temperature of dehydrohalogenation, and (*c*) the area under the curve corresponding to the dehydrohalogenation reaction. This area was then utilized to calculate the heat of dehydrohalogenation ($\Delta H°$) in a manner described in a previous report (5). Table I includes the onset and peak temperatures for all of the plastic formulas as well as the calculated heats of dehydrohalogenation.

In all experiments actual weights of the plastic samples were determined after dehydrohalogenation had occurred, and from this information it was possible to calculate the percentage weight loss included in Table I.

DISCUSSION

As has been indicated, the plasticized polyvinyl chlorides, at least in the temperature range studied, did not reveal any glass transition temperatures as the pure polymer did. In these cases, however, it may be assumed that the T_g values were present but occurred below ambient temperature or if they did occur above ambient temperature, they may not have been detected by the instrument.

A review of the results in Table I clearly reveals that the structure of the plasticizer can play a very important role in helping to stabilize the PVC resin. In the phthalate ester series, an increase in stability can be noted as the molecular weight of the plasticizer is increased. The most "protective" phthalate ester, and in fact the most protective plasticizer in the whole series, was the ditridecyl phthalate which had peak temperatures for dehydrohalogenation of 289.2° and a heat of dehydrohalogenation of 26.9 Kcal./mole, a value of 7 to 8 times that of the other phthalate esters and considerably higher than the $\Delta H°$ for any of the other plasticizers. Dibenzyl sebacate and trioctyl trimellitate had also high heats of dehydrohalogenations, 15.6 Kcal./mole and 20.6 Kcal./mole, respectively. Generally, these high heats of dehydrohalogenations indicate that greater stability is afforded the PVC resins when these are subjected to high processing temperatures. However, in the case of the dibenzyl sebacate there appeared to be an anomalous situation where the actual temperature for onset of dehydrohalogenation was depressed to a slight extent as compared to the other plasticized systems having high $\Delta H°$ values. Exact reasons for this depression are still not known.

It may be noted from the table that most of the plasticizers increase the temperature where dehydrohalogenation takes place, but for the most part once this temperature is reached, less energy ($\Delta H°$) is needed to bring about complete dehydrohalogenation.

The results of this study appear to demonstrate that higher molecular weight plasticizers have a

[a] Onset temperature at which dehydrohalogenation takes place. [b] Peak temperature at which dehydrohalogenation takes place.

greater protective effect than the lower ones and that an increase in the hydrophobic moiety of the plasticizers plays an important role in the protective mechanism afforded to the PVC.

The use of differential thermal analysis for the evaluation of a group of plasticizers in regard to their protective effects under purely thermal conditions reveals that this technique can give considerable information in a relatively short period of time which should be helpful when a new plasticizer is to be considered for a polyvinyl chloride formula.

Application of 1-(*N*-β-Hydroxyethyl-4-piperidyl)-3-(4-piperidyl)-propane in the Mannich Reaction I

Substituted β-Aminoketones

By RAJENDRA S. VARMA and W. LEWIS NOBLES

The Mannich reaction has been successfully performed using 1-(*N*-β-hydroxyethyl-4-piperidyl)-3-(4-piperidyl)propane (4-DI-PIP-OL). A series of Mannich bases has been prepared employing 4-DI-PIP-OL and various ketones. Characteristic infrared absorption bands for OH, $\overset{+}{N}H$, $-\overset{O}{\overset{\|}{C}}-$ groups are recorded. The compounds are to be screened for possible pharmacological activity.

MANNICH BASES have been prepared (1–25) for pharmacological testing as antispasmodics, analgesics, local anesthetics, or chemotherapeutic agents. Such compounds are usually prepared by the condensation of formaldehyde (paraformaldehyde) with ammonia, a primary or secondary amine, and a compound containing at least one active hydrogen atom. The condensation reaction may be illustrated as in Scheme I.

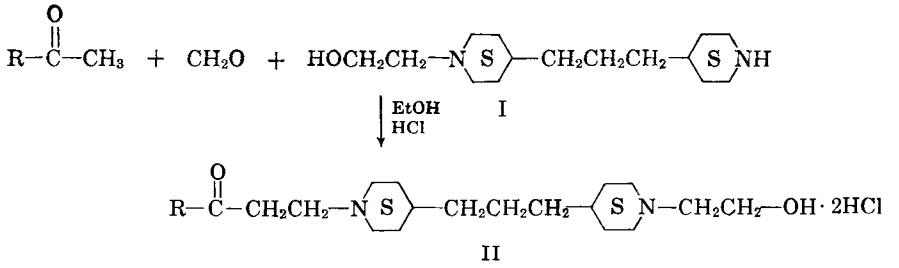

Scheme I

Mannich and Lammering (2) reported that β-piperidinopropiophenone hydrochloride possessed local anesthetic activity. Blicke and Blake (3) found that the corresponding Mannich base from 2-acetylpyrrole possessed marked activity of this type. Levvy and Nisbet (5) indicated that both piperidino and dimethylamino Mannich bases derived from 2-acetylthiophene demonstrated local anesthetic activity. Denton and his associates (6, 7) described the preparation and pharmacological evaluation of various β-dialkylaminopropiophenones and their derivatives. Many of these proved to be effective antispasmodics. Certain Mannich bases derived from α,β-unsaturated ketones have exhibited antibacterial activity (20). Many compounds prepared heretofore have possessed an alkylamino, dialkylamino, or azabicyclo amine as the amine moiety as well as a number of nitrogen heterocycles of various sizes. In this communication the Mannich reaction has been extended to include 4-DI-PIP-OL, a novel secondary amine. Recently it has been reported (26) that 1-(4-pyridyl)-3-(piperidyl)propane derivatives demonstrate anticonvulsant, antiparkinsonian, and antidepressant properties. In view of this and the multiplicity of pharmacological effects elicited by numerous ketonic Mannich bases, we have prepared a number of β-aminoketones of general structure II.

In a preliminary screening, compound *21* (Table I) has shown activity against both Gram-positive and Gram-negative bacteria. The detailed screening results will be published at a later date.

EXPERIMENTAL

Melting points were taken in capillary tubes on a Thomas-Hoover melting point apparatus and are uncorrected. Infrared spectra were recorded on a Perkin-Elmer model 137 spectrophotometer using a Nujol mull.

1 - (N - β - Hydroxyethyl - 4 - piperidyl) - 3 - (4-piperidyl)propane Dihydrochloride—4-DI-PIP-OL, 25.4 Gm. (0.1 mole), was suspended in 25 ml. of ethanol. Concentrated hydrochloric acid (21 ml.) was added to it in small portions with cooling and shaking. After the additions were completed, some ethanol was distilled off under vacuum and 100 ml. of acetone was added to it. On refrigeration, there was obtained the desired dihydrochloride in nearly quantitative yield, which was recrystallized to analytical purity from ethanol–acetone, m.p. 205°.

Anal.—Calcd. for $C_{15}H_{32}Cl_2N_2O$: C, 55.04; H, 9.86; N, 8.56. Found: C, 54.76; H, 9.73; N, 8.58.

N,N′ - Methylenebis[1 - (N - β - hydroxyethyl-4 - piperidyl) - 3 - (4 - piperidyl)propane] Tetrahydrochloride—To a mixture of 10.16 Gm. of 4-DI-PIP-OL, 20 ml. of ethanol, and 8.4 ml. of concentrated hydrochloric acid was added 1.2 Gm. of paraformaldehyde and the resulting reaction mixture was heated under reflux for 4 hr. At the end of this period, the reaction mixture was cooled and poured into 100 ml. of acetone. The entire mass, on refrigeration overnight, gave a viscous liquid on decantation of the upper layer of solvents. This liquid was dissolved in 20 ml. of ethanol; 50 ml. of acetone was then added. This treatment gave a white solid which was subsequently recrystallized to analytical purity from ethanol–acetone, m.p. 181–185° (softens at 75°); yield, 9.5 Gm. (71%).

Anal.—Calcd. for $C_{31}H_{64}Cl_4N_4O_2$: C, 55.84; H, 9.68; N, 8.40. Found: C, 55.49, 55.61; H, 10.25, 10.15; N, 8.32.

Mol. wt. (Rast method)—Calcd. for $C_{31}H_{64}Cl_4N_4O_2$: 666.69. Found: 692.

Mannich Base Dihydrochlorides—Three general methods were employed to synthesize these compounds.

Procedure A—The aminoketones were prepared by the general procedure of refluxing 0.1 mole of the ketone with 0.1 mole of 4-DI-PIP-OL dihydrochloride and 4.5 Gm. of paraformaldehyde in 25 ml. of absolute ethanol containing 1 or 2 drops of concentrated hydrochloric acid for 15 min. Another 1.5 Gm. of paraformaldehyde was added and refluxing continued for 2 hr. At the end of this time the warm solution was poured into 50 ml. of acetone and the contents refrigerated overnight. The solid thus obtained was recrystallized from ethanol–acetone.

Procedure B—To a suspension of 0.1 mole of 4-DI-PIP-OL in 25 ml. of ethanol was added 21 ml. of concentrated hydrochloric acid in small portions with cooling and shaking. Four and five tenths grams of paraformaldehyde was then introduced into the reaction vessel followed by the appropriate ketone. The resulting reaction mixture was refluxed for 3–5 hr. During this time the entire mixture went into solution. In a few cases, an amorphous solid product separated out at the end of this period. The contents were then poured into 50 ml. of acetone and refrigerated overnight or until a solid product separated. The product was removed by filtration and recrystallized from ethanol–acetone.

Procedure C—This method is similar to that of *B* except that aqueous 37% formaldehyde solution is used in place of paraformaldehyde.

Attempted Mannich Condensation Using Methylenebis-1-(N-β-Hydroxyethyl-4-piperidyl)-3-(4-piperidyl)propane Tetrahydrochloride—Equimolar proportions of *p*-chloroacetophenone and methylenebis amine salt were refluxed in 25 ml. of ethanol for 4 hr. Working up the reaction mixture gave only unreacted methylenebis amine salt.

Infrared Spectra of the β-Aminoketone Dihydrochlorides—Spectra of these compounds have been run in Nujol mull. In Table II are recorded absorption bands for OH, $\overset{+}{N}H$, and $-\overset{O}{\overset{\|}{C}}-$ groups. Thompson and associates (27) have reported absorption spectra of a number of tertiary amine salts and our observations are in agreement with them. Mannich bases may be regarded as tertiary amines and they do give bands due to $\overset{+}{N}H$. The $\overset{+}{N}H$ peak is usually broad and falls in the range of 2700–2326 cm.$^{-1}$.

DISCUSSION

4-DI-PIP-OL was converted to the dihydrochloride salt and condensed with various substituted ketones and formaldehyde. The source of formaldehyde was either paraformaldehyde or 37% aqueous formaldehyde solution. Attempts to prepare the Mannich bases using sym-trioxane were not successful. In most cases the condensation reaction was successful, and the products were easily isolated. In few cases, however, difficulty was encountered in

obtaining a pure sample. It was observed that some of the β-aminoketone hydrochlorides were very hygroscopic in the crude state, but this characteristic diminishes when the product is pure. All compounds were purified by crystallization from ethanol–acetone; some Mannich bases were not very soluble in ethanol; therefore, a few drops of water were added to facilitate dissolution. The yields were relatively low for most of the products obtained. Low yields may be attributed to the complexity of the products which arise in the Mannich reaction. Attempts to prepare Mannich bases using 3-acetylindole, 2-acetylpyridine, and 3-acetylpyridine were not successful.

It has been shown by Henry (28) that the reaction of two equivalents of an aliphatic amine with one equivalent of formaldehyde produces the methylenediamine. The work by Ingwalson (29) in attempts to prepare the Mannich base with *N*-phenylpiperazine, formaldehyde, and 2-nitropropane led to the conclusion that the only product of the reaction was bis-(*N*-phenylpiperazyl)-methane, as the properties of the product correspond with those reported by Prelog and Blazek (30). In our hands while attempting to prepare Mannich base from indanedione, formaldehyde, and 3-azabicyclononane hydrochloride, methylenebis (azabicyclononane) dihydrochloride was isolated and the expected Mannich base did not form (31). It is known (32–34) that methylenebis amines react with compounds possessing active hydrogens to produce normal Mannich bases. The authors have prepared the methylenebis amine salt of 4-DI-PIP-OL and attempted the condensation of it with 4-chloroacetophenone, but without success.

SUMMARY

Twenty-one β-aminoketone dihydrochlorides have been synthesized utilizing 4-DI-PIP-OL as a secondary amine and several substituted ketones as active hydrogen components under Mannich conditions for biological screening. Characteristic infrared absorption bands for OH, $\overset{+}{N}H$, and carbonyl groups are described.

Comparison of an Ultraviolet Spectrophotometric Assay and a Gas-Liquid Chromatographic Assay for 17α-Ethynylestradiol 3-Methyl Ether in Tablets

By ARVIN P. SHROFF and JOSEPH GRODSKY

Ultraviolet spectrophotometric and gas-liquid chromatographic methods for the analysis of tablets containing 17α-ethynylestradiol 3-methyl ether and 17α-ethynyl-19-nortestosterone have been developed. The results obtained by the two methods are compared. The gas-liquid chromatographic method is found to be superior to the ultraviolet method, especially on aged tablets. A complex from tablet excipients was found to interfere with the ultraviolet method and was identified by gas-liquid chromatography.

MORE THAN 5 million women in the U. S. and about 2 million women overseas are now using oral contraceptives. These oral contraceptives are composed of estrogen–progestin mixtures. Of the seven U. S. companies which offer 11 different dosage forms, eight forms contain the estrogen, 17α-ethynylestradiol 3-methyl ether (mestranol). This paper describes the development of ultraviolet spectrophotometric and gas-liquid chromatographic methods for the analysis of mestranol in tablets containing the estrogen and norethindrone and gives the results so obtained.

The steroidal estrogens, having the characteristic phenolic A-ring, have been quantitatively assayed by utilizing the well-known Kober reaction or various modifications thereof (1–4). Colorimetric determinations (5–11) based on the coupling of the phenolic hydroxyl group with diazotized amines and spectrofluorometric methods (12–14) have been reported for a number of estrogens. All these methods, though sensitive, lack to some degree the specificity required in the presence of other steroids and tablet excipients for a rapid and accurate analytical method.

Recently, a number of other methods have been employed including ion exchange (15) and paper chromatography (16). The inaccuracy of the latter method has been discussed by Schulz (17).

Klein and co-workers (18) have described the quantitative analysis of ethynylestradiol and methyltestosterone by ultraviolet spectrophotometry. Ethynylestradiol and mestranol have also been quantitatively determined by gas-liquid chromatography (17, 19, 20). The authors failed to duplicate the mestranol determination by GLC using the reported (17) parameters since the mestranol always decomposed in part to estrone methyl ether, thus making quantitation impossible.

This investigation describes an ultraviolet spectrophotometric assay and a gas-liquid chromatographic assay for mestranol. Both assays are performed in the presence of 17α-ethynyl-19-nortestosterone (norethindrone). In the GLC determination an XE-60 coated column and an internal standard was used. The steroids do not undergo any decomposition and can be separated without prior acylation or trimethylsilyl ether formation. Practical separation (by GLC) of steroids and a nonsteroidal substance having an U.V. interfering chromophore has also been achieved. The advantages and disadvantages of the two assay methods are also discussed.

EXPERIMENTAL

U.V. Assay Procedure

Apparatus—A Beckman model DU spectrophotometer with 1-cm. cells and a Cary recording spectrophotometer model 11.

Mestranol Standard Solution—Five milligrams of mestranol was accurately weighed into a 100-ml. volumetric flask and diluted to mark with spectral grade methylcyclohexane.

Method of Analysis for Standard Mestranol—The absorbance (at slit width 0.15 mm.) of the standard mestranol solution against spectral grade methylcyclohexane was measured at 316, 302, 287.7, and 278 mμ. The absorbance at 316 and 302 mμ was zero and the exact wavelengths of the peaks at 287.7 and 278 mμ were determined and their absorbance measured. The absorptivity (a) and the ratio of the two peaks (R) were calculated as follows:

$$a = \frac{A_{287.7} \times 100 \text{ ml.}}{\text{wt. in mg.}} \qquad R = \frac{A_{278}}{A_{287.7}}$$

Method of Analysis for Mestranol-Containing Tablets—A number of tablets containing about 200 mcg. of mestranol was put into a 29.5 × 80-mm. vial and treated with 4.0 ml. of water and 4.0 ml. of methylcyclohexane. The vial was shaken on a Burrell wrist-action shaker for 15–30 min. The mixture was centrifuged and a portion of the clear upper layer was transferred to a 1-cm. cell. The absorb-

Received August 24, 1966, from the Division of Organic Chemistry, Ortho Research Foundation, Raritan, NJ 08869
Accepted for publication January 18, 1967.
The authors thank Dr. I. Scheer for interest and encouragement and Mr. H. Barth, Quality Control Department, for technical assistance in obtaining ultraviolet analyses.

ance (at slit width 0.15 mm.) was read for the sample against spectral grade methylcyclohexane at 316, 302, 287.7, and 278 mμ. Two methods of calculation were used as follows: (*a*) algebraically, a straight line was extended through 316 and 302 mμ and the peak height at 287.7 mμ was measured from this base line. The micrograms of mestranol per tablet was calculated by the following formula (see Eq. 2 for the algebraic derivation)

$$[A^{\text{obs.}}_{287.7} - 2A_{302} + A^{\text{obs.}}_{316}] \times \frac{4.0 \text{ ml.} \times 1000}{a \times \text{No. of tablets}}$$

(*b*) Algebraically, a straight line was drawn from 302 mμ at a slope to make the ratio of A_{278} and $A_{287.7}$ parallel to the ratio R determined in the standard mestranol curve. The micrograms of mestranol per tablet was calculated by the following formula (see Eq. 11 for the algebraic derivation):

$$\frac{0.714}{1.714 - R}\,[2.4A^{\text{obs.}}_{287.7} - 1.4A^{\text{obs.}}_{278} - A^{\text{obs.}}_{302}] \times \frac{4.0 \text{ ml.} \times 1000}{a \times \text{No. of tablets}}$$

The average of the two values was used. If the difference between the two values was greater than 0.006%, then it was presumed that there was too much extraneous base line absorption and another assay was used.

GLC Assay Procedure

Instrument—F and M model 1609 with modified injection port. The modified injection port was made by F and M Scientific, Avondale, Pa., to eliminate the potential for inlet sample splitting and thus create less dead volume.

Column—A stainless steel column 21 × 1/4 in. i.d., packed with coated support, was employed.

Liquid Phase—A silicone gum nitrile (*e.g.*, F and M Scientific Corp. No. LP 125, designated as XE-60) was used.

Inert Support—Untreated siliconized diatomaceous earth[1] was suitable as support material. The column packing was prepared by coating the inert support with 4% XE-60 using distilled acetone as the solvent for the application of the liquid phase.

Column Conditioning—The stainless steel packed column was conditioned by passing nitrogen carrier gas for about 12–18 hr. at a rate of 72 ml./min. at a column temperature of 240°.

Instrumental Parameters—In the development of the analytical method a column temperature of 195°, inlet port temperature of 242°, and a detector temperature of about 300° were used. The flow rate was between 70–75 ml./min. for the carrier gas, nitrogen.

Mestranol Standard—Throughout this work commercial mestranol was used which has an *a*-value at 278 mμ of 6.5, in distilled ethyl alcohol.

Internal Standard—Throughout this work, estrone U.S.P. XVI was used.

Preparation of Column Packing—In a 500-ml. round-bottom flask, place 1 Gm. of XE-60 dissolved in 100 ml. of acetone. To this add 25.0 Gm. of untreated siliconized diatomaceous earth 60/80 mesh (F and M Scientific Corp. No. ST120) and evaporate the solvent under reduced pressure (preferably a rotary flash evaporator). Heat the powder on a water bath for about 2 hr. Collect the material which falls off with gentle tapping. The yield is about 24 Gm.

[1] Diatoport-S.

Standard Mestranol Solution—Weigh accurately about 25.0 mg. of reference standard mestranol in a 50-ml. volumetric flask and dilute to mark with ethyl alcohol.

Standard Estrone Solution—Place exactly 50.0 mg. of estrone U.S.P. XVI in a 50-ml. volumetric flask and dilute to mark with ethyl alcohol.

Preparation of a Typical Standard Curve—Pipet into three different vials exactly 1.0 ml. of the standard estrone solution. Evaporate to dryness over a steam bath and under a stream of nitrogen. To each vial add 0.80 ml. (about 400 mcg.), 1.0 ml. (about 500 mcg.), and 1.2 ml. (about 600 mcg.) of standard mestranol solution, respectively. Evaporate once again to dryness over a steam bath and under a stream of nitrogen. Dissolve each residue in 0.5 ml. of distilled acetone. Inject separately 6–7 μl. of each sample in the GC and adjust the attenuator to 320. Elute for at least 1 hr. Measure the areas of the two peaks separately after drawing a base line tangent to both minima of each peak. The area is obtained by multiplying the height of the peak by the width at one-half the peak height. The major peak close to the solvent front corresponds to mestranol and the one farthest away corresponds to estrone. A standard curve is obtained by plotting the ratio of the areas under mestranol and estrone *versus* the weight of mestranol and drawing the best straight line.

Analysis of Tablets—Place a number of tablets equivalent to about 1,000 mcg. of mestranol in a 29.5 × 80-mm. vial. To this add 10 ml. of distilled water and 10 ml. of methylcyclohexane (spectroquality reagent) by means of a pipet. Clamp the vial to a Burrel wrist-action type shaker and shake vigorously for 0.5 hr. and then centrifuge for 2 min. Pipet 5.0 ml. of the supernatant solution into a 21 × 50-mm. vial and evaporate to dryness over a steam bath and a stream of nitrogen. Add exactly 1.0 ml. of the standard estrone solution and once again evaporate as above. Treat this residue with 0.5 ml. of acetone and inject (6–7 μl.) into the GC. The attenuator is adjusted to 320. After at least 1 hr. the areas corresponding to the peaks of mestranol and estrone are calculated as indicated previously. (*Note:* There is an additional major peak due to norethindrone which appears between mestranol and estrone.) Using the ratio of these areas (mestranol/estrone) on the standard curve, find the amount of mestranol.

ALGEBRAIC DERIVATION FOR U.V. CALCULATIONS

Figure 1 represents an ultraviolet spectrum of norethindrone and Figs. 2 and 3 represent typical expanded scale spectra of mestranol. The algebraically extended lines in Figs. 2 and 3 are hypothetically magnified to explain the derivation for the two formulas used in mestranol calculation.

According to Fig. 2:

$$A^{\text{corr.}}_{287.7} = A^{\text{obs.}}_{287.7} - \text{PN} - A^{\text{obs.}}_{302} \qquad \text{(Eq. 1)}$$

Since triangle MPN = Δ302M316

$$\text{PN} = A^{\text{obs.}}_{302} - A^{\text{obs.}}_{316}$$

therefore,

$$A^{corr.}_{287.7} = A^{obs.}_{287.7} - 2A^{obs.}_{302} + A^{obs.}_{316} \quad \text{(Eq. 2)}$$

In Fig. 3:

$$A^{corr.}_{287.7} = A^{obs.}_{287.7} - X - A^{obs.}_{302} \quad \text{(Eq. 3)}$$

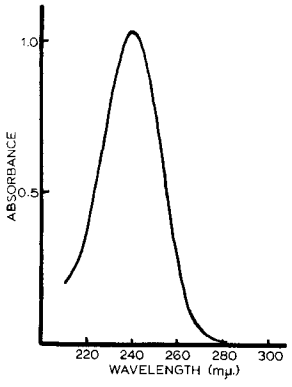

Fig. 1—U.V. absorption spectrum of norethindrone.

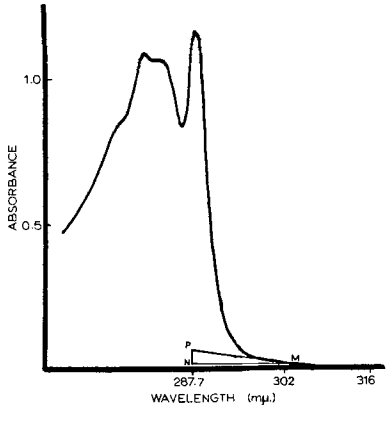

Fig. 2—U.V. spectrum of mestranol shown with the base line correction for Eq. 2.

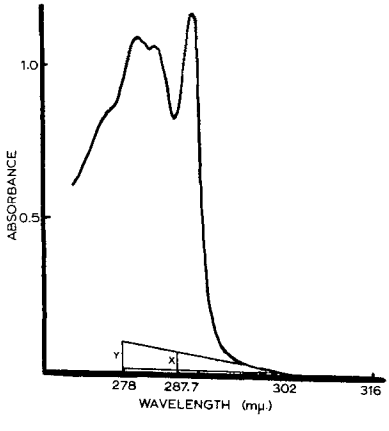

Fig. 3—U.V. spectrum of mestranol shown with base line correction for Eq. 11.

and

$$A^{corr.}_{278} = A^{obs.}_{278} - Y - A^{obs.}_{302} \quad \text{(Eq. 4)}$$

where

$$Y = \frac{302\ m\mu - 278\ m\mu}{302\ m\mu - 288\ m\mu} \times X \text{ (similar triangles)}$$

or

$$Y = 1.714\ x$$

Also Eq. 4 is equal to:

$$RA^{obs.}_{287.7} - RX - RA^{obs.}_{302} \quad \text{(Eq. 5)}$$

where R is the ratio of $A^{corr.}_{278}$ to $A^{corr.}_{287.7}$ and is obtained from a standard curve. By substituting the value of Y in Eq. 5 one obtains:

$$A^{obs.}_{278} - 1.714x - A^{obs.}_{302} = RA^{obs.}_{287.7} - RX - RA^{obs.}_{302} \quad \text{(Eq. 6)}$$

or

$$(1.714 - R)X = A^{obs.}_{278} - RA^{obs.}_{287.7} - A^{obs.}_{302} + RA^{obs}_{302}$$

and

$$X = \frac{A^{obs.}_{278} - RA^{obs.}_{287.7} - A^{obs.}_{302} + RA^{obs.}_{302}}{1.714 - R}$$

Substituting the value of X in Eq. 3 gives:

$$A^{corr.}_{287.7} = A^{obs.}_{287.7} - \left\{\frac{A^{obs.}_{278} + RA^{obs.}_{287.7} + A^{obs.}_{302} - RA^{obs.}_{302}}{1.714 - R}\right\} - A^{obs.}_{302} \quad \text{(Eq. 7)}$$

Multiplying Eq. 7 by $(1.714 - R)$ gives:

$$(1.714 - R)A^{corr.}_{287.7} = 1.714^{obs.}_{287.7} - RA^{obs.}_{287.7} - 1.714A^{obs.}_{302} + RA^{obs.}_{302} - A^{obs.}_{278} + RA^{obs.}_{287.7} + A^{obs.}_{302} + RA^{obs.}_{302} \quad \text{(Eq. 8)}$$

Solving Eq. 8 gives:

$$(1.714 - R)A^{corr.}_{287.7} = 1.714A^{obs.}_{287.7} - 0.714A^{obs.}_{302} - A^{obs.}_{278} \quad \text{(Eq. 9)}$$

Dividing Eq. 9 by (0.714) gives:

$$\left(\frac{1.714 - R}{0.714}\right)A^{corr.}_{287.7} = 2.4A^{obs.}_{287.7} - 1.4A^{obs.}_{278} - A^{obs.}_{302} \quad \text{(Eq. 10)}$$

or

$$A^{corr.}_{287.7} = \frac{0.714}{1.714 - R}\left[2.4A^{obs.}_{287.7} - 1.4A^{obs.}_{278} - A^{obs.}_{302}\right] \quad \text{(Eq. 11)}$$

RESULTS AND DISCUSSION

Tables I through IV summarize the data obtained in determining the accuracy, precision, and standard deviation for the ultraviolet spectrophotometric and gas-liquid chromatographic methods. The data indicate that both methods are in excellent agreement and can be used for routine assays. Therefore, several samples of formulation, prepared for clinical study, were subjected to the improved extraction procedure and analyzed by these two methods. The excipients of these formulated tablets consisted of lactose, cornstarch, magnesium stearate, and polyvinylpyrrolidone.

The results of the ultraviolet assay on tablets stored under various conditions are listed in Table V. The ultraviolet assay data on the original granulations included in the table agree with the theoretical amount of mestranol added. It is evident from the results that, on storage, there is an apparent decrease in mestranol content. This decrease could be either the result of an incomplete extraction or partial mestranol degradation or to extraneous material which gives a faulty algebraic base line. The latter enters into the calculation and could be responsible for low results.

To determine if mestranol was incompletely extracted or was partially degraded the gas-liquid chromatographic technique was used. Both pure and extracted mestranol showed no decomposition on the 4% XE-60 column. The tablets from the same lot used in the U.V. assay were subjected to the extraction procedure and analysis. The analysis by GLC was carried out using an internal standard technique. The data are summarized in Table VI. It is evident from the results that mestranol does not undergo any decomposition on storage, and that complete extraction was achieved.

The question of extraneous material being extracted from the tablets was also answered by the GLC technique. During the different GLC assays on aged tablets prominent unidentified peaks near the solvent front (Fig. 4) were noticed. These were negligible with fresh tablets. It had also been established that these peaks were not the normal degradation products of mestranol, norethindrone, and estrone. Working with the excipients of the tablets, these peaks were later identified as being generated from a complex formed between polyvinylpyrrolidone and magnesium stearate. This complex has an absorption in the ultraviolet which distorts the base line and invalidates both correction factors. The low results obtained in Table V are thus attributed to these base line distortions.

A comparison of the two methods suggests that the ultraviolet assay is not reliable for aged tablets because of the interfering chromophore. However, it is quite suitable for fresh tablets. The GLC assay is sensitive for both fresh and aged tablets. An additional advantage of the GLC technique is that it offers quantitation concurrently with fractionation, the latter being important in aged tablets. In conclusion, this study points out that mestranol does not undergo any degradation at various storage conditions.

TABLE I—ACCURACY OF THE U.V. METHOD OF ANALYSIS[a]

No.	Mestranol Added, mcg.	Mestranol Recovered,[b] mcg.	% Recovery
1	198.8	193.5	97.3
2	198.8	192.5	96.8
3	198.8	193.0	97.1
4	198.8	193.5	97.3
5	198.8	202.5	102.0

[a] $\bar{X}$ = 98.1%; σ = ±2.2%. [b] Average of two calculations.

SUMMARY

1. Ultraviolet spectrophotometric and gas-liquid chromatographic assay methods are described and compared.

2. The gas-liquid chromatographic assay method is shown to be sensitive for mestranol in both fresh and aged tablets.

3. A complex between polyvinylpyrrolidone and magnesium stearate is identified by GLC.

4. Mestranol does not undergo any decomposition when stored under various conditions.

Diffusion of Drugs Across the Isolated Mesentery

By LATIF S. SHENOUDA* and ALBERT M. MATTOCKS†

In order to obtain knowledge of the diffusion rates of pentobarbital, salicylic acid, and urea across the peritoneal membrane under ideal conditions, experiments with isolated rabbit mesentery were conducted. Diffusion coefficients of the drugs were applied to evaluate rates of dialysis at various conditions of pH. Pentobarbital and salicylic acid diffused across the isolated mesentery in both ionic and nonionic form, with no significant difference in rate due to pH. *In vivo* tests also make it appear that the ionized form of drugs may diffuse across the peritoneal membrane. These results suggest that the research for agents to promote dialysis should include substances other than alkalizing agents.

THE REMOVAL of drugs in poisonings by peritoneal dialysis has been the subject of many studies. Salicylates and barbiturates have been most commonly investigated due to the frequency with which they are involved in poisoning cases. The rates at which these drugs have been removed by peritoneal dialysis with the usual dialysis fluids have not been encouraging, and it is desirable that improved fluids and techniques be developed for this purpose. To proceed logically in this effort a more thorough knowledge is required of the mechanism by which drugs pass the membrane and the maximum rates which might be attained.

Berndt and Gosselin (1–3) indicated that the diffusion of ions and molecules through the peritoneal membrane may take place through pores.

Knochel *et al.* (4, 5) and Nahas and co-workers (6, 7) assumed that only the unionized forms of drugs pass the membrane and on this basis explained the effects of alkaline dialysis fluids on diffusion rates. Engel and Kerekes (8) claimed that the diffusion of a compound from the blood stream into the peritoneal cavity depends primarily on the chemical structure of the compound rather than its physical state.

The present investigation was undertaken to learn more of the nature of drug diffusion across the peritoneum *via* direct measurements on isolated membranes. The rabbit mesentery was selected for study, since the mesentery is the portion of the peritoneum thought to be most effective in dialysis. It was planned to determine the diffusion rates of pentobarbital and salicylate in solution at different pH values, thus to determine whether both ionized and unionized forms of the molecules diffuse. From the diffusion constants obtained, one might predict the maximum rates obtainable under ideal conditions. Urea, being unionized over a wide range of pH, was included in the study to evaluate direct effects of pH on the membranes.

MATERIALS AND METHODS

In order to obtain quantitative measurements on small volumes of dialysate, radioactive compounds were used: pentobarbital-2-^{14}C,[1] salicylic acid-1-^{14}C,[2] and urea-^{14}C.[3] Potassium chloride, A.R., was employed for calibration purposes. All other chemicals were of analytical reagent quality.

White grid Millipore membranes were selected for measurement of diffusion coefficients. It was felt that they would provide fast rates of diffusion and would fit the apparatus designed for animal membranes. The Millipore membranes used in this study had the following specifications: 37 mm. diameter, 0.45 ± 0.02 μ pore size, 150 ± 10 μ dry thickness, and porosity of 0.79 (9).

Isotonic solutions were used in all studies involving pentobarbital, salicylic acid, and urea. These solutions contained 0.005 moles/L. of $Na_2HPO_4 \cdot 7\ H_2O$, calculated quantities of 1 *N* HCl or NaOH to give the required pH, and sufficient NaCl to make the solution isotonic. The pH of all solutions were tested by measurement just prior to and following dialysis experiments.

The diffusion apparatus was constructed from two 125-ml. conical flasks. A 4-cm. tube with an expanded ground joint was sealed to the side of each flask. These joints could be clamped together, enclosing the membrane, by either a threaded or screw type clamp. The inside diameters of the joints were accurately measured. Stirring in both flasks was effected by glass stirrers driven by variable speed motors controlled by rheostats. The diffusion apparatus was mounted in a water bath at 37° ± 0.1°. A diagram of the diffusion apparatus is shown in Fig. 1.

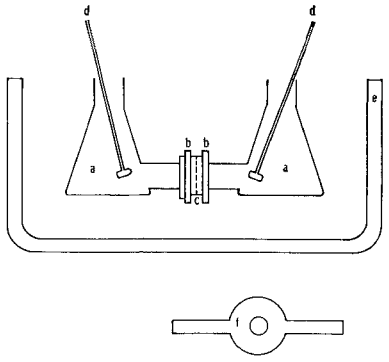

Fig. 1—Diffusion apparatus. Key: a, *conical flasks;* b, *aluminum clamp;* c, *membrane;* d, *glass stirrers;* e, *water bath;* f, *Teflon gaskets for mesentery membrane.*

EXPERIMENTAL PROCEDURE

Diffusion Through Millipore Membranes—A Millipore membrane, which had been previously soaked in water for at least 12 hr., was mounted between the two compartments and the joints were clamped. Then the apparatus was immersed in the water bath, leveled, and locked in position with a clamp. One hundred and fifty milliliters of potassium chloride solution in double distilled water, or of the drug in the isotonic solution of particular pH, was introduced into one compartment. A volume of double distilled water, in the case of KCl diffusion, or isotonic solution of the same pH, in the case of other substances, was introduced into the second compartment. Three different volumes, 150, 155, and 158 ml., were used in the latter compartment, depending on its capacity, in order to bring the liquid inside to the same level as that of the source solution. All solutions were equilibrated at 37° before use. The liquids in both compartments were stirred vigorously without creation of a vortex. Periods of 30 min. in the case of diffusion of potassium chloride, urea, and salicylic acid, and 90 min. in the case of pentobarbital, were allowed before the first sample was withdrawn from the sink compartment for analysis. Additional samples were removed every 10 min. for a period of 90 min. for potassium chloride diffusion, every 15 min. for a period of 2.5 hr. for urea, every 30 min. for a period of 4 hr. for salicylic acid, and every 30 min. for a period of 6 hr. for pentobarbital. Samples were withdrawn with a calibrated pipet which delivered 0.128 ml.

The Fajan's titration method (10) was used to assay potassium chloride samples. A manually operated microburet was utilized to deliver the 0.1 *N* silver nitrate titrant. Radioactivity measurement was employed with the samples withdrawn during diffusion of pentobarbital, salicylic acid, and urea. Each sample was added to a counting vial which contained 10 ml. of dioxane phosphor solution. The latter was prepared by dissolving 7.0 Gm. PPO, 2,5-diphenyloxazole, scintillation grade, 0.05 Gm. POPOP, (1,4-bis 2,5-diphenyloxazolyl)-ben-

[1] Supplied through the courtesy of Abbott Laboratories, North Chicago, Ill.
[2] Nuclear Chicago Corp., Des Plaines, Ill.
[3] Tracerlab, Waltham, Mass.

zene, scintillation grade, 50 Gm. of naphthalene, and 50 ml. of water in *p*-dioxane to make 1 L. The vials were counted in a Tri-Carb liquid scintillation counter using the average of three sets of counts. Suitable blanks and standards were counted with each set of tests. Results were calculated as the amount diffused over the given time interval.

Diffusion Through Isolated Mesenteric Membrane—Albino rabbits were sacrificed with intravenous pentobarbital. Immediately after death, the abdomen was opened and the broad, fan-shaped fold of the peritoneum connecting the convolutions of the jejunum and ileum with the posterior wall of the abdomen was separated. The separated tissue was immediately placed in normal saline solution and used for diffusion or stored in the refrigerator until used. When tissue was stored for longer than 24 hr., the saline was replaced daily. Membranes properly stored were not found to change in diffusion properties over periods up to 15 days. In several cases duplicate tests were performed on the same membrane to confirm this.

A piece of the mesenteric membrane freed from fat and blood vessels was mounted between a pair of Teflon gaskets, $^1/_{16}$ in. thickness, care being taken to avoid stretching the membrane. These gaskets had an outside diameter of $^7/_{16}$ in. and center opening which exposed an area of membrane of 1.266 cm.^{2} for diffusion.

The mesenteric membrane mounted between the Teflon gaskets was firmly clamped in the diffusion apparatus by means of a screw type clamp and the membrane was tested to insure that there was no leakage before use. The diffusion procedure was the same as previously described.

Since it was of some concern that the isolated membrane might in some way function differently from that in the live animal, a simple *in vivo* test was made to see whether both ionic and nonionic forms of a drug may diffuse. For this purpose it was decided to measure the transfer in the reverse direction, from peritoneum to blood, since pH of the dialysis fluid can be altered and buffered. Two tests were run on rabbits with pentobarbital in the dialysis fluid, using 100 mg. ^{14}C tagged pentobarbital in 150 ml. of intraperitoneal injection. In one rabbit an acid fluid consisting of isotonic phosphate buffer, pH 2.6, 0.15 *M*, was used; in the second an isotonic THAM solution, 0.15 *M*, was used. The concentration of nonmetabolized drug in the dialysate and pH of the dialysate were determined in samples removed in approximately 10-min. intervals over a period of about 100 min. Pentobarbital was measured by the method of Brodie *et al.* (11) but utilizing radioactive counting of the extracts rather than spectrophotometric measurement.

Results and Treatment of Data—The rate of diffusion between two well-stirred compartments separated by a membrane can be represented by Eq. 1. The detailed derivation of this equation is discussed by Lueck *et al.* (12).

$$\log_{10}\left[\left(1+\frac{V_1}{V_2}\right)C_1-\frac{V_1}{V_2}C_0\right]=-\left(\frac{V_1+V_2}{V_1V_2}\right)\frac{DA\epsilon}{2.303h}t+\log_{10}C_0 \quad \text{(Eq. 1)}$$

where

V_1 = volume of solution in source compartment in ml.,
V_2 = volume of solution in sink compartment in ml.,
C_1 = concentration of diffusing substance in source compartment at time, t,
C_0 = initial concentration of penetrant in source compartment,
D = diffusion coefficient of the penetrant in cm.^{2}/min.,
A = surface area of membrane in cm.^{2},
ϵ = porosity of membrane,
h = thickness of the membrane in cm.

In special cases where $V_1 = V_2$, Eq. 1 reduces to

$$\log_{10}(2C_1-C_0)=-\frac{2DA\epsilon}{2.303Vh}t+\log_{10}C_0 \quad \text{(Eq. 2)}$$

A plot of lefthand side of Eqs. 1 or 2 *versus* time should yield a straight line. From the slope of this line and known values of the cell constant the diffusion coefficient can be readily calculated.

The cell constant is obtained from diffusion measurements of a substance of a known diffusion coefficient with the same apparatus and membrane by dividing the slope of the line, from Eq. 1, by D. Thus,

$$\text{cell constant}=\frac{V_1+V_2}{V_1V_2}\cdot\frac{A\epsilon}{2.303h} \quad \text{(Eq. 3)}$$

or

$$\frac{2A\epsilon}{2.303hV} \quad \text{(Eq. 4)}$$

where $V_1 = V_2$.

The diffusion of 1 *M* potassium chloride through Millipore membranes was measured and using the known diffusion coefficient of 1.4356×10^{-3} cm.^{2}/min. (13) the cell constant was calculated. The mean value of nine experiments was 0.7264 cm.$^{-2}$ with a standard deviation of 0.0054 cm.$^{-2}$. With same apparatus and same type of membrane the diffusion of pentobarbital, salicylic acid, and urea was measured, and their diffusion coefficients were calculated as described above. These values, each the average of six measurements, were: for pentobarbital, 5.917×10^{-4} cm.^{2}/min.; salicylic acid, 6.901×10^{-4} cm.^{2}/min.; and urea, 1.018×10^{-3} cm.^{2}/min. Diffusion measurements at several pH values revealed no significant difference in diffusion coefficients with the Millipore membranes. A typical plot of diffusion data by Eq. 2 is presented in Fig. 2.

Measurements were then made of the diffusion of pentobarbital, salicylic acid, and urea through isolated mesentery at several pH values in isotonic solution. The data were plotted according to Eqs. 1 or 2, and results were calculated as permeability coefficients, $\frac{D\epsilon}{h}$, by dividing the slopes by the area of membrane exposed and multiplication by 2.303 and the appropriate volume factors. Coefficients obtained are presented in Tables I–III. Typical diffusion curves are shown in Figs. 3–5.

These data demonstrate that the three compounds diffused quite rapidly across the mesentery. For pentobarbital, the data indicated a slight

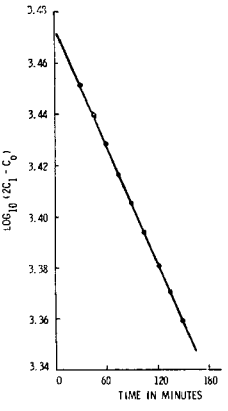

Fig. 2—Typical diffusion curve with Millipore membrane. Urea at pH 7.4.

decrease in permeability with increase in pH, but the differences are not significant when examined by statistical analysis. Using a value of 7.66 for the apparent dissociation constant of pentobarbital, from Krahl (14), it is estimated that the compound is completely dissociated at pH 11.7, 84.6% at pH 8.4, 35.5% at pH 7.4, and completely undissociated at pH 3.7. If the only species to diffuse were the undissociated molecule, one would expect great differences in diffusion rates with the different pH values used. Thus, one must conclude that both ionic and nonionic forms diffuse with approximately equal facility.

The diffusion rates of salicylic acid show that this compound diffused equally rapidly at pH 3.0 and 7.4. Salicylic acid is 50% dissociated at pH 3.0 and completely dissociated at pH 7.4. Thus, both species appear to diffuse equally well across the mesentery.

The permeability coefficients for urea at different pH values were essentially the same, as seen in Table III. This indicates that there was no appreciable effect of pH on the membranes, urea being undissociated at the pH range studies.

In several cases urea was run on membranes which had been previously used for pentobarbital. The ratios of diffusion rates of pentobarbital to urea were used to determine whether the membrane had been affected by the experimental conditions. These ratios were comparable to the ratio of the individual diffusion coefficients of the compounds, indicating no change in the performance of the membranes.

Although it is not known whether pores exist in the mesentery membrane, it is of interest to calculate the "apparent porosity" of these membranes. Such values give one a means of comparing penetrability of mesentery with other membranes and of predicting amounts which might diffuse under a variety of conditions. "Apparent porosities" can be calculated from average permeability coefficients, the measured diffusion coefficients for the three compounds, and the value of 38.5 μ for the thickness of the membrane (15). These calculations gave an average porosity of 29%, which is quite high as compared to most membranes. Calculating porosities from permeabilities with the different drugs, the values from pentobarbital data ranged from 22 to 36%, those from urea, 20 to 35%, and from salicylic acid, 29 to 39%. These differences in values for different drugs were not significantly greater than the variations between individual membranes with a single drug.

Results of the *in vivo* tests are presented in Table IV and curves of dialysate concentrations with time are shown in Fig. 6. From the data it is seen that the pentobarbital diffused rapidly at both high and low pH. This suggests that both ionic and nonionic forms diffuse, as was found with the isolated membrane.

and nonionic forms of salicylate and pentobarbital diffuse across the isolated mesenteric membrane. Since the same buffer is on both sides of the membrane in the *in vitro* tests it is inconceivable that neutralization at the surface or within the membrane could occur. Whether this truly represents the transport in the live animal is difficult to test directly, since under all biological conditions the blood and extracellular fluid must be maintained at nearly normal pH, and the buffer substances of the blood may maintain neutrality within the membrane. The *in vivo* test strongly indicates, however, that the ionic form of pentobarbital does diffuse across the peritoneal membrane, since otherwise the concentration gradient of unionized molecules in the alkaline fluid would be low enough to have a pronounced effect on the dialysis rate. Rather than retard the diffusion, the THAM appeared to increase the rate. Other data (16) on effect of THAM on dialysis of urea show an increased rate of dialysis which cannot be attributed to pH effect.

These data suggest that the effects of THAM on rates of removal of drugs by peritoneal dialysis are not primarily a pH effect and that the search for new agents to improve the rates of dialysis should go beyond the testing of alkalizing substances.

Absorption and Activity of Some Derivatives of Griseofulvin

By L. J. FISCHER* and S. RIEGELMAN

Some derivatives of the 4′-keto group of griseofulvin were prepared which had increased water solubility and greater absorption potential. The derivatives, which exhibited little or no *in vitro* activity against *Microsporum gypseum*, were found to be converted to griseofulvin *in vivo*. After intravenous administration to rabbits, several of the derivatives were rapidly converted to griseofulvin. Griseofulvin plasma levels resulting from oral doses of the derivatives were found to be equal to, or in most instances significantly higher than, the levels produced by equal doses of griseofulvin, but of shorter duration. Evidence for the degradation of the derivatives in the gastrointestinal tract is presented.

PREVIOUS REPORTS have shown griseofulvin to be irregularly and incompletely absorbed from the gastrointestinal tract of man (1–3) and laboratory animals (4, 5). The incomplete absorption, which often produces low blood and tissue levels, appears to be a result of the slow rate of dissolution of the drug in the gastrointestinal fluids due to its extremely low solubility in water. Fischer and Riegelman (6) have shown that the solution-rate-limited absorption of griseofulvin in rabbits was by a pseudo zero-order process and that the drug was eliminated rather rapidly ($t^1/_2$ = 77 ± 14 min.) from the blood following intravenous injection.

Numerous attempts have been made to increase blood levels resulting from an oral dose of the drug. By increasing the specific surface area of orally administered griseofulvin threefold, many workers have reported experimental animal and human peak blood levels to be approximately twice those obtained with the same dose of regular particle size griseofulvin (7–14). However, Crounse (13) has observed that a double dose of microcrystalline griseofulvin did not significantly raise serum levels in some individuals and that these levels may still fall short of the proper inhibitory levels for the antibiotic. The administration of surfactants with an oral dose of griseofulvin generally has produced erratic results in animals (9, 12) and has not significantly increased blood levels in man (14). The oral administration of griseofulvin with lipids or after meals with high fat content has been shown to increase blood levels (9, 13, 15); however, the mechanism by which absorption is facilitated by lipids has not been clarified.

Although many attempts have been made to increase griseofulvin absorption by various methods, no previously published report has investigated the preparation and administration of derivatives of griseofulvin having increased water solubility and greater absorption potential. The derivatives were chosen so that active griseofulvin would be a possible product of their enzymatic metabolism in the body. The more water-soluble derivatives were expected to be absorbed more completely from the gastrointestinal tract, and if they were converted rapidly to griseofulvin in the body, increased blood levels of the antibiotic could be expected. In this manner the concept of drug latentiation was employed to increase plasma levels of griseofulvin following the oral administration of some derivatives of the 4′-carbonyl group of griseofulvin.

The derivatives of griseofulvin (I) selected to be prepared and tested were griseofulvin-4′-alcohol (II), griseofulvin-4′-oxime (III), griseofulvin-4′-carboxymethoxime (IV), and griseofulvin-4′-hemisuccinate (V). Griseofulvin-4′-

alcohol was selected for testing in this system because of a previous report suggesting *in vivo* activity in infected guinea pigs (16). Such secondary alcohols are converted to ketones or are conjugated in their normal routes of metabolism in the body (17). The hemisuccinate ester of griseofulvin-4′-alcohol, which will be called griseofulvin-4′-hemisuccinate for consistency, was prepared because its sodium salt could be administered in solution. The ester was expected to hydrolyze rapidly in the body to griseofulvin-4′-alcohol. Oximes also have been shown to be possibly converted to their corresponding ketones by enzymatic metabolism in the body (18). The carboxymethoxime derivative was chosen for testing because the molecule could be solubilized as the sodium salt and its metabolism could be expected to follow that of oximes.

EXPERIMENTAL

Synthesis—The method of preparation of the griseofulvin-4′-alcohol (II) was that of Kyburz *et al.* (16). The method of synthesis of the griseofulvin-4′-oxime (III) was that of Oxford (19). For the details of the synthesis of compounds IV and V and the evaluation of the purity of each compound, the reader is referred to the thesis (20).

Determination of Water Solubility—An excess of pure crystalline drug was placed in a 40-ml. glass-stoppered centrifuge tube and a 25-ml. quantity of distilled water was added. The tube was stoppered, sealed with paraffin, and heated for a brief period at 45–55° prior to being placed in a water bath at 37 ± 1° for not less than 24 hr. Agitation was accomplished by mechanically rotating the tubes end over end at 30 r.p.m.

Samples were taken with a pipet plugged with glass wool and quickly diluted to the appropriate volume with distilled water. Griseofulvin and griseofulvin-4′-alcohol were determined spectrophotofluorometrically with excitation at 315 mμ and analyzing at 450 mμ. The griseofulvin-4′-alcohol samples were also assayed using a spectrophotometric method at 293 mμ. The oxime and carboxymethoxime derivatives were determined spectrophotometrically at 294 mμ.

Intravenous Administration and Sampling—The derivatives which were administered intravenously were given as a solution in 75% *N,N*-dimethylacetamide (DMA) containing 20 mg. of drug/ml. The administration and sampling techniques were the same as described by Fischer and Riegelman (6) for the i.v. administration of griseofulvin to rabbits.

Oral Administration and Sampling—New Zealand white rabbits were used for oral administration of the drugs. A control dose of microcrystalline griseofulvin[1] was prepared as a suspension in 0.05% polysorbate 80[2] and administered using the technique previously described by these authors (6). The low concentration of polysorbate 80 was used to facilitate wetting of the powders and was not expected to influence absorption of the drug. In testing for *in vivo* activity, a dose of griseofulvin was administered to each animal, usually as the first dose of the experiment, to obtain a control level of the drug in plasma. Griseofulvin-4′-alcohol and -oxime were also administered as suspensions made by triturating the crystalline drug with the appropriate amount of polysorbate 80 and gradually adding water while mixing to make a suspension containing 20 mg. of drug/ml. No attempt was made to control the particle size of the derivatives in suspension. Griseofulvin-4′-hemisuccinate and -carboxymethoxime were administered as their sodium salts dissolved in distilled water. The interval between doses to the same animal was at least 1 week after the griseofulvin blood level from the previous dose had returned to zero.

The oral doses were administered through a stomach tube to rabbits briefly anesthetized with halothane as previously described (6). Samples were taken by making a small cut in the marginal ear vein with a scalpel blade and allowing the blood to flow into a heparinized centrifuge tube. Plasma was separated from the blood samples by centrifuging at 3500 r.p.m. The rabbits were permitted normal food (Purina commercial rabbit chow) and water *ad libitum* during the experiment unless specified otherwise.

Microbiological Assay for Griseofulvin Activity—Activities of the griseofulvin derivatives on *Mycrosporum gypseum* were compared to the activity of griseofulvin on the same organism using the cylinder plate assay reported by Knoll, Bowman, and Kirshbaum (21). Activities were determined in phosphate buffer at pH 8.0 and in fresh rabbit plasma. The activity of griseofulvin in the presence of some of the derivatives was also tested. All activities reported were an average of three or more separate determinations.

After a dose of griseofulvin or a griseofulvin derivative, the plasma griseofulvin activity reported was a result of six to nine determinations on a particular plasma sample as described by Knoll (21) in the assay procedure.

Thin-Layer Fluorimetric Analysis—Griseofulvin and griseofulvin-4′-alcohol were determined quantitatively in plasma using the TLC fluorimetric assay reported by Fischer and Riegelman (22).

Griseofulvin could be separated from griseofulvin-4′-oxime in a plasma ether extract by using

[1] Griseofulvin (lot No. 0524, specific surface area 13.–1.7 M.²/Gm.) was obtained from McNeil Laboratories, Fort Washington, Pa.

[2] Marketed as Tween 80 by Atlas Chemical Industries, Wilmington, Del.

a solvent system of 55% chloroform, 25% ether, and 20% acetone. Griseofulvin (R_f approximately 0.5), separated from the oxime derivative (R_f approximately 0.3) in the aforementioned solvent system, could be determined quantitatively using the TLC fluorimetric assay. It was found that standard griseofulvin readings were the same regardless of whether the ether–acetone (3:2) or the above-mentioned solvent system was used. Griseofulvin-4′-carboxymethoxime could also be separated from its parent compound by employing the 55% chloroform, 25% ether, and 20% acetone system. In this system the carboxymethoxime derivative would not move from the original spot while griseofulvin had an approximate R_f of 0.5.

Thin-layer chromatograms of plasma ether extracts were scanned with the adapted Photovolt TLC Densitometer to provide recording of the fluorescent spots over the entire length of the chromatogram. The scans were started on the original spot (labeled "S" on the TLC fluorimetric recordings) and were terminated when no more spots were observed or the fluorescent residue from plasma was detected near the end of the chromatogram. The heights of the observed peaks were proportional to the amount of fluorescent material on the spot when the previously described (22) application and development techniques were employed.

It should be noted that griseofulvin and griseofulvin-4′-alcohol concentrations determined by the TLC fluorimetric assay will be reported as mcg./ml. in plasma. Griseofulvin concentrations determined by the microbiological assay will be referred to as mcg./ml. of griseofulvin *plasma activity*. The activity, in this case, means the inhibition of growth of the test organism compared to griseofulvin, and not pharmacological activity as such.

RESULTS AND DISCUSSION

The griseofulvin-4′-derivatives which are shown in Table I exhibited varying degrees of increased water solubility. Reduction of the 4′-carbonyl group of griseofulvin to hydroxyl increased the solubility of the molecule approximately eighteen-fold. The solubility of the 4′-alcohol derivative was determined by fluorescence and ultraviolet methods and good agreement occurred between the different assays. A ninefold increase in solubility occurred for the 4′-oxime derivative, whereas the 4′-carboxymethoxime exhibited a somewhat smaller increase. The additional molecular weight of the 4′-carboxymethoxime molecule seems to account for a solubility lower than that of the oxime derivative. Because of its instability in aqueous solution, the solubility of griseofulvin-4′-hemisuccinate was not determined.

Griseofulvin-4′-oxime was the only derivative exhibiting *in vitro* antifungal activity, as shown in Table II. The activity of this derivative appeared to be somewhat characteristic upon observation of the zones of inhibition on the test plates. The zones consistently had a characteristic yellow color on their periphery which was not observed on the inhibition zones of griseofulvin. On closer examination, the oxime derivative appeared to inhibit production of aerial mycelium, and possibly sporulation, beyond the zone of total inhibition. Generally, the oxime appeared to be $^1/_7$th as active as griseofulvin on *M. gypseum* when tested in buffer and in serum. The combinations of griseofulvin and oxime tested produced slightly higher activity than griseofulvin alone; however, the oxime and griseofulvin activities were not proportionally additive. The griseofulvin alcohol and carboxymethoxime derivatives were found not to be active at the 50 mcg./ml. level. The hemisuccinate was not active at 10 mcg./ml. in buffer and was not tested further because its logical hydrolysis product, griseofulvin-4′-alcohol, was found not to be active.

The fact that little or no *in vitro* activity was exhibited by the derivatives was not surprising in view of the previous work on the structure–activity relationships of griseofulvin analogs. Crosse *et al.* (23) have studied the activity of more than 300 analogs of griseofulvin against dermatophytic and plant pathogenic fungi. Generally, it was found that substitutions on the griseofulvin molecule altered the spectrum and diminished the activity of the antibiotic. However, some substitutions at the 2′- and 3′-positions by groups which impart lipid solubility to the molecule increased and then decreased activity as a particular series was ascended. Many of the derivatives showed increased *in vivo* activity on plant and dermatophytic fungi (23–25). From the results of previous testing of griseofulvin analogs, it appears that increased *in vitro* activity

is accomplished by making particular substitutions on the molecule which increase lipid solubility; however, the more active compounds, due to their decreased water solubility, cannot be translocated efficiently *in vivo* to their site of action against the invading fungi. In such a situation the preparation of derivatives which have greater absorption potential and which will be converted to griseofulvin metabolically is a logical recourse to increase blood levels of the antibiotic.

The griseofulvin derivatives, which were prepared and tested as described, were administered to rabbits in order to evaluate their *in vivo* activity. The compounds, which showed little or no *in vitro* activity, were initially tested by assaying the plasma for antifungal activity following oral doses to test animals. As many derivatives as possible were administered to a particular animal to reduce the influence of individual animal variation on the results of the *in vivo* testing. An oral dose of griseofulvin (150 mg./Kg.) administered to rabbit 30 resulted in the typical plasma griseofulvin activity level (microbiological assay) shown in Fig. 1. A dose of griseofulvin-4′-alcohol (150 mg./Kg.) to the same animal reached a peak griseofulvin activity in 2 hr., which was approximately 8 hr. sooner than the corresponding dose of griseofulvin had reached its peak. The duration of activity, however, was much shorter when the alcohol derivative was administered. An increased dose of griseofulvin-4′-alcohol (200 mg./Kg.) produced a higher peak plasma activity of 1.8 mcg./ml. and again fell rapidly to zero at 12 hr. Griseofulvin-4′-hemisuccinate given in solution produced a rapid, higher peak plasma activity; however, the duration of activity was only 5 hr. Since these derivatives did not show griseofulvin activity *in vitro*, it appeared that conversion to griseofulvin had taken place in the body.

An oral dose of griseofulvin-4′-oxime (150 mg./Kg.) produced a more rapid but similar peak plasma griseofulvin activity compared to that produced by the same dose of griseofulvin, as represented by rabbit 31 in Fig. 1. Using the microbiological assay, it was not possible to determine definitely whether the plasma activity after a dose of the oxime derivative, which was slightly active *in vitro*, was due entirely to conversion or could be attributed in part to high blood levels of the derivative. The characteristic yellow color produced by the oxime derivative was observed on the periphery of zones of inhibition during the assay of plasma samples taken after an oral dose of oxime. Therefore, the activity appeared to be manifested in part by the oxime derivative. An oral dose of griseofulvin-4′-carboxymethoxime (200 mg./Kg.) did not exhibit plasma antifungal activity in any rabbit to which it was administered.

Following a dose of griseofulvin-4′-alcohol, the total fluorescence of the plasma was determined using the spectrophotofluorometric assay for griseofulvin (6). The fluorescence spectrum of the alcohol derivative is identical to the spectrum of griseofulvin, and the intensities were found to be additive in plasma. In three different animals given an oral dose of griseofulvin-4′-alcohol the peak plasma fluorescence time was between 4 and 8 hr., and at these times the plasma exhibited little or no antifungal activity as determined by the microbiological assay. Rabbit 30 shown in Fig. 1 (closed triangles) had peak fluorescence in the 8-hr. plasma sample which showed no griseofulvin plasma

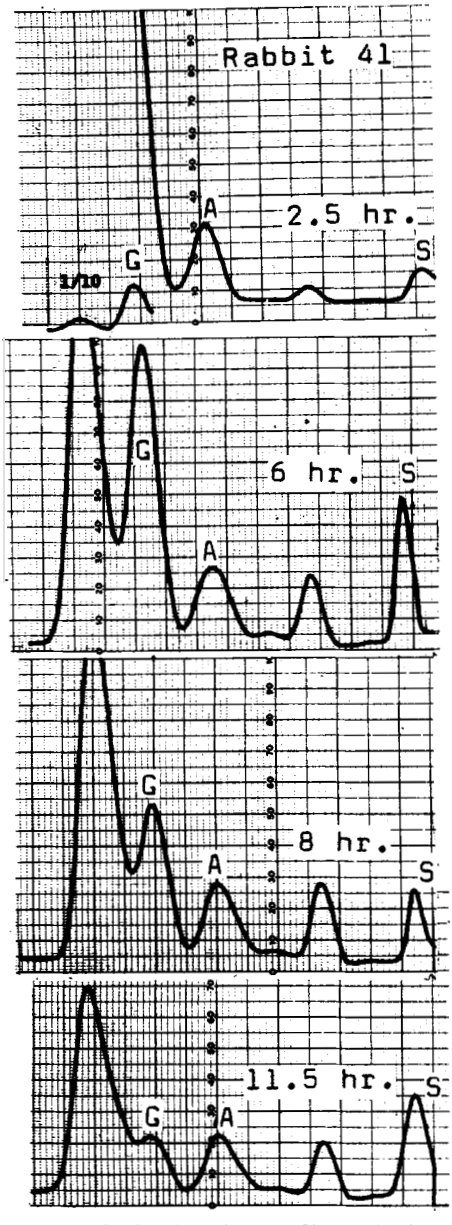

Fig. 2—TLC fluorimetric recordings of chromatograms containing fluorescent products extracted from 1 ml. of plasma following an oral dose of 200 mg./Kg. of griseofulvin-4′-alcohol.

activity. If conversion of the alcohol derivative to griseofulvin were taking place after absorption of the alcohol, and if only these two compounds were present in the blood, then peak plasma fluorescence should correspond to peak plasma griseofulvin activity.

In order to investigate the short duration of plasma griseofulvin activity, thin-layer chromatography was employed to separate the fluorescent constituents in the plasma following oral administration of griseofulvin-4′-alcohol. The TLC fluorimetric scans in Fig. 2 present the events which took place in the blood following an oral dose of 200 mg./Kg. of the alcohol derivative to rabbit 41. Each peak on the recording represents a fluorescent spot on the chromatogram. Fluorescent products in addition to griseofulvin (G) and griseofulvin-4′-alcohol (A) begin to make their appearance in the 2.5-hr. plasma sample. The three new fluorescent spots, one moving in front of griseofulvin and two trailing the alcohol derivative, are quite prevalent in the remaining plasma samples while griseofulvin plasma concentration falls. The appearance of other fluorescent substances in the plasma, besides the alcohol derivative and its parent compound, then, is accompanied shortly thereafter with falling griseofulvin levels. In rabbit 40, which showed high, somewhat prolonged griseofulvin levels, the appearance of the additional fluorescent substances was delayed, and they were initially observed beyond the 5-hr. sample. The discrepancy between peak plasma fluorescence and peak plasma griseofulvin activity, therefore, is due to the appearance of additional fluorescent products in the blood some time after an oral dose of griseofulvin-4′-alcohol.

Plasma samples from rabbit 39, given a 20 mg./Kg. intravenous dose of griseofulvin-4′-alcohol infused over a 15-min. period, were assayed for griseofulvin and its alcohol derivative using the TLC fluorimetric method (22). The first sample, taken 15 min. after completion of the infusion, exhibited the highest concentrations (Fig. 3). Thereafter, the plasma concentration of each substance decreased in a linear fashion when plotted against time on semilogarithmic paper. Griseofulvin, resulting from conversion of the alcohol derivative, had an apparent biological half-life of 70 min. in this animal. Griseofulvin-4′-alcohol in the plasma expectedly decreased more rapidly and had an apparent half-life of 28 min. A TLC fluorimetric scan of the extracted plasma samples showed that after an i.v. dose of the alcohol derivative only griseofulvin alcohol and griseofulvin were present in amounts detectable by the fluorescent technique. The fact that no additional fluorescent

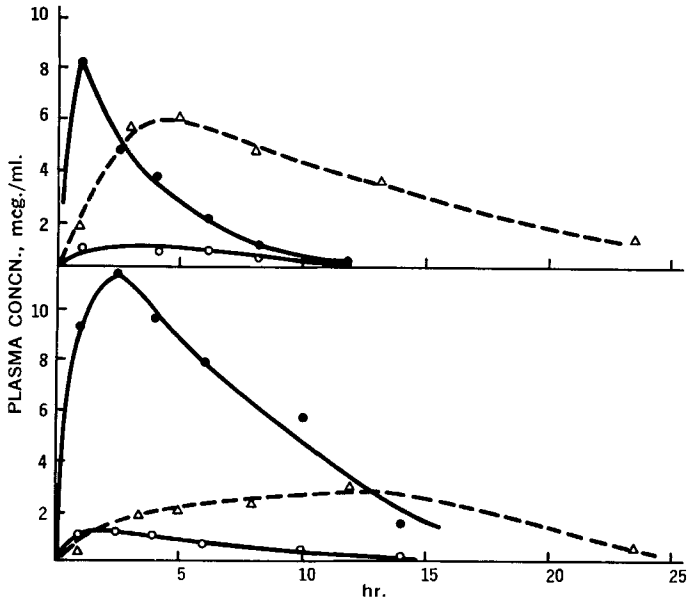

Fig. 4—Plasma concentration-time curves of griseofulvin and griseofulvin-4′-alcohol (TLC fluorimetric assay) following an oral dose of the alcohol derivative. A plasma level curve (broken line) from a control dose of griseofulvin is also shown. Oral dose—200 mg./Kg. griseofulvin alcohol. Key: ●, griseofulvin; ○, griseofulvin alcohol. Oral dose—200 mg./Kg. griseofulvin. Key: △, griseofulvin. Top, rabbit 41; bottom, rabbit 40.

products were found in the blood following i.v. administration of the alcohol derivative suggested that their appearance following an oral dose might be attributed to the degradation of the 4′-alcohol in the gastrointestinal tract.

An oral dose of griseofulvin-4′-alcohol (200 mg./Kg.) given to rabbit 40 (Fig. 4) produced high griseofulvin plasma levels and corresponding low griseofulvin-4′-alcohol levels as determined by the TLC fluorimetric assay. Griseofulvin reached an abnormally high plasma concentration of 11.5 mcg./ml. and had a duration of 20 hr. One week later the same animal was given an oral dose of griseofulvin (200 mg./Kg.) and exhibited a normal blood level picture as seen in the broken line curve on Fig. 4. This animal appeared to have an unusually high capacity for converting the alcohol derivative to griseofulvin. Another animal (No. 41) given a 200 mg./Kg. oral dose of the alcohol derivative exhibited the more typical blood level seen in Fig. 4. Plasma griseofulvin rose to a peak of 8.0 mcg./ml. in 1 hr. and decreased rapidly. The griseofulvin-4′-alcohol level again was consistently low. The control dose of griseofulvin produced rather high levels of griseofulvin (broken curve) showing this animal to be a good absorber of the drug.

It is particularly interesting to note that the level of griseofulvin-4′-alcohol, as represented by the data shown by rabbits 40 and 41 in Fig. 4, remains at a low, essentially constant level in the blood and at the same interval the griseofulvin level reaches a peak and rapidly falls. The alcohol derivative was shown to be approximately 18 times more soluble in water than griseofulvin and one can assume, therefore, that it should be more rapidly absorbed. The data obtained from the i.v. injection of the alcohol indicated that it has a very rapid elimination rate constant. The persistent griseofulvin-4′-alcohol blood level from an oral dose, then, must be due to a solution-rate-limited process where the low consistent blood level results from a steady state between the absorption and the rapid elimination processes. One then is left with the problem of how to explain why the griseofulvin blood levels (with a slower elimination rate) do not continue to persist at a high level as long as the griseofulvin-4′-alcohol remains in the blood and can be converted to griseofulvin.

Figure 5 shows plots of the heights of the fluorescence peaks found by a TLC fluorimetric scan, against time for one of the rabbits (No. 40) receiving an oral dose of griseofulvin-4′-alcohol. The curves give a semiquantitative measure of the appearance and elimination of all extracted and resolved fluorescent substances in the plasma follow-

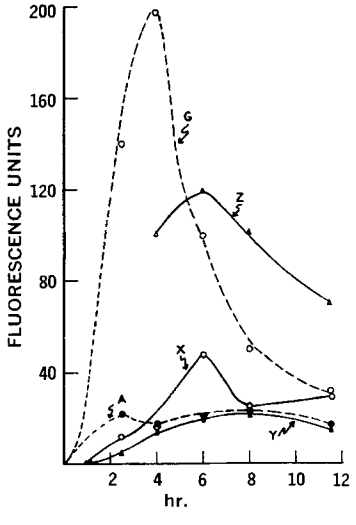

Fig. 5—Peak intensity of fluorescent spots from TLC fluorimetric scans of plasma extract chromatograms plotted against time. The rabbit (No. 41) received a 200 mg./Kg. oral dose of griseofulvin-4′-alcohol. Key: A, griseofulvin-4′-alcohol; G, griseofulvin; X, Y, and Z, unidentified compounds.

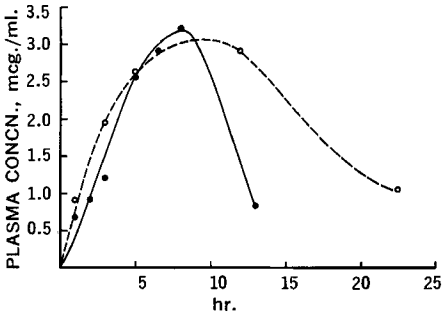

Fig. 6—Griseofulvin plasma concentration-time curves following single 200 mg./Kg. oral doses of griseofulvin (○) and griseofulvin-4′-oxime (●). (Rabbit 45.)

ing an oral dose of the alcohol derivative. From the curves, one observes that the unidentified spot, labeled X, which has the lowest R_f value, and another unidentified spot, labeled Y, trailing behind griseofulvin alcohol, appear after a short period of time and have consistently low values as does griseofulvin-4′-alcohol. The more intense spot (labeled Z in Fig. 5) moving slightly ahead of griseofulvin also has a later peak time than griseofulvin and has somewhat higher values than the other unidentified fluorescent products. It should be pointed out that none of these secondary fluorescent products are 6-demethyl griseofulvin, a metabolite of griseofulvin which does not fluoresce under these conditions and has a different R_f than any of the new compounds. Assuming that the fluorescent yield of each of the spots is not drastically different, it appears from the shapes of the curves that either substance X or Y could be converted to substance Z by a mechanism similar to the conversion of the alcohol derivative to griseofulvin. The proposed oxidative conversion of one of the assumed products (X or Y) to substance Z may compete with griseofulvin alcohol for enzymatic metabolism sites. This competition would explain the falling griseofulvin levels upon the appearance of the unidentified fluorescent substances. Even though the griseofulvin plasma level falls rapidly, it is obvious that some conversion of the alcohol is taking place as the apparent half-life of griseofulvin in the plasma after the peak level is approximately 2 to 4 hr., which is longer than the 77-min. half-life observed after an i.v. dose. It appears, then, that the short duration of griseofulvin plasma levels following an oral dose of the alcohol deriva-

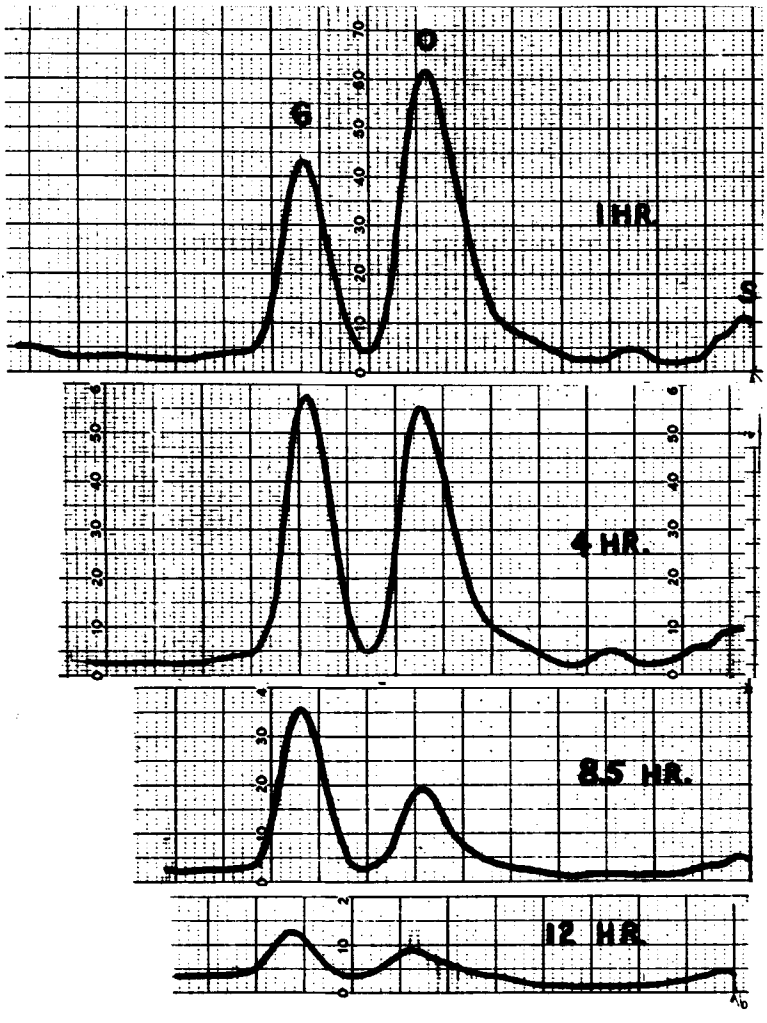

Fig. 7—TLC fluorimetric recordings of chromatograms showing fluorescent products extracted from plasma samples (1 ml.) following oral administration of 200 mg./Kg. of griseofulvin-4′-oxime. The fluorescent spot attributed to griseofulvin is labeled G, and that of the 4′-oxime as O. (Rabbit 46.)

tive was due to the degradation of the derivative in the gastrointestinal tract and the possible competition of the degradation products or products with griseofulvin-4′-alcohol for oxidative enzyme sites.

Due to the low fluorescence intensity of the oxime derivative, only griseofulvin plasma concentration was determined by the TLC fluorimetric method following administration of griseofulvin-4′-oxime to rabbits. The 4′-oxime derivative appeared to be converted to griseofulvin at a much slower rate than the 4′-alcohol. After intravenous administration of the 4′-oxime, low levels of griseofulvin from 0.38 to 0.6 mcg./ml. were observed in the plasma sample and during a 100-min. study reach a peak in 1 hr. Unlike the 4′-alcohol derivative, high griseofulvin plasma levels exhibiting apparent first-order elimination from the blood were not observed upon i.v. administration of the oxime. The oxime derivative was observed to be toxic when administered intravenously and the rabbit expired in 2 hr. Another animal given an identical i.v. dose of the oxime derivative exhibited a similar blood level and did not die during the experiment; however, heavy hemolysis was observed in the plasma samples of this animal.

An oral dose of griseofulvin-4′-oxime (200 mg./Kg.) to rabbit 45 produced a plasma griseofulvin curve (closed circles) similar in peak concentration, but of shorter duration than the control dose of griseofulvin (open circles) as seen in Fig. 6. As a result of oral doses of griseofulvin-4′-oxime the possible toxicity of this derivative was evidenced by the hemolysis of the early blood samples.

The slow conversion of the oxime derivatives to griseofulvin was seen in the TLC fluorimetric scans (Fig. 7) of plasma extracts after administration of a 200-mg./Kg. oral dose of griseofulvin-4′-oxime. In interpreting Fig. 7, it must be recalled that the oxime is approximately $^1/_{10}$th as fluorescent as griseofulvin. The earlier blood samples showed high levels of the oxime to be present along with lower levels of griseofulvin. From a preliminary extraction curve, there appeared to be approximately 15 to 20 mcg./ml. of the oxime derivative in the 4-hr. sample which contained 12 mcg./ml. of griseofulvin. Griseofulvin plasma concentration essentially decreased with the fall in oxime concentration and at 12 hr. only small amounts were present in the plasma. Oximes have been reported (18) to have other metabolites in addition to their corresponding ketones. It is probable, therefore, that griseofulvin is not the only metabolite of the oxime derivative. The spot trailing griseofulvin-4′-oxime on the 1- and 4-hr. TLC scans in Fig. 7 may be another metabolite or possibly a gastrointestinal degradation product of the oxime derivative. No attempts were made to characterize any metabolite other than griseofulvin.

Oral doses of griseofulvin-4′-carboxymethoxime have been shown to produce no *in vivo* griseofulvin activity, using the microbiological assay. In order to substantiate this finding, an intravenous dose (15 mg./Kg. in 75% DMA) of this derivative was given to rabbit 43. No evidence of hemolysis was observed in the blood samples taken from this animal. The first plasma sample, taken 15 min. after the 10-min. infusion of the drug, was found to contain only a trace amount of griseofulvin. A 30-min. sample exhibited no trace of the antibiotics. It was disappointing to observe that griseofulvin-4′-carboxymethoxime was not converted to griseofulvin after i.v. or oral administration. This derivative may be excreted rapidly by the kidneys, possibly by an active process, due to the similarity of the carboxymethoxime moiety to many substances actively secreted by the tubules. In addition, the $=N—O—CH_2—$ linkage in this compound may be stable to oxidative metabolism in the rabbit.

Effect of Mescaline on Cardiopulmonary Dynamics

Method for Determination of Right Ventricular Pressure in the Guinea Pig

By VINCENT DE PAUL LYNCH, EMMETT CLEMENTE, and STEVEN CARSON*

The effect of mescaline on respiratory dynamics, right ventricular pressure, and the ECG in the guinea pig is presented. A procedure for the acquisition of normal right ventricular pressure is described. The mean value for the latter was 13.4 ± 4.6 mm. Hg. Mescaline in low dosages (1 to 20 mg./Kg.) produced a slight increase in heart rate; higher dosages (50 to 240 mg./Kg.) induced bradycardia and conduction disturbances. Respiratory rate, resistance of the airways, and minute volume increased significantly, while tidal volume and compliance decreased. The decrease in compliance was near maximum (−70 and −77 per cent) with high dosages (50 and 100 mg./Kg.). Right ventricular pressure increased, average 45 per cent, following moderate dosages of mescaline (25 mg./Kg.). Diphenhydramine and chlorpheniramine (range 0.4 to 0.7 mg./Kg.) in sufficient concentration to block the effect of histamine (4 mg./Kg.) were utilized to observe possible mescaline antagonistic activity. However, the antihistamines were ineffective against mescaline. It appears probable that mescaline does not owe its activity on these parameters to histaminic receptor stimulation.

ALTHOUGH the effects of mescaline on the central nervous system (CNS) are well documented, its mode of action is unclear (1–3). Unfortunately, the peripheral activities of mescaline have not been subject to as much critical evaluation. It must be emphasized that while analogies are often misleading and erroneous, when comparing peripheral to central effects, a valid working hypothesis may be obtained. Moreover, the current theory concerning the mechanism of action (central) of LSD had, in large part, developed from peripheral studies (4–7). In view of this concept, studies were conducted to observe the effect of mescaline on the cardiopulmonary system in the guinea pig. The investigation was divided into three phases: the effect of mescaline on (*a*) the electrocardiogram, (*b*) right ventricular pressure, and (*c*) respiratory dynamics.

Deniker (8), in studies designed to determine electrolyte alterations induced by mescaline in man, reported a significant decrease in serum potassium. Speck (9) determined heart rate and blood glucose levels in rats challenged with mescaline. She reported that both parameters decreased significantly following intermediate and high doses. Wolbach *et al.* (10) noted that mescaline had a variable effect on pulse rate in man.

The ECG was monitored in the present study since any of the above phenomena could be reflected in this parameter (11). Furthermore, at present there are no available data concerning the effect of mescaline on the guinea pig ECG.

Cochin *et al.* (12) conducted distribution studies in the dog and observed that mescaline entered ventricular tissue. While such findings do not signify that mescaline has an effect on cardiac tissue, it was necessary nevertheless to take cognizance of this possibility. This is true especially in light of reports that mescaline has a variable effect on pulse rate and blood pressure (8, 10, 13). Most investigators agree that systemic blood pressure rises following high doses of mescaline (9, 14–16). It has been established that changes in blood pressure are accompanied by alterations in cardiac activity and respiratory function. It was reasoned, therefore, that if right ventricular pressure was monitored, variations in all related systems would be manifested in this parameter. However, an investigation of this nature could not immediately be undertaken because there are no unequivocal data available regarding the normal variations and mean value of this parameter in the guinea pig. Consequently, this research was designed to obtain the latter information as an initial step. After this was accomplished, an evaluation of the effect of mescaline on the same system was commenced.

The availability of techniques for the cannulation of various vascular networks has facilitated the investigation of cardiopulmonary function (17, 18). Whereas most investigators have used the rat as the test animal (19, 20), the guinea pig was chosen in the present study because of its

susceptibility to respiratory stress (21) in addition to the aforementioned reasons.

During the course of experiments involving the initial phase in this study, mescaline was observed to exert a potent effect on respiration. Doses comparable to those used in human experimentation, and previously reported to have little effect on this parameter in other species (10, 15, 22), were observed to cause a pronounced effect. Moreover, the induced changes closely resembled those produced by histamine (23). In view of these findings, this study was expanded ultimately to observe the action of mescaline on the cardiopulmonary system, its similiarity to histamine, and the possible antagonism of antihistamines upon induced alterations.

MATERIALS AND METHODS

Measurement of Right Ventricular Pressure—Adult male and female guinea pigs, weighing between 700 and 1000 Gm., were anesthetized intraperitoneally with sodium pentobarbital (35 mg./Kg.). The preparation of ventricular catheters and surgical procedures of Popovic (24) were modified in these studies according to the following procedures.

Ventricular catheters (polyethylene tubing, 0.011 in. i.d. × 0.024 in. o.d., No. P.E. 10, Clay-Adams) were prepared at least 24 hr. prior to intubation and allowed to soak in an antiseptic solution of benzalkonium chloride[1] (1:120). The tip of the catheter was shaped in the form of a right angle with the aid of a pencil soldering iron. The angled flexure was approximately 3 mm. from the tip. A small bulb (formed by rotating the catheter over a heat source) was placed a critical distance from the flanged tip of the catheter contingent upon the weight or size of the animal (Table I). The flange was produced with the soldering pencil and served the purpose of minimizing damage to the vessel linings (Fig. 1). The length of the catheter (20 cm.) was held constant so that changes in pressure could not be attributed to a variability in the tubing length. A 22-cm. stainless steel stylet (No. 32 gauge) was inserted into the catheter up to the flexure. The catheter was filled with heparinized saline (4 mg./ml.) and the external tip flame-sealed around the stylet.

An incision of approximately 2 cm. was made so that the midpoint of the incision coincided with the point at which the right transverse scapular vein joined the right external jugular vein. The jugular vein was dissected free and the cephalad portion permanently ligated while the peripheral end was secured with a loose ligature. The catheter was introduced distally into the vessel as close as possible to the junction of the right external jugular and right transverse scapular veins, and then advanced toward the heart. The loose ligature was secured after the bulb of the catheter had entered the vessel, the stylet removed, and the catheter flushed with a volume of saline slightly in excess of the capacity

of the catheter (0.02 ml.). The validity of correct placement of the catheter was ascertained by raising the tip of the catheter approximately 5 cm. above the level of the heart and observing the ventricular pattern which was produced after the catheter was connected to a pressure transducer and monitored by a direct writing recorder (Fig. 2, C). It was then flushed with heparinized saline and sealed. This was accomplished by the application of a hemostat approximately 6 cm. from the tip of the catheter and the insertion of a 5-cm. piece of stainless steel wire (No. 30 gauge). This procedure eliminated the necessity of cutting the tip of the catheter before each pressure determination or blood sample withdrawal which would be required if heat sealing were used. The catheter was exteriorized by placing it into the lumen of a needle (No. 13 gauge) and pushing the needle underneath the skin around the

neck until the desired area for immobilization was reached.

A Sanborn fluid pressure transducer, model 368B (range ±40 mm. Hg), was connected to a Sanborn recorder, model 350, for the sensing and recording of the ventricular pressure. Lead II was monitored with a Sanborn Twin-Viso recorder (model M-60-13000B, series 203). Connection between the catheter and transducer was accomplished according to the following procedure.

A needle adaptor was connected between the catheter and a short piece (5 cm.) of coiled polyethylene tubing (P.E. No. 10). A gasket was formed on the free end of the coiled tubing and sealed within a male-female B-D adaptor (size A for P.E. 10–50). The final connection was made by placing a male to male Luer adaptor between the female end of the B-D adaptor and the female adaptor of the transducer. The transducer was calibrated to record the pressures within the transducer limits at various attenuation settings.

After the surgical procedure had been completed, the animal was placed into a cylindrical Lucite chamber. The electrodes utilized for the conventional electrocardiographic (ECG) recordings were strategically placed in the chamber so that contact with the electrodes was achieved in the normal resting position. This apparatus facilitated simultaneous recording of right ventricular pressure and electrocardiographic leads I, II, or III. Provisions for obtaining intraventricular ECG recordings had been initiated, but were not completed during the study.

Drug Effects on Right Ventricular Pressures—Anesthetized guinea pigs, weighing between 750 and 1000 Gm., were utilized when studying the effect of antihistamines on the changes induced by histamine and mescaline on this parameter. A control period of 60 min. was maintained prior to injection of the test compound. Readings were obtained at a definite interval to correlate with those taken in the respiratory phases. Antihistamines (chlorpheniramine and diphenhydramine, dosage range 0.4 to 0.8 mg./Kg. i.p.) were administered to observe possible antagonistic action against histamine (4 mg./Kg.) and mescaline (25 mg./Kg.). The antihistamines were administered 15 min. prior to the histamine or mescaline challenge (Table II).

Electrocardiographic Recordings—Unanesthetized male and female guinea pigs, weighing between 700 and 1000 Gm., were used. To record the heart rate, the animal was confined in a plastic container in a prone position. The leads were secured to the forelegs so that lead I could be recorded. An arbitrary time period of 15 min. was allowed to elapse before the ECG recordings were begun. The animal was then removed from the container and injected intraperitoneally with mescaline or with the solvent (water). The latter served as the control. Various dosages of the drug were administered (ranging from 1 to 240 mg./Kg.), and the influence on the ECG was recorded at specific

intervals over a 240-min. period following injection.

Measurement of Respiratory Dynamics Utilizing the Amdur Technique—Tidal volume, respiratory rate, minute volume, compliance, resistance, and flow rate were recorded in the anesthetized guinea pig (weighing between 230–290 Gm.). The technique utilized was a modification of the Amdur method (25). Control readings were begun following a 30-min. recovery from catheterization. Control readings were taken every 3 min. for a period of 15 min. to insure parameter stability. The animal was then injected intraperitoneally with drugs of varying doses (Table III), and tracings were obtained at the specified intervals for a period of 1 hr.

Drug Effects on Respiration in the Intact Animal—In order to evaluate the effect of mescaline on the respiration of the intact animal, 12 animals in groups of four were given mescaline in doses of 5, 25, and 100 mg./Kg. intraperitoneally. Respiratory rate was counted at specific intervals over a 1-hr. period; the same procedure was followed for the control values (Table IV). Six animals were used to demonstrate the effect of diphenhydramine on the per cent change in the respiratory rate at peak responses to a histamine or mescaline challenge. The drugs and doses used are given in Table V.

RESULTS

Measurement of Right Ventricular Pressure—Normal right ventricular measurements were carried out in a series of 49 anesthetized guinea pigs. Electrocardiograms as well as right ventricular pressure was monitored in 16 animals at specific intervals for a period of 3 hr. Lead II was recorded simultaneously with the ventricular pressure at 0, 15, 30, 45, 60, 90, 120, 150, and 180 min. after cannulation. Due to instrument difficulty, ECG data have been compiled in nine of the 16 runs mentioned above.

Frequency distribution histograms were plotted for pressure values obtained immediately after cannulation (Fig. 3, A) and for the average value obtained during the 3-hr. exposure periods (Fig. 3, B). Histogram A exhibits a normal distribution pattern. The arithmetic mean was 13.4 mm. Hg, with a standard deviation of ±4.6 mm. Hg. Observation of the difference between the pressure immediately after cannulation and the average value after the 3-hr. exposure period was made and found in most instances to be small. In the majority of cases, the difference recorded was less than 1.0 mm. Hg (ranging from −1.1 to +2.5). Generally, when the difference was greater than +1.0 mm. Hg, the animal exhibited signs of partial recovery from the initial level of anesthesia. Marshall and Hanna (26) stated that under general anesthesia the mean arterial blood pressure in the guinea pig was lower than when the animal was conscious and active. More recently, Rudolph and Scarpelli (27) observed reduction in blood pressure after intravenous administration of pentobarbital in the unanesthetized dog. Popovic and Kent (28) have demonstrated the effect of anesthesia upon cardiac output presenting evidence that cardiac output is reduced under anesthesia. The ECG data and heart rate values obtained in these experiments correspond closely with those described by Lombard (29).

Drug Effects on Right Ventricular Pressure—Six anesthetized animals (35 mg./Kg. sodium pentobarbital) were injected intraperitoneally with mescaline and right ventricular pressure and lead II were monitored. In all cases a rise in pressure was noted in approximately 2 min. following injection. The rise in pressure correlates remarkably well with the onset of hyperpnea in the respiratory phase. The magnitude and duration of the pressure rise varied from animal to animal; however, the return to control values was initiated at about 30 min. after administration of the compound. During the entire test period there appeared compensatory changes, although this phenomenon was not observed during the control period (60 min.).

Animals exhibiting marked changes in pressure also demonstrated ECG alterations. In general, there was no significant change in pulse rate while marked changes occurred in conduction. One animal exhibited A-V block and inversion as well as diphasic "T" wave changes. Overall, the changes in ECG were not consistent. In some animals, the "T" wave was observed to reverse polarity and appear "tented," while in others it became more negative. However, the effect observed on the ECG was noted to occur between 5 and 10 min. after mescaline injection in all cases.

Three animals were injected with histamine. The ventricular pressure was observed to both rise and fall dramatically throughout the first 10 min. following administration. Following this phase, the pressure usually fell with an abrupt cessation of cardiac activity a few minutes thereafter. It is noteworthy to mention that this marked fluctuation in pressure was also observed with mescaline.

In order to assess the effect of antihistamines on

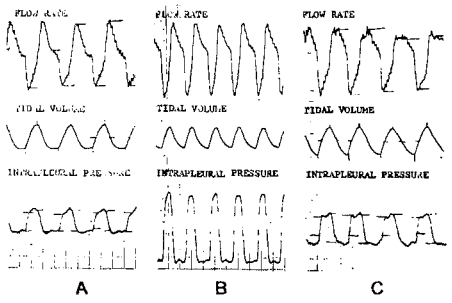

Fig. 5—Simultaneous effect of mescaline on various respiratory parameters in the unanesthetized guinea pig. Key: A, *control;* B, *test period, 5 min. following 100 mg./Kg i.p. of mescaline;* C, *recovery at 60 min.*

mescaline, the compounds were first tested on histamine challenged animals. As can be observed in Table III, the antihistamines blocked the previously pressor and lethal effects of histamine. The antihistamines did not effectually block the action of mescaline either on the rise in ventricular pressure or in respiratory rate, in dosages which were sufficient to curtail the effects of histamine. These findings are also borne out in the respiratory study on the intact animal.

Electrocardiographic Recordings—A series of 12 animals was used for this phase. Administration of mescaline in dosages of 1, 3, 8, 10, and 20 mg./Kg. did not exhibit a significant change in pulse rate or in wave characteristics when compared with control. However, when higher dosages were administered (50, 100, 200, and 240 mg./Kg.) there appeared to be a significant decrease in rate beginning at 10 min. and lasting for approximately 1 hr. (Fig. 4). In most of the latter cases, a "T" wave change was evident at 10 min. and was terminated at approximately 60 min. In general, low doses produced no significant change in the above parameters; high doses had a rather rapid but transient effect on pulse rate and "T" wave of the guinea pig ECG. A more critical evaluation of the electrical characteristics was limited due to instrument inefficiency.

Respiratory Data Utilizing the Amdur Technique—In all animals tested and with all dosages employed (5, 25, 50, and 100 mg./Kg.), there was exhibited an increase in respiratory rate and resistance; however, tidal volume and compliance decreased. Because of the marked increase in respiratory rate, the minute volume also increased. The changes in the above parameters occurred rapidly, usually within the first 3 min. The magnitude of the effect was observed to be dependent upon the dose. The maximum effect was demonstrated to range from 10 to 30 min. following administration of the compound. A return to control values usually began after 30 min. and was complete by 60 min. (Fig. 5). Furthermore, a considerable amount of compensation occurred throughout the test period, which was reflected in a "see-saw" activity of the respiratory rate and the dependent minute volume as well as in the other parameters monitored.

The most consistent change was observed in the compliance decrease. The per cent decrease in compliance at maximum effect for 5, 25, 50, and 100 mg./Kg. of mescaline was 33, 66, 70, and 77, respectively. It was noted on many occasions that the effect of this compound was in large part dependent upon the susceptibility of the animal, which in turn was dependent upon the physical state. Indeed, an animal with respiratory disturbances will, in many instances, not respond typically to the compound.

Pretreatment with diphenhydramine (0.7 mg./Kg.) did not alter the decrease in compliance following the administration of mescaline (25 mg./Kg.). Diphenhydramine alone was observed to cause either an increase or no change in compliance (Table II).

Drug Effects on Respiration in the Intact Animal—With all dosages employed, mescaline produced a significant increase in respiratory rate and activity of the animals. The effect was very rapid at all dose levels beginning at approximately 1 to 3 min. Termination of the effect was observed to occur between 20 and 30 min. after injection. The respiratory rate at the end of the test period (60 min.) was usually below control rate. This was also observed in the catheterized animals. The average per cent increase in respiratory rate for a total of 1 hr. at 5, 25, and 100 mg./Kg. was 23.2, 33.2, and 51.6, respectively. However, if only the first 20 min. were considered, the per cent increase was greater because the major effect of the compound was occurring during this period (Table IV). It is interesting to note that several animals in all dosage groups exhibited both coughing and very strong abdominal contractions. At times, the con-

tractions were so powerful as to propel the animal forward.

The effect elicited by mescaline on compliance of the lung and airway resistance is quite similar to that which has been observed for histamine (25). In order to observe the effect of antihistamine pretreatment on the respiratory changes produced by mescaline, without the influence of anesthesia and surgical trauma, several animals were given diphenhydramine (0.7 mg./Kg.) 15 min. prior to mescaline (25 mg./Kg.) or histamine (4.0 mg./Kg.). There were no significant changes induced by diphenhydramine alone; however, mescaline produced its characteristic symptoms with or without pretreatment of the antihistamine. Marked hyperpnea and coughing were noted within 5 min., the maximum occurring between 10 and 20 min. The effect of histamine was antagonized by the antihistamine (Table V).

DISCUSSION

Patterns of Right Ventricular Pressure—Observation of the pressure waves indicated that they could be grouped into three basic forms. The first demonstrated a typical peripheral pulse pattern (Fig. 2, A). The second showed a smoother wave with a slight flattening of the apical region (Fig. 2, B), and the third, which though similar to the second, was devoid of flattening of the apical region (Fig. 2, C). Dissection of the site of catheter insertion revealed that where the first wave formation was present, the catheter resided in the ventricle in proximity to the valve of the pulmonary artery. The other two pressure patterns differed only with respect to their location within the ventricular lumen, the former lying in the lower third and the latter in the upper third of the lumen. From an examination of the tracings of the former situation, the flattened apical region could be accounted for by assuming that at the peak of systole the catheter was forced against the ventricular wall (because of the narrowness of the lumen in that area) and resulted in a momentary interference with blood flow through the catheter. The apically flattened curves resulted from the catheter positioned in the narrower area of the ventricle, whereas the smooth waves described above resulted from the positioning of the catheter in the wider portion of the ventricle. The results indicated that slight movement of the catheter within the right ventricle may lead to a fourfold difference in pressure. There appeared to be an "optimal-position pressure relationship." When the catheter lay in the upper third of the ventricular lumen, the pressure was higher than that found when the catheters were positioned in the lower two-thirds of the ventricle.

In these studies, the ventricular pressure was determined to be less than 4.0 mm. Hg when the catheter tip lay under the papillary muscle. In this situation, the catheter could not, as a rule, be repositioned without damage to the overlying musculature. The ventricular pattern was characteristic when this occurred. The wave was small (low pressure) and considerably wider, whereas the apex of the wave was usually flattened. If the catheter was found to be pressing against the tissue anywhere within the ventricle, the wave formed was relatively wide and the pressure low (lower than 5.0 mm. Hg). In these studies, lead II was monitored simultaneously with pressure determination. These data are in accord with previously published reports.

Ventricular pressure variations reported in the literature seem to have been dependent upon positioning of the catheter as well as the methodological problems having little or nothing to do with the normal physiological state of the test animal.

The changes (decrease) in compliance observed with the higher dosages of mescaline (50 and 100 mg./Kg.) reflect near maximal decrease in this parameter (30–33). Concomitantly, the resistance in the airways increased. Moreover, because both effects occur at approximately the same time, it is difficult to assess the primary response. However, if mescaline exerts its respiratory effects in a fashion similar to other compounds, *e.g.*, serotonin or histamine (4), which induce a rapid and shallow respiratory pattern, one can attribute these effects to a primary change in compliance rather than resistance. If the respiration were deep and slow, this would tend to implicate the changes in resistance as the more susceptible function (31).

Decrease in compliance has been attributed to increased permeability and accumulation of blood in the pulmonary-capillary network of the lungs for histamine by Hughes, May, and Wittecombe (34, 35). However, spasm of the vascular network has also been demonstrated to cause the compliance to decrease. The effect of mescaline in low doses could be explained from the latter observations since the intrapleural pressure, although increased significantly, would at times approach control level. However, when higher doses were employed, the possible spasmogenic effect could not be compensated. Aviado (36) stated that methoxamine could influence pulmonary blood flow, but not directly influence the bronchiolar and pulmonary vascular smooth muscles. The consequences of a primary systemic pressor action, however, include reflex increase in vagal tone which can include bronchoconstriction. Moreover, the pressor effect of mescaline might serve to explain the changes observed, if an analogy can be made with methoxamine. Furthermore, Speck (9) demonstrated that bradycardia was produced following mescaline administration. This effect has been confirmed in this study. The possibility of reflex bronchoconstriction accounting, at least in part, for the action of mescaline on respiration has merit. Luduena, O'Malley, and Ogen (37) have demonstrated that lung edema can be produced by intravenous administration of epinephrine into rabbits. They attributed the edema to the intense and sustained high arterial blood pressure with increased left ventricular work load leading to elevated capillary pressure and then edema. It has been demonstrated that the edema produced in the dog by epinephrine is probably mediated by its peripheral action only.

Mescaline has been observed to increase systemic blood pressure in the cat (38), to cause severe peripheral vasoconstriction in the rat (9), and to produce constriction of various smooth muscle preparations *in vitro* (4, 6, 7); the latter effect has also been confirmed in this laboratory. The possibility exists that the lung edema observed in this study following intermediate and high dosages of mescaline (25 to 100 mg./Kg.) could be attributed to a similar mechanism as that postulated for epinephrine.

Because of the similarity with the observed respiratory change (in cannulated and intact animals) and the ventricular pressure between histamine and mescaline, antihistamines were employed in concentrations sufficient to block the effect of histamine. The results demonstrate that the antihistamines were not effective against mescaline; therefore, mescaline is probably not liberating histamine or stimulating histaminic receptor sites. It may be plausible that some of the effects on right ventricular pressure may be explained on a physical basis, due to the marked forcefulness induced by mescaline on respiratory movements. Moreover, this effect appears to be multifaceted: a combination of facilitated venous return, due to severe respiratory movements, increased peripheral vasoconstriction, and possibly a spasmogenic effect on the pulmonary vascular network.

Low doses of mescaline produced a slight increase in heart rate; however, higher doses produced bradycardia. The latter effect was also reported by Speck (9). Because the rise in blood pressure parallels the fall in heart rate, a baroreceptor mechanism appears to be, at least partly, responsible for the bradycardia. The effect of mescaline on the ECG was not remarkable at low dosages (1, 3, 8, 10, and 20 mg./Kg.). However, at higher doses in the intact and cannulated animal, conduction changes were evident. The most prominent effect was observed as an increase in positive polarity of the "T" wave. This effect is quite similar to those reported for various sympathomimetic amines, especially phenylephrine (39). The observed changes could have been mediated *via* a central and/or peripheral mechanism as has been demonstrated for phenylephrine. Because mescaline exerts a strong influence on the central nervous system, the effect on the cardiopulmonary system *via* central mechanisms cannot be dismissed. The "T" wave appeared to be "tented," a phenomenon observed when the serum potassium level is elevated (11). However, Deniker (8) reported that in humans, the serum potassium level fell within the first 10 min. and the effect was maximum between 30 and 60 min. following the intravenous administration of mescaline (10 mg./Kg.).

SUMMARY

The effect of mescaline on respiratory dynamics and the electrocardiogram in the unanesthetized guinea pig was determined. A procedure is described for the acquisition of normal right ventricular pressure in the anesthetized guinea pig and the action of mescaline on this parameter.

1. The mean value obtained for right ventricular pressure was 13.4 ± 4.6 mm. Hg.

2. Mescaline (25 mg./Kg.) and histamine (4.0 mm. Hg) caused a marked increase in right ventricular pressure. Pretreatment with antihistamines in sufficient concentration to curtail the effects of histamine did not antagonize the action of mescaline.

3. The action of mescaline on respiratory dynamics (compliance, resistance of the airways, tidal volume, minute volume, flow rate, and respiratory rate) in the unanesthetized animal resembled the effect of histamine. However, pretreatment with diphenhydramine did not alter these responses to mescaline. Mescaline, in various doses, including that used in human experimentation, produced a marked increase in the respiratory rate in the intact guinea pig. Diphenhydramine effectively antagonized the action of histamine but not of mescaline on this parameter in the intact animal.

4. Control ECG data obtained in these experiments are in accord with previously published reports. Mescaline did not significantly alter heart rate in low to intermediate dosages (1 to 25 mg./Kg.); however, bradycardia was apparent with higher dosages (50 to 240 mg./Kg.). Conduction disturbances were manifested at the high dose levels, the most consistent being a "T" wave alteration.

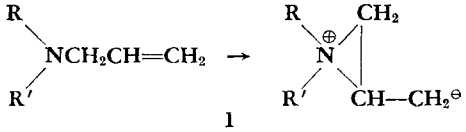
Synthesis of Possible Cancer Chemotherapeutic Agents Based on Enzyme Rationale VI

Allylamine Derivatives

By K. C. TSOU, SURESH B. DAMLE, R. W. CRICHLOW, R. G. RAVDIN, and HARRY W. BLUNT

The participation of electron pair on the nitrogen atom with the olefinic π electron in allylamines makes possible the formation of an ethylenimonium-carbanion pair (I), a reactive intermediate analogous to the ethylenimonium ions that are formed



1

in nitrogen mustards. The opportunity of such participation decreases as the electron density of the nitrogen is suppressed by the formation of an amide. This interesting participation reaction suggested the evaluation of a number of allylamine amides so that they could be mediated by the difference in amidase activity between normal and neoplastic tissues. Physical data support this novel participation, and preliminary antitumor screening data of several compounds are reported. *N,N'*-Diallyl β-aziridino propionamide was found to be an effective agent against Dunning leukemia in both solid and ascites forms.

IN THE DESIGN and preparation of new drugs, one of the interesting approaches is to take advantage of the difference in enzyme activity between normal and neoplastic cells (1–3).

A scheme is proposed to develop cancer chemotherapeutic agents which are acted upon *in vivo* by enzymes to liberate compounds toxic to the tumor, if the enzyme concentration is higher in the tumor. (Scheme I, where A–B represents a drug that can be acted upon at the site indicated by the dotted line, and where the asterisk designates the toxic moiety.)

$$\underset{\text{less or nontoxic than } A}{A \text{ -}\!\!\!\!\!\!\text{:}\!\!\!\!\!\!\text{-} B} \xrightarrow[\text{enzyme}]{} \underset{\text{toxic agent}}{A^* + B}$$

Scheme I

If the enzyme level is lower in tumor, then a more toxic compound that can be detoxified by enzyme in the normal cell but not in tumor cell should be used. (Scheme II.)

$$\underset{\text{more toxic than } A \text{ or } B \text{ to tumor}}{A \text{ -}\!\!\!\!\!\!\text{:}\!\!\!\!\!\!\text{-} B} \xrightarrow[\text{enzyme}]{} \underset{\text{nontoxic}}{A + B}$$

Scheme II

Thus, in such synthetic work, one is confronted with both what enzyme difference should be used and with what toxic agents should be incorporated. The choice of cytotoxic moiety, hemisulfur mustard, $ClCH_2CH_2SCH_2CH_2OH$, was used in early work (2). This was based on the low hematopoietic effect of this compound as reported by Seligman, Rutenberg, Persky, and Friedman (4). Subsequent preclinical work indicated that hemisulfur mustard compounds often exhibit neurotoxicity (5) which could complicate the clinical management of such types of drugs. Thus, the effort has continued along the line of synthesis of compounds with reduced neurotoxicity and/or drugs that incorporate other one-arm alkylating agents, such as heminitrogen mustard[1] and aziridines (3). In addition, the authors also considered hexahydroazepine derivatives (6) as nonclassical alkylating agents. While much remains to be done in these compounds, the delay in hematopoietic effect in a pilot clinical trial (7) suggested that it would be worthwhile to consider also other nonclassical alkylating agents. The present paper reports a study of allylamine derivatives as potential alkylating agents, and the synthesis of allylamine amides as possible cancer chemotherapeutic agents based on the previously proposed rationale.

DISCUSSION

It is generally accepted that ethylenimonium ion is the active intermediate of nitrogen mustard

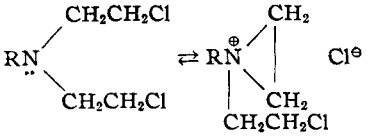
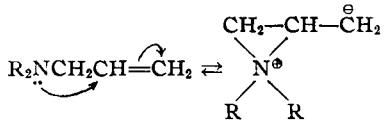
(HN_2) (8) and that very likely biological alkylation is related to its formation (9). The formation of this transition state depends on the nucleophilic displacement of the nitrogen atom onto the carbon adjacent to the chlorine atom (Scheme III). Thus, it is not unreasonable to ask whether in allylamine derivatives a similar type of nucleophilic attack of electrons from the nitrogen atom could take place as shown in Scheme IV.



Scheme III



Scheme IV

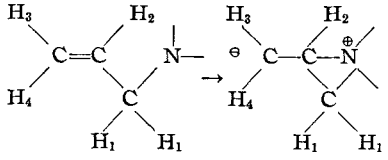
Such transition state could very well be favored if the carbanion could be stabilized by solvation as in the case of the chloride ion in HN_2. Thus, it is tempting to suggest that in the biological system allylamine might be stabilized through an internal ion pair and then act as potential alkylating agents. A careful investigation of the physical and chemical properties of some allylamine derivatives indeed suggested such possibilities could exist.

The pKa of allylamine (I), diallylamine (II), triallylamine (III), methyldiallylamine (IV), and dimethylallylamine (V) are listed in Table I (10). As the number of allyl group increases, the basicity decreases slightly in II, and significantly in III. This is in contrast to what is expected from the pKa values of ethylamine (10.63), diethylamine (10.93), and triethylamine (10.72), since increasing substitution generally results in slightly increased basicity. The substitution of methyl groups in IV and V also seems to result in a decrease in basicity, rather than the anticipated increase that one may expect from the hyperconjugation effect of the methyl group. It seems that these data could obviously be explained by an overlap of the electron pair on the nitrogen with the olefinic electrons. This is also suggested by their ultraviolet spectroscopy as shown in Table I, where additional suggestive evidence is apparent. Allylamine has a max. at 210 mμ which is clearly due to the participation of nitrogen electron with the π olefin, or a p–σ–π interaction in the triad =N—CH_2—CH= of diallylamine caused both bathochromic and hyperchromic effect as expected. The high intensity value (olefins are usually at 10–190 mμ) shows clearly that this is not due to the amine $n \rightarrow \sigma$ itself (usually ~1000) (11).

Examination of the infrared spectra of allylamine, diallylamine, and *N*-methyldiallylamine and other allylamines provides additional useful evidence of the formation of such "incipient ethylenimmonium ion." Thus, the strong 3075 cm.$^{-1}$ and 3005 cm.$^{-1}$ bands that are present in all aziridine derivatives are also in the substituted allylamines (12). In both diallylamine and methyldiallylamine, there was found the usual 2865 cm.$^{-1}$ methylene band and a very strong band at 2805 cm.$^{-1}$, but it is not so evident in monoallylamine. This 2805 cm.$^{-1}$ band can best be assigned as an unsymmetrical C—H stretching of the methylene group. The displacement of carbon 2–3 double bond to a single bond carbanion could contribute to an additional resonance vibration resulting in an increase in the intensity of this band.

A comparison of the nuclear magnetic resonance spectra of the allylamines reveals even more interesting data (Fig. 1).

As illustrated in Scheme V, if such intramolecular participation contributes to these compounds, the amine nitrogen should become less negative and the H_1 proton could be expected to shift to a higher field (or "curtain effect") (13). The chemical shifts



Scheme V

of H_1 in Table II indeed support this mechanism, especially when compared with propylamine. Thus, the theoretical H_1 value of dimethylallylamine (V) can be calculated from the Shoolery additive constant (14) to be 3.11, yet the found value is only 2.83. Correspondingly, an increase in carbanion character of the terminal allylic carbon is expected to cause chemical shifts of the terminal protons towards low field.[2] The slight increase in δ of H_3 in Table II obviously is in line with this expectation. There was no change in $J_{4,2}$ and $J_{3,2}$ in these compounds when compared with I in the liquid state, and there was also no significant change in J_{trans}/J_{cis} ratio. When one examines a molecular model, the approaching nitrogen to C_2 results actually in little change of the dihedral angle between $H_{4,2}$ and $H_{3,2}$; this is, very likely, why one may not expect any significant change in coupling constants.

More recently, Ferretti and Tesi (16) reported an observation of Prévost reaction in *N*-allylmorpholine in which they obtained a 2-morpholino-1,3-propandiol instead of the expected 1,2-diol. Independent of their work, a similar reaction of iodine chloride with *N*-allylpiperidine, followed by hydrolysis, has also been found by us to yield 2-piperididino-1,3-propanediol. These reactions thus provide indirect support for the formation of an ethylenimonium ion among allylamines.

---

[2] The study of the chemical shift of proton attached to a carbanion has not hitherto been reported. It should especially be noted that the present case is not that of a delocalized allyl anion, CH_2=CH—$CH_2^{\ominus}$, where one might expect a shift to high field due to shielding. Where electron density can be localized on the terminal carbon, as in the present case, an anisotropic effect would predict a downfield shift. (See *Reference 13*, p. 176.) The nearest example the authors know of is the investigation of *N*-ethylallenimine by Roberts, who stated that the "vinyl proton does not change significantly with temperature" (15). While Roberts did not say whether it also shifted up or down slightly, it is important to note that the vinyl proton remained discrete, did not exchange with the ring proton, and therefore did not become involved in the following scheme:

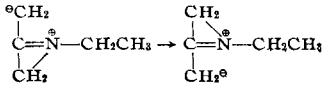


TABLE I—PHYSICAL PROPERTIES OF ALLYLAMINES

Compd.	B.p., ° C.	pKa[a]	U.V. Spectra[b] $\lambda_{max.}$ (mμ)	U.V. Spectra[b] $\epsilon_{max.}$	Retention Time,[c] sec.

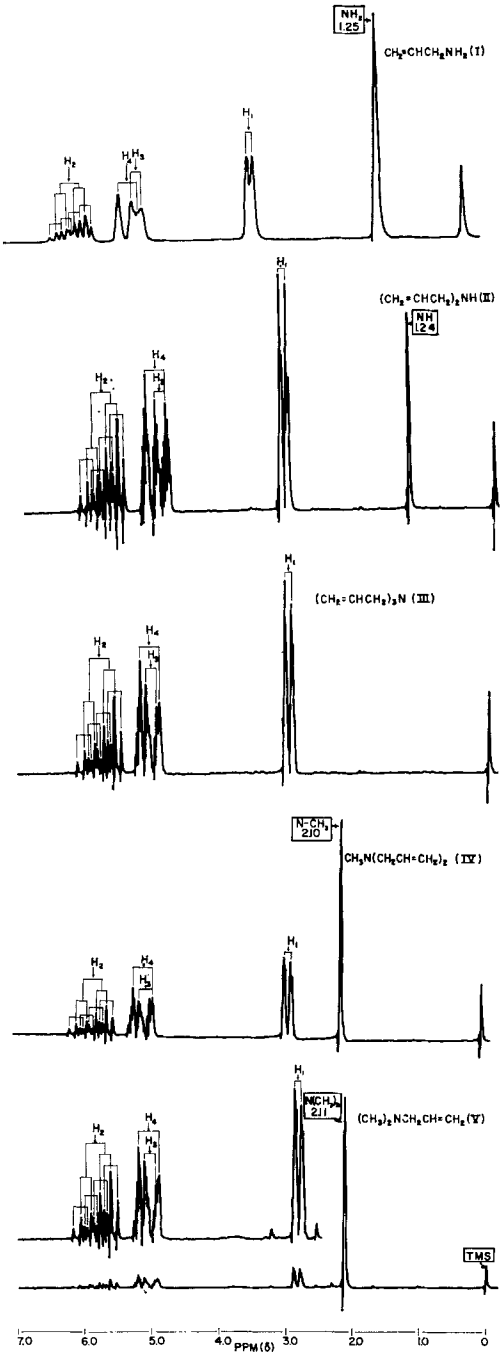

Fig. 1—Nuclear magnetic resonance spectra of allylamines.

While much of the assessment of the chemical data was in progress, exploratory screening of allylamine derivatives was simultaneously begun in different tumor systems through the generous cooperation of Cancer Chemotherapy National Service Center. Even though most of the data have appeared in their report (17), a discussion of these data in a summarized manner is certainly appropriate and not repetitious.

Allylamine, diallylamine, and triallylamine were compared in the sarcoma 180 system. The protocol of the screening has been described (17), and the results are summarized in Table III. It is of interest to note that diallylamine was found to have some tumor inhibitory activity in the sarcoma 180 system, even though the reproducibility in the confirmatory test was poor. No additional screening has been run in other systems.[8]

In another study, the authors were evaluating amidase hydrolysis of normal and neoplastic tissue on substrates of the *N*-acylaziridines (3), and occasionally high hydrolysis rate was noted in neoplastic tissue. First, if allylamine were to be incorporated in an amide, the electron density of the nitrogen atom would be suppressed and thereby reduce the opportunity for the allylamine to cyclize to an ethylenimonium ion. And yet, upon enzymatic hydrolysis, the allylamines could then undergo the incipient ethylenimonium ion formation as postulated.

In reviewing the literature on amidase activity, one noted that the hydrolysis of amides has been reported high in several tumors. Greenstein (18) reported fivefold increase in the hydrolysis activity of leucyl glycine in hepatoma over mouse liver. Goldbarg and Rutenberg (19) reported also the higher rate of hydrolysis of leucyl β-naphthylamide in cancer of the pancreas, using a method originally developed by Green, Tsou, Bressler, and Seligman (20). Burstone (21) and Hosoda, Takase, and Yoshida (22) also reported independently high activity in gastric cancer with the use of the same substrate. It thus seems of interest that a number of α- and β-amino diallyl amides might simulate closely the environmental requirement of the enzyme.

To survey the first requirement, *N*-allylacrylamide, *N,N'*-diallylacrylamide, and *N,N'*-diallylmethacrylamide were chosen for exploratory purposes. The use of acrylic acid derivatives was preferred because interesting results had been found when acrylamide (NSC No. 7785) was screened in its activity against adenocarcinoma 755. These allylamides were also compared in the CA-755 system. As can be seen readily (Table IV), *N,N*-diallylmethacrylamide did pass the primary screening

[8] One must add that the analogous methallylamines are not active in the CCNSC screening systems.

system, even though it failed later in sequential tests. In the second group, one of the earliest compounds that we prepared is *N,N*-diallyl β-aziridinopropionamide (DAAP). It was prepared readily by the addition of ethylenimine to diallylacrylamide. While this series of compounds is still being extended, DAAP was found to be active in screening against the Dunning leukemia system (Table V), both in solid and ascites form. Curative doses

were effected in 20–40 mg./Kg. range. The remarkable low toxicity of DAAP was also found to be true in dog experiments where severe leucopenia were never noticed in 20–40 mg./Kg. dose in contrast to many known difunctional alkylating agents. Dimethyl β-aziridinopropionamide was also prepared in order to compare the alkylating effect of the β-aziridino group. Such a study will be reported elsewhere in a lymphoma system (23). The corresponding β-methylaziridino derivative was also made, but was found to be less effective.

It is obvious that much remains to be done to extend these observations and to verify our speculative rationale. Whether the low toxicity and effective antitumor activity of DAAP provides a worthwhile clue to our enzyme rationale remains to be shown. Such study is in progress.

EXPERIMENTAL

Allylamine, diallylamine, and triallylamine were obtained from the Shell Chemical Co. They were distilled free from inhibitor and sealed in ampuls under nitrogen for screening. For spectroscopic study, they were further purified by gas chromatography as shown in Table I.

N-Allylacrylamide and *N,N*-diallylacrylamide were obtained from the Monomer-Polymer Laboratory, Borden Chemical Co., and again purified just before sending to the screener.

N,N-Diallylmethacrylamide—To a solution of methacrylyl chloride (24) (20.92 Gm., 0.2 mole) in 50 ml. of dry benzene was added a mixture of diallylamine (19.5 Gm., 0.2 mole) and triethylamine (22.2 Gm., 0.2 mole) in 50 ml. of dry benzene. The addition was completed in 1 hr. The reaction mixture was stirred at room temperature overnight and filtered to remove triethylamine hydrochloride. The filtrate was evaporated under aspirator to

remove solvent and was distilled under high vacuum to yield 30.0 Gm. (89%) of the product, b.p. 90–92°/15 mm.

Anal.[4]—Calcd. for $C_{10}H_{15}NO$ (165.23): C, 72.69; H, 9.15; N, 8.48. Found: C, 72.57; H, 9.03; N, 8.19.

N,N-Diallyl β-Aziridinopropionamide—A 8.3-Gm. quantity of pure ethylenimine was added to 12 Gm. of *N,N*-diallylacrylamide (distilled, b.p. 108–110°/3.0 mm.) in 10 min. The solution was stirred for 2 hr. and allowed to stand overnight at room temperature. It was then distilled under reduced pressure to give 12.7 Gm. (80%) of the product, b.p. 110–114°/0.5 mm.; n_D^{20} = 1.4906; $d.^{25}$ = 0.9752. I.R. 3.17 μ (aziridine), 3.26, 3.32, 6.02, 6.78 μ.

Anal.—Calcd. for $C_{11}H_{18}N_2O$: C, 68.01; H, 9.34; N, 14.42. Found: C, 67.84; H, 9.41, N, 14.43.

N,N-Diallyl β-(2-Methyl)aziridinopropionamide—A 11.4 Gm. quantity of propyleneimine was added to 15.1 Gm. of *N,N*-diallylacrylamide in 10–15 min. with stirring and cooling. The solution was stirred continuously for 2 hr. and then allowed to stand overnight. The reaction mixture was then distilled under reduced pressure to yield 16.0 Gm. (77%) of *N,N*-diallyl β-(2-methyl)aziridinopropionamide, b.p. 101–102°/0.4 mm.; n_D^{20} = 1.4867; $d.^{26}$ = 0.9766.

Anal.—Calcd. for $C_{12}H_{20}N_2O$: C, 69.19; H, 9.68; N, 13.45. Found: C, 69.16; H, 9.90; N, 13.72.

N,N-Dimethyl β-Aziridinopropionamide—Ethylenimine (13.2 Gm., 0.3 mole) was added to a solution of dimethylacrylamide (14.9 Gm., 0.15 mole) in 30 min. with stirring. The mixture was allowed to stand overnight. The solvents were removed under aspirator and the product distilled under high vacuum to give 7.8 Gm. of the product, b.p. 71–72°/0.4 mm.; n_D^{20} = 1.4750; $d.^{24}$ = 0.9741.

Anal.—Calcd. for $C_7H_{14}N_2O$: C, 59.12; H, 9.92; N, 19.71. Found: C, 59.06; H, 9.89; N, 19.76.

Reaction of Allylpiperidine with Iodine Monochloride—To a benzene solution of ICl (1.6 Gm.) was added 1.3 Gm. of allylpiperidine slowly, and the reaction mixture was warmed for 10 min. and allowed to stand overnight. After removal of benzene, the residue turned reddish and failed to crystallize even though some yellow crystals appeared first. Purification of this oil was not successful. This mixture was then heated in an alkali suspension (4 *N* NaOH) and extracted with three 50-ml. portions of ether. The combined ether extract was dried with sodium sulfate and evaporated to dryness. An oily residue again resulted. This was distilled under reduced pressure to yield 0.6 Gm. of a lemon yellow oil, b.p. 149–152°/3 mm.; n_D^{27} = 1.4930, and analyzed to be 2-piperidino-1,3-propanediol (25).

Anal.—Calcd. for $C_8H_{17}NO_2$: C, 60.34; H, 10.77; N, 8.80. Found: C, 60.12; H, 10.52; N, 8.99.

[4] Microanalysis by Dr. S. M. Nagy, Belmont, Mass.

Similar reactions were carried out with methylallylamine, cyclohexylallylamine, and triallylamine, but the products were not separated as cleanly as in the case of allylpiperidine.

Gas chromatography was determined with a Wilken's Autoprep 700 under the conditions described in Table II.

Infrared spectra were determined on a Perkin-Elmer 421 diffraction-grating spectrophotometer, using 0.025 mm. KBr cell.

Nuclear magnetic resonance spectra were determined on a Varian HR-60 NMR spectrophotometer in the Department of Chemistry through the generous cooperation of Dr. C. C. Price.

Dog Toxicity Study of N,N-Diallyl β-Aziridinopropionamide—Three dogs each were given 20 and 40 mg./Kg. in a single injection of this compound in isotonic saline (50%) intravenously, and blood samples were withdrawn periodically and blood counts carried out in the Hematology Laboratory, University Hospital of Pennsylvania. All dogs survived. One dog was given 75 mg./Kg. This dog, however, died of distemper.

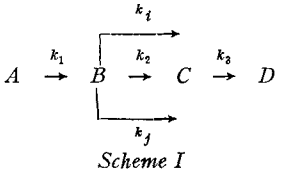
Method for Estimating Rate Constants for Absorption, Metabolism, and Elimination from Urinary Excretion Data

By JOHN G. WAGNER

A method is described for estimating the first-order rate constants for absorption, metabolite formation, and all-over loss of drug from the body if the time course of urinary excretion of the metabolite and an estimate of the rate constant for urinary excretion of the metabolite are available. The rate constants are estimated by drawing only two graphs and performing simple calculations which are described in detail. A simulation example is given where the rate constants were estimated with small errors when the rate constant for absorption was only twice the magnitude, and the rate constant for urinary excretion of metabolite only three times the magnitude of the rate constant for over-all loss of drug from the body. If the estimate of the rate constant for urinary excretion of metabolite is appreciably in error, the other rate constants are estimated with sufficient accuracy that they may be used as preliminary estimates for iterative computer programs which provide "least squares" fitting and which estimate all parameters simultaneously.

THE SAME type of equation used to construct absorption plots (1) may also be used to prepare plots of the cumulative amount or per cent of a metabolite formed as a function of time. Once such a plot is constructed, its resolution into components is the key to the complete elucidation of the kinetics of certain common pharmacokinetic models.

A common pharmacokinetic model is the catenary chain with parallel branches, such as shown in Scheme I where all the rate constants are first-order rate constants.



Scheme I

The most common situation would be the one where A represents a drug at the absorption site in the gastrointestinal tract in the case of oral administration or in the muscle in the case of intramuscular administration, B represents the drug, and C represents a metabolite (formed from the drug) in the blood and other fluids of distribution, and D represents the metabolite C in urine. The parallel paths, indicated by the arrows alongside the $B \rightarrow C$ step, represent other paths for disposal of the drug from the blood and other fluids of distribution. For example, k_i could be the first-order rate constant for urinary excretion of unchanged drug, and k_j could be the rate constant for formation of an additional metabolite. There could be other parallel paths in addition to the two shown, or there may be one or none. The number of paths does not influence the method to be described. Another possible situation equally amenable to the method is where A would represent the drug in blood and other fluids of distribution, B would represent a primary metabolite formed from A; this primary metabolite would be excreted in the urine (say the k_i path) but also would be converted to two other metabolites—one along the k_j path, the other being C; again, D represents the metabolite C in urine.

If the over-all rate constant for loss of B from the body is designated k, then, as Scheme I is written, $k = k_2 + k_i + k_j$. In other words, k is the sum of all the first-order rate constants involved in branches initiating at B. Let X_A, X_B, X_C, and X_D be the amounts in compartments A, B, C, and D, respectively, at time t and X_A^0 be the initial amount in A at time zero. The equations which give these amounts as a function of time, t, contain one exponential term for X_A, two exponential terms for X_B, and three exponential terms for X_C and X_D. The rate constants in the exponents of the exponential terms are k_1 for X_A, k and k_1 for X_B, and k, k_1, and k_3 for X_C and X_D. One can use the "feathering" or back-projection technique on a plot of the logarithm of the amount not excreted *versus* time. However, when three exponentials are involved, this method is subject to large errors; especially one often obtains very poor estimates of the larger two rate constants, which are usually k_1 and k_3.

The method to be discussed assumes there is available an approximation of the rate constant k_3; *i.e.*, the rate constant for urinary excretion of the metabolite C. This is sometimes available. For example, Levy (2) and Elliott (3) determined

Received November 16, 1966, from the Medical Research Division, The Upjohn Co., Kalamazoo, MI 49001
Accepted for publication December 20, 1966.

the first-order rate constant for urinary excretion of salicyluric acid in man, and Nelson *et al.* (4) determined the same rate constant for rats. Hence, the method to be proposed is applicable to the acetylsalicylic acid–salicylic acid–salicyluric acid system. It is always wise to estimate k_3 in a separate study since one should ensure that levels of C obtained, when A is administered, are not high enough to saturate the active secretory pathway in the kidney. One could determine k_3 for a metabolite of a drug administered to a human or animal, at the same time as the other rate constants were operative, by administering the drug in cold (nonradioactive) form and a dose of ^{14}C- or ^{3}H-labeled (radioactive) metabolite; the counting of radioactivity in the urine, and appropriate mathematical treatment, would yield the estimate of k_3; this estimate, employed with the data obtained by the normal chemical methods for C in the urine (compartment D), would provide estimates of k_1 and k.

The optimum method of estimating the constants X_A^0, k, k_1, k_2, and k_3 from a given set of X_D, t values is to estimate the constants simultaneously with an appropriate iterative digital computer program and a digital computer of sufficient capacity and speed. Such programs require preliminary estimates of the constants. The method to be proposed is an excellent one for obtaining such preliminary estimates, providing there is an adequate distribution and number of data points. A guide to obtaining an adequate distribution of data points will be the subject of a separate publication (5).

EXPERIMENTAL

Assume that $X_B = X_C = X_D = 0$ and $X_A = X_A^0$ at $t = 0$. The equations apply to all cases when no two or all of the rate constants k, k_1, and k_3 are exactly equal. Let X_D^∞ be the amount of metabolite (mass units) ultimately excreted in the urine. Urine should be collected for at least eight or nine half-lives of the drug to ensure that X_D, at this time, is close enough to X_D^∞. Then, for Scheme I, we have

$$\frac{dX_D}{dt} = k_3 X_C \qquad \text{(Eq. 1)}$$

$$X_C = X_A^0\left(\frac{k_2}{k}\right) \times \left[\frac{k_1 k e^{-kt}}{(k_1 - k)(k_3 - k)} - \frac{k_1 k e^{-k_1 t}}{(k_1 - k)(k_3 - k_1)} + \frac{k_1 k e^{-k_3 t}}{(k_3 - k_1)(k_3 - k)}\right] \qquad \text{(Eq. 2)}$$

$$X_D = X_A^0\left(\frac{k_2}{k}\right) \times \left[\frac{k_1 k_3(1 - e^{-kt})}{(k_1 - k)(k_3 - k)} - \frac{k k_3(1 - e^{k_1 t})}{(k_1 - k)(k_3 - k_1)} + \frac{k k_1(1 - e^{-k_3 t})}{(k_3 - k_1)(k_3 - k)}\right] \qquad \text{(Eq. 3)}$$

where t is time measured from time of administration, which is considered zero time. The cumulative amount of B converted to C in time T is given by

$$\frac{k_2}{k}\int_0^T \frac{dX_B}{dt}\cdot dt = X_C + X_D = \left[\left(\frac{1}{k_3}\cdot\frac{dX_D}{dt}\right) + X_D\right] \qquad \text{(Eq. 4)}$$

Substituting for X_C and X_D from Eqs. 2 and 3 into Eq. 4 and simplifying gives

$$\left[\left(\frac{1}{k_3}\cdot\frac{dX_D}{dt}\right) + X_D\right] = X_D^\infty \times \left[1 - \left\{\left(\frac{k_1}{k_1 - k}\right)e^{-kt} - \left(\frac{k}{k_1 - k}\right)e^{-k_1 t}\right\}\right]$$

when $k_1 > k$ (Eq. 5)

and $$\left[\left(\frac{1}{k_3}\cdot\frac{dX_D}{dt}\right) + X_D\right] = X_D^\infty \times \left[1 - \left\{\left(\frac{k}{k - k_1}\right)e^{-k_1 t} - \left(\frac{k_1}{k - k_1}\right)e^{-kt}\right\}\right]$$

when $k > k_1$ (Eq. 6)

where $X_D^\infty = X_A^0(k_2/k)$. It should be noted that Eqs. 5 and 6 are actually the same equation but, to avoid confusion, have been written so that the exponential terms are always positive with the given conditions.

Let

$$\%X_D = \frac{X_D}{X_D^\infty} \times 100 \qquad \text{(Eq. 7)}$$

and

$$Y = \left[\left(\frac{1}{k_3}\cdot\frac{\Delta\%X_D}{\Delta t}\right) + \widehat{\%X_D}\right] \qquad \text{(Eq. 8)}$$

$\frac{\Delta\%X_D}{\Delta t}$ represents the observed excretion rate measured over the interval $t_2 - t_1 = \Delta t$; this rate is an approximation of the derivative $\frac{dX_D}{dt}$. The $\%\hat{X}_D$, appearing in Eq. 8 is assumed to be the estimate of the cumulative per cent of metabolite excreted at the midpoint, T, of the excretion interval. In practice, it may be estimated from a smooth curve drawn through a plot of cumulative per cent excreted against time (*i.e.*, $\%X_D$ *versus* t).

Case When $k_1 > k$—From Eqs. 5 and 8, one can see that if $(100 - Y)$ is plotted on the logarithmic (base 10) scale of semilogarithmic graph paper against T, the line drawn through the terminal points will have a slope $-\frac{\hat{k}}{2.303}$. If this line is extrapolated back to $t = 0$, the intercept, I, will be (in natural numbers, not logarithms),

$$I \simeq 100\left(\frac{k_1}{k_1 - k}\right) \qquad \text{(Eq. 9)}$$

Rearrangement of Eq. 9 gives

$$\hat{k}_1 = \frac{\hat{k}}{1 - \frac{100}{I}} \qquad \text{(Eq. 10)}$$

If residuals, R, are taken, where

$$R = Ie^{-\hat{k}T} - (100 - Y) \qquad \text{(Eq. 11)}$$

and R is plotted on the logarithmic scale of the semilogarithmic graph paper against T, then the slope of the residual line will be $-\frac{\hat{k}_1}{2.303}$ and the value of R at $T = 0$ will be $I - 100$.

Case When $k > k_1$—Similarly, from Eqs. 6 and 8, the terminal line drawn through a semilogarithmic plot of $(100 - Y)$ against T will have a slope $-\frac{\hat{k}_1}{2.303}$ and an intercept, I', such that

$$I' \simeq 100\left(\frac{k}{k - k_1}\right) \qquad \text{(Eq. 12)}$$

Rearrangement of Eq. 12 gives

$$\hat{k} = \frac{\hat{k}_1}{1 - \frac{100}{I'}} \qquad \text{(Eq. 13)}$$

If residuals, R', are taken, where

$$R' = I'e^{-\hat{k}_1 T} - (100 - Y) \qquad \text{(Eq. 14)}$$

and, R is plotted on semilogarithmic paper against T, then the slope of the line will be $-\frac{\hat{k}}{2.303}$ and the value of R' at $T = 0$ will be $(I' - 100)$.

Hence, the equations provide a method of getting one estimate of the smaller of the two rate constants k and k_1, and two estimates of the larger of these two rate constants. It should be noted that one really does not know which is the smaller of the two, but the assumption is usually made that $k_1 > k$ unless there is evidence to the contrary.

The method of estimating k, k_1, and k_2 is then as follows.

(*a*) Measure urinary excretion rates long enough to obtain a good estimate of X_D^∞.

(*b*) Convert all X_D amounts to percentages according to Eq. 7.

(*c*) Calculate the percentage excretion rates, $\frac{\Delta \%X_D}{\Delta t}$, for each excretion interval.

(*d*) Estimate the $\%X_D$ values at the midpoints, T, of the excretion intervals from a $\%X_D$, t plot.

(*e*) Calculate the values of Y for each excretion interval according to Eq. 8.

(*f*) Plot $(100 - Y)$ on the logarithmic scale of semilogarithmic graph paper against T.

(*g*) Draw a straight line through the points at the tail end of this plot and extrapolate the line to $t = 0$.

(*h*) Multiply the absolute value of the slope of the line by 2.303 to obtain the estimate of the smaller of the two rate constants, k and k_1, with dimensions time^{-1}.

(*i*) Make the first estimate of the larger of the two rate constants, k and k_1, from the intercept of the terminal line using Eqs. 10 or 13.

(*j*) Estimate residuals for those points which are not on the terminal line using Eqs. 11 or 14.

(*k*) Plot the residuals on the logarithmic scale of the semilogarithmic graph paper against T.

(*l*) Either graphically determine the slope of the residual line to obtain the second estimate of the larger of the two rate constants, k and k_1, or, more elegantly, calculate the slope of the least squares line forced through the point at $t = 0$ by means of the formula

$$|\text{slope}| = \frac{\Sigma[\log_{10}(I - 100) - \log_{10}R] \cdot T}{\Sigma T^2} \qquad \text{(Eq. 15)}$$

(*m*) If all metabolites and unchanged drug have been measured in urine to "infinite time" (*i.e.*, for at least eight to nine half-lives, $0.693/k$, assuming k is smaller than k_1 and k_3), then k_2 may be estimated. Convert all the amounts of metabolites and unchanged drug excreted to "infinite time" to mass units equivalent to metabolite C; then the sum of these amounts is $\widehat{X_A}^0$. Or, if absorption is complete, then $X_A{}^0$ is equal to the dose administered, but this is not a good assumption in the usual case. Estimate k_2 from the relationship

$$\hat{k}_2 = \frac{X_D^\infty}{\widehat{X_A}^0} \cdot \hat{k} \qquad \text{(Eq. 16)}$$

The method is illustrated by simulations based on Scheme I.

Example 1—Assignments made were $X_A^\circ = 100$ units, $k_1 = 0.500$ hr.$^{-1}$, $k_2 = 0.150$ hr.$^{-1}$, $k = 0.250$ hr.$^{-1}$, and $k_3 = 0.75$ hr.$^{-1}$. Hence, $X_D^\infty = \frac{0.15}{0.25} \times 100 = 60$ units, and $k_1/k = 2$.

Example 2—Assignments were the same as in example *1* except it was assumed there was a 25% error in k_3 on the high side; *i.e.*, $k_3 = 1.0$ hr.$^{-1}$ was used instead of $k_3 = 0.75$ hr.$^{-1}$.

Example 3—Assignments made were $X_A^\circ = 100$ units, $k_1 = 1.250$ hr.$^{-1}$, $k_2 = 0.150$ hr.$^{-1}$, $k = 0.250$ hr.$^{-1}$, and $k_3 = 1.0$ hr.$^{-1}$. Hence $X_D^\infty = 60$ units and $k_1/k = 5$.

RESULTS

Example 1—Table I gives the detailed calculations made for example *1*. The observed data are represented by the t and X_D values listed in columns 1 and 3 of this table. The $\%\widehat{X_D}$ values at the midpoints, T, may be estimated from a smooth curve drawn through the data points such as shown in Fig. 1. The semilogarithmic plot of $(100 - Y)$ *versus* T is shown in Fig. 2. Due to the data points used, and since $k_1/k = 2$, there are only two points available to draw the appropriate terminal line. The tangent line should be drawn, and not a line through the last few points which form a slight curve, since $[d \log_{10}(100 - Y)/dT]_{T \to \infty} = -k/2.303$. There will usually be few points to estimate the terminal line when $2 \leq k_1/k < 3$ if $k_1 > k$ or when $2 \leq k/k_1 < 3$ if $k > k_1$.[1] When the ratio of rate constants is greater than these ranges, there will be more points for fitting the terminal line (*e.g.*, see example *3*).

The terminal line has a slope of -0.1095; hence $\hat{k} = 0.252$ hr.$^{-1}$. The real value is 0.250 hr.$^{-1}$. The intercept of the terminal line is 200; hence, $\hat{k}_1 = \frac{0.252}{1 - \frac{100}{200}} = 0.504$ hr.$^{-1}$. The real value is 0.500 hr.$^{-1}$. The slope of the residual line, forced through $\log_{10}(I - 100)$, is 0.2214; hence, $\hat{k}_1 = 0.510$ hr.$^{-1}$. Thus, the two estimates of k_1 agree quite closely.

Figure 3 is a plot of the cumulative amount of metabolite formed as a function of time. The points are the Y,T values used to make the estimates above. The line shown on the plot is the theoretical line obtained from

$$100 - \left[1 - \left(\frac{k_1}{k_1 - k}\right)e^{-kt} - \left(\frac{k}{k_1 - k}\right)e^{-k_1 t}\right]$$

[1] The method is practically useless when $1 < k_1/k < 2$, if $k_1 > k$, or when $1 < k/k_1 < 2$ if $k > k_1$ unless an extraordinarily good analytical method is available for the drug.

[a] $Y = \left[\frac{1}{k_3} \cdot \frac{\Delta\%X_D}{\Delta t} + \%\hat{X}_D\right]$. [b] $Ie^{-\hat{k}T}$ are the line values obtained from the terminal linear segment extrapolated to $t = 0$. (See Fig. 1.) In Fig. 1 the value of I is 200. [c] R is the residual, *i.e.*, $R = Ie^{-\hat{k}t} - (100 - Y)$. [d] The absolute value of the slope of the residual line (Fig. 1) is given by $|\text{slope}| = \frac{\hat{k}_1}{2.303} = \frac{\Sigma[\log_{10}(I-100) - \log_{10}R]T}{\Sigma T^2}$, where $\hat{k}_1 = (2.303)(|\text{slope}|)$ in hr.$^{-1}$.

which after substitution of the given constants yields

$$100 - [1 - \{2e^{-0.25t} - e^{-0.50t}\}]$$

One can see, indirectly, that with adequate and frequent sampling, the estimation of the derivatives, $\frac{d\%X_D}{dt}$, by the "excretion rates," $\frac{\Delta\%X_D}{\Delta t}$, is excellent except for the very initial part of the plot.

Example 2—This example was a test to see what the effect of a relatively large error in k_3 would be. From the terminal line a value of $\hat{k} = 0.254$ hr.$^{-1}$ was obtained. The intercept, I, was 234 from which $\hat{k}_1 = 0.449$ hr.$^{-1}$. Hence, use of a value of k_3, which was 25% higher than the true value, gave a value of $\hat{k}$ which was 1.6% higher than the true value, and a value of $\hat{k}_1$ which was 10.2% lower than the true value.

Example 3—In this example $k_1/k = 5$ and there are 11 points to determine the terminal line shown in Fig. 4. The least squares line for the $\log_{10}(100 - Y)$, T points in the range $2.2 \leq T \leq 22$ has a slope of -0.110 and an intercept of 127.6. Hence $\hat{k} = 0.253$ hr.$^{-1}$, obtained from the slope, and $\hat{k}_1 = 1.16$ hr.$^{-1}$, obtained from the intercept. The slope of the least squares line, forced through $\log_{10}(I-100)$, from residuals, corresponding to $T = 0.2$, 0.6, 1.0, and 1.6 hr., is -0.489; hence, $\hat{k}_1 = 1.13$ hr.$^{-1}$. The true values were $k = 0.250$ hr.$^{-1}$ and $k_1 = 1.25$ hr.$^{-1}$.

DISCUSSION

The method gives two estimates of the larger of the two rate constants k and k_1. Usually, but not always in pharmacokinetics, $k_1 > k$ and $k_3 > k$. In the absence of additional information, these are reasonable assumptions. Frequently in pharmacokinetic studies in which Scheme I applies, blood is sampled also and the blood and urine are analyzed for unchanged drug in addition to measurement of metabolite in urine as assumed in this report. If k is smaller than k_1 and k_3, the terminal linear segments of a plot of the logarithm of the plasma concentration of total (free and protein bound) unchanged drug against time and a plot of the logarithm of amount of unchanged drug not excreted *versus* time will also yield estimates of $k/2.303$.

If unchanged drug is measured in the urine, then application of the method of Wagner and Nelson (1) to these data should yield the same estimate of k_1, within error, as that obtained from the above method using data derived from measuring the metabolite in urine. A result such as this was found with the data of Levy (2).

When applying the above method to data derived from urine assays care must be taken in drawing the line through the terminal points of the semilogarithmic $(100 - Y)$, T plot. Terminal points

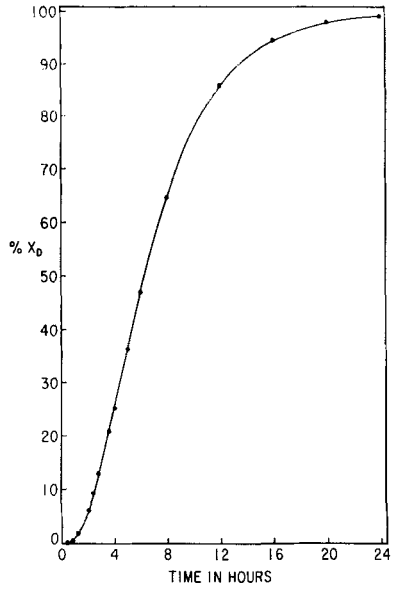

Fig. 1—The $\%X_D$ against time, t, plot for example 1. The points correspond to the cumulative per cent of the metabolite excreted to the end of the simulated urine collection periods at 0.4, 0.8, 1.2, 2, 2.4, 2.8, 3.6, 4, 5, 6, 8, 12, 16, 20, and 24 hr.

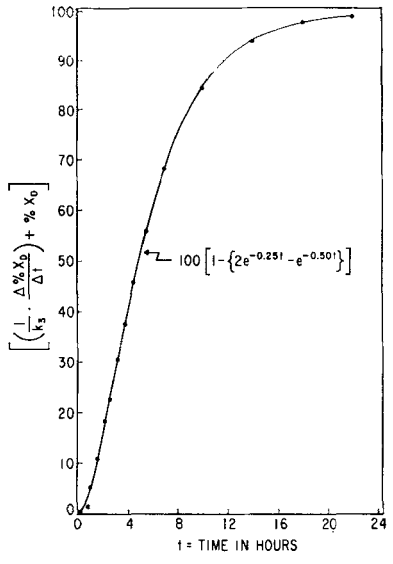

Fig. 3—A plot of the cumulative amount of metabolite formed against time for example 1. The points are the Y,T values listed in Table I from which the estimates of the rate constants were made. The line shown on the plot is the theoretical line for the model and assignments of the rate constants.

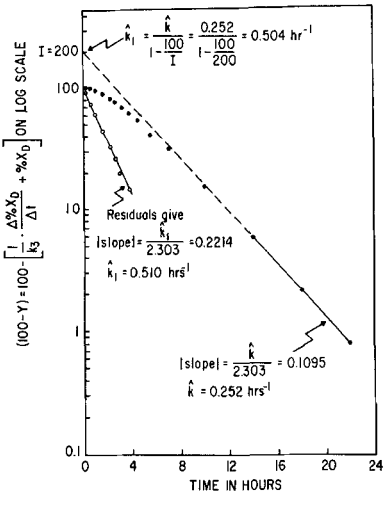

Fig. 2—Illustrating the semilogarithmic plots of (100−Y) and the residuals, R, against the midpoint, T, for example 1.

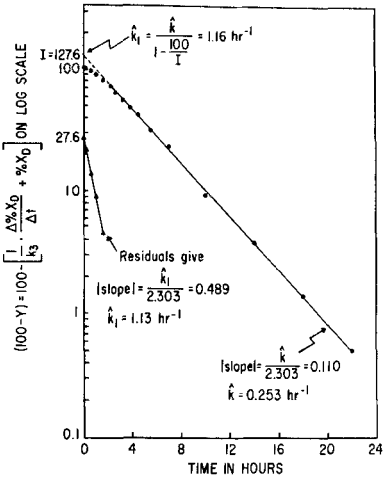

Fig. 4—Illustrating the semilogarithmic plots of (100−Y) and R against T for example 3.

on this plot will be derived from excretion rates which are relatively small in magnitude and which arise from urine collections obtained very late in the study and, hence, contain very little metabolite, if the ratio of the rate constants k_1 and k is between 1 and 3. The curvature of the points on the plot will indicate when this is the case. Assay error and the sensitivity of the assay will greatly affect the terminal points in these cases. The tendency will be for these inaccurate points to lie below the proper terminal line. The same problem exists in estimating the smallest of any two or more rate constants from the tail and of any type of semilogarithmic plot when the rate constants are within a factor of about 3 of each other. When applying the method to semilogarithmic $(100 - Y),T$ plots which have significant curvature, it is wise to make one, two, or more estimates of where the terminal line should be drawn and compare the results with other knowledge available about the particular system with which one is working.

It should be noted that the cumulative curves of

Figs. 1 and 3 arise from exponential equations only, *i.e.*, there are no zero-order rate constants involved. The curves are nearly linear for almost 50% of the ordinate scale. This phenomenon, and its implications in relation to recent publications concerning parallel zero-order and first-order kinetics (2, 4) will be the subject of a separate publication (6).

Quantitative Evaluation of the Heat-Stabilizing Properties of Organotin Compounds in Rigid Polyvinyl Chloride Using Differential Thermal Analysis

By R. K. O'LEARY, J. FOY, W. L. GUESS, and J. AUTIAN

Rigid polyvinyl chloride bottles are in current use in Europe for a host of products including foods, drugs, and cosmetics. In this country, a number of pharmaceutical and cosmetic firms are exploring the possibilities of this plastic container for packaging of one or more products. Presently, a number of vinyl systems are effectively stabilized against thermal and radiation degradation by the use of organotin compounds. In order to ascertain the efficiency of organotins to stabilize rigid vinyls, a quantitative study was undertaken on a series of vinyl formulations containing various organotin compounds using differential thermal analysis. These techniques proved to be extremely helpful in evaluating the materials from both a qualitative and quantitative point of view. Furthermore, the same techniques appear to have great promise in predicting the most suitable plastic formula for achieving the most stable plastic item when thermal or radiation damage becomes a potential problem.

ONE OF THE most widely used polymers in the medical science field is polyvinyl chloride (PVC). Its primary application has been in the construction of blood bags, surgical tubings, containers for biological products, catheters, and a host of other items. As is well established, vinyl resins are inherently unstable materials and are prone to thermal and oxidative degradation (1). This instability is primarily due to the imperfections and anomalies on the polymer chain, such as unsaturated chain endings and chain branching and to certain incorporated oxygen functions such as hydroperoxy groups. During the heat processing and throughout the active life of the polymer, these structural abnormalities will be the initiating points of the degradation process. In 1936, Yngve discovered that certain organotin compounds proved effective in minimizing the deterioration of PVC (2). During the past 20 years hundreds of structurally modified organotin compounds have been used as PVC heat and light stabilizers. Much has been written on their mode of action, but even up to the present time no generally agreed theory has evolved.

Within the past several years, great commercial interest has been shown in the development of the clear, colorless, rigid polyvinyl chloride bottles which now enjoy a great deal of success in Europe as food and drug containers. Generally, it has been found that the organotin compounds are the most efficient stabilizers for the clear, colorless bottles, even though some question of toxicity may be raised if the organotin compound would be leached into a product (3). Extraction tests following generally accepted procedures, however, have demonstrated that the rigid vinyls have little propensity to release a constituent to an extracting medium, and thus the safety of the bottle may be quite acceptable for any intended drug or cosmetic use.

Since the stabilizers play a key role in producing an acceptable rigid polyvinyl chloride, and since the organotins appear to be in general the most suitable stabilizers, it was decided to undertake a study using differential thermal analysis to evaluate which of a group of organotin compounds might give the greatest protection against thermal degradation. As will be demonstrated, differential thermal analysis proved

Quantitative Evaluation of the Heat-Stabilizing Properties of Organotin Compounds in Rigid Polyvinyl Chloride Using Differential Thermal Analysis

By R. K. O'LEARY, J. FOY, W. L. GUESS, and J. AUTIAN

Rigid polyvinyl chloride bottles are in current use in Europe for a host of products including foods, drugs, and cosmetics. In this country, a number of pharmaceutical and cosmetic firms are exploring the possibilities of this plastic container for packaging of one or more products. Presently, a number of vinyl systems are effectively stabilized against thermal and radiation degradation by the use of organotin compounds. In order to ascertain the efficiency of organotins to stabilize rigid vinyls, a quantitative study was undertaken on a series of vinyl formulations containing various organotin compounds using differential thermal analysis. These techniques proved to be extremely helpful in evaluating the materials from both a qualitative and quantitative point of view. Furthermore, the same techniques appear to have great promise in predicting the most suitable plastic formula for achieving the most stable plastic item when thermal or radiation damage becomes a potential problem.

ONE OF THE most widely used polymers in the medical science field is polyvinyl chloride (PVC). Its primary application has been in the construction of blood bags, surgical tubings, containers for biological products, catheters, and a host of other items. As is well established, vinyl resins are inherently unstable materials and are prone to thermal and oxidative degradation (1). This instability is primarily due to the imperfections and anomalies on the polymer chain, such as unsaturated chain endings and chain branching and to certain incorporated oxygen functions such as hydroperoxy groups. During the heat processing and throughout the active life of the polymer, these structural abnormalities will be the initiating points of the degradation process. In 1936, Yngve discovered that certain organotin compounds proved effective in minimizing the deterioration of PVC (2). During the past 20 years hundreds of structurally modified organotin compounds have been used as PVC heat and light stabilizers. Much has been written on their mode of action, but even up to the present time no generally agreed theory has evolved.

Within the past several years, great commercial interest has been shown in the development of the clear, colorless, rigid polyvinyl chloride bottles which now enjoy a great deal of success in Europe as food and drug containers. Generally, it has been found that the organotin compounds are the most efficient stabilizers for the clear, colorless bottles, even though some question of toxicity may be raised if the organotin compound would be leached into a product (3). Extraction tests following generally accepted procedures, however, have demonstrated that the rigid vinyls have little propensity to release a constituent to an extracting medium, and thus the safety of the bottle may be quite acceptable for any intended drug or cosmetic use.

Since the stabilizers play a key role in producing an acceptable rigid polyvinyl chloride, and since the organotins appear to be in general the most suitable stabilizers, it was decided to undertake a study using differential thermal analysis to evaluate which of a group of organotin compounds might give the greatest protection against thermal degradation. As will be demonstrated, differential thermal analysis proved

a very useful tool in deducing quantitatively the most suitable formula in a relatively short period of time.

EXPERIMENTAL

Materials and Apparatus—*Polyvinyl Chloride*—The PVC's used are listed with their corresponding weight average molecular weights.[1]

PVC Identification	Wt. Av. Mol. Wt.
PVC 65	62,000
PVC 105	83,000
PVC 161	91,000
PVC 120	107,000
PVC 123	114,000

Organotin Stabilizers—Di-*n*-butyltin diacetate, di-*n*-butyltin β-mercaptopropionate, di-*n*-octyltin β-mercaptopropionate, di-*n*-butyltin diisooctylthioglycolate, and bis-(di-*n*-butyltin monolauryl maleate) (Advance Division, Carlisle Chemical Works, Inc., New Brunswick, N. J.). Di-*n*-butyltin dilaurate, and di-*n*-butyltin maleate (M & T Chemicals, Inc., Rahway, N. J.). Di-*n*-butyltin diisooctyl maleate and di-*n*-butyltin dilauryl mercaptide (Cardinal Chemical Co., Columbia, S. C.).

Polyvinyl Chloride Films—In those cases where stabilizers are used, the polymer (600 Gm.) and the stabilizer (in the desired concentration) are placed into a 1-gal. laboratory Hobart mixer[2] and mixed for 30 min. The films of the polymers are prepared by milling them on a Farrell-Birmingham mill[3] having a chromium plated variable-speed roller. Prior to milling each film, the mill's rollers are carefully cleaned with practical grade stearic acid.[4] The temperature of the rollers is maintained at 175° and the duration of the milling is 5 min. During the final phase of the operation, the separation of the rollers is adjusted to furnish films having thicknesses in the range of 0.040–0.045 in. Cut samples $5^7/_8 \times 5^7/_8$ in. from the milled stock are then press polished on an electrically heated compression press[5] with platens cored for water cooling. The molds containing the samples are then heated for 3.5 min. at 35,000 lb. of pressure and rapidly cooled to 120° before removing the test sample from the mold. All samples are finally allowed to condition at room temperature and 50% relative humidity for 48 hr. prior to their use.

Differential Thermal Analysis Apparatus (DTA)—The apparatus consists of a combined controlled atmosphere differential thermal analyzer and effluent gas analyzer model KA-2-HD with a quick-cool furnace model F-1DF, and two L&N Speedomax H strip chart recorders. This instrument is manufactured and described by Robert L. Stone Co., Austin, Tex. (4, 5).

The sample holder assembly, model SH-M4CAZ, consists of two separate, circular Platinel differential thermocouples and a Chromel-Alumel furnace couple which is utilized for programming as well as recording the temperature of the furnace. The sample holder and recorder system permit the recording of two separate thermograms simultaneously. The recorder is linear in time only and has a chart speed of 1.0 in./min. The sample and reference compartments are cylindrical aluminum pans with a diameter of 3.5 mm., a depth of 1.5 mm., and a weight of 1.4 mg. The temperature scale of the instrument is calibrated using the known crystallographic inversion temperature of ammonium thiocyanate (88°) and the melt transition temperature of tin (231.8°). The heat transfer coefficient for the differential thermocouple is determined by utilizing the heat of fusion of tin (14 cal./Gm.). The calibration is performed utilizing a linear programming rate of 12.6°/min. and nitrogen as the dynamic gas to prevent any oxidative effects. The material under study is placed in the sample container and no reference material is used. The K value determined is 3.09×10^{-7} cal./mm.^{2}. Various range settings of the d.c. amplifiers provide identical K values. All areas are measured in triplicate with a plane planimeter and the results are averaged.

Effect of Molecular Weight on Transition Temperatures—In order to establish certain standards or guidelines in regard to temperatures at which transitions occur in polyvinyl chlorides of the different weight average molecular weights, samples of each of the polymers were run in the differential thermal analysis instrument at a heating rate of 6.0°/min. Highly calcined, 80-mesh alumina (Al_2O_3) was used as the reference. In all determinations exactly 1-mg. samples were employed. Nitrogen was the dynamic gas on the DTA runs, and helium was used for the effluent gas analysis.

Figure 1 illustrates a typical thermogram with the several transition temperatures. It will be noted that two transition temperatures are evident. The lower transition temperature may be considered as the glass transition temperature and may further be referred to as the main glass transition temperature (T_g). These T_g values for the various molecular weights are shown in Table I and reveal that this transition temperature increases from 80.9° for the lowest molecular weight (62,000) to a high of 87.3° for the highest molecular weight (114,000). A second transition temperature, which presently will be referred to as a depolymerization transition temperature (T_t), is seen at 200.6° for all of the polymers, regardless of weight. From the various thermograms, it was possible also to evaluate the peak temperature at which dehydrohalogenation took place as well as calculate the standard heat of transition of $\Delta H°$ for the dehydrohalogenation process. The method of calculation for $\Delta H°$ is included under *Appendix*. These values and constants are also included in Table I, and it appears that as the weight average molecular weight increases, the polymer has greater thermal stability. This is, however, an assumption since there are some polymers which show better thermal stability to active burning and produce thermograms that indicate a lower decomposition temperature. The reason for this is that some combustibles or noncombustibles are released at a lower temperature; a protective char is formed on the surface of the polymer which prevents further active burning.

Figure 2 illustrates the thermograms of the dehydrohalogenation transitions of the polymers studied. It should be noted that the lower molec-

TABLE I—EFFECT OF MOLECULAR WEIGHTS ON TRANSITION TEMPERATURE AND DEHYDROHALOGENATION PROCESS OF POLYVINYL CHLORIDES

Wt. Av. Mol. Wt.	Glass Transition Temp., °C. T_g	T_t	Dehydrohalogenation Peak Temp.	ΔH (Kcal./mole)	Effluent Gas Peak, mm.²/mg. of Sample
62,000	80.9	200.6	275.9	20.3	212
83,000	82.8	200.6	282.1	25.8	267
91,000	83.9	200.6	283.2	29.2	300
107,000	85.8	200.6	284.6	30.4	330
114,000	87.3	200.6	285.2	33.2	369

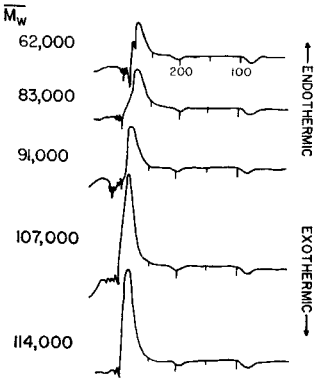

Fig. 2—The effects of molecular weight on the polyvinyl chloride thermogram.

ular weight polymers have their HCl evolution transitions interrupted by multiple exothermic reactions typical of bond scission. The higher molecular weight polymers do not reveal this type of polymer chain degradation, but merely exhibit large dehydrochlorination endotherms.

As each of the samples were run, there was a simultaneous recording of the effluent gas evolution, and as may have been anticipated, the greater the molecular weight, the greater will be the volume of HCl released for a unit weight of polymer. The quantity of HCl released with each polymer is included in Table I but is expressed as the area under the curve rather than in units of volume.

Effect of a Group of Dialkyltin Stabilizers on Glass Transition Temperatures—A series of experiments was conducted with a group of organotin compounds at three different concentrations (1.5, 3.0, and 5.0 p.h.r.) using one molecular weight polymer (114,000). The highest molecular weight polymer was used in this case because the previous experiment demonstrated that the most thermally stable polymer was the polymer having the weight average molecular weight of 114,000. The glass transition temperatures for these formulations have been included in Table II. In every case except one (dibutyltin dilauryl mercaptide at 1.5) the glass transition temperature was reduced below the 87.3° T_g for the pure polymer. Furthermore, the decrease continued as the concentration of the stabilizer was increased. These T_g values demonstrate that for this group of stabilizers, a plasticizing effect is noted, and that the extent of plasticization is dependent upon the compound and its concentration.

TABLE II—EFFECT OF DIALKYLTIN STABILIZERS ON GLASS TRANSITION TEMPERATURE OF A POLYVINYL CHLORIDE (114,000)[a]

Stabilizer	Concn. Level In Polymer	Transition Temp., °C.
Dibutyltin diacetate	1.5	83.3
	3.0	81.5
	5.0	74.1
Dibutyltin diisooctyl thioglycolate	1.5	80.3
	3.0	75.8
	5.0	71.3
Dioctyltin β-mercaptopropionate	1.5	83.7
	3.0	84.8
	5.0	83.9
Dibutyltin β-mercaptopropionate	1.5	82.6
	3.0	84.3
	5.0	85.5
Dibutyltin diisooctyl maleate	1.5	81.5
	3.0	78.7
	5.0	73.6
Bis(dibutyltin mono-) lauryl maleate	1.5	81.9
	3.0	78.1
	5.0	76.9
Dibutyltin dilauryl mercaptide	1.5	88.7
	3.0	77.0
	5.0	72.9
Dibutyltin dilaurate	1.5	79.1

	5.0	76.9
Dibutyltin maleate	1.5	83.9
	3.0	82.6
	5.0	81.9

[a] T_g of pure polymer is 87.3°C.

Effect of a Selected Group of Dialkyltin Stabilizers on Dehydrohalogenation—Since the main purpose of heat stabilizers is to prevent or retard degradation of polymers when exposed to heat, differential thermal analysis was conducted on polyvinyl chloride films containing two concentrations of a specific organotin compound. In these films only the lowest molecular weight (62,000) polymer was used since, as has been revealed before, this material has the least thermal stability of the group of polymers studied. Four organotin compounds were used and these were based upon those which have or are known to be the most used compounds in vinyl formulations requiring a high degree of heat stability. From the various thermograms, the onset temperature of dehydrohalogenation and the temperature of peak degradation were found. Heats of dehydrohalogenation were also calculated and, from the effluent gas recording, the peak area of gas evolved was evaluated. All these values or constants are included in Table III.

TABLE III—EFFECT OF SELECTED DIALKYLTIN STABILIZERS ON THE DEHYDROHALOGENATION OF POLYVINYL CHLORIDE

Stabilizer	Concn.	Onset of Transition, °C.	Peak Transition, °C.	Heat of Transition, cal./Gm.	Peak Area of Effluent Gas Analysis, mm.²/mg. of Sample
Pure polymer	0	221.0	275.9	20.31	212
Dibutyltin diisooctyl thioglycolate	1.5	266.3	284.3	13.17	
	3.0	271.2	285.2	11.58	370

	3.0	277.2		[a]	400

[a] Thermogram produced multiple endo- and exotherms from 276.8° to 326.3°C.

DISCUSSION

Differential thermal analysis permits the evaluation of a final plastic material such as polyvinyl chloride and allows in a relatively short period of time an assessment of how a number of parameters will influence the final product. In the case of this report differential thermal analysis was conducted under an inert environment (nitrogen) to eliminate oxidative effects.

As Table I shows, the main glass transition temperature increases with an increase in molecular weight. This results from a decrease in the polymers' fractional free volume. Generally, the glass transition temperature is considered as that point in the temperature scale where a material will be glass-like (below T_g) or rubber-like (above T_g). Perhaps a better way to think about the glass transition temperature is that as the T_g decreases a more pliable material will result.

Increase in the molecular weights of the pure polymers (Table I) had very profound effects upon retarding the dehydrohalogenation of the polymer. The dehydrohalogenation transition can be considered as the temperature where rapid polymer degradation starts to take place and thus may be related to the stability of the polymer. As may be seen from Table I, the heat requirement for dehydrohalogenation is increased by 13 cal./Gm. when the molecular weight of the PVC is increased from 62,000 to 114,000. In applications where heat treatments (for example to produce a certain device) reach temperatures above normal processing conditions, a higher molecular weight polymer will be the most suitable, providing all other factors are constant.

As has been reported before (see Table II), various organotin compounds incorporated in a specific polyvinyl chloride will reduce the glass transition temperature. The ability of these compounds to influence the T_g may on occasions be beneficial as for example when there is a need for a more ductile plastic, but without the desire to add any plasticizer. In this case, the addition of dibutyltin diisooctyl thioglycolate reduced the T_g from 87.3°, for the pure polymer, to 80.3° at a 1.5 concentration or to 71.3° for a concentration of 5.0. Compare the values just quoted to those values for dioctyltin β-mercaptopropionate. At a concentration of 1.5 the dioctyltin β-mercaptopropionate reduces the T_g to 83.7°, but further increase of the stabilizer to 3.0 or 5.0 has little additional effect on the T_g. These decreases in T_g may be attributed to a plasticizing effect on the polymer such that an increase in fractional free volume results (6,7).

Differential thermal analysis also was very valuable in conveying at which temperatures rapid dehydrohalogenation of the polymers will occur with some of the most widely used organotin compounds. As can be seen in comparing the compounds in Table III, in each instance the tin compounds were able to increase the temperature of dehydrochlorination from 221° for the pure polymer to values of above 260° (approximately). An interesting result, not readily explainable, is the reduction of the heat of dehydrohalogenation from 20.3 cal./Gm. to values of nearly half. In other words, these values (ΔH) indicate that once the plastic has reached a temperature where rapid dehydrohalogenation is to commence, less energy will be needed to bring about the degradation. The authors have reported this same phenomenon when different plasticizers were added to PVC (8).

The analysis of the data gathered from the use of the differential thermal analysis instrument for the limited number of polymers reported in this paper demonstrates that the technique can become a powerful tool for laboratories wishing to evaluate the stability of plastic materials, particularly the vinyl types. The results of the experiments reported here confirm the ability of organotin compounds to protect rigid polyvinyl chloride at thermal histories which would be destructive to the pure polymers. This fact is not a new revelation but the use of the differential thermal analysis instrument permits quantitizing results; thus, a more logical and scientific assessment of vinyl formulations can take place, replacing more laborious techniques currently used.

APPENDIX

The heat of dehydrohalogenation may be calculated by the expression (9–11):

$$\text{peak area} = \int_{t_1}^{t_2} \Delta T dt = \frac{HM}{g\tau_s} \quad \text{(Eq. 1)}$$

t_1 = onset temperature of transition,
t_2 = sample temperature equals reference temperature,
ΔT = differential temperature,

M = mass of the reactive sample,
g = constant dependent on the furnace and sample holder geometry,
τ_s = thermal conductivity of the sample.

If the instrument is calibrated with a suitable standard, such as tin whose heat of fusion is 14 cal./Gm., then g and τ_s can be reduced to one constant, K, the heat transfer coefficient of the system.

K is determined for each thermocouple by means of the following equations which describe the response of the system:

$$\frac{\text{area}}{\text{Gm.}} = \frac{\text{area of fusion transition of tin} \times \text{range setting } (\mu\text{v.})}{\text{wt. of tin, Gm.}} \quad \text{(Eq. 2)}$$

$$\frac{\Delta H_f \text{ of tin (cal./Gm.)}}{\text{area/Gm.}} = \frac{\text{cal.}}{\text{area}} = \frac{\text{cal.}}{\text{mm.}^2} = K \quad \text{(Eq. 3)}$$

The heats of transitions can thus be determined by the following equation:

$$\Delta H_f = \frac{K \times \text{peak area in mm.}^2 \times \text{range setting } (\mu\text{v.})}{\text{sample wt., Gm.}} \quad \text{(Eq. 4)}$$

Dissolution of Sodium Salicylate from Tablet Matrices Prepared by Wet Granulation and Direct Compression

By EDWARD MARLOWE* and RALPH F. SHANGRAW

A quantitative evaluation of dissolution of active ingredients from tablets is discussed. An investigation of filler-binder, lubricant, disintegrating agent, and hardness on the dissolution rate of sodium salicylate from tablet bases was studied by means of a 4 × 3 × 2 × 2 factorial experiment and analysis of variance. The utilization of a filler, spray-dried lactose, which required no preliminary granulation, gave significantly faster release rates than granulations prepared with acacia mucilage, starch paste, or ethylcellulose. The presence of a disintegrating agent notably affected the dissolution rate of the active ingredient, especially where wet granulation was employed. The release of sodium salicylate from several bases was a result of the interaction of many variables and was not dependent solely upon the effect of an individual component.

THE EFFECT of formulation and processing factors on the dissolution rate of active ingredients from compressed tablets has been the subject of a number of reports. Wensley (1), using a modification of the Gershberg-Stoll apparatus, investigated the effects of granulating agents and pressure on the dissolution rate of sodium bicarbonate tablets. Kadar and Walker (2) studied the *in vitro* release of sulfathiazole from compressed formulations using a modification of the U.S.P. XV tablet disintegration apparatus. The effects of particle density and neutral ionic and nonionic compounds on the dissolution rate of slightly soluble acidic drugs were determined by Parrott *et al.* (3). In a later study by the same workers (4) the influences of bases and buffers on rates of dissolution of acidic solids were investigated. Levy (5–7) studied the effect of formulation factors on the dissolution rate of the active ingredient. Included in the factors studied were the agitation intensity, granule size, starch concentration, compression pressure, and lubricants.

With the advent of new machines and materials, a great many tablets formerly prepared by wet granulation can now be manufactured by direct compression. Various direct compression fillers have been evaluated: spray-dried lactose by Gunsel and Lachman (8) and by Duvall *et al.* (9), microcrystalline cellulose by Reier and Shangraw (10), amylose by Kwan and Milosovich

Dissolution of Sodium Salicylate from Tablet Matrices Prepared by Wet Granulation and Direct Compression

By EDWARD MARLOWE* and RALPH F. SHANGRAW

A quantitative evaluation of dissolution of active ingredients from tablets is discussed. An investigation of filler-binder, lubricant, disintegrating agent, and hardness on the dissolution rate of sodium salicylate from tablet bases was studied by means of a 4 × 3 × 2 × 2 factorial experiment and analysis of variance. The utilization of a filler, spray-dried lactose, which required no preliminary granulation, gave significantly faster release rates than granulations prepared with acacia mucilage, starch paste, or ethylcellulose. The presence of a disintegrating agent notably affected the dissolution rate of the active ingredient, especially where wet granulation was employed. The release of sodium salicylate from several bases was a result of the interaction of many variables and was not dependent solely upon the effect of an individual component.

THE EFFECT of formulation and processing factors on the dissolution rate of active ingredients from compressed tablets has been the subject of a number of reports. Wensley (1), using a modification of the Gershberg-Stoll apparatus, investigated the effects of granulating agents and pressure on the dissolution rate of sodium bicarbonate tablets. Kadar and Walker (2) studied the *in vitro* release of sulfathiazole from compressed formulations using a modification of the U.S.P. XV tablet disintegration apparatus. The effects of particle density and neutral ionic and nonionic compounds on the dissolution rate of slightly soluble acidic drugs were determined by Parrott *et al.* (3). In a later study by the same workers (4) the influences of bases and buffers on rates of dissolution of acidic solids were investigated. Levy (5–7) studied the effect of formulation factors on the dissolution rate of the active ingredient. Included in the factors studied were the agitation intensity, granule size, starch concentration, compression pressure, and lubricants.

With the advent of new machines and materials, a great many tablets formerly prepared by wet granulation can now be manufactured by direct compression. Various direct compression fillers have been evaluated: spray-dried lactose by Gunsel and Lachman (8) and by Duvall *et al.* (9), microcrystalline cellulose by Reier and Shangraw (10), amylose by Kwan and Milosovich

Received January 18, 1965, from the School of Pharmacy, University of Maryland, Baltimore, MD 21201

(11), and anhydrous lactose by Batuyios (12).

However, wet granulation continues to be widely employed, and proponents of this process argue that dissolution of active ingredients from granulated matrices is equal or may be superior to that from direct compression matrices. The object of this investigation was to study the individual effects and possible interactions of filler, binder, disintegrating agent, lubricant, and pressure on the release of an active ingredient from tablets prepared by wet granulation and compare such tablets with those made by direct compression. By means of statistical analysis, the magnitude of the individual factors as well as interactions were determined.

EXPERIMENTAL

Apparatus and Method—Many methods have been utilized for studying dissolution rates from tablets. The apparatus used in this study was similar to the one utilized by Patel and Foss in their studies on binding (13). A typical cell is shown in Fig. 1. Various membranes were studied in an attempt to find one which would give rapid equilibrium and at the same time provide adequate filtration. Many membranes were found to be unsatisfactory because they exhibited extremely long equilibrium times, possessed poor wet strengths, or gave rise to cloudy solutions. However, four thicknesses of a thin paper membrane[1] proved to overcome these difficulties. As no apparatus or procedure can exactly duplicate *in vivo* conditions, all dissolution studies are relative, and the most important considerations are ones of reproducibility, practicality, and reasonableness. The apparatus and method appeared to qualify in these respects.

The plastic cell was assembled, 15 ml. of distilled water placed on each side of the membrane, and the entire assembly placed in a water bath maintained at 37°C. When the experimental temperature was reached, two tablets from each batch were inserted into one side of the cell. The cell was rotated in the water bath at a rate of 15 r.p.m. At specified intervals, 1-ml. samples were removed from the cavity on the other side of the membrane, appropriately diluted, and assayed spectrophotometrically.

The dissolution procedure is not as simple as would be desirable. The manual removal of samples and their assay are time consuming, and interruption of the rotation of the cell is necessary while samples are withdrawn. Even though the tablet remains immersed in the liquid and the removal procedure standardized, there is a chance for a slight distortion (reflected in a delay) in the dissolution profile. Obviously, an automatic sampler and analyzer would be advantageous.

Formulation and Preparation of Tablets—Sodium salicylate was chosen as an active ingredient due to its solubility characteristics and ease of assay. Test solutions were diluted with distilled water and absorbance read on a Beckman DU spectrophotometer at 296 mμ. It was found that approximately 6 min. were required to obtain equilibrium when a solution of sodium salicylate was placed into one side of the dissolution cell. Although a 6-min. equilibrium time is longer than might be ideally desirable, a high percentage of the drug does pass the membrane rapidly, and the delay is not unreasonable when comparable *in vivo* absorption conditions are considered.

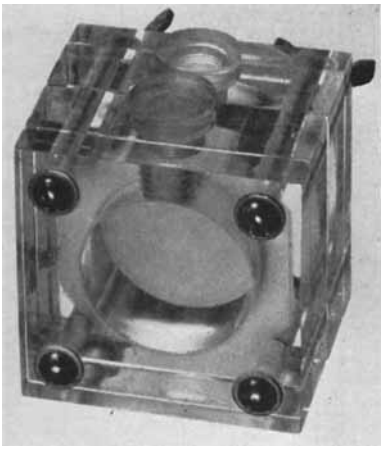

Fig. 1—Plastic dissolution cell.

Tablets were prepared containing 50 mg. of sodium salicylate made up to a total weight of 400 mg. with binder, lubricant, disintegrating agent, and filler. Two fillers (lactose and spray-dried lactose), three binding solutions (5% ethylcellulose in alcohol, 10% acacia mucilage, and 10% starch paste), and three lubricants (1% magnesium stearate, 1% hydrogenated vegetable oil,[2] and 3% of a soluble lubricant composed of a 1:1:2 ratio of DL-leucine, calcium benzoate, and polyethylene glycol 4000) were studied. Absence of a disintegrating agent was compared to 10% cornstarch. Since no granulation was necessary with spray-dried lactose, only 5% starch was added, and the difference in weight was made up with additional spray-dried lactose. The sodium salicylate, starch, and lubricant were blended with the spray-dried lactose, and tablets compressed directly.

The tablets prepared by wet granulation were manufactured by first blending the lactose, sodium salicylate, and one-half the starch (when present), and then moistening the powder blend with the appropriate binding solution. An attempt was made to maintain an equal amount of solid binder in the final granulation. The wet mass was forced through a No. 8 screen and allowed to dry overnight in an oven at 120°F. The dry granules were passed through a No. 12 screen and the lubricant and remaining starch blended into the mixture. Tablets were compressed to two different hardnesses (Strong-Cobb 3.5 and 6.5) on a Stokes model A-3 single punch tablet press.

Tablets were prepared utilizing all possible combinations of filler-binders (lactose–ethylcellulose, lactose–starch paste, lactose–acacia, and plain spray-dried lactose), lubricants, disintegrators, and hardnesses, giving a 4 × 3 × 2 × 2 factorial experiment with 48 batches of tablets. In order to

eliminate variables other than those under consideration, attempts were made to standardize the amount of active ingredient in each tablet as well as tablet weight and thickness.

Results and Treatment of Data—The per cents of dissolution of sodium salicylate from the various tablet formulations are shown in Figs. 2–8. Tablets prepared by direct compression with spray-dried lactose uniformly exhibited more rapid dissolution patterns. In all cases except where no disintegrating agent was employed (Fig. 8), dissolution was complete within 12 min. This includes the uniform delay necessary for equilibrium which is inherent in the experimental method employed. All tablets prepared by wet granulation displayed slower release rates, particularly during the latter stages. The ethylcellulose binding solutions gave the slowest release rates in all cases where disintegrating agents were employed, but no real differences could be noted when a disintegrating agent was not used. In general, an increase in tablet hardness retarded dissolution, while the presence of starch dramatically increased it.

In order to give the data mathematical significance

and to point up interactions between formulation components, an analysis of variance was carried out. The method used for analysis was a $4 \times 3 \times 2 \times 2$ factorial experiment representing four filler-binders, three lubricants, two disintegrating agents, and two compression hardnesses. In order to make use of all the data collected at all nine time intervals, it would have been necessary to calculate a $9 \times 4 \times 3 \times 2 \times 2$ factorial experiment. Because this would have been cumbersome to handle and necessitate the use of a computer, a single time was selected.

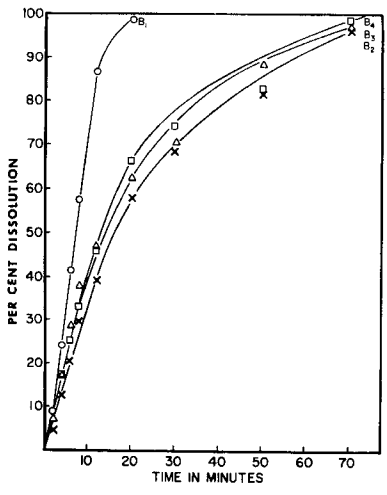

Fig. 8—Comparison of filler-binders in a tablet formula containing no starch, magnesium stearate, and 6.5 S.-C. hardness. Key: B_1, *spray-dried lactose;* B_2, *ethylcellulose and lactose;* B_3, *acacia mucilage and lactose;* B_4, *starch paste and lactose.*

The 8-min. per cent dissolutions chosen as data from that time interval were influenced less by the membrane equilibrium time and had not reached 100% for most formulations. The analysis of variance is shown in Table I.

DISCUSSION

From Table I it can be seen that filler-binders and presence of a disintegrating agent are significant at a 5% level. This was to be expected from visual examination of the data. No two factor interactions were significant at the 5% level which can be attributed to the large mean squares associated with the three factor interactions, two of which (binder–hardness–disintegrating agent and binder–disintegrating agent–lubricant) were significant. These are exactly the same three factor interactions found significant by Kwan *et al.* (14) in their study using disintegration times as end points. By utilization of a t test, it was shown that spray-dried lactose and acacia–lactose give significantly different mean availability times. The calculated t value was 3.93 as compared to a significant value at 95% of 2.02. Since acacia–lactose gave the second fastest availability rate, it can be concluded that spray-dried lactose is significantly superior to the other filler-binders tested in this study.

Analysis of variance was then repeated utilizing only the data obtained from the three filler-binders which required prior granulation, *i.e.*, acacia–lactose, starch–lactose, and ethylcellulose–lactose. The binder effect previously obtained was no longer significant, indicating no substantial difference between acacia, starch, and ethylcellulose. This can be attributed to the lack of differences when no disintegrating agent is employed, as it appears obvious that when a disintegrating agent is used (Figs. 2–7) ethylcellulose gives a much slower release rate. The same three factor interaction, binder–hardness–disintegrating agent, again was shown to be significant. More important, the two factor interaction, binder–disintegrating agent,

became significant. This can be attributed to the large effect the disintegrating agent had on the acacia and starch granulations as opposed to the small effect on the ethylcellulose.

Tablet hardness did not have a significant effect in either study. However, hardness did appear to affect the rate of dissolution from those formulations containing starch. Analysis of variance of 8-min. dissolution data from all tablets containing starch was calculated. Hardness still did not show up as a significant factor, although the binder–hardness interaction was extremely significant. One of the reasons for lack of significance was the softness of tablets obtained from both pressure settings. It is probable that tablets of both hardnesses possessed sufficient pore spaces to promote capillary water penetration and subsequent tablet rupture. The high interaction term can be attributed in large measure to the little effect hardness had in spray-dried lactose tablets, even in the presence of starch.

In order to further substantiate that the presence of a disintegrating agent was significant, a *t* test was carried out on the mean per cent dissolution of sodium salicylate from 6-min. samples containing starch and no starch. The difference between the means was found to be significant, the calculated *t* value being 2.64 as compared to a table value of 2.01 for significance at the 95% level.

One further study was conducted to show the importance of binders on dissolution for all values of time. In this case, the per cent availabilities of all the filler-binders were compared at different time intervals, keeping pressure constant (high), lubricant the same (magnesium stearate), and including starch in the formulations. Analysis of variance indicated that binders were even more significant when compared over all the time intervals. Of course, time showed up highly significant as would be expected.

In order to make a more meaningful study, the disintegration times of all batches prepared were determined by the U.S.P. XVI method. An analysis of variance of the mean disintegration times was computed. The same single effects, filler-binder and disintegrating agents, appeared significant at the 95% level as well as the two factor interaction of filler-binder and disintegrating agent. However, no three factor interactions were significant due to the fact that the residual or error term against which three factor interactions were tested was large. This can be attributed to the large inherent error in disintegration time determinations which arise from indistinct end points and operator variability. The statistical analysis of the U.S.P. disintegration results failed to demonstrate the interplay between component variables present in normal formulations and reflected in *in vitro* release data.

In an attempt to summarize the preceding experiments, the mean dissolution per cents for 8-min. samples and the mean disintegration times are presented in Tables II and III. Both tables denote analogous results indicating that an 8-min. dissolution test gives the same indications of component effects as much longer disintegration times. The spray-dried lactose showed superior release rates followed by acacia–lactose, starch–lactose, and ethylcellulose–lactose.

In order to present these dissolution data in a manner which more closely approximates disintegration times, an attempt was made to determine the mean 100% dissolution times. However, this end point did not always give good comparable data as can be seen from the dissolution curves in Figs. 2–8. Thus, the times necessary for samples to reach 80% dissolution were chosen for comparison and the means of these values are presented in Table IV. These figures substantiate the same order of dissolution previously described. However, the difference between acacia and starch as binders is negligible. It is quite apparent from Tables III and IV that the time for 80% availability appears to differ significantly from the mean disintegration time. Even taking into consideration a delay in equilibrium time, the dramatic increase in the amount of time necessary to obtain only 80% dissolution points up the inadequacy of the U.S.P. XVI disintegration method for determining active ingredient release patterns.

One of the objects of this investigation was to study the effect of a water-soluble lubricant com-

posed of a DL-leucine, polyethylene glycol 4,000, and calcium benzoate on the availability of active ingredients. It was hoped that the soluble lubricant would increase dissolution over the more conventionally used stearates. However, lubricant variation did not appear significant in any of the studies. As shown in Fig. 9, which represents the data in a typical formulation containing starch, acacia–lactose, and compressed at high pressure, the soluble lubricant exhibited the fastest dissolution rate, followed by hydrogenated vegetable oil and then magnesium stearate. This pattern, although showing only slight differences, was consistent throughout all the work.

The results of the investigation indicate that for this particular active ingredient and the various factors studied, direct compression uniformly gives rise to faster dissolution rates than wet granulation. In addition, direct compression is clearly less time consuming and requires less equipment than wet granulation. On the other hand, both acacia and gelatin gave tablets which exhibited acceptable dissolution profiles when a disintegrating agent was present, indicating that wet granulation is still an effective means of preparing powders for compression. It appears, however, that economics alone will lead to a steady decrease in the utilization of wet granulation procedures, and the process will eventually be confined to those drugs which cannot be adapted to direct compression techniques.

SUMMARY AND CONCLUSIONS

1. An apparatus and procedure for the determination of the *in vitro* dissolution of active ingredients from tablets is described.

2. The effect of filler-binders, lubricants, disintegrating agents, and hardness on the dissolution of sodium salicylate from tablet bases was studied by means of a $4 \times 3 \times 2 \times 2$ factorial experiment.

3. Tablets prepared by direct compression with spray-dried lactose exhibited faster dissolution rates for sodium salicylate than tablets prepared by wet granulation.

4. Dissolution of an active ingredient from a tablet matrix is generally not dependent solely on the effect of a single component or production

specification, but is the result of the interaction of many variables.

Preliminary Investigation of the *Z*-Value Measure of Relative Solvent Polarity in Micellar Solubilization

By STEVEN G. BJAASTAD and NATHAN A. HALL

The *Z*-value method for determining solvent polarity has been applied to surfactant solutions containing camphor and 2-heptanone. The surfactants used were partially purified polysorbate 80, potassium laurate, and dodecyltrimethylammonium chloride. As the surfactant concentration increased the *Z*-value decreased, indicating that the solubilized ketones encountered an environment of decreasing polarity. In the polysorbate 80 system 2-heptanone appeared to be solubilized deeper in the micelle interior than camphor. Both ketones in 0.2 *M* potassium laurate solutions were solubilized in more highly polar environments than in 0.2 *M* dodecyltrimethylammonium chloride solutions.

SURFACTANTS, as agents for making aqueous solutions of poorly water-soluble substances, continue to be of interest in pharmaceutical as well as many other systems. The solute is considered to be solubilized by the less polar micellar pseudophase, and this type of solubilization has been shown to affect the chemical and biological properties of the solubilizate. Compounds are thought to be solubilized in various regions of the micelle: on the surface, in the palisade layer, or in the lipophilic micellar core (1, 2). It is logical to assume, therefore, that solubilized molecules would encounter regions of varying polarity.

Riegelman *et al.* (3) have shown that the ultraviolet absorption spectra of solubilized compounds alter upon solubilization and have drawn certain conclusions regarding the micellar region of solubilization from the spectra of solubilized systems. The ultraviolet spectral investigations of Sasaki *et al.* (4) indicated that the micellar interior in solubilized systems does contain some water.

Although polarity is reflected by a number of measurements on bulk liquids, such as dielectric constant and refractive index, the correlation of such measurements with the liquid's solvent properties has been shown to have many limitations. No single measurement appears to be valid in more than a general way for predicting solubility and the effect of a given solvent on the properties of its solutions. Several investigators have attempted to improve the situation by developing empirical methods to assess the relative polarity of a series of solvents (5–9). One of these, the *Z*-value method developed by Kosower (9), appeared to be promising enough for use in examining micellar solubilized systems and was the subject of this study.

Based upon the assumption that the first layers of solvent around a molecule or ion will be appreciably different in dielectric constant from that measured for the bulk solution, Kosower originated the *Z*-value method for measuring the relative polarity of the layer of solvent molecules immediately surrounding the solute molecule (cybotactic region). The *Z*-value was defined as the energy of electronic transition corresponding to the charge-transfer absorption band of 1-ethyl-4-carbomethoxy pyridinium iodide. The shift of this band to longer wavelengths, occurring with solvents of decreasing polarity, was found to correlate well with other phenomena, such as rates of hydrolysis and keto–enol equilibria, which were known to be sensitive to solvent polarity. Subsequently, many substances were found to exhibit solvent-sensitive absorption spectra and

Preliminary Investigation of the *Z*-Value Measure of Relative Solvent Polarity in Micellar Solubilization

By STEVEN G. BJAASTAD and NATHAN A. HALL

The *Z*-value method for determining solvent polarity has been applied to surfactant solutions containing camphor and 2-heptanone. The surfactants used were partially purified polysorbate 80, potassium laurate, and dodecyltrimethylammonium chloride. As the surfactant concentration increased the *Z*-value decreased, indicating that the solubilized ketones encountered an environment of decreasing polarity. In the polysorbate 80 system 2-heptanone appeared to be solubilized deeper in the micelle interior than camphor. Both ketones in 0.2 *M* potassium laurate solutions were solubilized in more highly polar environments than in 0.2 *M* dodecyltrimethylammonium chloride solutions.

SURFACTANTS, as agents for making aqueous solutions of poorly water-soluble substances, continue to be of interest in pharmaceutical as well as many other systems. The solute is considered to be solubilized by the less polar micellar pseudophase, and this type of solubilization has been shown to affect the chemical and biological properties of the solubilizate. Compounds are thought to be solubilized in various regions of the micelle: on the surface, in the palisade layer, or in the lipophilic micellar core (1, 2). It is logical to assume, therefore, that solubilized molecules would encounter regions of varying polarity.

Riegelman *et al.* (3) have shown that the ultraviolet absorption spectra of solubilized compounds alter upon solubilization and have drawn certain conclusions regarding the micellar region of solubilization from the spectra of solubilized systems. The ultraviolet spectral investigations of Sasaki *et al.* (4) indicated that the micellar interior in solubilized systems does contain some water.

Although polarity is reflected by a number of measurements on bulk liquids, such as dielectric constant and refractive index, the correlation of such measurements with the liquid's solvent properties has been shown to have many limitations. No single measurement appears to be valid in more than a general way for predicting solubility and the effect of a given solvent on the properties of its solutions. Several investigators have attempted to improve the situation by developing empirical methods to assess the relative polarity of a series of solvents (5–9). One of these, the *Z*-value method developed by Kosower (9), appeared to be promising enough for use in examining micellar solubilized systems and was the subject of this study.

Based upon the assumption that the first layers of solvent around a molecule or ion will be appreciably different in dielectric constant from that measured for the bulk solution, Kosower originated the *Z*-value method for measuring the relative polarity of the layer of solvent molecules immediately surrounding the solute molecule (cybotactic region). The *Z*-value was defined as the energy of electronic transition corresponding to the charge-transfer absorption band of 1-ethyl-4-carbomethoxy pyridinium iodide. The shift of this band to longer wavelengths, occurring with solvents of decreasing polarity, was found to correlate well with other phenomena, such as rates of hydrolysis and keto–enol equilibria, which were known to be sensitive to solvent polarity. Subsequently, many substances were found to exhibit solvent-sensitive absorption spectra and

were utilizable for Z-value determinations. In 1961 Kosower showed that the low intensity n to π^* electronic transitions of cyclic ketones were sensitive to changes in solvent polarity and one, cyclohexanone, could be used as a secondary standard for determining solvent Z-values (10).

In applying the Z-value method to solubilized systems it was assumed that the electronic transitions, as reflected by the ultraviolet absorption peak shifts, are due to the same forces of interaction between the solute and its cybotactic region in solubilized systems as in simple binary alcohol–water systems. In absence of information to the contrary, it was further assumed that the electronic transitions in the solute depend only upon the Z-value of the solvent, thus making the solubilizate behavior regular and predictable.

The study reported here involved the application of the Z-value method to the examination of the environment of several ketones in aqueous surfactant solutions. The surfactants chosen were an anionic agent, potassium laurate; a cationic agent, dodecyltrimethylammonium chloride; and a nonionic agent, polysorbate 80. Two micellarly solubilized ketones, camphor and 2-heptanone, were used and two ketones with appreciable water-solubility, cyclohexanone and norcamphor, were also used for comparison. Subsequent to this investigation, the behavior of camphor in polysorbate 20 solutions was studied (11).

EXPERIMENTAL

Materials—The surfactants, potassium laurate, dodecyltrimethylammonium chloride, and partially purified polysorbate 80, were prepared by a previously described method (12). Norcamphor (Aldrich Chemical Co.) and D-camphor (Eastman Organic Chemicals) were purified by sublimation immediately before use. The cyclohexanone and 2-heptanone (Matheson, Coleman and Bell) were purified by preparation of the bisulfites, regeneration with alkali, and fractional distillation. Solvents of reagent grade were not further purified. The n-hexanone was fractionally distilled after washing with acid permanganate. Acetonitrile was dried over P_2O_5 and fractionally distilled. Ethanol was redistilled at atmospheric pressure.

Surfactant solutions of the ketones which were saturated were prepared by adding an excess of solute and shaking for 24 to 48 hr. at room temperature. For spectral readings the solutions were filtered into the absorption cells through a Swinney filter adapter (0.45-μ disk) attached to a hypodermic syringe. Solutions not saturated were made of such concentration that the absorbance maxima could be readily determined.

Procedure—Spectral measurements were made in matched cylindrical absorption cells (10 and 1 mm. light path) with a model 14 Cary recording spectrophotometer. The reference cell for each measurement contained only the solvent or surfactant solution. The absorption maxima were determined by placing the solvent in each of the matched absorption cells and a solvent–solvent base line was recorded between 310 mμ and 250 mμ. The cell in the sample compartment was then removed, emptied, and filled with the ketone-containing solution. After the chart paper and wavelength scale were returned to their starting positions and the sample cell replaced, the spectrum between 310 mμ and 250 mμ was recorded at a scanning speed of 0.25 mμ/sec. The location of the spectral peak was noted, and a 10-mμ spectral recording was made over the region including the peak at a scanning speed of 0.05 mμ/sec. The slow speed 10-mμ recording was repeated twice and values of the three determinations were averaged. Repeated observations showed that this method gave maxima of $\pm$0.4 mμ precision.

This procedure gave the following absorption maxima for the ketones in simple aqueous solution: camphor, 284.1 mμ; norcamphor, 281.6 mμ; 2-heptanone, 272.2 mμ; and cyclohexanone, 277.1 mμ.

The energy of the n–π^* transition (E_t) was calculated from the wavelength of the absorption maxima ($\lambda_{max.}$) through the use of the relationship (13):

$$E_t = 2.859 \times 10^4/\lambda_{max.\ (in\ m\mu)}\ \text{Kcal./mole}$$

Solvent polarity (Z) values for the solvents used in this study were obtained from the published works of Kosower (9, 10, 14) or were determined from the measured absorption maximum of dissolved cyclohexanone. The Z-value of a given solvent could be calculated from the equation expressing its linear relationship with the transition energy of cyclohexanone:

$$E_t = 0.14650\ Z + 89.234\ (10)$$

The solvents used and their Z-values are listed in Table I.

none, the absorption maxima in the solvents listed in Table I were carefully measured, and a plot of E_t *versus* Z was made. With 2-heptanone, only a single linear correlation was evident; however, with camphor and norcamphor two linear correlations were found. One line described the correlation in water-containing solvent systems and another the anhydrous systems. Table II indicates the results of the least squares regression analysis of the data for the ketones used in this study.

Ketones in Aqueous Surfactant Systems—Initially the absorption maxima for various ketones were measured in partially purified polysorbate 80 solutions to determine whether the method would show lower polarity regions for the solubilized ketones than for those which were water-soluble. Because of their appreciable water-solubilities, norcamphor and cyclohexanone were examined in less than saturated solutions. The plot of Z *versus* polysorbate 80 concentration for saturated solutions of camphor and 2-heptanone is shown in Fig. 1.

The Z-values for norcamphor and cyclohexanone in polysorbate 80 solutions up to 2% showed an environment of essentially the same polarity as water, indicating that significant quantities were not included in the micellar phase. Camphor and 2-heptanone, both possessing low water-solubility, would be expected to be included in the micelles, and the Z-value of the surfactant system indicates an increasingly less polar environment as the surfactant concentration increased. At low surfactant concentrations both ketones behaved as if in an aqueous environment, however.

The lower polarity of the environment of the ketones may come about through the increased concentration of micelles at higher surfactant concentrations, increased micellar organization, or deeper penetration of the micelles by the ketone molecules. Interpretations of X-ray data (2, 15) suggest that micellar organization does increase with concentration. The relative regions of solubilization in the micelle can be deduced by comparing the changing Z-values of the two ketones. With increasing concentrations of polysorbate 80, 2-heptanone apparently encounters a less polar environment than camphor, hence it is probably deeper within the micelle. One would expect 2-heptanone, a rather flexible molecule, to be able to penetrate the micellar interior farther than camphor, a bulky molecule of rigid spherical shape. Possible multilayer adsorption or tail-to-tail adsorption following initial adsorption, as described by DeLuca and Kostenbauder (16), also might account for the less polar environment of 2-heptanone, however.

The decrease in Z-value did not appear to depend upon the concentration of solubilizate, even though the saturated solutions with the lower Z-values do contain higher solubilizate concentrations. When spectra of solutions containing a constant concentration of camphor (1 mg./ml.) were measured, the Z-values were the same as in the saturated solutions

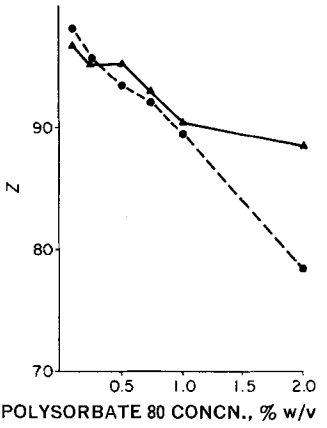

Fig. 1—Solvent polarity (Z) versus *polysorbate 80 concentration for saturated solutions of* D-*camphor* (▲) *and 2-heptanone* (●).

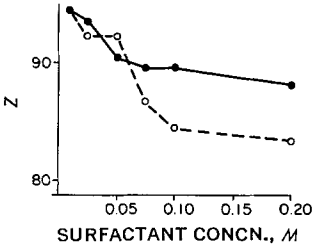

Fig. 2—Solvent polarity (Z) versus *molar surfactant concentration for* D-*camphor in potassium laurate solutions* (●) *and in dodecyltrimethylammonium chloride solution* (○).

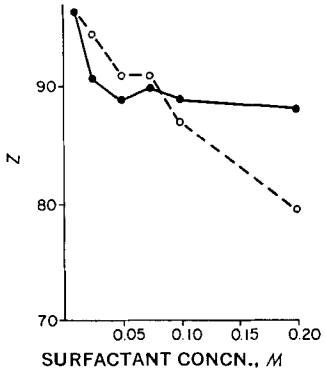

Fig. 3—Solvent polarity (Z) versus *molar surfactant concentration for 2-heptanone in potassium laurate solutions* (●) *and dodecyltrimethylammonium chloride solutions* (○).

within experimental error. Bjaastad and Brown (11) also found constant Z-values for varying camphor concentrations in polysorbate 20 solutions.

The behavior of the Z-value with concentration was also examined with the anionic surfactant, potassium laurate, and the cationic agent, dodecyltrimethylammonium chloride. The data from saturated camphor solutions were plotted for Fig. 2, and the data for saturated 2-heptanone solutions were plotted for Fig. 3.

Examination of Figs. 2 and 3 shows that the environmental polarity of the solubilized ketones begins to fall off above the CMC of both ionic surfactants (about 0.02 M). Dodecyltrimethylammonium chloride solutions exhibit the less polar cybotactic regions at high surfactant concentrations. In the potassium laurate solutions, however, the Z-value appears to attain a plateau. Klevens (2) has reported that potassium laurate achieves "full colloidal form" at about 0.15 M.

The Z-value method of measuring the polarity of the cybotactic region for micellar systems containing solubilizates appears to show promise. The polarity revealed by the method seems to conform to current micellar theories. Experimental refinements through the use of cells with shorter light paths may make possible the study of higher surfactant concentrations and solubilizates with higher molar absorptivities. Since the Z-value is an empirical measure, studies involving its use probably will not have great theoretical significance; however, further investigation of the method is warranted to gain more knowledge of solubilization in complex micellar systems.

Preparation of Tritium-Labeled Compounds II

Chlorphenesin Carbamate by Exposure to Tritium Gas and Determination of Intramolecular Distribution of Tritium

By RICHARD C. THOMAS, DONALD R. BUHLER, and GEORGE J. IKEDA

Incorporation of stably bound tritium in purified chlorphenesin carbamate was 141 μc. per curie-day exposure. The intramolecular distribution of radioactivity was determined by a combination of biological and chemical degradation methods. Aromatic substitution predominated, accounting for 95 per cent of the tritium; two-thirds of this was located *ortho* to the chlorine substituent. The remaining 5 per cent of the radioactivity resided at the number one position of the alkoxy side chain.

CHLORPHENESIN CARBAMATE[1] [3-(*p*-chlorophenoxy)-1,2-propanediol 1-carbamate; I] is a new, centrally acting skeletal muscle relaxant recently discussed by Matthews *et al.* (1).

I

This report describes the preparation of labeled chlorphenesin carbamate by the tritium gas exposure method of Wilzbach (2) and determination of the intramolecular distribution of tritium in the resulting product.

This compound was prepared in a radioactive form to facilitate a study of its metabolism, part of which has recently been reported (3, 4). Exchange labeling by exposure to tritium gas was employed since previous experience (5) in this laboratory, as well as in others, with compounds of comparable structure indicated that incorporation of tritium would be adequate and purification would be feasible.

Advantage was taken of the rather unique pathway for metabolism of chlorphenesin carbamate in the rat (3) (Scheme I) to determine the complete intramolecular distribution of tritium in

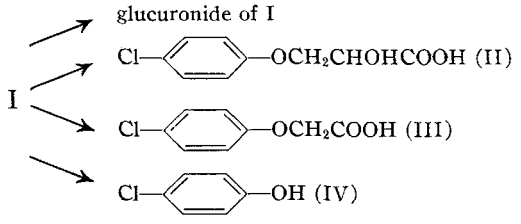
this compound. The location of tritium on the side chain was determined by measuring the specific activities of the metabolites isolated from urine. Thus, the differences in molar specific activities of I and II, II and III, and III and IV represent tritium incorporation on the number one carbon atom (and amide nitrogen), the number two carbon atom, and the number three carbon atom, respectively. Bromination of one of the metabolites, *p*-chlorophenol (IV), was employed to locate tritium on the aromatic ring. The specific activity of the bromination product, 2,6-dibromo-4-chlorophenol (V), represents tritium incorporation *ortho* to the chlorine substituent, whereas the difference in specific activities of IV and V represents tritium incorporation *ortho* to the alkoxy side chain.



Major Metabolites of Chlorphenesin Carbamate (I) in the Rat (3)

Scheme I

EXPERIMENTAL

Radioactivity Measurements—All counting was performed with a Tri-Carb[2] model 314X or 314EX2A liquid scintillation spectrometer at −8° under conditions suitable for measuring tritium. Appropriate aliquots of samples were dissolved in 15 ml. of diotol scintillator (6) [toluene–dioxane–methanol (350:350:210 by volume) containing 73 Gm. of naphthalene, 4.6 Gm. of 2,5-diphenyloxazole, and 0.08 Gm. of 1,4-bis-2-(5-phenyloxazolyl)-benzene per L.]. The absolute counting efficiency for each sample was determined by recounting following addition of an internal standard of tritium-labeled toluene and results then expressed as microcuries (μc.) or disintegrations per minute (d.p.m.). Paper chromatograms were scanned for radioactivity with a Forro[3] 2-π or 4-π radiochromatogram scanner.

Paper Chromatography—Chromatograms were developed by the descending method using Whatman No. 2 paper in the following systems: (*a*) 1-butanol–water (4:1 by volume); (*b*) 1-butanol–piperidine–water (81:2:17 by volume); (*c*) Bush B-3 (7), benzene–Skellysolve C–methanol–water (333:667:800:200 by volume); (*d*) Mattox BFW (8), paper impregnated with formamide–methanol (1:1 by volume), mobile phase butyl acetate–formamide–water (100:5:5 by volume); and (*e*) Zaffaroni type paper (9), impregnated with formamide–methanol (1:1 by volume), mobile phase benzene–chloroform (1:1 by volume) saturated with formamide.

[3] Forro Scientific Co., Evanston, Ill.

Exposure to Tritium and Purification of Chlorphenesin Carbamate—A 2-Gm. sample of finely pulverized chlorphenesin carbamate was exposed to 4 c. of carrier-free tritium gas at room temperature in the dark for 32 days under approximately 0.2 Atm. tritium pressure. Following removal of the tritium gas, the crude sample was dissolved in ethanol and the resulting solution was evaporated to dryness *in vacuo*. Labile tritium was completely removed by repeating this procedure twice. The specific activity of the product at this stage was 76 μc./mg. This material was recrystallized twice from ethanol with the aid of charcoal to yield 1.55 Gm. of product having a specific activity of 27.3 μc./mg. Paper chromatography in the butanol–water, the butanol–piperidine–water, and the Bush B-3 systems, followed by scanning for radioactivity, showed 70% of the radioactivity apparently associated with chlorphenesin carbamate and the remaining 30% associated with an impurity less polar than the desired product. The sample was dissolved in methylene chloride and the solution was applied to a 2.8 × 122 cm. adsorbent magnesium silicate[4] column. The column was developed by the gradient technique using 2 L. of 20% acetone in Skellysolve B and 2 L. of 75% acetone in Skellysolve B while collecting 100-ml. fractions. The product emerged at approximately 45% acetone in Skellysolve B and comprised three major weight fractions. Each of these fractions revealed a single radioactive zone corresponding to chlorphenesin carbamate when subjected to paper chromatography as previously described. However, the three fractions had specific activities of approximately 9.5, 10.2, and 22.9 μc./mg., respectively, indicating the presence of a high specific activity impurity not resolved from the desired product by the three paper chromatography systems employed. This was confirmed in that paper chromatography in the Mattox BFW and the Zaffaroni systems revealed two radioactive zones, one of which corresponded to chlorphenesin carbamate, in the cases of the two fractions having the higher specific activities. The fraction having a specific activity of 9.5 μc./mg. revealed a single radioactive zone corresponding to the desired product. This fraction was diluted with an equal weight (0.590 Gm.) of nonradioactive chlorphenesin carbamate and recrystallized from ethanol–water to yield 1.00 Gm. of product having a specific activity of 4.5 μc./mg. and a melting point of 89–89.5° (capillary, uncorrected; authentic chlorphenesin carbamate had the same melting point). The ultraviolet and infrared spectra of the product corresponded to those of authentic chlorphenesin carbamate. The material showed a single radioactive zone corresponding to the mobility of the desired product in each of the five previously mentioned paper chromatography systems.

Biological Degradation of Tritium-Labeled Chlorphenesin Carbamate—The isolation and characterization of the major urinary metabolites of tritium-labeled chlorphenesin carbamate in rats have been described (3). The specific activities of the

[4] Marketed as Florisil by the Floridin Co., Tallahassee, Fla.

isolated and purified chlorphenesin carbamate (I), *p*-chlorophenoxylactic acid (II), and *p*-chlorophenoxyacetic acid (III), recovered from the urine of rats which had received an oral dose (200 mg./Kg.) of the labeled chlorphenesin carbamate, were determined, and are listed in Table I.

The specific activity of I, recovered from the urine following hydrolysis of the glucuronide conjugate, was 5.8×10^7 d.p.m./m*M*. This was somewhat less than the value of 5.9×10^7 d.p.m./m*M* for the administered drug. The difference probably reflects a slight loss of tritium label *in vivo* (3).

The specific activity of the volatile metabolite, *p*-chlorophenol (IV), was estimated to be 5×10^7 d.p.m./m*M* on the basis of spectrophotometric determination of concentration in a chloroform solution. For an accurate determination of its specific activity, a nonvolatile derivative was prepared that could be further purified and would not lose exchangeable tritium during its formation. Thus, a portion of radioactive IV was condensed (as described in detail for its chemical degradation below) with chloroacetic acid under basic conditions to yield a small amount of crude III. The derivative was purified by recrystallization from methylene chloride to yield 1 mg. of III. This material was further purified by thin-layer chromatography on silica gel GF[5] using the system chloroform–methanol–formic acid–water (1000:100:4:96 by volume). The radioactive zone comprising III was eluted with 0.1 *N* HCl and the acid solution was extracted four times with chloroform. The concentration of III in the extract was determined by measuring its absorption at 227 mμ using the absorptivity for standard III at this wavelength (a = 62.76). The radioactivity was determined on duplicate aliquots of the extract and the specific activity of III then calculated. The value of 5.5×10^7 d.p.m./m*M* for the specific activity of IV determined in this manner is reported in Table I.

Chemical Degradation of p-Chlorophenol—A portion of the chloroform solution of radioactive IV, containing 7.1 mg. and 3.0×10^6 d.p.m. isolated from the urine of rats in the study described above (3), was mixed with 180 mg. of nonradioactive IV[6] carrier, and the chloroform solution was then extracted twice with 2-ml. portions of 1 *N* NaOH solution, and finally with 10 ml. of water. The combined basic extracts and washing were acidified with dilute H_2SO_4 and the solution was subjected to steam distillation. The distillate, containing the purified, diluted IV, was acidified with dilute H_2SO_4 and extracted five times with chloroform. The organic phase was washed with water to yield a chloroform solution of radioactive, diluted IV containing 2.74×10^6 d.p.m.

As a check on the reliability of the dilution and distillation procedures, the concentration of dilute IV in the chloroform extract was calculated from a measurement of its absorption at 283 mμ using the absorptivity of authentic IV at this wavelength (a = 14.16). The solution was found to contain 160 mg. of diluted IV, thus giving a calculated specific activity of 2.2×10^6 d.p.m./m*M*. For an accurate determination of its specific activity, however, one-half of the chloroform solution containing 80 mg. (0.62 m*M*) and 1.36×10^6 d.p.m. of tritium-labeled diluted IV was added to 0.3 ml. of 5 *N* NaOH (1.5 m*M*) and the chloroform was removed *in vacuo*. Chloroacetic acid (79 mg., 0.75 m*M*) and 0.8 ml. of water were then added to the mixture which was heated under reflux for 6 hr. The cooled reaction mixture was then diluted with 10 ml. of water, acidified with dilute H_2SO_4, and extracted four times with ethyl ether. The ether solution was in turn extracted with 10 ml. of 0.2 *M* $NaHCO_3$ followed by water. The combined basic extract and washing were acidified with dilute H_2SO_4 and then extracted four times with ethyl ether. The combined ether extracts were washed with water and then evaporated to dryness *in vacuo* and the crude diluted III was recrystallized twice from methylene chloride to yield 54 mg. of crystals, m. p. 156–157° [capillary, uncorrected; lit. (3) value 157–158°]. The infrared spectrum of the purified material was identical with that of authentic III. The specific activity of diluted III (and therefore of diluted IV) was 2.13×10^6 d.p.m./m*M*, a value in excellent agreement with that (2.08×10^6 d.p.m./m*M*) calculated based on dilution of IV with the carrier.

Anal.—Calcd. for $C_8H_7ClO_3$: C, 51.49; H, 3.78; Cl, 19.00. Found: C, 51.54; H, 4.02; Cl, 19.50.

The second half of the chloroform solution of tritium-labeled diluted IV, containing 1.36×10^6 d.p.m., was extracted with 2 ml. of 1 *N* NaOH and then washed twice with 2-ml. portions of water. The combined basic extract and washings were adjusted to pH 7 with 1 *N* HCl and approximately 2 ml. of a bromine solution (800 mg. KBr dissolved in 5 ml. of water and containing 0.16 ml. of bromine) was added dropwise with stirring until a yellow color persisted (10). The white precipitate was removed by filtration, washed with water, and then recrystallized twice from methanol–water with the aid of charcoal to yield 74 mg. of crystals having a melting point of 89–90° [capillary, uncorrected; lit. (10) value 90°]. The infrared spectrum of the product was identical with that of authentic 2,6-dibromo-4-chlorophenol (V). Previous NMR studies carried out on nonradioactive V, similarly pre-

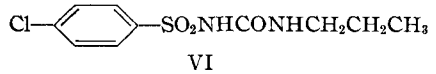
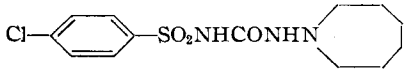
RESULTS AND DISCUSSION

Incorporation of tritium into chlorphenesin carbamate was satisfactory, giving a specific activity of 9.0 μc./mg. (corrected for dilution with nonradioactive carrier). The incorporation of stably bound tritium was thus 141 μc./curie-day exposure, based on the weight of material exposed, the amount of tritium used, the length of the exposure, and the specific activity of the purified product. This falls within the range obtained (67–165 μc./curie-day exposure) for a series of seven sulfonylurea hypoglycemic agents (exposed as sodium salts), having structures somewhat similar to chlorphenesin carbamate (5). Two of the most closely related sulfonylureas, chlorpropamide (VI) and glypinamide (VII),



VI



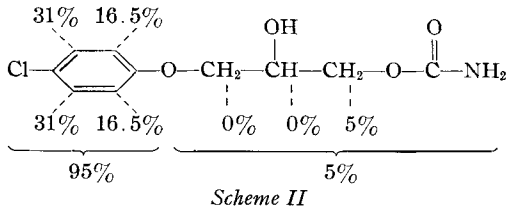
VII

incorporated 161 and 137 μc. of tritium per curie-day exposure, respectively.

The radiochemical purity of compounds labeled by exposure to tritium gas must be carefully determined, as first pointed out by Wilzbach (2). During the exposure, impurities having extremely high specific activities often are formed in trace amounts by weight. Although these high specific activity impurities have little effect on the chemical purity of the product, they can drastically reduce its radiochemical purity. In the present work, three paper chromatography systems showed the presence of one impurity in the tritiated chlorphenesin carbamate prior to column chromatography and no impurities in the major weight fractions eluted from the column. However, the specific activities of the column fractions varied indicating the presence of a second high specific activity impurity, resolved from chlorphenesin carbamate by the column, but not by the three paper chromatography systems. The presence of this impurity was then confirmed with two additional paper chromatography systems.

The data in Table I show the distribution of stably bound tritium in chlorphenesin carbamate exposed to tritium gas to be as shown in Scheme II. The side chain thus contains only 5% of the total molecular radioactivity. This must represent incorporation of tritium on the number one carbon or the amide nitrogen since this amount of tritium was lost upon oxidation of chlorphenesin carbamate to *p*-chlorophenoxylactic acid. Nuclear magnetic

[7] Determined in $CDCl_3$ with a Varian model A-60 instrument using tetramethylsilane internal standard by Dr. G. Slomp and his associates.



Scheme II

resonance studies (11), however, have demonstrated that the amide hydrogens of chlorphenesin carbamate are readily exchangeable with solvent, so tritium in this position would have been lost during purification of the labeled material. Consequently, the side chain tritium label must reside at the number one carbon atom.

The preferential incorporation of tritium into aromatic positions is in agreement with the results of Wilzbach (2) and Ache *et al.* (12) for toluene, Cacace *et al.* (13) for anisole, Meshi and Sato (14) for benzoylvaline, Krizek *et al.* (15) for diethyl benzylacetamidomalonate, and Golder *et al.* (16) for 2,6-di-*tert*-butyl-4-methylphenol. In the latter case, however, there was not a great difference between incorporation of tritium in aromatic positions and in the 4-methyl group. This may be due to shielding of the aromatic positions by the *tert*-butyl groups.

The aromatic ring, accounting for 95% of the molecular radioactivity of chlorphenesin carbamate, contained nearly twice as much tritium *ortho* to the chlorine substituent as *ortho* to the alkoxy side chain.

The distribution of tritium in several other disubstituted benzene derivatives, tritiated by the gas-exposure method, has been reported. Anthranilic acid (17) preferentially incorporates tritium *ortho* to the amino group, whereas salicylic acid (14) preferentially incorporates tritium *ortho* and *meta* to its hydroxyl group; 39% *ortho* and 48% in one or both of the two *meta* positions.

Previous studies with monosubstituted benzene derivatives, tritiated by exposure to tritium gas, have shown that tritium is preferentially incorporated in *ortho* and *para* positions regardless of whether the substituent is nucleophilic or electrophilic. Thus, nitrobenzene (13), chlorobenzene (13), toluene (2, 12), and benzoic acid (14) favor *ortho* incorporation, and anisole (13) favors *para* incorporation. Furthermore, Cacace *et al.* (13) have shown that total incorporation of tritium in the aromatic ring also is nearly independent of the chemical nature of the substituent present; nitrobenzene, chlorobenzene, and anisole, exposed to tritium under identical conditions, attain similar specific activities.

These results suggest that a homolytic, rather than a heterolytic, mechanism is involved in the incorporation of tritium into aromatic positions. Garnett *et al.* (17) proposed such a mechanism to explain the distribution of tritium in anthranilic acid. Ache *et al.* (12) suggested a relationship between incorporation of tritium in aromatic positions and homolytic aromatic substitution. As shown in Table II, a good correlation indeed exists, except for the *meta*/*para* substitution ratio in the case of nitrobenzene.

Pratt and Wolfgang (18) and Wexler (19) have systematically studied the exchange of tritium gas

with methane in the gaseous phase. They concluded that methane incorporates tritium by several mechanisms, all involving heterolytic reactions of positively charged transient species. It would be difficult to apply these mechanisms to more complex systems, particularly to a condensed phase system such as chlorphenesin carbamate.[8] However, it seems unlikely that an electrophilic reaction mechanism could explain the distribution of tritium on the aromatic ring of chlorphenesin carbamate or the other aromatic compounds discussed above.

[8] It is interesting to note that the distribution of tritium in chlorobenzene is essentially the same whether it is tritiated in the gaseous phase or in the presence of excess liquid chlorobenzene (13).

Drug Standards

Outline of Details for Official Microbiological Assays of Antibiotics

By AMIEL KIRSHBAUM and BERNARD ARRET

Tables are presented listing pertinent data required for 57 different microbiological assays, including those for all antibiotics approved for human use in the United States.

In 1959, the authors published an "outline" for assaying antibiotics (1). Development of new methods, modifications and improvements of old ones, and development of methods for antibiotics which have since been discovered necessitate a revision and updating of that publication. As in the earlier article, pertinent information has been tabulated as a ready guide for the analyst performing microbiological assays of antibiotics. Complete details for the assays are not given since these tabulations are prepared for those already familiar with the basic methods. Procedural information can be found in the Code of Federal Regulations (2).

Received October 26, 1966, from the Division of Antibiotics and Insulin Certification, Bureau of Science, Food and Drug Administration, U. S. Department of Health, Education, and Welfare, Washington, DC 20204
Accepted for publication December 27, 1966.

PREPARATION OF MICROBIAL SUSPENSIONS

Since the earlier publication, a uniform procedure for preparation of microbial suspensions has been

TABLE II—COMPARISON OF TRITIATION[a] AND HOMOLYTIC AROMATIC SUBSTITUTION[b]

Accepted for publication December 27, 1966.

PREPARATION OF MICROBIAL SUSPENSIONS

Since the earlier publication, a uniform procedure for preparation of microbial suspensions has been

TABLE I—TEST ORGANISMS FOR VARIOUS ASSAYS

		ATCC No.
(*A*)	*Staphylococcus aureus*	6538P
(*B*)	*Sarcina subflava*	7468
(*C*)	*Sarcina lutea*	9341
(*D*)	*Staphylococcus epidermidis*	12228
(*E*)	*Saccharomyces cerevisiae*	9763
(*F*)	*Bordetella bronchiseptica*	4617
(*G*)	*Bacillus cereus* var. *mycoides*	11778
(*H*)	*Bacillus subtilis*	6633
(*I*)	*Klebsiella pneumoniae*	10031
(*J*)	*Escherichia coli*	10536
(*K*)	*Streptococcus faecalis*	10541
(*L*)	*Micrococcus flavus*	14452
(*M*)	*Microsporum gypseum*	14683
(*N*)	*Sarcina lutea*	9341a

described (3). A modification of this procedure is used for preparing and standardizing most of the microbial suspensions, as follows.

Maintain the test organism on slants of medium No. 1 and transfer to a fresh slant once a week. Using 3 ml. of U.S.P. saline T.S., wash the organism from the agar slant (which has been incubated for 24 hr. at 32–35°) onto a large agar surface of medium No. 1 such as that provided by a Roux bottle containing 300 ml. of agar. Incubate for 24 hr. at 32–35°. Wash the resulting growth from the nutrient surface, using 50 ml. of sterile U.S.P. saline T.S.

Determine the dilution of the suspension with saline that will give a 25% light transmission reading at a wavelength of 580 mμ in a spectrophotometer

TABLE II—MEDIA

Medium	Ingredients	Gm.
(*1*)[a]	Peptone	6
	Pancreatic digest of casein	4
	Yeast extract	3
	Beef extract	1.5
	Dextrose	1
	Agar	15
	Distilled water to make	1000 ml.
	pH 6.55 ± 0.05 after sterilization	
(*2*)[a]	Same as medium *1*, except omit pancreatic digest of casein and dextrose	
(*3*)[a]	Peptone	5.0
	Yeast extract	1.5
	Beef extract	1.5
	Sodium chloride	3.5
	Dextrose	1.0
	Monobasic potassium phosphate	1.32
	Dibasic potassium phosphate	3.68
	Distilled water to make	1000 ml.
	pH 7.0 ± 0.05 after sterilization	
(*4*)[a]	Same as medium *1*, except omit pancreatic digest of casein	
(*5*)[a]	Same as medium *2*, except the pH is adjusted so that it is 7.9 ± 0.1 after sterilization	
(*8*)[a]	Same as medium *2*, except the pH is adjusted so that it is 5.65 ± 0.05 after sterilization	
(*9*)[a]	Pancreatic digest of casein	17.0
	Papaic digest of soy bean	3.0
	Sodium chloride	5.0
	Dibasic potassium phosphate	2.5
	Dextrose	2.5
	Agar	20
	Distilled water to make	1000 ml.
	pH 7.25 ± 0.05 after sterilization	
(*10*)[a]	Same as medium *9*, except use 12 Gm. instead of 20 Gm. of agar. Boil to dissolve the ingredients; then add 10 ml. of polysorbate 80.	
(*11*)[a]	Same as medium *1*, except the pH is adjusted so that it is 7.9 ± 0.1 after sterilization.	
(*13*)[a]	Peptone	10
	Dextrose	20
	Distilled water to make	1000 ml.
	pH 5.65 ± 0.05 after sterilization	
(*18*)[b]	Same as medium *11*, except boil to dissolve the ingredients; then add 20 ml. of polysorbate 80.	
(*19*)[b]	Peptone	9.4
	Yeast extract	4.7
	Beef extract	2.4
	Sodium chloride	10.0
	Dextrose	10.0
	Agar	23.5
	Distilled water to make	1000 ml.
	pH 6.1 ± 0.1 after sterilization	
(*20*)[b]	Dextrose	40.0
	Peptone	10.0
	Chloramphenicol	0.05 (activity)
	Agar	15.0
	Distilled water to make	1000 ml.
	pH 5.65 ± 0.05 after sterilization	
(*21*)[b]	Dissolve 10 mg. of cycloheximide per ml. of distilled water and sterilize by filtration through a membrane filter having a porosity of 0.22 mμ. Aseptically, add 20 ml. of the sterile solution to each liter of medium *20* which has been autoclaved and cooled to 50°.	

[a] Numbers correspond to those used in "Assay Methods of Antibiotics" Grove, D. C., and Randall, W. A., Medical Encyclopedia Inc., New York, N. Y., 1955, p. 220. [b] Numbers assigned by authors.

TABLE III—BUFFERS

Buffer		
I	**1% Phosphate Buffer, pH 6.0 ± 0.05**	
	Dibasic potassium phosphate	2 Gm.
	Monobasic potassium phosphate	8 Gm.
	Distilled water to make	1000 ml.
III	**0.1 M Phosphate Buffer, pH 7.9 ± 0.1**	
	Dibasic potassium phosphate	16.73 Gm.
	Monobasic potassium phosphate	0.523 Gm.
	Distilled water to make	1000 ml.
IV	**0.1 M Monopotassium Phosphate Buffer, pH 4.5 ± 0.05**	
	Monobasic potassium phosphate	13.6 Gm.
	Distilled water to make	1000 ml.
VI	**10% Phosphate Buffer, pH 6.0 ± 0.05**	
	Same as I, except use 10 times as much of each salt.	
X	**0.2 M Phosphate Buffer, pH 10.5 ± 0.1**	
	Dibasic potassium phosphate	35 Gm.
	10 *N* sodium hydroxide	2 ml.
	Distilled water to make	1000 ml.

such as a Bausch & Lomb Spectronic 20, using a round cell with an inside diameter of 1.2 cm.; a Beckman model B spectrophotometer, using a 1.0-cm. square cell; or any other suitable instrument. Use U.S.P. saline as the blank for all instruments. Determine the amount of suspension to be used by test plates or test broth (2, 3).

The test organisms used for the various assays are listed in Table I. The media and buffers are listed in Tables II and III, respectively.

DETAILS OF ASSAY PROCEDURES

Pertinent information for cylinder plate assays is given in Table IV and for turbidimetric assays in Table V.

The third column of the tables, titled "Inoculum," lists the dilution of the stock suspension necessary to obtain 25% light transmission and, in parentheses, the volume of suspension to be added to each 100 ml. of seed medium for plate assays or broth for turbidimetric assays. Those volumes followed by *Footnote b* are added from a dilution of the stock suspension; those without the footnote are added directly from the stock suspension. For example, for penicillin G, the suspension requires a 1 + 19 dilution to give 25% light transmission, and 1.0 ml. of the stock suspension is used per 100 ml. of seed agar. It is stressed that these values are guides only, and each laboratory should perform its own standardization.

For those assays to which the uniform procedure

TABLE IV—PLATE DIFFUSION ASSAYS

should immediately be further diluted with the indicated buffer to obtain a stock solution of convenient concentration.

The entries under "Final Concn. for Std. Curve" are self-explanatory, except that the italicized concentration in each instance is the reference concentration. Authentic standards are supplied by the U.S.P. or N.F. for those antibiotics listed in these compendia.

SUMMARY

Five tables have been presented listing pertinent data required for 57 different microbiological assays, including those for all antibiotics approved for human use in the U. S. For those analysts already familiar with basic procedures, the tables give all of the information necessary for the performance of the assays.

Improved Assay for Dibasic Calcium Phosphate

By LARRY M. KLEINMAN* and HERBERT SCHRIFTMAN

Phosphate ion interference in chelometric titration of calcium can be eliminated by extracting the anion as phosphomolybdic acid. A titrimetric procedure for calcium ion in dibasic calcium phosphate is described. Thermogravimetric analysis shows that dibasic calcium phosphate dihydrate is thermally stable to at least 80°, obviating conversion to the pyrophosphate before assay. The proposed procedure has advantages of speed and accuracy over the U.S.P. assay.

DIBASIC CALCIUM phosphate is an important raw material used in medicine as a calcium replenisher. It has extensive use in pharmacy as an excipient, where it is especially valuable in tablets made by direct compression. Although the official compendia have adopted chelometric titrations for assay of most calcium salts (1), the classical oxalate precipitation and permanganate titration were retained in U.S.P. XVII (2) for dibasic calcium phosphate because phosphate ion interferes with the direct titration of calcium. A procedure which circumvents this interference is reported here.

Assay of dibasic calcium phosphate by the U.S.P. method was found cumbersome and slow in these laboratories, and the values obtained were biased at the low end of the specification. Ion-exchange separation of calcium and phosphate (3) proved unsatisfactory due to incomplete elution of calcium from the resin. Phosphate can be assayed gravimetrically as magnesium pyrophosphate (4), but that procedure has no advantage over the present U.S.P. assay.

Solvent extraction of phosphate as phosphomolybdic acid (5, 6) removes the interference to chelometric titration of calcium, and the yellow color of the extract affords a means for quantitative spectrophotometric determination of phosphate ion as well as obviating an identification test for phosphate. Although quantitation of both the cation and anion are possible, titration of the calcium suffices for quality control of the salt.

In the U.S.P. assay, the salt is dried at 800–850°, and results are reported on the dried basis. In employing this procedure one can omit the drying step because thermogravimetric analysis indicates (*a*) dihydrate is stable to at least 80° and (*b*) samples showed about 1% or less moisture. However, the addition of a simple "loss on drying" or a thermogravimetric determination can provide the data necessary for obtaining an accuracy of better than 1%.

Received June 22, 1966, from the Pharmaceutical Research and Development Laboratories, Warner-Lambert Research Institute, Morris Plains, NJ 07950

Accepted for publication November 17, 1966.

* Cooperative graduate student, Northeastern University School of Pharmaceutical Sciences, Boston, MA 02115

The authors express their sincere appreciation to Dr. Thomas H. Simon for the thermogravimetric analyses of the salt and to Dr. Lester Chafetz for his encouragement and assistance in the preparation of this manuscript.

EXPERIMENTAL

Materials and Supplies—Dibasic calcium phosphate dihydrate U.S.P., hydroxy naphthol blue indicator (U.S.P. XVII, p. 1068), concentrated, 10%, and 1 *N* hydrochloric acid, 40% sodium molybdate, "mixed solvent" (1:1 *n*-butanol–chloroform), 10% sodium hydroxide, exsiccated sodium phosphate N.F., 0.05 *M* disodium ethylenediaminetetraacetate (EDTA), a Beckman DU spectrophotometer, a duPont Thermogravimetric analyzer, model 950, and standard laboratory glassware were used in this work.

Determination of Calcium—Accurately weigh about 1000 mg. of dibasic calcium phosphate dihydrate,[1] and transfer it to a 100-ml. volumetric flask. Add 30 ml. of 10% hydrochloric acid to dissolve the salt, and dilute the solution to the mark with water. Transfer a 5.0-ml. aliquot of the solution to a 250-ml. separator containing 20 ml. of water, 3 ml. of 40% sodium molybdate, and 2 ml. of concentrated hydrochloric acid. Extract the yellow phosphomolybdic acid with three 20-ml. vols. of mixed solvent. Wash the combined extracts with 10 ml. of 1 *N* hydrochloric acid, and add the washings to the aqueous layer.

Adjust the pH of the aqueous layer to 12.5 by adding about 20 ml. of 10% sodium hydroxide. Add 300 mg. of hydroxy naphthol blue indicator, and titrate the violet solution to a persistent blue end point with standard 0.05 *M* EDTA.

$$\% \ CaHPO_4 \cdot 2H_2O = V \times M \times 172.09 \times 100/5 \times 100/\text{mg. sample}$$

where V = volume of titrant used, and M = molarity of titrant.

Thermogravimetric Analysis—Samples were heated at rates and spans described in Figs. 1 and 2.

RESULTS

Comparison with U.S.P. Assay—Two lots of dibasic calcium phosphate dihydrate were assayed by the proposed and U.S.P. procedures by two different analysts on different days. The results are presented in Table I.

No interference from chlorides, alkali metal cations, or fluoride was encountered in the chelometric assay of dibasic calcium phosphate in a formulation.

[1] Compensate for weight of water which can be expeditiously removed by drying for 3 hr. at 60° *in vacuo*.

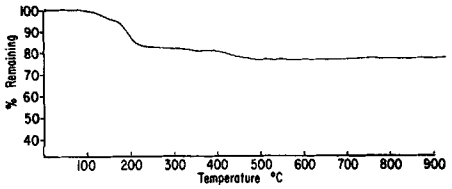

Fig. 1—Thermogram of dibasic calcium phosphate dihydrate U.S.P. over a 900° range. A loss in weight of sample is not noted until a temperature close to 100° is reached. The sample then continues to lose weight up to 500°, at which point no further loss is evident. The per cent remaining was measured as 78, which corresponds to the percentage of anhydrous calcium phosphate present in the dihydrate salt. The equipment was operated at a rate of 25° per minute.

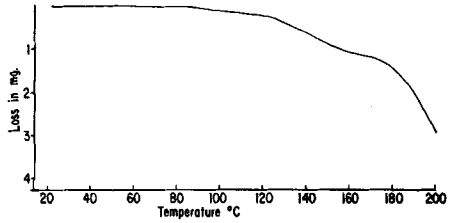

Fig. 2—Similar to Fig. 1, except that the temperature scale was expanded over the 0–200° span at a rate of 20° per minute. This thermogram indicates no loss in weight of sample below 82°.

SUMMARY AND CONCLUSIONS

1. A chelometric titration procedure for dibasic calcium phosphate has been described which compares favorably with the U.S.P. assay in simplicity, speed, and accuracy.

2. Extraction of phosphate as phosphomolybdic acid by an *n*-butanol–chloroform (1:1) mixture eliminates the interference of the anion in the titration of the calcium ion and obviates identification test B in the U.S.P. monograph for the salt.

3. Thermogravimetric analysis of samples indicated that the dihydrate is stable to at least 80° and their moisture content was 1% or less, thus justifying the elimination of the drying step which is required in the U.S.P. method. Furthermore, ignition of sample converts the salt to the pyrophosphate which would obviate the use of the proposed procedure.

4. A thermogravimetric determination of free moisture content provides the correction factor for obtaining accuracy of better than 1%. Alternatively, a loss on drying technique (see Table II), although not as accurate, gives a reasonable indication of free moisture present.

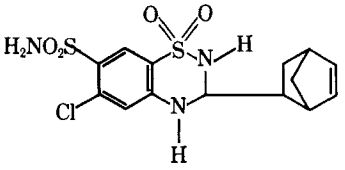
Qualitative and Quantitative Tests for Cyclothiazide

By EDWARD F. SALIM* and W. W. HILTY†

Provisional, unofficial monographs are developed by the Drug Standards Laboratory, in cooperation with the manufacturers of the drug concerned, for publication in the *Journal of Pharmaceutical Sciences*. The ready availability of this information affords discriminating medical and pharmaceutical practitioners with an added basis for confidence in the quality of new drug products generally, and of those covered by the monographs particularly. Such monographs will appear on drugs representing new chemical entities for which suitable identity tests and assay procedures are not available in the published literature. The purity and assay limits reported for the drugs and their dosage forms are based on observations made on samples representative of commercial production and are considered to be reasonable within expected analytical and manufacturing variation.

6 - CHLORO - 3,4 - DIHYDRO - 3 - (5 -NORBORNEN-2 - YL) - 7 - SULFAMOYL - 1,2,4 - BENZOTHIADIAZINE-1,1-DIOXIDE; $C_{14}H_{16}ClN_3O_4S_2$; mol. wt. 389.88. The structural formula of cyclothiazide may be represented as:



Physical Properties—Cyclothiazide occurs as a white to nearly white, practically odorless powder, and melts with decomposition at about 220° (U.S.P., class I). It is practically insoluble in water and in chloroform, sparingly soluble in alcohol, and freely soluble in acetone and in methanol.

Identity Tests—A 1 in 100,000 solution of cyclothiazide in methanol exhibits ultraviolet absorbance maxima at about 271 mμ [absorptivity (*a*) about 57] and 315 mμ, and absorbance minima at about 242 and 295 mμ. The spectrum is shown in Fig. 1.

The infrared spectrum of a 0.5% dispersion of cyclothiazide in potassium bromide, in a disk of about 0.82 mm. thickness, is shown in Fig. 2.

Transfer 20 mg. of cyclothiazide to a test tube and dissolve in 5 ml. of methanol. Add 1 ml. of hydrochloric acid and warm on a steam bath for 5 min.: the liquid acquires a blue color and a yellow fluorescence.

Purity Tests—Determine the water content of cyclothiazide by the titrimetric (Karl Fischer) method: not more than 1% is found.

Char about 1 Gm. of cyclothiazide, accurately weighed, cool the residue, add 1 ml. of sulfuric acid, heat cautiously until evolution of sulfur trioxide ceases, ignite, cool, and weigh: the residue does not exceed 0.2%.

Assay—Transfer about 400 mg. of cyclothiazide, accurately weighed, to a 125-ml. conical flask, and dissolve in 40 ml. of ethylenediamine. Add 5 drops of a solution of *o*-nitroaniline in benzene (1 in 100), and titrate with 0.1 *N* sodium methoxide, using a magnetic stirrer and taking precautions against absorption of atmospheric carbon dioxide as by the use of an atmosphere of nitrogen. Perform a blank determination and make any necessary correction. Each milliliter of 0.1 *N* sodium methoxide is equivalent to 19.49 mg. of $C_{14}H_{16}ClN_3O_4S_2$. The amount of cyclothiazide found is not less than 97% and not more than 101.5%, calculated on the anhydrous basis.

Received September 26, 1966, from the *Drug Standards Laboratory, AMERICAN PHARMACEUTICAL ASSOCIATION, Washington, DC 20037

Accepted for publication December 9, 1966.

† Eli Lilly and Co., Indianapolis, IN 46206. Eli Lilly and Co. has cooperated by furnishing samples and data to aid in the development and preparation of this monograph.

The authors express their appreciation to J. M. Woodside and E. G. Spinks, Eli Lilly and Co., and Carolyn Damon and Hannah Klein, the Drug Standards Laboratory, for valuable contributions to the monograph.

DOSAGE FORMS OF CYCLOTHIAZIDE

Cyclothiazide Tablets

Identity Test—The solution prepared from the tablet sample in the *Assay* exhibits absorbance maxima and minima at the same wavelengths as the cyclothiazide standard solution.

Assay—Weigh and finely powder not less than 20 cyclothiazide tablets. Weigh accurately a portion of the powder, equivalent to about 2 mg. of cyclothiazide, and transfer to a separator. Add 5 ml. of water and extract with four 25-ml. portions of a mixture of chloroform–methanol (4:1), filtering each portion through chloroform-washed cotton into a suitable beaker. Evaporate the combined extracts on a steam bath in a current of air to dryness. Transfer the residue quantitatively with the aid of about 100 ml. of methanol to a 200-ml. volumetric flask, dilute to volume with methanol, and mix. Concomitantly determine the absorbance of this solution and of a standard solution of cyclothiazide, in the same medium, at a concentration of about 10 mcg./ml., in 1-cm. cells, at the maximum at about 271 mμ, with a suitable spectrophotometer, using methanol as the blank. Calculate the quantity, in milligrams, of $C_{14}H_{16}ClN_3O_4S_2$ in the portion of tablets taken by the formula $0.2C \times (A_u/A_s)$, in which C is the exact concentration of the standard solution, in mcg./ml., A_u is the absorbance of the sample solution, and A_s is the absorbance of the cyclothiazide standard solution. The amount of cyclothiazide found is not less than 90% and not more than 110% of the labeled amount.

DISCUSSION

U.S.P. and N.F. terminology for solubility, melting range, reagents, *etc.*, has been used wherever feasible.

Cyclothiazide[1] is an oral diuretic agent useful in

[1] Marketed as Anhydron by Eli Lilly and Co., Indianapolis, Ind.

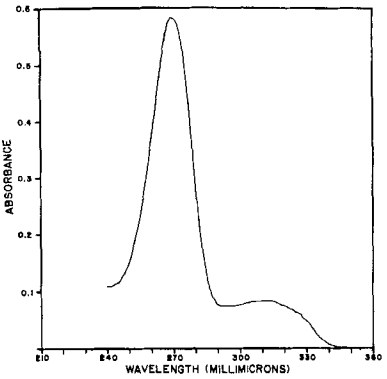


Fig. 1—Ultraviolet absorption spectrum of cyclothiazide in methanol (10 mcg./ml.); Beckman model DK-2A spectrophotometer.

conditions in which increased urinary excretion of sodium chloride and water is desirable. It is also effective for reduction of hypertension, alone or in combination with other antihypertensive agents.

Identity Tests—The identity tests included for the drug substance are satisfactory for distinguishing cyclothiazide from official compounds of similar structure. The ultraviolet absorption spectrum of cyclothiazide is significantly different from the spectrum of chlorothiazide in methanol (single absorbance maximum at 280 mμ) for identification purposes. The color and fluorescence observed when cyclothiazide is warmed in hydrochloric acid solution are not characteristic of chlorothiazide or hydrochlorothiazide and constitute a differentiating test.

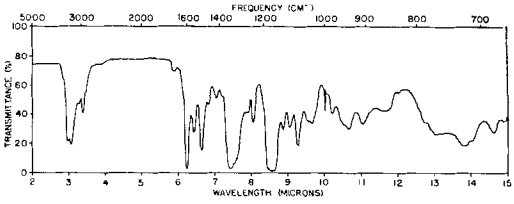

Fig. 2—Infrared spectrum of cyclothiazide in potassium bromide disk (0.5%); Perkin-Elmer model 21 spectrophotometer, sodium chloride prism.

Quantitative Tests—The nonaqueous titration of cyclothiazide with sodium methoxide using *o*-nitroaniline as the indicator gave an average value of 99.4 ± 0.3%.[2] The assay recoveries are calculated on an equivalent based on two titratable groups in the molecule for the conditions specified. Cyclothiazide dissolved in dimethylformamide and titrated with 0.1 *N* sodium methoxide to a thymol blue end point exhibits only one acidic group and a corresponding equivalent of 38.99 mg./ml. of titrant. Analysis of commercial tablets by the spectrophotometric method gave an average value of 99.2 ± 1.2%[2] of the labeled amount of cyclothiazide. The suitability of the procedure was verified by an average recovery of 100.3 ± 0.6%[2] of a standard cyclothiazide solution carried through the extractive steps as included in the tablet assay.

[2] Maximum deviation from the mean value.

Colorimetric Determination of Iodochlorhydroxyquin and Diiodohydroxyquin

By JOHN J. WINDHEUSER and DIAN Y. CHU

A method has been developed for the extraction and determination of 8-hydroxyquin derivatives utilizing cupric ion as a chelating agent. The method is highly sensitive and simple to carry out. The effect of time, pH, and cupric ion concentration has been investigated.

ALTHOUGH introduced into use as medicinal agents more than a half century ago, the halogenated derivatives of 8-hydroxyquinoline are still of significance today. The analysis of these drugs has been carried out by a number of methods. Fresenius (1) reported a colorimetric method by formation of a colored complex with ferric ion in a glacial acetic acid. The system suffered from a marked sensitivity to variation in the moisture content of the system. Haskins and Luttermaser (2) modified the system by dissolving the drugs or dried extracts from urine in 2-methoxymethanol[1] forming ferric complexes which were reported to be less sensitive to moisture variations. Both systems had the problem of interference by other phenolic compounds which might be present in the systems. Official compendia have utilized extraction techniques followed by halogen determination (3), precipitation as a metal chelate (4), and ultraviolet absorption (5). The halogen determination and metal chelate precipitation methods lack the sensitivity of the spectrophotometric methods. On the other hand, the direct spectrophotometric method suffers from interference by other absorbing species.

In this communication the development of an analytical procedure based on the formation of a

copper chelate which is readily extractable into chloroform yielding a stable and highly reproducible yellow color, proportional to the 8-hydroxyquinoline derivative present, is reported. This highly sensitive procedure is simple and rapid and readily adaptable to unit dose analysis

EXPERIMENTAL

Reagents—Iodochlorhydroxyquin U.S.P. and diiodohydroxyquin U.S.P. Cupric sulfate solution, 0.1% $CuSO_4 \cdot 5H_2O$ reagent grade, was dissolved in distilled water. All other reagents used were of analytical reagent grade. Spectrophotometric measurements were carried out using 5-cm. cells in a Cary model 14 or 15 spectrophotometer.

Standard Solutions—Twenty milligrams of iodochlorhydroxyquin or 20 mg. of diiodohydroxyquin are dissolved in sufficient 3 *N* hydrochloric acid to make 100.0 ml.

Analytical Procedure—Prepare a solution of the drug to be assayed in such a manner in 3 *N* hydrochloric acid so that 5.0 ml. contain approximately 1 mg. of the active substance. In the case of tablets, the drug can be extracted from a powdered aliquot of a single tablet or a composite sample of the desired number with 3 *N* hydrochloric acid. In the case of a cream, the required amount of cream equivalent to 20 mg. of the drug is weighed and treated in the manner described below. A sample containing the equivalent of 20 mg. of the drug is placed into a glass-stoppered conical flask and 75 ml. of 3 *N* HCl is added and the mixture shaken for 30 min. on a mechanical shaker. The solution is filtered into a 100-ml. volumetric flask and the flask rinsed with sufficient 3 *N* HCl and passed through the filter to make 100.0 ml. of test solution.

Pipet 5 ml. of the test solution (in the case of diiodohydroxyquin a 1-ml. sample is used) into a 125-ml. separator and add enough 1 *N* sodium hydroxide to make 50 ml.; add 0.5 ml. of the 0.1% copper sulfate solution, mix well, and extract with 25-ml., 15-ml., and 10-ml. fractions of water-saturated chloroform. Adjust the volume of the chloroform extract to 50 ml. and determine the absorbance of the solution at 430 mμ in a 5-cm. cell against a water-saturated chloroform blank. The concentration of the sample can be calculated as follows:

$$\left(\frac{A_{\text{sample}}}{A_{\text{std.}}}\right) \times (\text{concn. of the std.}) = \text{concn. of the test soln.}$$

From this the concentration in the dosage form can be readily calculated.

Figure 1 shows the absorption curve of the iodochlorhydroxyquin–copper complex and the diiodohydroxyquin complex showing essentially the same characteristics with maxima at 430 mμ.

DISCUSSION

Figure 2 depicts the adherence to Beer's law of the absorbance of the complex as a function of drug concentration. At values of greater than 0.6 mg./50 ml. of diiodohydroxyquin, there is a negative deviation due to the insolubility of the copper complex. The method was applied to solutions of the pure drugs, oral tablets, vaginal tablets, and creams and showed a standard deviation of ± 1.1%.

Investigation of Variables—*Effect of Time on the Color Stability*—Samples of iodochlorhydroxyquin were assayed and the absorbances determined immediately and at varying time intervals up to 96 hr. The results as shown in Fig. 3 indicated no change in absorbance over the time of the observations.

Effect of pH of the Test Solution—A 5.0-ml. sample containing 1.035 mg. of iodochlorhydroxy-

quin in 3 *N* HCl was diluted to 50 ml., the pH being adjusted by the addition of 1 *N* NaOH, and then extracted as under the general procedure. The absorbance was determined at 430 mμ. Figure 4 shows the results, indicating that the system is highly pH dependent with increasing absorbance at higher pH. Attempts were made to find invariant absorbance at higher hydroxyl ion concentration. As shown in Fig. 4 trials using 1, 2, and 3 *N* sodium hydroxide to dilute the test sample prior to extraction produced invariant results. Based upon this, 1 *N* sodium hydroxide was used for all dilutions prior to extraction. From the pH-extraction profile, it would appear that only the ionized form of the drug formed the copper chelate. In the intermediate pH range, the profile is not presented, due to the marked variation of results which might possibly be attributed to the insolubility of the drug at these pH values. It might be suggested that in this region the neutral form of the drug itself can also be extracted into the chloroform layer. At low pH the absorbance of the chloroform layer goes to zero due to nonextractability of the protonated drug. It is obvious from the profile that the most accurate and reproducible results are obtained at high hydroxyl ion concentration.

Effect of Copper Concentration—To determine the dependence of the extractable chelate formation on the molar ratio of cupric ion to iodochlorhydroxyquin, an experiment was conducted at constant drug concentration and varying the copper concentration.

As shown in Fig. 5, the absorbance of the extracted chelate reaches a maximum and further addition of copper sulfate does not result in increased absorbance as might be anticipated. Since all work was carried out with concentrations of iodochlorhydroxyquin less than 1 mg./50 ml. of aqueous sample, 0.5 ml. of 0.1% copper sulfate solution was utilized in this study. It is obvious that if higher concentrations were utilized, the copper sulfate concentration would have to be increased.

The stoichiometry of the complex can be estimated from Fig. 5 by extending the horizontal and vertical lines to point A, the point at which equivalance is reached. It was found that at this point 1.6×10^{-6} moles of Cu^{++} ion had been added to the system containing 3.3×10^{-6} moles of iodochlorhydroxyquin. On the assumption that the complexation reaction is essentially complete, the ratio of Cu^{++} to drug would be 1:2.06 which is in good agreement with the 1:2 complex suggested by others (6) for the interaction of cupric ion with 8-hydroxyquinoline.

SUMMARY

Based upon the formation of an extractable chelate between 8-hydroxyquinoline derivatives and cupric ion, an assay has been developed for several medicinally important drugs. The method is simple, rapid, and highly sensitive. Interference from other drugs or dosage form adjuvants has been minimized. The method is suitable for unit dosage form analysis.

Automated Analysis of Erythromycin

By NORBERT R. KUZEL and HENRY F. COFFEY

An automated method has been developed for the analysis of erythromycin by adaptation of the long-established manual U.V. procedure. The method uses a basic automatic analyzer (Technicon AutoAnalyzer) arrangement and a Hitachi Perkin-Elmer spectrophotometer. The method features the concept of the simultaneous determination of a sample and its associated blank in a dual-channel arrangement. A unique cell positioner controlled by a modified liquid sampler enables the use of only one spectrophotometer and one recorder to monitor both channels. In this manner critical phasing problems have been eliminated. The system is capable of making at least 300 measurements per man per day. This method has been developed for use in fermentation broths, process samples, purified materials, and dosage forms.

ERYTHROMYCIN[1] is a broad spectrum antibiotic that has been marketed for many years. Kuzel *et al.* (1) published a spectrophotometric method for the manual determination of this antibiotic. This method is still used routinely in these laboratories. The method is useful for the determination of erythromycin in dosage forms, process samples, and fermentation broths. This manual method is based on a mild alkaline hydrolysis of erythromycin producing a chromophore which has an absorbance peak at 236 mμ. To determine materials other than erythromycin which have an absorbance at 236 mμ, the erythromycin is blanked out by a mild acid treatment. The absorbance difference between the two determinations has been shown to be due to erythromycin alone even in the case of degraded samples or in fermentation broths.

Since sample loads had become increasingly large, it became necessary to consider an automated method. It was decided to attempt automation of the spectrophotometric method because of the long history of reliability of this method. Certain requirements were imposed on the automated method. A 1-hr. service is often required on certain samples, so it became imperative that samples and blanks be determined simultaneously. Second, it was desired to duplicate as much as possible the manual method and this involved contending with high blanks in fermentation samples. The first requirement necessitated the use of either two separate analytical trains or a dual-channel system. The second requirement would tend to eliminate differential spectrophotometry since phasing problems become very serious with two highly absorbing solutions and a relatively low net absorbance. The purpose of this paper is to describe a dual-channel system for the analysis of erythromycin, but more importantly to describe a generalized approach to precise, dual-channel spectrophotometry using only one spectrophotometer and one recorder.

EXPERIMENTAL

Apparatus—The analytical system consisted of the following modules: (*a*) automatic sampler[2] (modified), proportioning pump, and heating baths (modified) from Technicon Instruments, Inc., Chauncey, N.Y.; (*b*) a Hitachi Perkin-Elmer spectrophotometer model 139; (*c*) micro flow cells 9120-NO5, from A. H. Thomas; and (*d*) a Honeywell Electronic 15 recorder (linearized).

Procedure—Figure 1 shows a flow diagram of the automated method including all pump tubing sizes. A sample is drawn from a liquid sampler and is split into two equal portions.

One half of the sample is drawn into the sample channel shown in the lower portion of the figure, and the other half to the blanking channel shown in the upper portion of the figure. The sample channel will be described first. Sodium hydroxide (0.25 *N*) is diluted with water, and the diluted alkali is added to the sample stream, segmented with air, and mixed. The stream is heated in one coil of a 65° heating bath, cooled, and debubbled just before it enters flow cell A of the spectrophotometer.

The other half of the sample is diluted with water, and 0.5 *N* sulfuric acid is added through an H3 fitting. The stream is segmented with air, mixed, and the erythromycin inactivated in the 43° heating bath fitted with 19 ft. of 0.076 i.d. Teflon tubing. As the stream leaves the inactivation bath, 0.35 *N* sodium hydroxide is added to adjust the stream to the same alkalinity as the sample stream. The blank stream enters the second coil of the 65° heating bath, is subsequently cooled and debubbled, and enters flow cell B of the spectrophotometer.

The streams are drawn through the flow cells by pumping a controlled amount from the flow cells while the excess solution and air flow to waste just

[2] AutoAnalyzer Sampler II.

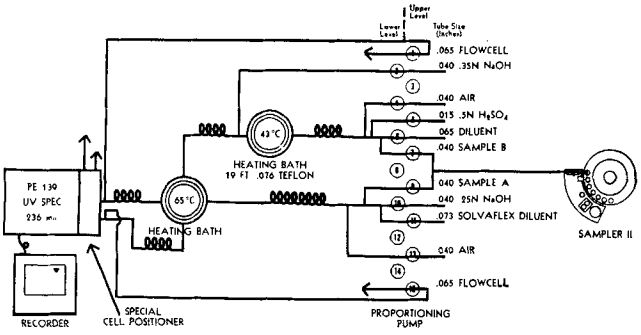

Fig. 1—Flow diagram of the automated method for erythromycin.

ahead of the flow cells. The two channels are alternately monitored in the spectrophotometer at 236 mμ by use of a unique cell positioner. The cell positioner is controlled by a modified liquid sampler.

Standards are run about every 10 or 20 samples, since the stability of the system has been excellent. Reference standard erythromycin base is dissolved in about 10 ml. of methanol and diluted to a concentration of about 250 mcg./ml. with pH 7.0 phosphate buffer. Only one concentration of standard is used since the response of the system is linear. Samples are diluted to about the same concentration as the standard, with the exception of fermentation broths, which are diluted with water so that the maximum absorbance of the sample does not exceed the absorbance range of the analytical system. In these laboratories, this is equivalent to about 20–100 mcg. of erythromycin per ml. of diluted broth. Duplicate cups of sample solutions are generally placed in the liquid sampler, and the results of the duplicates are averaged for calculation purposes. The sampler is operated at 20 samples per hour with a 1:2 sample rinse ratio, so that about 10 samples and blanks in duplicate are processed each hour. Polyoxyethylene (23) lauryl ether[3] is added to deionized water, and this solution is used as the diluent in the automated method.

RESULTS AND DISCUSSION

The automated method follows Beer's law over the entire absorbance range of the system, and the steady state response is very stable. In fact, the steady state has been used to follow long-term hydrolysis curves of several esters of erythromycin in a dynamic system. Figure 2 is a photograph of typical response curves obtained on standards and relatively pure materials. The response at the left of the photograph shows the stable base line obtained and the ability to match flow cell blanks with the cell positioner. The short spikes seen on the base line are the switch points of the flow cells. Peaks 1, 3, and 5 are standards and peaks 6, 8, and 10 are the blanks associated with the standard. Peaks 7 and 9 are the first sample and 12 and 14 are the associated blanks. It is apparent that the blanks are located about midway between sample peaks and are offset from their respective samples by 5 places due to the difference in transit times of the two channels. A time delay coil could be installed in the sample stream to provide adjacent sample and blank peaks if

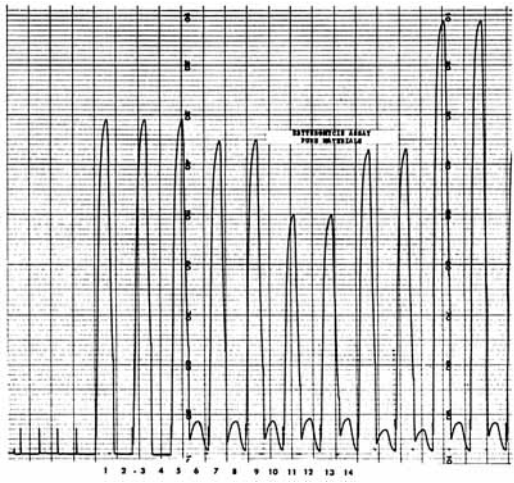

Fig. 2—Recording of replicate samples of erythromycin standards and samples of relatively pure materials illustrating the dual-channel recording technique.

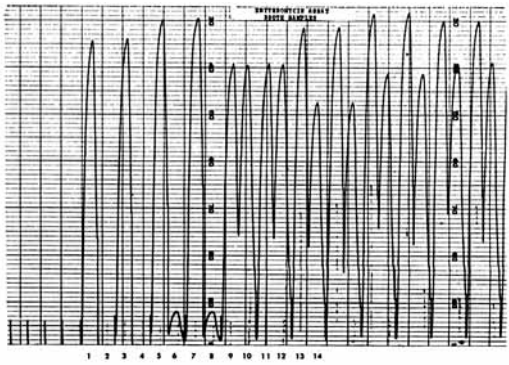

Fig. 3—Recording of replicate samples of erythromycin fermentation broth samples.

desired. The excellent reproducibility of the system is evident in the illustration. There is no sample interaction, although this is not clearly illustrated in Fig. 2 because of the necessity for cell switching. In practice, small changes in phasing occur from day to day and within days; but since only individual peaks need to be observed, rephasing is hardly ever re-

TABLE I—COMPARATIVE DATA ON ERYTHROMYCIN SAMPLES

Lot No.	Manual	Automatic	Microbiological
1	938 mg./Gm.	937	970
2	932 mg./Gm.	926	933
3	905 mg./Gm.	907	965
4	930 mg./Gm.	936	960
5	20,600 mcg./ml.	20,300	
6	44,900 mcg./ml.	44,700	
7	2,430 mcg./ml.	2,670	2,180
8	2,100 mcg./ml.	2,180	2,320
9	1,480 mcg./ml.	1,560	1,280

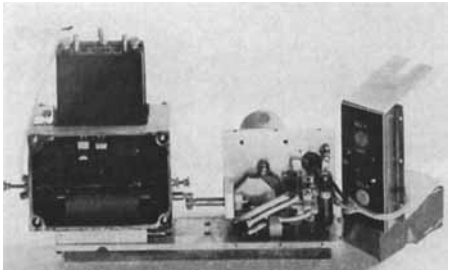

Fig. 4—Interior of the cell positioner.

quired. A water blank is inserted in the sample tray occasionally to assure that no base line drift has occurred. Relative standard deviations of the average of five replicates corrected for blank are typically less than 1%. Occasionally deviations greater than those indicated are observed in the sample readings, but when the associated blanks are subtracted, the relative standard deviations are normal. This may occur because of some contamination of the sample by the sample cup since sample cups are not prewashed in this laboratory.

Figure 3 illustrates typical response curves obtained on fermentation broth samples. Peaks 1 and 3 are standards and 6 and 8 are the respective blanks. Peaks 5 and 7 are the first broth sample and 10 and 12 are the blanks for the first sample. The blank absorbances in this case are much higher, and net absorbances are relatively small. The need for precision in the system is readily evident. This also illustrates the problems that would occur if a differential spectrophotometric method were employed since only slight phasing changes would result in gross errors.

Some comparative results are shown in Table I. Validity of the analysis is demonstrated by comparison with microbiological assays. The first four results are on relatively pure materials, the next two on process samples, and the last three on fermentation broths. The automatic and manual methods are in good agreement, and both closely follow the results obtained by microbiological analysis.

Previous experience in this laboratory with a large number of flow cells has resulted in a distinct preference for the design of the A. H. Thomas flow cell. This flow cell has excellent clearance characteristics, has a small internal volume, and any occasional air bubbles are readily cleared. The authors also wanted to use the Hitachi Perkin-Elmer model 139 spectrophotometer because of its excellent stability and proven performance. The only cell positioner available for this combination of components was the A. H. Thomas cell positioner but, unfortunately, it was not designed to position microflow cells with small cell windows, and large errors were observed in its use due to positioning problems alone. With no other cell positioner commercially available, the authors decided to design and build a precision cell positioner. Figure 4 is a photograph of the interior of the cell positioner that was constructed from this design. Only two positions were required for this application, so a unit was designed that would position between two adjustable stops. The stops can be seen mounted into the ends of the cell compartment. A new cell holder carriage was made to provide a firm grip on the cell holder. The manual cell positioner shaft was removed from the cell compartment and was replaced by a smooth shaft fitted at one end with a ball joint which engaged a pin fastened to the underside of the cell holder carriage. The other end of the shaft was connected by means of a partially threaded pin to the shaft of the cell positioner assembly. The cell holder carriage can be easily uncoupled from the cell positioner and moved manually to one of the other two cell positions, if desired. A Slo Syn motor (SS25 Superior Electric Co., Bristol, Conn.) operates a yoke fabricated from an acetyl resin[4] which in turn is mounted on the sliding shaft of the cell positioner. The yoke drives the shaft until one end of the cell holder carriage contacts one of the adjustable stops and the remainder of the stroke is taken up by a spring located within the arms of the yoke. A similar action occurs on the return stroke. The spring between the arms of the yoke is slidably mounted on the cell positioner shaft and is retained by small horseshoe-shaped keepers. In addition to providing facilities for overtravel of the yoke, the spring also assures a firm reproducible contact with the adjustable stops and reproducible cell positioning. The stops are adjusted from the outside of the cell compartment for proper cell alignment and matching of cell blanks. The Slo Syn motor used in this device caused an annoying vibration in the cell positioner, and the condition was corrected by installation of a 500 ohm 5-w. variable resistor in parallel with the motor. This dropped the voltage applied to the motor to about 50 v.

A cell positioner should be interlocked with the rest of the analytical train so that a slow cumulative drift cannot occur. The positioner just described is controlled by a special modification of the automatic sampler. Figure 5 shows a wiring diagram of the control circuit for the cell positioner. A microswitch was installed on an existing mounting post inside the sampler. This switch is labeled as Technicon sampler switch in the diagram and is actuated by a double rise split cam attached to the shaft of the sampler timing motor. The cam on the timing motor is split so that the ratio of dwell times in positions A and B of cell positioner can be varied, if necessary. As the sampler switch is moved to one position, it completes a circuit through the switch on the cell positioner and through the motor. The motor will drive until a single rise cam attached to the motor shaft opens the cell positioner switch and

[4] Marketed as Delrin by E. I. duPont de Nemours & Co., Wilmington, Del.

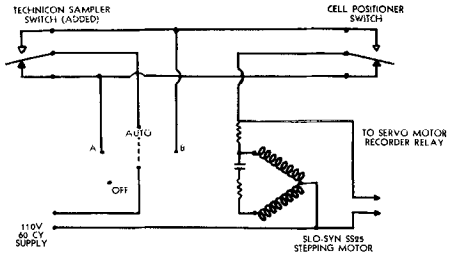

Fig. 5—Wiring diagram of the control circuit for the cell positioner.

thus opens the circuit. This action corresponds to one switching movement of the flow cells. The sampler timing motor continues to run until the double rise cam returns the sampler switch to its former position, whereupon the motor circuit is again closed and the motor drives to its former position, thus completing its switching cycle. Large spikes resulting from temporary blockage of the light path due to switching are prevented from being recorded on the recorder by insertion of an air damped relay into the servo motor circuit of the recorder. The relay is activated every time the motor is energized. The delay can be adjusted to essentially eliminate any spikes without significant loss of meaningful recorded data. The cell positioner can also be operated manually for set-up purposes by use of the A and B position manual switch. The cell positioner as described was designed for a sampling rate of 20 per hour. If a higher sampling rate is desired, the number of raised portions on the split cam mounted on the sampler timing motor must be increased to correspond to the number on the programming cam controlling the sampler.

Approximate phasing of the two channels was accomplished in the usual way by insertion of a time delay coil in one of the channels. The cell positioner must then be phased with the sampler so that cell positioning is achieved at the appropriate time. This was accomplished by designing a new programming cam for the sampler. A double rise split cam was fabricated from the acetyl resin and both halves of the split cam can be rotated with respect to the center hub of the cam which is driven by the timing motor. Adjustment of the split cam provides for a variable sample to rinse ratio. Rotation of the adjusted split cam on the hub provides for advance or delay of sampling with respect to the double rise cam controlling the cell positioner and in effect controls the time span between sampling and cell positioning.

The absorbance of the solutions in both channels is recorded on a Honeywell Electronic 15 strip chart recorder equipped with a 1 cycle log-characterized slide wire and having a range of 0 to 1 absorbance unit. This recorder provides a very precise and reliable recorder for spectrophotometric work at moderate cost. Linear potentiometric recording cannot be done on the instrument modified in this manner; but since this recorder was to be used for spectrophotometric work only, this limitation is not serious.

The lengths of the various heating coils, the temperatures of the baths, and the concentration of reagents were all experimentally determined to substitute for the conditions found in the manual method. A 9-min. acid inactivation of the erythromycin at 43° with 0.5 *N* sulfuric acid was found to be equivalent to the 1-hr. inactivation at room temperature with 0.25 *N* sulfuric acid as performed in the manual method. A plateau between 38 and 48° was found for the inactivation temperatures. Any temperatures above or below these figures produce high and invalid blanks.

Certain special precautions need to be observed in the use of this system. Because of the low wavelength, *i.e.*, 236 mμ, considerable and variable extraneous U.V. absorbance can be picked up from some lots of Tygon tubing especially in the presence of warm alkaline solutions. Teflon, polyethylene, or glass tubing was used throughout the system except for the pump tubings. The cell compartment was fitted with an A. H. Thomas high rise cell cover and the cells were connected to the debubbler fitting with thin wall flexible polyethylene tubing. Relative dilutions in the two channels are important in a dual-channel system, especially where one channel is a blanking channel having high absorbance. In an attempt to determine relative dilutions, erythromycin was run as a sample in both channels, but subsequently it was found that some erythromycin was destroyed in the extra heating step of the blank channel. A stable compound having U.V. absorbance at 236 mμ was needed, and sodium benzoate was found to work very well for this purpose. The pump tubings are adjusted until both channels provide the same dilution of the sample. The model 139 spectrophotometer has a very rapid response, and somewhat noisy tracings were initially obtained. By using the spectrophotometer in its slow response mode, very smooth response curves were obtained without any loss in precision.

ANALYTICAL POTENTIAL

Aside from the use of this method for the analysis of erythromycin, this paper describes a general method of monitoring two analytical streams for both U.V. and colorimetric methods while using only one spectrophotometer and one recorder. This was made possible by the design of a precise cell positioner obviating the need for differential spectrophotometry and its attendant phasing problems. The unique design of the cell positioner also permits the use of microflow cells in a cell positioner suitable for use with a Hitachi Perkin-Elmer spectrophotometer. The cell positioner design could easily be adapted for use with other spectrophotometers. The concept of a cell positioner controlled by the modified automatic sampler could be utilized in a number of other applications.

Automated Determination of Rat Adrenal Ascorbic Acid in the Bioassay of Corticotropin

By WILLIAM F. BEYER

An automated procedure for the determination of rat adrenal ascorbic acid used in the U.S.P. XVII bioassay of corticotropin is described. Ascorbic acid analyses of manually filtered, adrenal gland homogenates are performed with buffered 2,6-dichloro-indophenol sodium. A sample–rinse ratio of 1:2 is used and sample carry-over is not detectable. AutoAnalyzer Sampler II, proportioning pump, colorimeter, and recorder are used. The coefficient of variation for the automatic procedure is approximately 1 per cent at an effective sampling rate of 60/hr. An IBM 1620 computer is used for calculations of ascorbic acid determinations and for the bioassay of corticotropin using a 3 × 3 statistical design. Assay results using automated and manual ascorbic acid values compare favorably.

THE DEPLETION of ascorbic acid of rat adrenal glands is used as the measure of response in the bioassay of corticotropin as directed by U.S.P. XVII (1). For the subcutaneous assay, hypophysectomized rats are injected in random order with varying doses of standard or test preparations using a 3 × 3 design. Three hours after injection, the paired adrenals are removed, freed of excess tissue, weighed, and homogenized in 2.5% metaphosphoric acid. The ascorbic acid content of each pair of adrenal glands is then determined using buffered 2,6-dichloro-indophenol sodium. Statistical analyses are applied to ascorbic acid values to determine potency, precision, and validity of the assay. This report describes an automated procedure for the determination of rat adrenal ascorbic acid used in the bioassay of corticotropin. The automated method, based on the U.S.P. XVII procedure, requires manual filtration of adrenal gland homogenates. Automatic sampler,[1] proportioning pump, colorimeter, and recorder are used, permitting the analysis of 60 samples per hour, including wash between samples.

MATERIALS AND METHODS

Instruments—Automatic sampler, proportioning pump, colorimeter with 524 mμ filters and 1.5-cm. flow cell, recorder, and chart reader.

Reagents—(*a*) 2,6-Dichloro-indophenol sodium, 48.0 mg./1000 ml. Filter and store in a brown bottle under refrigeration. (*b*) Sodium acetate trihydrate, 45.3 Gm./1000 ml. Adjust to pH 7 with acetic acid. Store in a brown bottle under refrigeration. (*c*) Color reagent, equal parts of 2,6-dichloro-indophenol sodium and sodium acetate trihydrate solutions are mixed when cold. Store in a brown bottle under refrigeration. (*d*) Metaphosphoric acid, 2.5%. (*e*) Rinse solution for automatic sampler, 4.0 ml. of polysorbate 80 is dissolved in 1000 ml. 2.5% metaphosphoric acid.

Standards—Accurately weighed quantities of U.S.P. ascorbic acid reference standard or house standard are dissolved in 2.5% metaphosphoric acid within the range of 3 mcg./ml. to 11 mcg./ml. for the standard curve. Prepare just prior to use.

Test Samples—Paired adrenal glands of test rats are freed of excess tissue, weighed, and homogenized in 12.0 ml. of 2.5% metaphosphoric acid using a tapered glass tissue homogenizer.[2] Clear filtrates are then obtained using Whatman No. 2 filter paper placed in collection funnels.[3]

Procedure—Using the manifold as shown in the flow diagram of Fig. 1, the rinse line of the automatic sampler is placed in rinse solution for automatic sampler, and all other lines in water. With all instruments operating, a 99% transmission base line is established. The color reagent line is placed in iced color reagent and the sample line with probe is properly positioned in the rinse compartment of automatic sampler. Following a stable transmittance recording, the sampling rate is set at 60/hr. with a 1:2 sample–rinse ratio. Standards are placed in duplicate cups for the standard curve and test samples in single cups.

Calculations—The recorded transmittance peaks for each level of ascorbic acid standard are plotted, and a chart reader is used to determine the microgram per milliliter concentration of each test sample. A computer program is written in Fortran (formula translation) to calculate ascorbic acid in terms of milligrams ascorbic acid per 100 Gm. of adrenal tissue. The program also transforms the random order of samples into proper dosage groups, checks for outliers, and carries out statistics for the bioassay.

RESULTS AND DISCUSSION

Initial experiments with various manifold systems and sampling rates produced unreliable results and unsatisfactory recordings. Most of the difficulties were due to sample carry-over, erratic movement of the air bubble between sample and rinse, and pulsation from the pump action. Carry-over was eliminated by severing the 0.090-in. sample line at

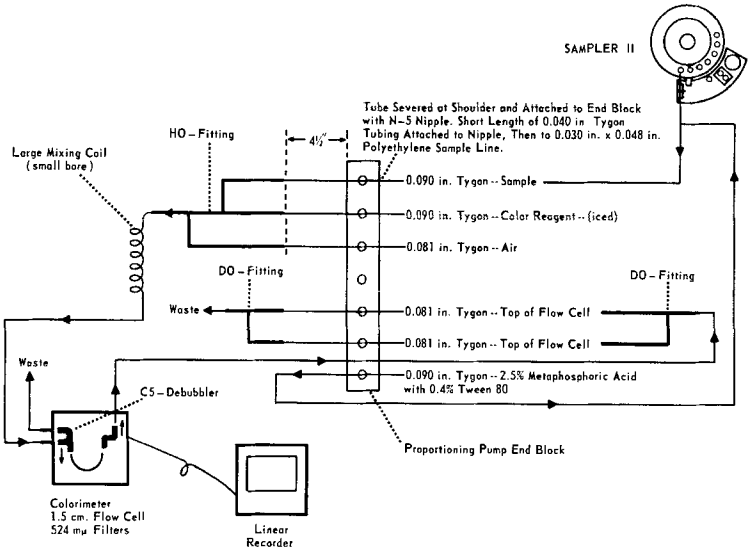

Fig. 1—Manifold flow diagram for the automated determination of ascorbic acid in rat adrenal gland homogenate. Analyses are made using Technicon AutoAnalyzer equipment: colorimeter, proportioning pump, recorder, and assorted tubing. Sampling rate is 60/hr. with a 1:2 sample–rinse ratio.

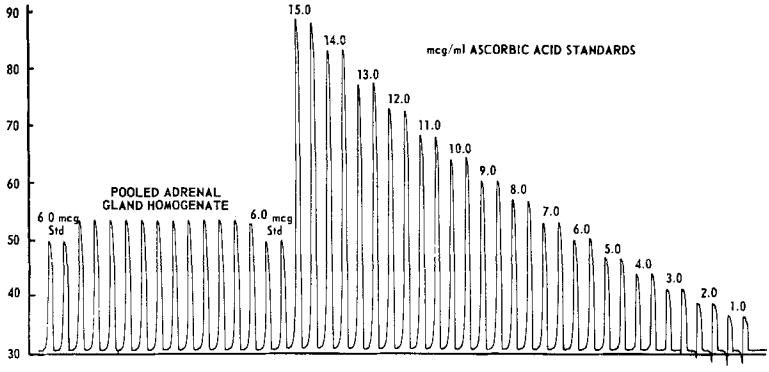

Fig. 2 — Transmittance-concentration recording of ascorbic acid standards and replicate sampling of pooled adrenal gland homogenate.

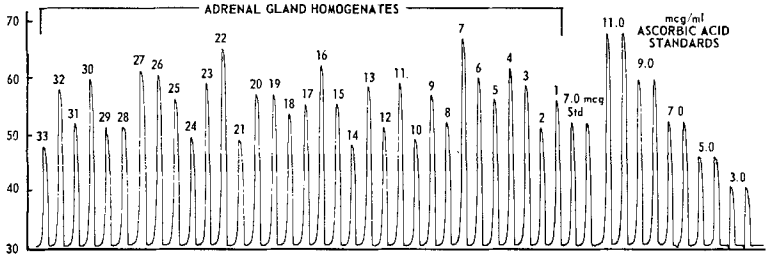

Fig. 3 — Representative transmittance recording of ascorbic acid standards and adrenal gland homogenates from a corticotropin bioassay.

the end block (Fig. 1) and attaching it to a 0.030 × 0.048-in. polyethylene sample line, and by using a 1:2 sample–rinse ratio. Satisfactory movement of the air bubble between samples and rinse occurred when polysorbate 80 was added to the metaphosphoric acid rinse. Polysorbate 80 also reduced the deposition of fatty material from adrenal gland homogenates on the walls of the sample line. The effect of pulsation was lessened by allowing approximately 4.5 in. of manifold tubing to extend beyond the exit end of the end block and by using an H-O cactus.

Twelve milliliters of 2.5% metaphosphoric acid was used in place of the 8.0 ml. as directed by U.S.P. XVII in order that adequate adrenal gland homogenate was available for both automated and manual ascorbic acid determinations. The concentration of 2,6-dichloro-indophenol was reduced to compensate for the greater volume of adrenal gland homogenate.

Attempts to filter the adrenal homogenate automatically with Technicon's continuous filter using various filter papers and a Millipore[4] nylon roll filter

were unsatisfactory. Dialysis was not attempted in these studies; however, it is possible that newer membranes permitting more efficient dialysis and a flow cell with a longer light path would provide the necessary sensitivity.

Figure 2 gives a recorder tracing of ascorbic acid standards in the range of 1.0–15.0 mcg./ml. and replicated samples of pooled adrenal gland homogenates. The uniformity of replicate analyses and the return to base between samples can be noted. When the values for the standards of Fig. 2 are plotted, a linear relationship exists for the logarithm of transmittance and ascorbic acid concentration. Figure 3 gives transmittance recordings for standards and a portion of the recordings from adrenal gland homogenates in a typical corticotropin bioassay.

The precision of the automated method was determined by repetitively assaying 2.0, 4.0, 6.0, 8.0, 10.0, and 12.0 mcg./ml. ascorbic acid standards and pooled adrenal gland homogenate. In Table I, it can be seen that the coefficients of variation range from 0.36% to 1.49%, with less precision occurring at lower ascorbic acid concentrations.

Recovery of ascorbic acid with the automated procedure was determined by adding standard to various quantities of adrenal gland homogenate. An average recovery of 99.9% was obtained, varying from 99.1% to 101.0% (Table II). Similar ascorbic acid values for adrenal gland homogenates were obtained for both automated and manual methods of assay. Table III shows a representative adrenal ascorbic acid depletion assay for corticotropin with ascorbic acid determined on parallel samples of homogenate. It can be noted that statistical data for the corticotropin bioassay of Table III are in close agreement. Numerous additional bioassays have been carried out using both manual and automated procedures for adrenal ascorbic acid with satisfactory results.

[a] Ascorbic acid determinations were made on each pair of rat adrenals by both manual (M) and automated (A) procedures. Statistical analysis carried out as directed by U.S.P. XVII.

An alternate procedure has been developed for calculations of adrenal gland ascorbic acid based on absorbance readings. Absorbance paper is used in conjunction with a single 8.0-mcg./ml. level of ascorbic acid standard. A computer program is used that provides for the subtraction of recorded absorbance readings of standard and test samples from the absorbance of the color reagent +2.5% metaphosphoric acid base line. The program also provides for the computation of milligrams ascorbic acid per 100 Gm. of paired adrenal glands based on the relative absorbances of the 8-mcg./ml. standard and test samples and on the weights of paired adrenal glands. The computer program places ascorbic acid values in their proper dosage groups and provides for statistical calculations for the assay as directed by U.S.P. XVII.

SUMMARY

An automated procedure is described for the determination of ascorbic acid in rat adrenal gland homogenates in the bioassay of corticotropin. The procedure, based on that of the U.S.P. XVII, permits the analysis of 60 samples/hr. with a coefficient of variation of approximately 1%. Ascorbic acid was recovered satisfactorily from standard samples spiked with varying amounts of adrenal gland homogenate. Corticotropin bioassays using ascorbic acid results obtained with manual and automated procedures compare favorably.

The automated ascorbic acid procedure and the computer program should have application in the Parlow ovarian ascorbic acid depletion bioassay of luteinizing hormone, chorionic gonadotropin, and pregnant mare's serum (2).

Estimation of Volume of Distribution and Half-Life of a Compound After Rapid Intravenous Injection

By JOHN G. WAGNER and JACK I. NORTHAM

It is common practice to plot the plasma or serum concentrations of a compound obtained following rapid intravenous injection on semilogarithmic graph paper, then estimate the rate constant ($\hat{\beta}$) for loss of compound from the body or half-life ($0.693/\hat{\beta}$) from the slope of the terminal linear segment, extrapolate the linear segment to time zero, and divide the intercept into the dose to obtain the apparent volume of distribution ($\hat{V}_d$). Under certain conditions the estimates obtained by this procedure may be valid. However, this report shows that if the model which applies is a two compartment open system, then the $\hat{V}_d$ estimated by this method is always an overestimate of the true total volume ($V_1 + V_2$), and the error depends upon the relative values of V_1/V_2 and K_1/K_2 where K_1 is the first-order rate constant for distribution and K_2 is the first-order rate constant for loss from the inner compartment. The half-life estimates ($0.693/\hat{\beta}$) will always be greater than the true half-life ($0.693/K_2$), and $\hat{\beta}$ as an estimator of K_2 also depends on the ratios V_1/V_2 and K_1/K_2.

IT IS COMMON practice[1] (1–5) to plot the plasma or serum concentration of a compound obtained following rapid intravenous injection on semilogarithmic graph paper, then estimate the rate constant for loss of compound from the body ($\hat{\beta}$) or the half-life ($0.693/\hat{\beta}$) from the slope ($\hat{\beta}/2.303$) of the terminal linear segment; and extrapolate the linear segment to time zero and divide the intercept ($\hat{B}_1$) into the dose (D) to obtain the apparent volume of distribution, pool size, or "space" ($\hat{V}_d$). If the model which applies to the particular system involves a single compartment and the initial nonlinearity of the semilogarithmic plot is assumed to be due to mixing, then the estimates $\hat{\beta}$ and $\hat{V}_d$ would be very close to those expected on the basis of the appropriate mathematical expression.

Nelson (6), however, pointed out that the error in the estimated volume of distribution may be substantial if there are two compartments with volumes V_1 and V_2 and the volume of the outer compartment (V_2) is large, and rate of attainment of equilibrium is slow. This report will show that if the model which applies is a two compartment open system, then $\hat{V}_d$ always overestimates the true total volume

Estimation of Volume of Distribution and Half-Life of a Compound After Rapid Intravenous Injection

By JOHN G. WAGNER and JACK I. NORTHAM

It is common practice to plot the plasma or serum concentrations of a compound obtained following rapid intravenous injection on semilogarithmic graph paper, then estimate the rate constant ($\hat{\beta}$) for loss of compound from the body or half-life ($0.693/\hat{\beta}$) from the slope of the terminal linear segment, extrapolate the linear segment to time zero, and divide the intercept into the dose to obtain the apparent volume of distribution ($\hat{V}_d$). Under certain conditions the estimates obtained by this procedure may be valid. However, this report shows that if the model which applies is a two compartment open system, then the $\hat{V}_d$ estimated by this method is always an overestimate of the true total volume ($V_1 + V_2$), and the error depends upon the relative values of V_1/V_2 and K_1/K_2 where K_1 is the first-order rate constant for distribution and K_2 is the first-order rate constant for loss from the inner compartment. The half-life estimates ($0.693/\hat{\beta}$) will always be greater than the true half-life ($0.693/K_2$), and $\hat{\beta}$ as an estimator of K_2 also depends on the ratios V_1/V_2 and K_1/K_2.

IT IS COMMON practice[1] (1–5) to plot the plasma or serum concentration of a compound obtained following rapid intravenous injection on semilogarithmic graph paper, then estimate the rate constant for loss of compound from the body ($\hat{\beta}$) or the half-life ($0.693/\hat{\beta}$) from the slope ($\hat{\beta}/2.303$) of the terminal linear segment; and extrapolate the linear segment to time zero and divide the intercept ($\hat{B}_1$) into the dose (D) to obtain the apparent volume of distribution, pool size, or "space" ($\hat{V}_d$). If the model which applies to the particular system involves a single compartment and the initial nonlinearity of the semilogarithmic plot is assumed to be due to mixing, then the estimates $\hat{\beta}$ and $\hat{V}_d$ would be very close to those expected on the basis of the appropriate mathematical expression.

Nelson (6), however, pointed out that the error in the estimated volume of distribution may be substantial if there are two compartments with volumes V_1 and V_2 and the volume of the outer compartment (V_2) is large, and rate of attainment of equilibrium is slow. This report will show that if the model which applies is a two compartment open system, then $\hat{V}_d$ always overestimates the true total volume

$(V_1 + V_2)$, and the error depends upon the relative values of V_1/V_2 and K_1/K_2, where K_1 is the first-order rate constant for distribution and K_2 is the first-order rate constant for loss from the inner compartment. That is, the errors involved in $\hat{V}_d$ as an estimator of $V_1 + V_2$ and $\hat{\beta}$ as estimator of K_2 depend on the ratios V_1/V_2 and K_1/K_2. If a compound is widely distributed in body water, then physiologically (7, 8) one might expect V_2 to be considerably greater than V_1; hence, $V_1/V_2 < 1$ and $\hat{V}_d$ will be a poor overestimator of $V_1 + V_2$ and $\hat{\beta}$ will be a poor underestimator of K_2.

The equations appropriate to the two compartment open system in which drug is lost only from the inner compartment are given under *Appendix* where all symbols are defined. Based on Eqs. 13 through 16 of the *Appendix*, a digital computer program was written which allowed print-out of the values β/K_2, α/K, and $\hat{V}_d/(V_1 + V_2)$ when the input data were V_1/V_2 and K_1/K_2. Values of β/K_2, α/K_1, and $\hat{V}_d/(V_1 + V_2)$ were obtained corresponding to $K_1/K_2 = 0.1$, 0.5, 1, 2, 5, 10, and 100 and $V_1/V_2 = 0.125$, 0.25, 0.5, 1, 2, 4, and 8. These data allowed preparation of Figs. 1 and 2.

Figure 1 is a plot of the ratio β/K_2 *versus* the ratio K_1/K_2 on a log-log scale. The figure illustrates that over the range considered β/K_2 ranges from 0.0113 when $K_1/K_2 = 0.1$ and $V_1/V_2 = 0.125$ to 0.889 when $K_1/K_2 = 100$ and $V_1/V_2 = 8$. As $V_1/V_2 \to \infty$, $\beta/K_2 \to 1$. Hence, half-life estimates $(0.693/\hat{\beta})$ will always be greater than the true half-life $(0.693/K_2)$.

Figure 2 is a plot of the ratio $\hat{V}_d/(V_1 + V_2)$ *versus* the ratio K_1/K_2 on a log-log scale. The figure illustrates that when $K_1/K_2 < 5$ and $V_1/V_2 < 1$ relatively large errors are made in the estimated volume. When $K_1/K_2 \gtrsim 100$, then V_d is within 1% of $(V_1 + V_2)$, provided V_1/V_2 is not extremely small.

When employing experimental data, estimates $\hat{B}_1$ and $\hat{\beta}$ of the intercept B_1 and the slope β, respectively, are usually obtained by the method of least squares using the terminal ln C_1 and time t values.[2] Table I gives an indication of the relatively small errors involved in this procedure in the absence of experimental error. In the case of some experimental data, however, the number of available points and the accuracy and precision of the assay would influence the estimates.

Additional observations about the two compartment open system may be of interest. During the interval $t < t'$, $C_1 > C_2$ but during the interval $t' < t < \infty$, $C_2 > C_1$ where $t' = \ln(\beta/\alpha)/(\beta - \alpha)$. When $10 < K_1/K_2 < 100$ and $t > t'$, C_2 is always only slightly greater than C_1 and for all practical purposes $C_1 \simeq C_2$. For a given ratio K_1/K_2 the smaller the ratio V_1/V_2 the more delayed is t'; for example, with $K_1/K_2 = 1$, $t' = 7.45$, 9.84, 11.4, and 13.4 hr. when $V_1/V_2 = 1$, 0.5, 0.33, and 0.2, respectively. For given values of V_1 and V_2 the smaller the ratio K_1/K_2, the more delayed is the time at which a semilogarithmic plot of C_1 *versus* time apparently becomes linear. Conversely, when $K_1/K_2 \geq 100$ a semilogarithmic plot of C_1 *versus* time becomes linear within an hour or less postadministration if the true half-life $(0.693/K_2)$ is 6 hr. or less.

It should be noted that if a compound is administered by any other route than intravenously (*e.g.*, orally, intramuscularly, *etc.*) and the terminal linear segment of the semilogarithmic plot of the serum or plasma concentration is extrapolated to zero time, the quotient obtained by dividing the intercept into the dose is not a "volume of distribution." The number obtained in such a case is a complex function of many variables among which are the following: (*a*) the true volume of distribution, (*b*) *all* the rate constants involved in the model which applies to the particular set of data, (*c*) the fraction of the dose absorbed, and (*d*) the lag time between time of administration and the time when absorption begins.

APPENDIX

The Two Compartment Open System with the Dose (D) Introduced into Compartment 1 at Zero Time.—Let V_1 be the volume and C_1 be the concentration of unchanged drug at time t in the inner compartment or pool and V_2 be the volume and C_2 be the concentration of unchanged drug at time t in the outer compartment or pool. Let K_1 be a first-order rate constant representing the instantaneous fraction of drug in compartment 1 being transferred to compartment 2 and K_2 be a first-order rate constant representing the instantaneous fraction of drug in compartment 1 which is being lost

[2] This approximation is valid since

$$-\beta = \lim_{t \to \infty} \left\{ \frac{d \ln C_1(t)}{dt} \right\}$$

TABLE I—INDICATION OF THE SMALL ERRORS INVOLVED WHEN THE INTERCEPT B_1 AND THE SLOPE β ARE ESTIMATED BY THE METHOD OF LEAST SQUARES USING THE TERMINAL ln C_1, t VALUES[a]

K_1/K_2	Time Range, hr.	B_1	$\hat{B}_1$[b]	β	$\hat{\beta}$	$\hat{V}_d$ $100/B_1$	$\hat{V}_d$ $100/\hat{B}_1$
1	17–24	.00553	.00609	.0441	.0482	18,100	16,400
2	13–24	.00758	.00760	.0506	.0508	13,200	13,150
5	11–24	.00901	.00899	.0549	.0548	11,100	11,120
10	9–24	.00950	.00950	.0563	.0563	10,530	10,530
100	1–24	.00995	.00995	.0576	.0576	10,050	10,050

[a] For all examples shown $V_1 = V_2 = 5{,}000$, $K_2 = 0.1155$, and a dose of 100 units was placed in compartment 1 at time zero. [b] $\hat{B}_1$ is the antilogarithm of the estimated intercept and $\hat{\beta}$ is the estimated slope obtained by the method of least squares for the regression of ln C_1 on time where $C_1 = A_1e^{-\alpha t} + B_1e^{-\beta t}$, and t was taken at 0.5-hr. intervals over the time range indicated.

from compartment 1. For convenience refer to the compartmental diagram shown in Fig. 1. Let D be the dose of drug introduced into the inner compartment at time zero.

The appropriate differential equations, which incorporate Fick's law, are:

$$V_1 \frac{dC_1}{dt} = -V_1K_1 (C_1 - C_2) - V_1K_2C_1 \quad \text{(Eq. 1)}$$

and

$$V_2 \frac{dC_2}{dt} = V_1K_1 (C_1 - C_2) \quad \text{(Eq. 2)}$$

The time-concentration curves resulting from the solution are:

$$C_1 = A_1e^{-\alpha t} + B_1e^{-\beta t} \quad \text{where } \beta < \alpha \quad \text{(Eq. 3)}$$

and

$$C_2 = A_2e^{-\alpha t} + B_2e^{-\beta t} \quad \text{(Eq. 4)}$$

A semilogarithmic (base e) plot of C_1 *versus* t is terminally linear with slope-β and intercept ln B_1 (by extrapolation). The residuals give a linear semilogarithmic plot with slope-α and intercept ln A_1. It follows that $(C_1)_{t=0} = A_1 + B_1$.

In Eq. 3,

$$A_1 = \frac{(K_1 + K_2 - \beta)(C_1)_{t=0}}{\alpha - \beta} \quad \text{(Eq. 5)}$$

and

$$B_1 = \frac{(K_1 + K_2 - \alpha)(C_1)_{t=0}}{\beta - \alpha} \quad \text{(Eq. 6)}$$

In Eq. 4,

$$A_2,B_2 = \pm \frac{K_1V_1(C_1)_{t=0}}{(\beta - \alpha)V_2} \quad \text{(Eq. 7)}$$

By appropriate algebraic manipulation we find

$$K_1 = \frac{A_1\alpha + B_1\beta}{A_1 + B_1} \quad \text{(Eq. 8)}$$

$$K_2 = \frac{\alpha\beta(A_1 + B_1)}{A_1\beta + B_1\alpha} \quad \text{(Eq. 9)}$$

$$V_1 = \frac{D}{A_1 + B_1} \quad \text{(Eq. 10)}$$

$$V_2 = V_1 \cdot \frac{K_1K_2}{\alpha \cdot \beta} \quad \text{(Eq. 11)}$$

$$C_1 = C_2 \text{ and } C_2 = \text{a maximum at } t' = \frac{\ln \beta - \ln \alpha}{\beta - \alpha} \quad \text{(Eq. 12)}$$

Equations 1 through 11 have been reported in similar or modified form by Teorell (9), Gaudino (10), Dominguez (11), Tait *et al.* (12), and Cornfield *et al.* (13).

In preparing Figs. 1 and 2 the following equations were employed:

$$\beta/K_2 = \left[1 + \frac{K}{f} - \sqrt{\left(1 - \frac{K}{f}\right)^2 + 4K}\right]/2 \quad \text{(Eq. 13)}$$

where $K = K_1/K_2$, $V = V_1/V_2$, and $f = V_2/(V_1 + V_2) = \frac{1}{V+1}$.

$$\frac{\hat{V}_d}{V_1 + V_2} = (1 - f) \cdot \left[\frac{\alpha/K_2 - \beta/K_2}{\alpha/K_2 - K - 1}\right] \quad \text{(Eq. 14)}$$

The latter is conveniently calculated since, when getting β/K_2, one can easily calculate:

$$\alpha/K_2 = \left[1 + \frac{K}{f} + \sqrt{\left(1 - \frac{K}{f}\right)^2 + 4K}\right]/2 \quad \text{(Eq. 15)}$$

In addition one can calculate α/K_1 as follows:

$$\alpha/K_1 = (V_1/V_2)/(\beta/K_2) = V/(\beta/K_2) \quad \text{(Eq. 16)}$$

Isolation and Identification of Benzyl Ether in a Sample of Basil Oil

By DENNIS POGANY, CHARLES L. BELL, and ERNST R. KIRCH

A gas chromatographic fraction of a sample of basil oil was found to contain benzyl ether, a compound heretofore not reported to be present in this oil. Identification was established by comparison of various spectra of known samples of the ether. It was further observed that the published mass spectral data for benzyl ether was in error.

IN THE COURSE of an investigation dealing in part with the analysis of an essential oil obtained from basil, it became necessary to establish the reproducibility of the method of assay. For this purpose a commercial[1] sample of oil of basil was purchased and subsequently analyzed by gas chromatographic and spectroscopic methods. It was observed that among other known components (1, 2) an ether (benzyl ether) could be isolated from this particular sample of oil.

EXPERIMENTAL

The oil of basil was subjected to gas chromatographic separation and the fractions were examined spectroscopically.

Gas Chromatography—Instrument: Aerograph Autoprep, model A-700, gas chromatograph equipped with a thermal conductivity detector. Conditions: a 20 ft. × 3/8 in. o.d. aluminum column packed with 30% SE-30 on Chromosorb W (mesh 45/60) was used. The flow rate of the carrier gas, helium, was 200 ml./min. The oven temperature was programmed (nonlinear) between 100 and 250°. Sample: an 0.5-ml. portion of the oil was injected for each of five consecutive runs.

Nuclear Magnetic Resonance Spectroscopy—Instrument: Varian model A-60. Conditions: an approximately 50% solution of the fraction and a known sample of benzyl ether were prepared using $CDCl_3$ + 1% TMS[2] and the spectrum was taken in a glass microcell at probe temperature.

Mass Spectroscopy—Instrument: Hitachi-Perkin-Elmer model RMU-6D. Conditions: the sample was introduced through the reservoir and a heated glass inlet kept at a temperature of 200° and at a sample pressure of 2×10^{-7} mm. The ionizing electron beam was set at 75 ev.

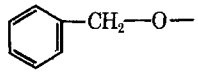
Infrared Spectroscopy—Instrument: Perkin-Elmer grating infrared spectrophotometer model 337. Conditions: the sample was introduced as a film between two sodium chloride plates.

RESULTS AND DISCUSSION

Fractions of oil of basil isolated by preparative gas chromatography were examined by mass spectroscopy and the *m/e* values obtained were those expected for terpenoids or sesquiterpenoids. Some of the compounds identified so far include the following: 1,8-cineole, linalool, anethole, methyl chavicol, *o*- or *p*-methoxy cinnamaldehyde, and methyl eugenol. The sesquiterpene fractions, all with an *m/e* of 204, have not as yet been completely identified.

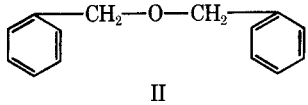
Upon examination of the last fraction of the oil which eluted approximately 1.5 hr. after injection in the gas chromatograph, it was found that its apparent parent ion in the mass spectrum was at *m/e* 107. This was unexpected for two reasons. First, the time of elution in the nonpolar liquid phase in general followed the order of increasing molecular weight, and second, this odd-numbered molecular weight indicated the presence of an odd number of nitrogens (3) in the molecule. Since the chemical analysis of this particular fraction did not show the presence of nitrogen, it was assumed that the apparent molecular ion, 107, was actually a fragment of a larger parent ion. Further examination of this fraction by nuclear magnetic resonance showed a very simple spectrum with only two sharp absorption signals, one at 4.54 δ and one at 7.33 δ downfield from the tetramethylsilane signal. Their integrated areas were in the ratio of 2:5, respectively. The signal at 7.33 δ indicated an unconjugated phenyl group resonance. The position of the less intensive signal at 4.54 δ is at a somewhat lower field than expected for a simple R—CH_2—O— group. This indicates that the methylene group is adjacent not only to an oxygen but also to another deshielding group.

From these data it was assumed that the compound has the structural element shown in I.



I

The absence of any other signal in the NMR spectrum and the lack of exchangeable protons as well as the mass spectral data lead to the postulation that the molecule is a symmetrical ether with the formula shown in II.



II

An infrared spectrum of the fraction was taken and compared with that of benzyl ether reported in the Sadtler standard spectra. These spectra were found to be identical (4). It was concluded, therefore, that the fraction as isolated was indeed benzyl ether.

As further verification, benzyl ether was not only prepared in our laboratory (5) but also purchased from the Eastman Kodak Co. Both samples were purified by gas chromatography and examined spectroscopically. The mass, infrared, and NMR

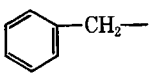
TABLE I—SIX MOST ABUNDANT PEAKS IN THE SPECTRA OF BENZYL ETHER IN DECREASING ORDER OF ABUNDANCE

Peak No.	Present Findings m/e	Present Findings % Rel. Abundance	Published Findings (6) m/e	Published Findings (6) % Rel. Abundance
1	92	100	77	100
2	91	83	105	75
3	79	20	106	74
4	65	18	51	57
5	77	17	50	33
6	107	15	78	22

spectra were found to be identical with those of the fraction obtained from the oil.

Six major peaks are shown in the mass spectrum of benzyl ether as published in a compilation of mass spectral data (6). In the comparison of our observations with these published data the great discrepancy shown in Table I was found. The spectrum as reported (6) is obviously in error since compounds having a moiety (III) will invariably give rise to a *m/e* 91 fragment (tropylium ion) in substantial abundance. It has been reported that benzyl ether slowly decomposes to benzaldehyde (7). A comparison of the six major peaks for benzaldehyde with those in the spectrum published for benzyl ether showed that they were coincidental and almost identical in relative abundances.



III

The correct mass spectrum of benzyl ether is shown in Fig. 1. The lack of the parent ion (*m/e* 198) is not entirely unexpected since it is a common occurrence with higher molecular weight ethers (8). In this case the parent ion is apparently much less stable than either the benzyloxy or the tropylium ions.

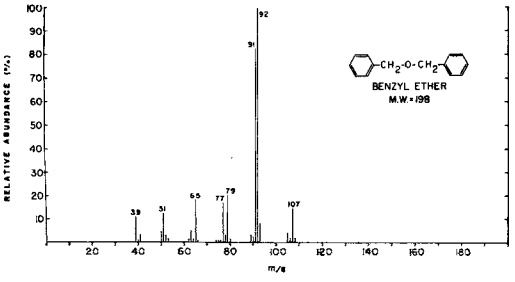


Fig. 1—Mass spectrum of benzyl ether.

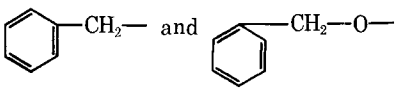
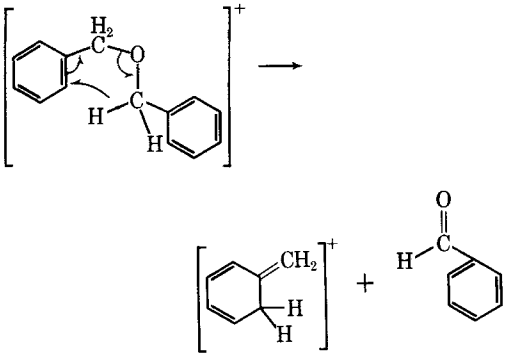
The cleavage of the carbon–oxygen bond occurs readily, giving rise to IV and V with the positive charge being carried by either fragment (*m/e* 91 and *m/e* 107); however, the very stable tropylium ion (*m/e* 91) is favored and has the greater abundance.



IV V

The *m/e* 92 fragment is the base peak and somewhat unexpected; however, this occurrence has been reported for compounds with the general structure of AR—CH_2—O—RH (9). This can occur by the postulated rearrangement (10) shown in Scheme I.



m/e 92

Scheme I

Based on the comparison of the spectral data of the fraction isolated from oil of basil with those of the known samples of benzyl ether, the presence of the latter has been definitely established in a sample of oil of basil, in a concentration of about 4%. Another sample of oil of basil was obtained in this laboratory by steam distillation of *Ocimum basilicum* L., var. *glabratum* Bentham, sub-var. *vulgare* Alefeld, forme *thyrsiflorum* L.[3] The benzyl ether could not be detected in this particular oil. Studies reported on the chemical composition of *O. basilicum* as reviewed by the authors have not indicated the presence of this ether in the oil.

Benzyl ether was detected by MacLeod *et al.* as a component not natural to lemon in a commercial sample purported to be cold-pressed lemon oil (11). These investigations suggest that the ether had been added to the sample of lemon oil.

Modification of Iron Toxicity and/or Absorption in Mice

By THEODORE H. EICKHOLT* and WALLACE F. WHITE

A study was made of the toxicity of iron administered orally in mice under various conditions. In a quantitative 6-group technique α-aminoacetic acid effected a statistically significant increase in mortality rate of iron. Conversely, sodium succinate reduced the mortality rate of iron with statistical significance. Comparisons of slopes of dosage response curves of mortality rates of iron administered orally with and without additives showed very close parallelism.

IRON COMPOUNDS have received considerable attention regarding methods of improving absorption and decreasing irritation. Dietary factors have been found to have a great influence upon the absorption of iron. Gastric acidity, ascorbic acid, SH groups of proteins, and other reductants in foods help convert ferric iron to the apparently more readily absorbable ferrous form.

Many different iron compounds alone or with other additive compounds have been employed in the attempt to increase iron absorption and decrease the usual side effects of orally administered iron. Iron choline citrate chelate (1, 2), ferrous fumarate (3–5), ferrous aminoacetosulfate (6–10), an iron carbohydrate complex (11), and combinations of iron with polyol monolaurate (12), polysorbate 20,[1] polysorbate 80[2] (13, 14), magnesium aluminum hydroxide (15), and D-sorbitol (16–18) are several common examples.

It was, therefore, the purpose of this study to demonstrate any influence which glycine and sodium succinate had on the mortality rate of orally administered iron, a greater mortality resulting from increased toxicity or absorption and a reduced mortality resulting from decreased toxicity or absorption at a given dose of iron.

EXPERIMENTAL

In the initial stages of this toxicity study it was observed that unfasted animals gave erratic results when fed iron compounds orally (19). Likewise, it was found that mice fasted 22 ± 2 hr. were much more uniformly sensitive to iron toxicity than were unfasted mice. Also, although mice fasted under conditions preventing their exposure to feces and sawdust have been shown to increase their susceptibility to iron toxicity (19), the Fairfield Webster female mice in this study were all fasted 22 ± 2 hr. with water *ad libitum*, and exposed to both of these elements to prevent the complication of cannibalism. The animals weighed approximately 25 Gm. The room temperature of 24° was kept as constant as possible. All medication was given by the oral route *via* stomach intubation. The doses of all compounds were calculated on a milligram per kilogram basis and the number of animals dead after 24 hr. was observed; the remaining animals were observed for a period of 30 days for any possible latent effects.

To limit variability, the following experimental design was employed in which 60 mice were divided at random into the following six groups for concurrent testing.

Group A—Controls; received 0.3 ml. distilled water.

Group B—Additive; received an additive compound without iron (at one or more subsequent dose levels).

Group C—Iron standard; a solution containing 125 mg. of ferrous sulfate (25 mg. of iron) per ml.,[3] referred to hereafter as ferrous sulfate solution, dose 160 mg. Fe/Kg.

Group D—Iron standard; ferrous sulfate solution, 240 mg. Fe/Kg.

Group E—Ferrous sulfate solution, 240 mg. Fe/Kg. and additive at dosage level of group *B*.

Group F—Ferrous sulfate solution, 240 mg. Fe/Kg., and additive at dosage level of group *B*.

All six groups received the solutions within a 1-hr. period. The experiment was repeated to give totals of 20 mice per group. The iron doses were chosen so as to provide a range for observation of possible protection as well as potentiation of the iron toxicity by the additive compounds.

The additives were employed as 20% solutions. Two doses of glycine were employed in the attempt to determine the effect of the additive on the toxicity of iron.

The data from the six-group design were analyzed to determine statistically significant differences between the iron administration alone and with the additive. The basis for the estimation of toxicity was a quantal response in which a probit analysis was employed [Finney (20), Burns (21), Fisher and Yates (22)]. The analyses, per cent mortality values, ρ values, and confidence limits were calculated on each individual group of ten animals as well as on the data from the combined groups giving 20 animals per group so as to observe any day-to-day variation, if present.

For confirmation of the analyses of the additives found to be significant, five 27-Gm. mice were fasted 22 ± 2 hr. with water *ad libitum*, and given orally 3.2 mg./Gm. α-aminoacetic acid and 48 mcg. Fe/Gm. Another group of five 27-Gm. mice were similarly fasted and given orally 3.2 mg./Gm. sodium succinate and 48 mcg. Fe/Gm. Both groups were allowed 1 hr. before sacrificing and subsequent separation of the gastrointestinal tract from the remainder of the carcass. The five carcasses and five gastrointestinal tracts of each group were combined and digested with sulfuric and nitric acids until only a clear solution in sulfuric acid with

a small amount of white precipitate remained. These four resulting solutions were cooled, made up to 100 ml. in a volumetric flask, and used as earlier described under the modified Fisher method for the determination of iron used in this laboratory (23). The colorimetric analysis was made after the iron was liberated and oxidized with sulfuric acid and potassium persulfate and treated with potassium thiocyanate.

Calculations of slopes of dosage response curves for iron administered orally with and without additives were performed to determine their parallelism.

RESULTS AND DISCUSSION

The data obtained using the six-group design are presented in Table I.

The results of the statistical analyses of the separate and combined data are summarized as follows. Glycine, 3.2 mg./Gm., potentiated the toxicity of orally administered iron and sodium succinate, 3.2 mg./Gm., decreased the toxicity of orally administered iron. Both of these results were shown to represent statistically significant differences.

The results of the chemical determinations of iron content in mice in which the additive agents produced statistical results are given in Table II.

The dose of 48 mcg. Fe/Gm. mouse for a 27-Gm. animal would amount to 1.296 mg. iron and added to the previously published average iron content per mouse of 1.457 mg. would be a calculated total of 2.753 mg. or 102 mcg. Fe/Gm., compared to the determined average figure of 2.270 mg. and 84 mcg. Fe/Gm. An average of 483 mcg. Fe or 18 mcg. Fe/Gm. mouse was unaccounted for, as noted previously, probably due to the inherent properties of the colorimetric method itself.

However, the averages of iron content in the respective glycine and succinate gut, 840 and 1000 mcg., represent iron absorption of 456 and 296 mg., respectively, on the basis of the calculated 1.296 mg. of iron administered orally. This serves to support the statistical significance arrived at in the statistical calculations, *i.e.*, glycine potentiates while sodium succinate inhibits iron absorption.

In these experiments, calculations of slopes of dosage response curves in which mortality rates of iron administered orally without additives were obtained. The mean slope was 7.038, compared with a mean slope of 7.577 for the average of groups in which iron and additives were administered together. This very close parallelism between slopes would appear to indicate that death was due to iron toxicity and that the effect of additives was merely to modify absorption.

The 60 mice in the control groups receiving oral intubations of distilled water were without deleterious effects and were alive after the 30-day observational period, indicating that the technique itself was not a contributing factor in this toxicity study.

SUMMARY AND CONCLUSIONS

A study was made of the absorption of iron administered orally to mice under various conditions.

Of the additive compounds tested using the quantitative 6-group method, glycine showed a statistically significant increase in the mortality of iron. Likewise, sodium succinate gave a statistically significant reduction in the mortality of iron. These significant results were verified by oral administration of the compounds with iron, subsequent digestion, and chemical determination of the iron content by the modified Fisher method reported earlier.

Calculation of slopes of dosage response curves, in which mortality rates of iron administered orally with and without additives were compared, showed close parallelism.

The technique of oral intubation was demmonstrated to be adequate for the study of absorption and safe, as exemplified by the lack of deleterious effects on the control groups of animals receiving only distilled water.

TABLE I—MODIFYING EFFECT OF ADDITIVES ON THE TOXICITY OF IRON ORALLY IN MICE USING THE STATISTICALLY DESIGNED SIX GROUP TECHNIQUE (PER CENT MORTALITY IN 24 hr.)[a]

Additive	Group B	Group C	Group E	Group D	Group F
		32 mcg. Fe/Gm.		48 mcg. Fe/Gm.	
	Additive Alone	Alone	Plus Additive	Alone	Plus Additive
Glycine					
1.6 mg./Gm.	0	10	30	50	60
3.2 mg./Gm.	0	5	15	20	55
Sodium succinate					
3.2 mg./Gm.	0	5	0	40	10

[a] Sixty mice in group *A* were given distilled water alone and all lived; therefore, group *A* is not included.

TABLE II—AVERAGES FROM MICE IN GROUPS OF FIVE OF IRON PRESENT PER MOUSE CARCASS AND GUT, SEPARATE AND COMBINED

Group	Av. Iron Content in Carcass, mg.	Av. Iron Content in Gut, mcg.	Av. Iron Content/ Mouse, mg.	Av. Iron Content/ Gm. Mouse, mcg.
3.2 mg./Gm. glycine and 48 mcg. Fe/Gm.	1.480	840	2.320	86
3.2 mg./Gm. Na succinate and 48 mcg. Fe/Gm.	1.220	1000	2.220	82

Vitamin C and Choline Content of *Chlorella vulgaris* and *C. pyrenoidosa*

By ROBERTSON PRATT and EVELYN JOHNSON

The choline content of *Chlorella vulgaris* and of *C. pyrenoidosa* (expressed as micrograms per milligram dry cell weight) remained relatively constant during a 3-week growth period. However, the concentration in the latter species exceeded slightly that of the former at all harvest times. In both species, after reaching a peak early in the culture period (5–7 days), the concentration of ascorbic acid decreased continuously. The total yield of both vitamins (micrograms per milliliter of culture) increased continuously because of the increment in cell mass.

THIS NOTE records data concerning yields of vitamin C (total ascorbic acid) and of choline from two species of unicellular green algae and is part of a continuing study of production of vitamins and accessory growth factors by *Chlorella vulgaris* and *C. pyrenoidosa* (1–5).

METHODS

The pedigree of the strains of *C. vulgaris* and of *C. pyrenoidosa* employed, the method of maintaining stock cultures, the composition and inoculation of stock and experimental culture solutions, and the details of environmental conditions provided and of harvesting experimental cultures have been described previously (1). In summary, an inorganic medium consisting of minerals and micro-elements was inoculated with the algae and was continuously aerated with a CO_2–air mixture. Continuous illumination (600 f.c.) was provided from a Mazda source and the temperature was maintained at 20.5 ± 0.5°. Cells were harvested at intervals during the 3-week culture period and vitamin C and choline content were determined.

Assays—*Vitamin C Activity*—Since ascorbic and dehydroascorbic acids exhibit equal antiscorbutic activity, the method of Roe and Osterling (6) was applicable and was employed to determine "total ascorbic acid." This entailed extraction of cells with a metaphosphoric acid mixture and treatment with a decolorizing agent[1] which oxidized ascorbic to dehydroascorbic acid and clarified the solution. The oxidized form was then coupled with 2,4-dinitrophenylhydrazine and the resulting derivative, when treated with H_2SO_4, produced a red color which could be quantitated photometrically.

Aliquots of each cell suspension were extracted in duplicate and each extract was assayed in duplicate for total ascorbic acid. The standard deviations of the assays were within ±5% of the mean; most were within ±2%.

Choline—Cells were autoclaved in 3% H_2SO_4 at 15 lb. pressure for 2 hr. and then were neutralized with BaOH, following the method of Horowitz and Beadle (7). After filtration, the extract was passed through a Permutit column to separate choline from methionine and to eliminate other substances which might interfere with the assay.

Choline content of the extract was determined using *Neurospora crassa* ATCC 9277 as the test organism in bacto-choline assay medium (8). Growth response of the organism was determined gravimetrically.

Aliquots of each cell suspension were extracted in duplicate and each extract was then assayed in duplicate. For all assays the standard deviation was within the range ±10% of the mean, generally falling in the range ±5% or less.

RESULTS

The maximum ascorbic acid content detected in the cells of both organisms was about 1.1 to 1.2 mcg./mg. of cell dry weight. This peak occurred in the early period of growth (5 to 7 days) and then the concentration declined continuously throughout the remainder of the 21-day culture period (Table I, A). Choline appeared more constant in concentration. The apparent trend in the average values for choline in *C. vulgaris* is not supported by the data from individual runs. Variations were random. Neither compound was detectable in the harvested culture medium.

When results are expressed in terms of micrograms per milliliter of culture, both compounds are seen to have increased continuously throughout the culture period (Table I, B). This is a reflection of the continuous increase in cell mass as growth progressed.

The levels of choline and the peak levels of ascorbic acid (Table I, A) compare favorably with data reported by Morimura (9) for short-term (2–3 days) synchronized cultures of *C. ellipsoidea*. He also found that the choline content remained fairly constant, but reported that ascorbic acid "increased considerably during the stages . . . in which the photosynthetic process occurred most actively." Confirmatory evidence for this view is provided by the facts that (*a*) in the present

This peak occurred in the early period of growth (5 to 7 days) and then the concentration declined continuously throughout the remainder of the 21-day culture period (Table I, A). Choline appeared more constant in concentration. The apparent trend in the average values for choline in *C. vulgaris* is not supported by the data from individual runs. Variations were random. Neither compound was detectable in the harvested culture medium.

When results are expressed in terms of micrograms per milliliter of culture, both compounds are seen to have increased continuously throughout the culture period (Table I, B). This is a reflection of the continuous increase in cell mass as growth progressed.

The levels of choline and the peak levels of ascorbic acid (Table I, A) compare favorably with data reported by Morimura (9) for short-term (2–3 days) synchronized cultures of *C. ellipsoidea*. He also found that the choline content remained fairly constant, but reported that ascorbic acid "increased considerably during the stages . . . in which the photosynthetic process occurred most actively." Confirmatory evidence for this view is provided by the facts that (*a*) in the present

Cabbage	267	50[b]
Carrots	103	4[b]
Oranges	...	49[b]
Parsley	...	193[b]
Pepper, bell	...	120[b]
Potato, white	121	17[b]
Spinach	253	59[b]

[a] Values for foods from "Nutritional Data," 5th ed., H. J. Heinz, Pittsburgh, Pa., 1962, and from Sebrell, W. H., and Harris, R. S., "The Vitamins," Academic Press Inc., New York, N. Y., vols. I and II, 1954. [b] Milligrams of vitamin/100 Gm. raw edible portion.

experiments of longer duration, ascorbic acid content of the cells declined continuously after achieving a peak level early in the culture period, and (*b*) the rate of photosynthesis continuously decreases with advancing age of the culture.

In the current study, the final concentration of ascorbic acid in the cells of *C. vulgaris* was approximately 40% of the early maximum. Previous work has shown that under similar conditions (differing only in light intensity) the rate of photosynthesis at day 21 is only about 43% of the rate determined on the fourth day (10). Calculations (10), based on data reported by Sargent (11), indicate that the decrease in rate of photosynthesis in cultures of *C. pyrenoidosa* may be somewhat greater than for *C. vulgaris*, and it may be significant that in the present experiments the ascorbic acid content in cells from 21-day-old cultures of *C. pyrenoidosa* was only about 35% of the early peak concentration.

The above observations and Morimura's report (9) seem to confirm in the thallophytes the conclusion, based on work with higher plants in 1928, that light has a beneficial effect on the production of ascorbic acid (12). Many of the numerous subsequent direct and indirect verifications of that report and of an association between ascorbic acid and photosynthesis in higher plants have been cited by Mapson (13).

Table II shows that *Chlorella* compares favorably with several conventional dietary sources of choline but less favorably with the better known sources of vitamin C.

In comparing vitamin C content of the *Chlorella* species with that of the dietary sources listed, allowance must be made for the fact that values for *Chlorella* are for dried material, whereas those for the other sources are for fresh material. Recent determination of fresh and dry weights of *Chlorella* revealed approximately 75% water content (70% in *C. vulgaris* and 78% in *C. pyrenoidosa*). Therefore, vitamin C content of the two algae, expressed in terms of fresh weight would be about 25% of the figures given in the table.

Oxazepam Excretion by Chlordiazepoxide-^{14}C-Dosed Dogs

By HAZEL B. KIMMEL and SIDNEY S. WALKENSTEIN

The metabolism of chlordiazepoxide was studied in dogs using the ^{14}C-labeled drug. Following a single 26 mg./Kg. dose, oxazepam amounting to 1.1 per cent of the dose was found in urine and 1.3 per cent in feces. The oxazepam was identified by thin-layer chromatography. Chronic administration of chlordiazepoxide at a daily dose of 5 mg./Kg. for 9 weeks had no significant effect on the amount converted to oxazepam.

In previous reports on the metabolism in dogs of chlordiazepoxide (1) (7-chloro-2-methylamino-5-phenyl-3H-1, 4-benzodiazepine 4-oxide) and diazepam (2) (7-chloro-1,3-dihydro-1-methyl-5-phenyl-2H-1,4-benzodiazepin-2-one), the authors concluded that the 3-position in the diazepine ring of chlordiazepoxide was not subject to metabolic attack. This would eliminate the possibility of oxazepam[1] (7-chloro-1,3-dihydro-3-hydroxy-5-phenyl-2H-1,4-benzodiazepin-2-one) formation from chlorodiazepoxide. However, evidence for the metabolic conversion of chlordiazepoxide to oxazepam in the dog in small but significant amounts has been obtained.

The conclusion is based on results of preliminary studies in which oxazepam was recovered from the urine of dogs fed "lactam" (7-chloro-1, 3-dihydro-5-phenyl-2H-1,4-benzodiazepin-2-one 4-oxide), a major metabolite of chlordiazepoxide (1), and on chromatographic evidence obtained in studies in dogs fed chlordiazepoxide labeled with ^{14}C in the 2-position of the diazepine ring (specific activity 1.2 μc./mg.). The effect of chronic administration of chlordiazepoxide on the conversion to oxazepam was also investigated.

EXPERIMENTAL

Four dogs were given nonradioactive chlordiazepoxide in 5 mg./Kg. daily oral doses for 9 weeks followed by a final similar dose of chlordiazepoxide-^{14}C. In one phase of this study, two female dogs were given single 26 mg./Kg. oral doses of tagged chlordiazepoxide, and urine and feces were collected at intervals up to 48 hr. For thin-layer chromatography, the urine samples were exhaustively extracted with ethylene dichloride, and the aqueous residues were treated with β-glucuronidase at pH 5.5 for 48 hr. and then re-extracted with ethylene dichloride. Feces were also extracted with ethylene dichloride, but without glucuronidase treatment, since in a previous study (3) oxazepam was found to be excreted in feces unconjugated. The ethylene dichloride extracts were concentrated under vacuum to small volume and subjected to thin-layer and paper chromatography. In addition to the many solvent systems given in the references cited, the following were employed in thin-layer chromatography: (*a*) on Whatman Silica Gel SG 41: benzene–pyridine–acetic acid (80:5:2, v/v/v); chloroform–acetone–ethanol (8:5:5, v/v/v); and chloroform–acetone–ethanol (8:1:1, v/v/v); and (*b*) on MN-Kieselgel G-HR: *n*-butanol–*n*-butyl ether–acetic acid (4:8:1, v/v/v); and (*c*) on Silica Gel G (Merck, Darmstadt): heptane–chloroform–ethanol (5:5:1, v/v/v). After solvent development and air drying, the chromatograms were placed in contact with DuPont Cronex II medical X-ray film for 1–4 weeks, depending on the amount of radioactivity present. Radioactive areas on thin-layer plates as defined by radioautography were scraped into scintillation vials for assay on a Packard Tri-Carb liquid scintillation spectrometer using a dioxane "cocktail" (100 Gm. naphthalene, 10 Gm. POP, 250 mg. dimethyl POPOP, and 200 ml. methanol in 1 L. spectroquality 1,4-dioxane).

RESULTS AND DISCUSSION

Figure 1 is a radioautograph of a paper chromatogram of urine samples applied directly without prior treatment or extraction. The characteristic shape and location of oxazepam glucuronide can be seen duplicated in the urine samples from dogs dosed with diazepam and chlordiazepoxide, respectively. However, this area in the diazepam sample contains, in addition, the glucuronide of 3-hydroxy-diazepam (7-chloro-1,3-dihydro-3-hydroxy-1-methyl-5-phenyl-2H-1,4-benzodiazepin-2-one), and the same fraction in the chlordiazepoxide urine may also contain other glucuronides. Glucuronidase treatment of urine resulted in the disappearance of this glucuronide area, and gave rise to an ethylene dichloride extractable substance which when chromatogramed in all thin-layer systems cited under *Experimental* migrated identically with

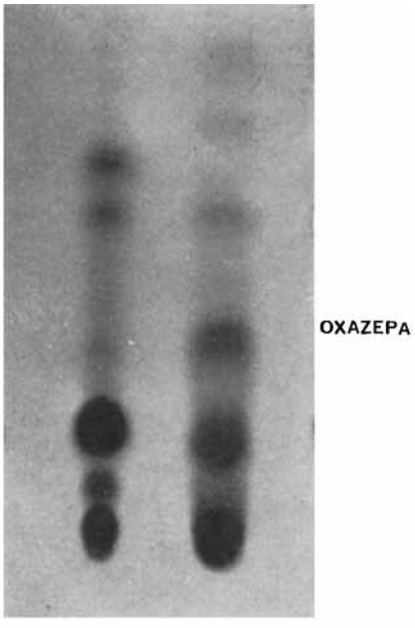

Fig. 2—Chromatogram made from urine collected between 24 and 48 hr. following a dose of ^{14}C-tagged drug to an animal on the chronic regimen.

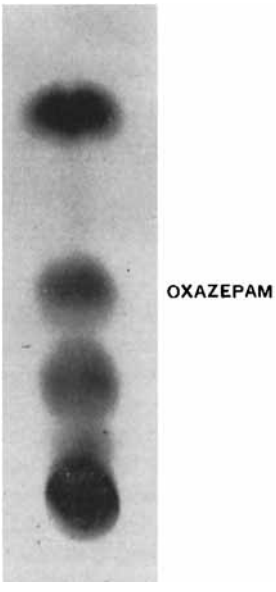

Fig. 3—Chromatogram made from feces collected between 24 and 48 hr. following a dose of ^{14}C-tagged drug to an animal on the chronic regimen.

authentic oxazepam. The chromatogram shown in Fig. 2 was made from urine collected between 24 and 48 hr. following a dose of ^{14}C-tagged drug to an animal on the chronic regimen. The oxazepam area accounts for about 16% of the radioactivity in this sample, as determined by scintillation counting. The corresponding area obtained from an extract of the 24–48 hr. feces collection (Fig. 3) of an acutely dosed animal contained 13%. The thin-layer systems which gave the best resolution of oxazepam were: (*a*) benzene–pyridine–acetic acid (80:5:2) on Whatman Silica Gel SG 41; (*b*) *n*-butanol–*n*-butyl ether–acetic acid (4:8:1) on MN-Kieselgel G-HR; (*c*) heptane–chloroform–ethanol (5:5:1) on Silica Gel G. Co-chromatography of extracts containing added nonradioactive oxazepam resulted in a single homogeneous spot at the R_f of oxazepam at which HCl-induced fluorescence corresponded exactly with the dark area on the radioautograph.

Prolonged administration of chlordiazepoxide appeared to have no effect on the extent of its conversion to oxazepam (Table I). Total amounts converted ranged from 2.4% in the acute study to 4.5% in the chronic study.

Cardiotonic Activity in Callus Tissue of *Digitalis mertonensis*

Sir:

It is well known that the quantitative estimation of digitalis glycosides by chemical methods does not always indicate an equivalent biological effect. There are many glycosides that do not produce a biological effect that are measured in chemical assays. Bioassay is therefore still preferred to the chemical assay when estimating the activity of cardiotonic glycosides (1–3).

Static cultures of callus tissue of *D. mertonensis* Buxton and Darlington seedlings were grown in the dark at 27° ± 1° in White's (4) modified basic media to which ingredients suggested by Staba (5) were added. To induce formation of callus in 14-day-old seedlings, 2,4-dichlorophenoxyacetic acid and 2-benzothiazoleoxyacetic acid in 1 and 2 p.p.m., respectively, were used. Thirty-seven-day-old callus tissue was harvested and dried, and a tincture was prepared from it according to the U.S.P. (6) method for digitalis leaf.

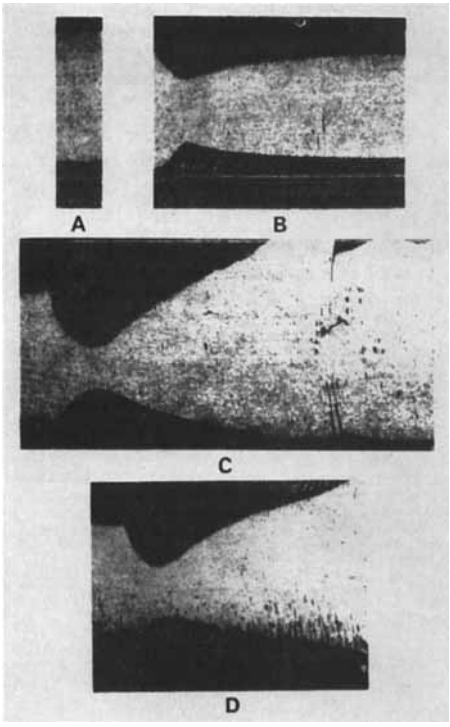

Fig. 1—Recordings of an isolated guinea pig heart preparation on administration of U.S.P. standard digitalis tincture and D. mertonensis *callus tincture* IB_{2c}. *Key:* A, *normal recording;* B, *effect of 0.25 ml. of 20% alcohol;* C, *effect of 25 mcg. total glycosides in diluted tincture of* IB_{2c} *injected in 3 graded doses over a period of 8 min. (note + inotropic response);* D, *effect on same preparation 1.5 min. following injection of 33 mcg. of total glycosides in diluted standard tincture.*

Isolated guinea pig heart preparations were used to study the cardiotonic activity of the callus. Guinea pigs of either sex weighing from 500 to 900 Gm. were used. The isolated mammalian heart technique was basically that of Langendorff (7). The perfusion fluid used was that suggested by Chenoweth and Koelle (8) slightly modified by using magnesium sulfate in place of magnesium chloride (9). Following cervical dislocation, the hearts were quickly removed and suspended in an Anderson-Craver heart perfusion apparatus (10). When the isolated heart, under a perfusion head pressure of 54 cm. of water and at a constant temperature of 37.5°, became stabilized, all extraneous tissues including the pericardium were dissected free. A stainless steel hook was inserted into the apex. The cardiac contractions were recorded on a slowly moving smoked kymograph by means of a cotton thread running from the hook, through a pulley system to a recording lever. All perfusate was discarded.

The tinctures were diluted sufficiently to reduce the concentration of alcohol to less than 25%. After recording the normal cardiac contractions, the effect of 0.25 ml. of 20% alcohol was recorded as a control. This was followed by equivalent doses of test sample. In each case the test sample was completely washed in by displacing the liquid in the injection spiral (1.5 ml.) with fresh perfusate. When the heart returned to normal, a diluted standard digitalis tincture was also introduced and its effect recorded. The results were then compared. (Fig. 1.)

It was found that the callus tincture produced a typical digitalis-like response in the isolated guinea pig heart. There was an increase in amplitude with a dose of 25 mcg. of total glycosides[1] over a period of 8 to 10 min. In four separate trials this effect was comparable to an increase in amplitude produced by 333 mcg. of total glycosides[1] in the standard digitalis tincture. However, in terms of dry callus 37.5 mg. was

[1] The total glycosides in the callus tincture and the standard digitalis tincture were calculated as digitoxin based on the Knudson and Dresbach colorimetric assay for total digitalis glycosides (11).

equivalent to the activity of 12 mg. of dried digitalis leaf.[2]

Digitalinum verum and verodoxin have been identified tentatively in *D. mertonensis* by thin-layer chromatography (12). *Digitalinum verum* has been shown to have cardiotonic activity in cats (13). Hence, it could be one of the active glycosides. From the data obtained thus far, it also seems that the glycosides present in the callus tissue are more active per gram weight of total glycosides as compared with those present in the leaf.

Tumor Inhibitors XXII. Senecionine and Senecionine *N*-Oxide, the Active Principles of *Senecio triangularis*

Sir:

In the course of the continuing search for tumor inhibitors from plant sources, an alcoholic extract of *Senecio triangularis* Hook. (*Compositae*)[1] was found to have reproducible activity against the Walker 256 carcinosarcoma tumor (intramuscular) in rats.[2] The fractionation of the active extract and the isolation and characterization of the active principles, senecionine (I) and senecionine *N*-oxide (II), are reported here. Senecionine has been isolated from *Senecio* species and other plants of the *Compositae* and *Leguminosae* (1, 2). While indirect evidence has been advanced for the occurrence of senecionine *N*-oxide in several plants (3–6), the isolation and characterization of the compound have not been reported previously.

The systematic fractionation of the alcoholic extract of *S. triangularis* is summarized in Scheme I; the *in vivo* assay data for the fractions obtained in a typical experiment are reported in Table I. The evaluation of assay results by CCNSC on a statistical basis in sequential testing is such that a material is considered active if it causes reduction of tumor weight to 42% or less.[2] The absence of tumor inhibitory activity from fractions B and C, coupled with the high yields of senecionine and senecionine *N*-oxide isolated from the alkaloidal mixture, support the conclusion that the latter two compounds were principally—if not solely—responsible for the tumor inhibitory activity of the alcoholic extract of *S. triangularis*. The present report appears to be the first recorded observation of the inhibitory activity of pyrrolizidine alkaloids against the Walker carcinosarcoma 256 tumor (intramuscular), although the activity of monocrotaline against the adenocarcinoma 755 tumor has been noted earlier (7).

When the isolation procedure of Koekemoer and Warren (8) was used (*i.e.*, partition of total extract between chloroform and 15% citric acid solution, and reduction of *N*-oxides in the aqueous layer with zinc and hydrochloric acid), the yield of total alkaloid was 1.65% of weight of dry plant. Hence, *S. triangularis* appears to be one of the richest sources of pyrrolizidine alkaloids (*cf. References 1, 2*).

Characterization of senecionine (I) was effected by comparison of (*a*) the melting points of the alkaloid and its picrate and nitrate derivatives

[1] Rhizomes, roots, stems, leaves and flowers, gathered in Colorado, August 1961. The authors acknowledge with thanks the receipt of the dried plant material from Dr. Robert E. Perdue, Jr., U. S. Dept. of Agriculture, Beltsville, Md., in accordance with the program developed with the USDA by the Cancer Chemotherapy National Service Center, National Cancer Institute, National Institutes of Health (CCNSC).

[2] Assays were performed by the Wisconsin Alumni Research Foundation and Hazleton Laboratories, Inc., under contract to the CCNSC. The procedures were those described in *Cancer Chemotherapy Rept.*, **25**, 1(1962).

Flow Sheet for the Isolation of Tumor-Inhibitory Principles from S. triangularis
Scheme I

and (*b*) the specific rotation and infrared and NMR spectra with recorded data (9–12). In addition, hydrolysis with barium hydroxide solution afforded retronecine (III) (isolated as hydrochloride) and senecic acid (IV), characterized by comparing melting points and spectra with recorded data (9, 13).

Senecionine *N*-oxide (II) was crystallized from chloroform–petroleum ether as a chloroform solvate, m.p. 141–142° dec., $[\alpha]_D^{28}$ −22° (c 1.32, $CHCl_3$), $\lambda_{max.}^{Nujol}$ 5.73, 5.81, 6.04 μ.[3]

Anal.—Calcd. for $C_{18}H_{25}NO_6 \cdot {}^2/_3\ CHCl_3$: C, 52.02; H, 6.00; Cl, 16.45; N, 3.25. Found: C, 51.52; H, 6.24; Cl, 17.64; N, 3.55.

The compound was characterized by reduction of II with zinc, copper sulfate, and sulfuric acid to I, and by oxidation of I with hydrogen peroxide to II (14).

The NMR spectrum of senecionine *N*-oxide is similar to that of senecionine, except that the signals corresponding to the protons on carbon atoms adjacent to the nitrogen are shifted downfield by 0.6 to 1.2 τ units. Thus, the signal for the C-8 proton, which appears as a multiplet centered at 5.68 τ in the spectrum of senecionine (15), is shifted to 4.50 τ in the spectrum of the

IV

N-oxide. The signals for the C-3 protons [multiplets at 6.14 and 6.53 τ for senecionine (15)] appear as a strong (2-proton) multiplet at 5.45 τ in the spectrum of the *N*-oxide. The shifts for protons on carbons adjacent to the nitrogen in the *N*-oxide are noteworthy, and may be valuable in structural studies of amines and their corresponding *N*-oxides.

It is noteworthy that various species of *Senecio* have been used in the treatment of cancer in many countries (16–19).[4] Indeed, *Senecio vulgaris*, known to contain senecionine (2), has been used since the 4th century A.D. for "tumors of the feet and sinews" (18), and since the 10th century for cancer (19). Furthermore, several other genera known to contain pyrrolizidine alkaloids [*e.g.*, *Petasites*, *Cynoglossum*, *Echium*, *Heliotropium*, *Tournefortia*, and *Cytisus* (2)] have also been described in folklore as plant remedies for cancer (16).

Received December 23, 1966.
Accepted for publication February 13, 1967.

This investigation was supported by grant CA-04500 from the National Cancer Institute, grant T-275 from the American Cancer Society, and a contract PH 43-64-551 with the Cancer Chemotherapy National Service Center, National Cancer Institute, National Institutes of Health, U. S. Public Health Service, Bethesda, Md.
Previous paper: Kupchan, S. M., Hemingway, R. J., Knox, J. R., Barboutis, S. J., Werner, D., and Barboutis, M. A., *J. Pharm. Sci.*, to be published.

* National Institutes of Health Predoctoral Fellow, 1966–1967.

REVIEWS

The Encyclopedia of Chemistry. 2nd ed. Edited by G. L. CLARK and G. G. HAWLEY. Reinhold Publishing Corp., 430 Park Ave., New York, N. Y. 10022, 1966. xxi + 1144 pp. 18 × 26 cm. Price $25.

The newly revised and updated version of this one-volume encyclopedia contains more than 800 articles, by approximately 600 authors covering the various aspects of chemistry. Special emphasis is given to current concepts such as chemical bonding, molecular orbitals, and coordination theory, in addition to new developments in instrumental analysis. To keep the book a reasonable size, biographies of the early prominent chemists, which appeared in the first edition, were deleted. Descriptions of organizations and societies and topics outdated or considered unessential in today's chemistry were also excluded. The length of the articles and the information included varies due to the varied authorship. For example, two pages are devoted to the physiology of digestion while one-half page covers diffusion and one-half page covers heterocyclic compounds with only one cross-reference included. Articles are in the book in alphabetical sequence with cross-references placed at the end of the article. A 30-page index is included as an aid in finding topics contained within an article. Some slight variations in alphabetizing exist also. For example, "Formulas, Chemical" is included in F's while "Chemical Nomenclature" is in the C's. In the latter case, nomenclature is not indexed. These, however, are probably minor faults. In general the writing is straightforward and the information is presented in an organized and concise fashion.

Staff review

Drugs in Current Use 1967. Edited by WALTER MODELL. Springer Publishing Co., Inc., N. 200 Park Ave. South, New York, N. Y. 10003, 1967. vii + 152 pp. 14 × 21 cm. Price $2.75. Paperbound.

Drugs of current clinical use or interest are presented with a concise summary of the information needed for their safe use and handling. Items are in alphabetical order. Trademark names are included and cross-referenced, but manufacturers are not identified. Except for a few items, such as the oral contraceptives, no combination products are listed. Information given for each drug varies from a short use and dose statement to a capsule summary which covers actions, uses, absorption, cautions, antidote, stability, dose, and preparations available. To keep the handbook size, many items are not included—immunologic agents, radiopaques, solvents, etc. In general, however, it appears that most of the drugs encountered day-to-day in the community pharmacy are covered.

Thesis Manual for Students in the Pharmaceutical Sciences. By THEODORA ANDREWS. Copies may be obtained from the Edward C. Elliott Hall of Music Box Office, Purdue University, Lafayette, Ind. 47907. 35 pp. 21 × 27.5 cm. Price $1.50. Paperbound.

Written by a pharmacy librarian, this 35-page booklet presents information basic to the writing of a research paper. The manual presents some ideas on how to search the pharmaceutical literature, and library, indexing, and abstracting services are listed and explained. Brief editorial comments point out the pertinent features and limitations of these various services and publications. Especially detailed information about the use of *Chemical Abstracts* is given. Recording and organizing data from literature sources is discussed with a sample method given. Suggestions on form and style of footnotes, references, abbreviations, etc. are also included with examples of each. Much of the information may seem to be almost too basic for those who are familiar with literature searches. However, for one who lacks this experience, it appears to present much useful information.

Encyclopedia of Industrial Chemical Analysis. Vols. 2 and 3. *General Techniques F–O* and *P–Z.* Edited by FOSTER DEE SNELL and CLIFFORD L. HILTON. Interscience Publishers, a division of John Wiley & Sons, Inc., 605 Third Ave., New York, N. Y. 10016, 1966. xi + 769 pp. 18.5 × 26 cm. Price $35 subscription, $45 single copy.

With the publication of these volumes, the first part of the "Encyclopedia" is now complete.

An example of the type of coverage given to a particular topic is the 40-page chapter on paper chromatography. A brief history of paper chromatography is given followed by a discussion of theory. Types of paper and factors involved in selecting the paper are considered as well as the various methods of development. Selection of the solvent system, sample preparation, application of the sample, detection, identification, sources of loss and error, experimental details, and applications are also covered. There are numerous cross-references within the chapter, so it appears the editors have avoided the duplication which often occurs in multi-authored books. Selected topics covered in these two volumes are: particle size and surface area, phase equilibria and its analytical applications, recorders, standard-setting organizations, x-ray methods of analysis, flammability determinations, magnetic susceptibility, nephelometry, and turbidimetry. The index to all three volumes is included in volume 3.

A review of volume 1 appeared in *J. Pharm. Sci.*, **55**, 993 (1966).

Tissue Culture in the Study of the Effects of Drugs

By M. DAWSON and W. F. DRYDEN

ALTHOUGH the techniques of cell, tissue, and organ culture have been known and developed over many years, surprisingly little use has been made of them until recently in pharmaceutical research for the direct examination of the effects, beneficial or adverse, on cells, healthy or abnormal, of substances of physiological or medicinal interest. Even now the full potential of the technique for this purpose is not being realized. The applications presently being made of tissue culture techniques are mainly in the fields of cytology, cell biochemistry and metabolism, cell differentiation, growing of viruses in cells, pathology (especially cancer), and the storage of viable material for transplantation. Thus, there is scope for considerable expansion in the application of tissue culture techniques to drug screening and action, where it can be a useful precursor or supplement to whole-animal tests in determining the effects of drugs at cellular level.

The method has several advantages, the most obvious being a reduction in the number of animal tests required, the relative cheapness of the technique, and the fact that less drug is used. Another advantage is that elimination of misleading results due to species difference may be brought about by the use of material of human origin. That species difference exists even at cellular level has been demonstrated (1, 2). Nevertheless, of the 1,461 references on the topic of the effects of drugs on cells retrieved by the Medlars organization recently, only 182 had made use of human cells. This organization is a computerized information retrieval system using tapes made from the references quoted in "Index Medicus." These 1,461 references cover the period mid-1963 to end-1966. Thus, it can be seen that even at the present time advantage is not being taken of the fact that tissue culture allows the use of human material on a scale not possible *in vivo*. There are, in fact, workers who deliberately choose amphibian material because it is poikilothermic. However, the present authors do not see that the provision of warmed surroundings, either in the form of a standard incubator or in the form of a warmed microscope stage, presents an insurmountable obstacle.

The use of cell culture also makes possible the setting up of replicate experiments and controls using identical material. Established cell lines are now easily available from many commercial suppliers. There is also a collection maintained by the American Type Culture Collection, and in Great Britain information on private collections is obtainable through the British Society for Cell Biology (formerly the British Tissue Culture Association).

Received from the Department of Pharmacy, University of Strathclyde. Glasgow, Scotland.
The authors thank Professor Elworthy for his interest and helpful advice.

Many cell lines are now stored deep-frozen to avoid the work of continuous subculturing and to keep down changes which may be introduced in new generations (3). It has, however, recently been observed that this does not guarantee freedom from variation in the course of time, and this point must be remembered if one is comparing current work with earlier work (4). Also even a few days' freezing and subsequent thawing have been observed (5) to cause cell changes, and even the dimethylsulfoxide usually used in the technique of deep freezing may *per se* produce cell changes (6, 7). Thus, although large quantities of uniform material may be used at any one time, caution must be observed in comparing results of experiments performed even on the same cell line if these experiments are long separated in time. Such changes in cells used may explain some of the contradictory findings periodically reported.

A further advantage of tissue culture is that the cells may be grown in a controlled environment. Many established lines will grow in chemically defined media. Also, if a solution of the test drug in nutrient medium is continuously perfused around the cells, the exact concentration of drug is known to which each cell is exposed for the duration of the experiment.

Surprisingly little use has been made too of cultures of diseased cells, other than cancer cells, most of the work so far having concerned either the killing of these, or freedom from toxicity on the part of the test drug toward healthy cells. There is also little work on mixtures of drugs to study synergism or antagonism, which could also be observed *in vitro*.

The tissue culture method has, however, the limitation that a drug metabolized to an active form *in vivo* could not be tested *in vitro* unless the active form were first prepared. A second disadvantage is that, although the cultured material may be structurally unchanged, it may have changed functionally (4, 8), *e.g.*, loss of neoplastic properties, loss of transplantability, respectively. Third, in systems which involve several cells, such as the central nervous system, the gross effect of a drug may not be demonstrable. Rather in this instance the often overlooked effects of the drug on the component cells of the system may be more easily elucidated by biochemical and cytophysiological means.

Finally, like the results of whole animal tests, those from tissue culture tests must of course be correlated with clinical findings. Once the need for such correlation and the limitations of the method are recognized, tissue culture may be seen to provide a useful means of assessing activity and toxicity of many drugs (9–12).

TISSUE CULTURE STUDIES ON DRUG ACTION

General—Perhaps the most complete list of publications on all aspects of tissue culture is that of Murray and Kopech (13) covering the years 1885–1950 and including some 15,000 references. There has since been a supplement to this. At present a bibliography by the same authors of more recent work is being published in parts, the first part having contained 1,213 references and the second part 1,244 references, this part coming out only 4 months later. This, taken in conjunction with the 1,461 Medlars references on drug action in tissue culture alone, is an indication of the vast increase in tissue work as a whole which has recently taken place. Obviously, a complete list of references even on this one aspect of tissue culture is beyond the scope of a single review article. Only the most important references since 1953 will be mentioned with in addition a few earlier works necessary for the explanation of the more recent work.

METHODS USED IN ASSESSING THE BENEFICIAL AND ADVERSE EFFECTS OF DRUGS ON CELLS

Many microscopic methods have been used for this purpose, varying from observation of cell death to observation of minor, reversible changes. When the end point of the experiment is death, vital staining has been used (14) to indicate the percentage killed. On the other hand, attention has been drawn (15) to the fact that increased cell permeability by a dye is not necessarily synonymous with loss of viability. Thus, some other index of cell death is preferable. Direct observations by microscope of hanging drop preparations of cells have been used (16, 17) either to follow slowing or stopping of growth, or to see changes within the cell. Chromosome examination is another measure sometimes used.

Usually phase-contrast microscopy is used to allow observation of live, unstained material, and this may be usefully allied to time-lapse filming to obtain a permanent continuous record of the experiment. The authors' design of such apparatus allows for controls being recorded simultaneously (18–22). Electron microscopy examinations are being undertaken with increasing frequency as will be seen from later sections of this paper.

In many experiments, use is made not of cell lines which have grown for many generations *in vitro*, but of primary explants of tissue fragments (23). These are sometimes preferred because of the changes, morphological, chromosomal, or metabolic, which may occur, apparently spontaneously, in cells after some time in culture.

A great amount of work on such explants of various tissues has been carried out by Pomerat and Leake (1), who measured the concentrations of many pharmaceutically important substances which would inhibit the outgrowth of cells from such explants. Others (24, 25) have also measured the area of explant growth, or the time of closing of a small hole punched in the explant (26). Such measures of area, however, take no account of the depth of the growth or of whether the cells in the halo of outgrowth are loosely or tightly packed.

One disadvantage of using fragments of tissue or small organs, as distinct from separated cells, is that the drug may not have access to the cells at the center of the piece or organ. This may lead to false results if the experiment is of the type where the material is exposed to the drug for a fixed time and then is returned to growth medium without drug. On the other hand, such conditions may be desirable for some experiments because they more nearly approximate to *in vivo* conditions where each cell, for example in a tumor, is not necessarily bathed in drug solution. Another point that must be kept in mind in examining outgrowths from explants is that the rate of growth of the different cell types in the explants will probably vary—for example, a small number of epithelial cells may first be seen and later be completely overgrown with a halo of fibroblasts. Adequate control experiments are necessary before any conclusions can be drawn about a drug having a differential toxicity for epithelial and fibroblast cells under such conditions.

Inhibition of macrophage migration from spleen explants has also been used as an index of toxicity (27), as has the rate of migration of white blood cells in cultures of these alone (28). An interesting technique (29) overlays monolayers of cells with semisolid agar, through which the drug diffuses from paper disks as in an antibiotic assay. The agar is then poured off, the cells incubated, and examined for death or other changes. A comparison can be made with control cells on the same monolayers since the agar localized the drug. The only criticism of the method would be that it is necessary to verify chemically, where the result is unchanged cells, that the drug did elute from the paper.

Other methods of measuring growth in tissue cultures have been fully described (30, 31) or reviewed (32). These methods include total cell counts, viable counts, nuclear counts (in hemocytometer chambers or electronic counters), cell size measurements, packed cell volume or dry weight measurements, estimation of cell constituents such as protein, DNA, RNA, measurements of glucose utilization, mitotic index or duration of mitosis, or of respiration (33–37). Among respiration techniques, the authors' experience shows that micro-techniques using Cartesian diver types of respirometer are particularly useful and give a relatively rapid result.

Thus there are many indices from which to choose. Those chosen should always in the authors' experience include looking for simple morphological change because this is usually more sensitive than other indices. However, a change capable of being expressed objectively is better than one that can be described only subjectively, *e.g.*, number of polynucleated cells produced would be better than simply change of shape of cell. In using the other indices, *i.e.*, cell number, weight, volume, or biochemical measurements, which can all be expressed mathematically, it is necessary to do sufficient experiments and simultaneous controls for results to be statistically sound. Regrettably, the extent of variation among normal, untreated, replicate tissue cultures is all too often not recognized. This is surprising, because in recent years the need for good design in conventional, whole animal, pharmacological experiments has become generally appreciated, and one would have thought the same principles would have been applied to tissue culture methods. It is impossible to evaluate work where insufficient replicates and no controls are done, nor under such circumstances can one know what relative "weight" to assign to the all too many papers showing contradictory results.

Finally, whatever method is adopted for assessing the effect of a drug on cells, fully detailed reporting of that method is absolutely essential. Even very minor experimental variations may affect the results. Items which should be included in reports are details of the cell type, strain, origin, duration and treatment between obtaining and growing, duration since explanting, temperature and atmosphere of growing, medium in which growing, and frequency and methods of feeding and subculture. Whether material is fresh or frozen/thawed may affect its appearance (5), and also the effect of a drug may vary with the growth phase of the cells when treated. If synchronized cultures are used, this should be stated. Growth can be affected even by whether the cultures are exposed to light and by whether centrifuging is a stage in the subculturing procedure (38). The converse effect, weightlessness, is still of course under active investigation!

Only if all these qualitative and quantitative aspects are planned for and reported is a paper of present or future value and able to be put in true perspective in relation to other papers.

GROUPS OF DRUGS WHICH HAVE BEEN EXAMINED BY TISSUE CULTURE METHODS

The various drugs which have been so examined fall into four main groups—anticancer agents, antimicrobial agents, hormones, and alkaloids. Although the latter is generally regarded as a chemical group, as opposed to the first three being pharmacological groups, from the point of view of change in cells, this too is a pharmacological group. There are fewer references to other drugs, and here these will be grouped under *Other Drugs*, including both chemical and biological substances.

There are few references to the substances, other than the active ingredient, in pharmaceutical formulations. Such items as vehicles, ointment bases, adjuvants, diluents, stabilizers, emulsifying agents, substances which increase viscosity (39), surface-active agents, tablet lubricants, disintegrants, coatings and polishes, flavorings and dyes, and materials used in surgical dressings and sutures—especially where the materials are new—are all items which could properly be examined by tissue culture. It is just as important that they be free from toxicity as it is for the active ingredient to be.

Anticancer Agents—It is extremely reasonable to use a cellular method for testing such drugs, since primarily a differential action on normal and malignant cells is being sought. Some of the material taken as "normal" in some experiments, however, scarcely merits this description, *e.g.*, benign growths which have been removed and varicose vein material (40).

The field of anticancer agent screening is in fact the place where the most active work is taking place using the tissue culture method. Such works may be said to have increased explosively since it was said (40) in 1961 that "the application of human cell cultures for the evaluation of cytotoxic activity of new carcinostatic agents has been reported by a few investigators."

The earlier papers in this field tended to emphasize the ease with which malignant cells could be grown *in vitro*, resulting in the availability of large amounts of uniform test material. This idea should be treated with reservation, however, from the viewpoints of both ease and uniformity. In considering ease of growth, although undoubtedly cells planted into a bottle or flask and grown to form a monolayer usually, in the case of normal cells, cease growing once intercellular contact is established—and in the case of malignant cells may not so cease—yet the proportion of explants of malignant tissue actually producing growth *in vitro* is far from 100% (41–44). Figures like 20–60% are more common. There has even been a report on a means of growing sarcoma cells free from healthy cells (45). Also, concerning uniformity of material produced, this has been taken for granted too much. Recent work has shown that variations do in fact occur over a period in cultured material. For example, cells have been shown to fail to maintain their blood groups in tissue culture (46), although this is not a unanimous finding, and chromosome variations have been observed (4). The heterogeneity of response of individual cells in neoplastic populations has also been discussed (47).

Clinical observations on the variation in response to the same drug in different patients with histologically indistinguishable tumors has resulted in the suggestion that it is useful to test drugs on primary explants of an individual patient's tumor at its particular stage of development (40, 42, 48–50). Also, in view of the current idea that an immune component may be concerned in some tumors, the concept of individual host specificity must be borne in mind (51). The idea of using the patient's own material may be very pertinent if the patient has been receiving chemotherapy because of the reported (52) difference between tumor materials from treated and untreated sources in terms of biochemistry, growth kinetics, and karyotype. On the other hand, it has been suggested (40) that prior *in vivo* chemotherapy made no difference to the tissue culture findings.

A further advantage of the tissue culture method for finding the best available drug for any one patient is that it saves involving the patient in the drugs, whose effects may be cumulative, synergistic, or antagonistic (51). In the authors' opinion it is erroneous to decry the tissue culture screening method (40) because of inconsistencies between clinical findings and tissue culture results with apparently identical samples. It would be more correct to realize that samples histologically the same might differ physiologically and functionally. A further advantage of using primary explant material from the patient is that it has not yet become overgrown with one dominant cell type at the expense of others. This is important in view of the numerous reports of many substances having different toxicities toward different cell types.

Whatever type of material, experimental method, and index of toxicity is used, it is necessary that all reports be presented in complete detail so that valid comparisons may be made. For example, results have varied (53) with the percentage of serum in the medium, and even undue chopping of the original material may

produce regenerative hyperplasia (54). Wilson and Barker (49) support the authors' opinion that one index of toxicity used should be morphology. They find it preferable to enzyme inhibition or ^3H uptake, and Morasca (55) finds it more sensitive than mitotic index change and ^3H uptake. Also George *et al.* (56) caution that antimitotic activity is not necessarily equivalent to antitumor activity, basing this conclusion on the fact that various antimitotic substances had very different antitumor activities.

The use of a tissue culture screening method has of late produced a flood of publications with the negative conclusion that "no differential effect was observed between this substance's action on normal and malignant cells." The greatest bulk of screening experiments is that carried out by and for the Cancer Chemotherapy National Service Center Screening Laboratories, the results of which are published in *Cancer Research* supplements. Both synthetic and natural substances are reported. For example, several of the monthly 1965 and 1966 issues contain reports on between 1,000 and 2,000 substances of either type. These reports cover only substances with which it was found not worth proceeding. There are now several years of experience behind the experiments of these workers, who have streamlined their test to use only one cell line (KB cells derived from a carcinoma of the nasopharynx). They did this after tests on more than 1,000 substances indicated less variation among different cell lines used simultaneously than with successive tests using one cell line. A note of caution must here be introduced, however, to mention the variations more recently found to occur in various KB lines with time (4). Only one index of toxicity is routinely used in these experiments: finding the dose inhibiting protein synthesis to 50% of the level found in controls. While this measure by no means exhausts the effects that these substances may produce in cells, it has been considered an adequate indication of whether further *in vivo* testing is likely to lead to any valuable findings. By mid-1966 these reports spoke of decreasing the amount of tissue culture work performed because it had not yet yielded any useful drug. In the authors' opinion decreasing is the wrong solution to this—a diversification of indices of toxicity used would be likely to lead to other results. Also, regrettably, tissue culture is not the only research method which has failed to yield useful anticancer drugs.

Other recent reports of anticancer screening are now numerous (44, 51, 54, 56–67). The gradual accumulation of contradictory findings among these reports further indicates the importance of detailed reporting of cells, media, cultural conditions, and index of toxicity used—for example, not simply referring to techniques as "standard" (44). The authors think, however, that this need for detail is very slow in being realized. Very few papers (68) draw attention to the advantages of using human rather than experimental animal material or to the good mathematical planning of experiments. For example, at least three dose levels separated in geometric progression (61, 64, 69–71), a principle long recognized (72) in whole animal techniques, are used.

There are many other publications dealing with the effects of drugs on malignant cells, but these were conducted to advance knowledge on the nature of the differences between these cells and normal cells, and thus the drugs were incidental to these experiments and not the main object. Such papers are therefore not within the scope of the present article. Often it is interesting to observe the comparison of malignant to embryonic cells in seeking factors affecting cell differentation—a large part currently played by tissue culture in cancer research.

However, clearly anticancer screening is a field in which much work remains to be done, both in seeking new substances and in choosing the best existing one for a particular patient. In the first case morphological change seems to be the most sensitive index to use, and in the second case, where time presses, the differential respirometer apparatus seems, in the authors' experience with melanomas, to form a suitable measure. Results may be obtained from this index more quickly than from simple growth or from such measures as dehydrogenase activity (51). The large number of replicate experiments possible *in vitro* facilitates the simultaneous examination of various modifications of a molecule found somewhat active in this field.

Antimicrobial Agents—Both antibacterial and antiviral drugs have been tested *in vitro* for freedom from toxicity toward cells. The method is particularly applicable to antiviral drugs where the viruses are growing intracellularly both *in vivo* and *in vitro*.

It is rather surprising to find some very early work (73) on antibacterials, including reports on *in vitro* tests for freedom from toxicity, and then to observe that there followed a long period when no such tests were performed. Only now is the method again being appreciated.

A notable early example of such work was its use by Sir Alexander Fleming in 1929 (28) in his original investigations of penicillin. He used the activity of leucocytes (species of origin not stated)

in broth as his criterion of toxicity, and reported that he could find no impairment of function in the presence of penicillin. Similar work with purer penicillin was later reported (74, 75). The latter work established the routine inclusion of penicillin in tissue culture media to prevent the growth of microorganisms, which multiply all too easily in any media supporting the growth of other cells. One group of organisms particularly troublesome in tissue culture is the *Mycoplasmataceae* (pleuro-pneumonia-like organisms). A by-product of work on their elimination is further information on the concentration of many antibiotics which are harmless to various cells, one report alone (76) mentioning 50 antibiotics. Other reports on relative toxicities of various antibiotics indicate (25) that chloramphenicol and chlortetracycline HCl[1] are more toxic in culture than penicillin, and actinomycin and xanthomycin (77, 78) more toxic than other antibiotics.

In the field of antimicrobial testing, nonhuman material is too often used, especially chick embryo material. This seems a needlessly indirect procedure. Early work by Sallé and co-workers (79–82) unfortunately used such material, but they made an advance in the field by reporting results in terms of "toxicity index," relating cell toxicity to antibacterial effect. This was based on the idea that a substance, although very active against bacteria, would have no clinical application if it were at the same time toxic to tissue. The work was extended (83, 84) to measure the maximum time of contact with a given concentration of drug compatible with cell growth, rather than the less realistic measure of maximum concentration allowing cell growth, and was later made quantitative (85) by measuring the number of tissue fragments out of 10 surviving in each part of the experiment and control.

Much of the work on antibacterials has involved ranking currently available substances in order of freedom from toxicity to cells, for example, the comparison of sulfonamides and proflavine (86, 87) on several cell types—the sulfonamides being found to be much less toxic than proflavine—or the comparison of several sulfonamides (88). More recent papers investigate in more detail how these substances affect cells, *e.g.*, proflavine has been reported to produce chromatid breaks (89) or the synthesis of an abnormal RNA (90), and recent work on sulfonamides (91) finds a contradiction in a non-increase in protein synthesis associated with an increase in ribosomes. Rightly, the conclusion is that much further work is required on the action of sulfonamides on cells. Several dyes have also been compared. For example, brilliant green, gentian violet, and acriflavine have been reported to be more toxic than proflavine (92).

Some experiments have been rather more complicated (93–97), being designed to study the effects of antibiotics on live bacteria once these were inside phagocytes. It was found that the phagocytes did, to a certain extent, prevent access of some antibiotics to the bacteria, *e.g.*, penicillin and streptomycin (93), penicillin, streptomycin, and erythromycin (94), streptomycin (95), ampicillin, erythromycin, and oleandomycin (96), but not benzylpenicillin (96), or chloramphenicol, or tetracycline (94). The other report (97) indicated that although the monocytes protected *B. abortus* against streptomycin alone, they did not protect if chlorpromazine were also present. The conclusion is that it helped the streptomycin to penetrate the cells. Similar work not confined to antibiotics, on ingested *M. tuberculosis* (98, 99), reported protection against streptomycin, viomycin, and neomycin B, but not oxytetracycline HCl[2] and isoniazid. The later work on antibiotics also deals with the more detailed effects of these on cells; *e.g.*, streptomycin has been reported to produce nonrandom chromosome breaks in leucocytes (100) and puromycin to inhibit RNA synthesis (101). Such work indicates that new antibiotics might well require careful screening *in vitro* before being marketed.

With all the work on antibacterial substances, only one paper (102) seems to have considered the toxic effects on skin cells of by-products of bacteria multiplying in wounds. This paper reported on pyocyanin from *Ps. pyocyanea* and concluded, from its effects on human skin cells and leucocytes *in vitro*, that it probably would not affect phagocytosis but that it might affect wound closure.

There is less available work on antiviral drugs, from which any useful conclusion can be drawn, than on antibacterial drugs, despite the large amount of work that has been carried out on antiviral chemotherapy. Most materials so far have unfortunately turned out to be too cytotoxic to use. It had been thought that the discovery of the existence of cell receptor sites for adsorbing viruses would have been helpful, but so far metabolic inhibitors once the virus is in the cell seem most useful (103). Many of the

[1] Marketed as Aureomycin by Lederle Laboratories, Pearl River, N. Y.

[2] Marketed as Terramycin by Chas. Pfizer and Co., New York, N. Y.

substances investigated are merely protein synthesis inhibitors, inhibiting virus only by inhibiting host cells. It seems unlikely (103) that there is any chance of inhibiting a pathway that occurs uniquely in infected cells, a problem analogous with that previously mentioned: finding a substance with a differential action on malignant and normal cells. In antiviral work, however, there is perhaps less scope because of greater species specificity (23), for using some of the exotic species of cells that have been chosen for antibacterial work simply because these cells happen to grow well in culture. Nevertheless, there are reports of the use of goldfish cells (104) and plant and insect cells (105) in the study of human pathogens.

Aside from the innumerable papers on various synthetic chemicals, there are also a few on natural products. Algal extracts (106) and bacterial extracts (107) have been screened, a few of each being reported as worth pursuing. Two other groups of workers (108, 109) have reported the interesting discovery of antiviral substances produced by apparently uninfected cells in culture, as distinct from the well-known production of interferon by virus-infected cells. The substances were effective against some enteroviruses (108) and influenza (109). The authors are cautious about interpreting their unexpected results. Tsilinsky's work (108), however, is extensively mathematical, and his conclusions seem entirely reasonable.

Thus, there is scope for much more work on antimicrobial substances for both systemic and topical use. One side effect of the large amount of tissue culture work done in connection with wound healing and skin grafting is that there are many papers on the growing of skin *in vitro*, either in fragments or reduced to cells (18, 26, 102, 103, 106, 107, 110–128). Also remnants of skin from grafts are readily available from surgical units. Thus, it is a practical proposition to grow skin *in vitro* in quantities suitable for testing ranges of potential topical antimicrobial substances for their effects on skin (129). In all reports on antimicrobial substances, as on anticancer substances, full details of materials and methods and statistics are required so that various papers may be compared. For example, the use of calcium-free medium to allow the cells to stay in suspension (130) could well create differences invalidating comparisons with other papers unless such points are kept in mind. The same authors remark on another important point: the differences of inhibition of respiration found, as between the use of tissue slices and individual cells. This again raises the problem of the drug's access to the cells, a point already noted in work on anticancer drugs. A further precaution to be observed in testing antiviral drugs for their effects on the morphology of cells is to distinguish these effects from the effects due to the viruses themselves. That such distinction is possible is seen from the work of Schauer and Likar (131). The principal advantages of the tissue culture method for antiviral screening of antimicrobial substances then appear to be: first, the number of replicates that can be set up; second, the overcoming of species differences, by the use of human material, in respect to both different species susceptibility to various viruses and different effectiveness of different drugs in different species. A further advantage is that quoted by Nemes (132) that one can find by histochemical techniques if the drug is being incorporated into the host cells.

Hormones—The use of tissue culture techniques in the study of the physiological and pharmacological properties of hormones is well established. As has been pointed out (133), the freedom from interference by nervous and other humoral influences prevents much confusion and conflicting conclusions. When one restricts the limit of perspective to those experiments which use pharmacological rather than physiological dose levels, one finds that the scene is dominated by the mass of work carried out on the steroids, natural or synthetic, although insulin and—to a lesser extent—thyroid hormone have received some detailed attention. These substances are used to replace natural deficiencies, and others are used in connection with hormone dependent or influenced tumors. They may therefore be classified as "drugs" in these circumstances. A recent review by LeDouarin (134) covers much recent work on the influence of most of the hormones and vitamins on the growth and differentiation of embryonic bone in culture.

Steroids—Considerable confusion existed in the literature concerning the early work on the adrenal steroids and their toxicity in tissue culture systems. Reports ranged from complete inhibition of growth at 100 mcg./ml. with slight inhibition at 50 mcg./ml. down to a marked restriction in growth at 0.3 mcg./ml. (135–140). The cells used in these experiments were largely fibroblasts derived from embryonic chick or mouse sources, although Geiger *et al.* (135) could only demonstrate inhibition using fibroblasts derived from adult sources. The variation in response obtained by the earlier workers could in part be attributed to the variation in cell type and culture systems used. It was subsequently shown that cells of epithelial origin were less af-

fected by steroids than were fibroblasts subjected to similar concentrations (138, 141, 142), although the closely related synthetic steroid, prednisolone, has been shown to increase the proportion of fibroblasts in cultures of bone marrow (143). This apparent anomaly is not substantiated by evidence from other sources, since prednisolone is regarded as more cytotoxic than cortisone (144, 145) and there must be some reserve until the complexities of a marrow culture system are better understood. There was also evidence that the observed effect was dependent upon growth vigor of the culture (146). Poor cultures were stimulated, while rapidly multiplying ones were inhibited. Whether the addition of steroid to the cultures returned suboptimal conditions to optimal and raised optimal to lethal, respectively, was not clarified, and the solution to the problem awaits further work. Pihl and Eker (142) obtained evidence for a tolerance period, after which a strain of liver cells was capable of multiplying even in the presence of a tenfold increase in prednisolone concentration.

Such dependence of results on the details of methods used in toxicity studies can only serve to emphasize the importance of standardizing the conditions of experiments before valid comparisons can be made.

The consensus of the reports would appear to point to a toxic or lethal concentration of 100 mcg./ml. below which the results are variable and also reversible (139). Below 10 mcg./ml. little or no effect was discernible by optical methods or by measuring cellular "growth" in one of its forms.

A similar series of studies was carried out on the related mineralocorticoid, deoxycorticosterone (DOCA), where doses of 35 and 70 mcg./ml. resulted in cellular hyperplasia and an accumulation of intracellular lipid. The changes were not reversible, but as with the glucocorticoids, fibroblasts showed much greater sensitivity than epithelium or endothelium (147, 148). When DOCA and cortisone acetate were added simultaneously to cultures, the effect of the former predominated (149). Whole thickness skin was used in these experiments, and its ability to serve as an autograft after a period in culture was used as a parameter in assessing the effect of these substances. It was found that the skin could be grafted back on the donor after 3 to 4 weeks of culture in a cortisone enriched medium as compared to the 10–14-day maximum time after which controls could not be regrafted. DOCA, on the other hand, while not prolonging the regrafting time, did maintain the structural integrity of the skin better.

This preservation effect of cortisone and related compounds in lower concentrations has been documented from other sources. Embryonic bones in organ culture (150) were maintained better in the presence of hydrocortisone than in its absence, while other reports, dealing with isolated cells in culture, have shown that at lower concentrations (0.1–10 mcg./ml.) the corticosteroids preserved the cells from the degenerative effects of culture exhibited by controls (151, 152). Others claim a positive stimulatory effect rather than simple preservation, using fibroblasts and low concentrations of drug (138, 153).

Not only fibroblasts but also glial cells in cultures of embryo rat cord ganglia (154) showed increased migration and better survival than controls, while in large pieces of tissue central necrosis, which is normally expected, was diminished. The production of myelin in this experiment was unaffected. It is of interest to note that the cells which show greatest sensitivity to the presence of steroid are those responsible for the structural framework and support of the tissues, a possible pointer to the mechanism of the anti-inflammatory properties of the steroids. It has been suggested that these cells may in normal culture be existing at a subphysiological level of steroid, and by adding low concentrations to the medium, the optimal level is attained. This suggestion has much to commend it in this instance where we are dealing with a drug which is also a normal constituent of the *in vivo* environment.

The fundamental reason for low concentrations being beneficial, however, is as obscure as ever. To answer the obvious question, attempts have been made to assess the influence of the corticosteroids on biochemical systems in cultivated cells.

The results of the simple toxicity tests are in part reflected in the data obtained at this level. High concentrations of cortisone were shown to depress the respiration of cells and increase glycolysis, while at lower concentrations aerobic respiration was stimulated (140). The level of alkaline phosphatase in epithelioid cells was raised by low concentration of prednisolone (155), while there was seen to be an increase in RNA synthesis which was not reflected in the RNA/DNA or protein/DNA ratios of the cultures (156). It must be assumed therefore that RNA turnover was increased. Such a fragmentary picture of the influence of the steroid on the molecular biology of the cell must be completed before any fundamental understanding of the influence of these drugs is possible.

The biochemical approach has been used by those interested in the use of steroids to alleviate inflammatory conditions. Mucopolysaccharide production by cells derived from articular or dermal tissue was found to be suppressed, despite a slightly increased rate of growth (153), and studies on the synthesis and subsequent sulfation of chondroitin in tissue culture (157) showed an inhibitory effect of steroids to be exerted at the latter stage.

Thus it becomes evident that while cells can be stimulated to reproduce more vigorously and maintain their morphology under the influence of the corticosteroids, the laying down by cells of a matrix for connective tissue is inhibited.

Kuchler and his co-workers have put forward an interesting theory on the mechanism whereby the corticosteroids achieve their effects (158, 159). The writers postulate, on the evidence obtained from experiments with synthetic steroids, such as estradiol and stilbestrol, that the drug molecules form a monolayer on the surface of the cell, thus preventing by occlusion of active sites, the transfer of ionized or highly polar substances across the cell membrane, as for example, amino acids. The work cited is rather small on which to base a theory so profound, but it is certainly worth pursuing. If this explanation is shown to be correct, then the lethal effects could be explained by a starvation of the cell, denied its nutrients by a blockade of steroid. However, the stimulating effect of lower concentrations awaits a rational explanation.

The chemical modifications which can be made to the steroid nucleus have led several workers to investigate the relationship between structure and activity. Substitution of a hydroxyl in the 11 position increased the toxicity markedly (160), while a keto group in the same position had little effect. Biswas and his colleagues (161) tested 99 different steroids in a simple system consisting of observing outgrowth of fibroblasts from explanted fragments of embryonic chick hearts, and of these substances 36 showed some degree of toxicity which could not be related to the chemical structure of the molecules. The stereochemical configurations were, however, not considered, and it is feasible that some evidence may be obtained to indicate a common mode of action. The addition of a fluorine atom to the molecule increased its toxicity despite the presence of other chemical groupings at other sites (162).

Berliner (163, 164) has observed that different types of cells vary in their metabolic substitution of the basic steroid molecule. On this basis, he postulates that the varying susceptibilities of cells may stem from the different cellular metabolites, which will vary in their toxicity. This work also deserves closer attention, and it is to be hoped that attempts will be made to place the suggestion on a firmer foundation than that upon which it presently rests.

The role of hydrocortisone in suppressing the immune mechanism of the body has been a source of considerable speculation and investigation resulting *inter alia*, in the discovery that cells pretreated for 1 hr. with hydrocortisone are more susceptible to infection by polio virus (165), although simultaneous addition of virus and steroid depressed the infectivity of the virus.

This latter observation received support in a series of experiments (166, 167) which showed that cortisone protected cells from the cytopathic effect of the virus normally caused possibly by lysis of lysosomal membranes, while Holowczak (168) showed that hydrocortisone and actinomycin D together substantially reduced the number of virus particles entering the cells.

The production of interferon by cells in culture is under intensive study, and the production of an antiviral substance by cells growing in the presence of hydrocortisone and virus (169) has been noted, although others claim that the presence of subtoxic concentrations of steroid depress the production of interferon by cells when in contact with pox or arbor viruses (170). Such an observation is in line with clinical observations, but the work is in its early stages and the whole question of interferon production and viral infectivity must be better understood before a rational explanation of the influence of steroids or any other drug is forthcoming.

The corticosteroids have not been the sole group of steroids to be examined for toxicity or activity in tissue culture systems. Of the sex steroids, estrone is unusual in that no toxic properties could be shown under the conditions of a simple outgrowth experiment (161). On the contrary, it was responsible for stimulating normal cell division in hamster ascites cells which would otherwise form multinucleate giant cells (171). This activity was suppressed by the incorporation, along with estrone, of progesterone or a chemical derivative. The degree of suppression could not be related to either chemical structure or progestational activity. Progesterone itself, and also the synthetic estrogen, estradiol, show varying toxicity to different cell types ranging from toxic to chick fibroblasts to growth stimulatory to other lines at similar concentrations (172, 173). Of the steroids tested on mouse mammary tumors, progesterone was the most toxic (174), although such a tissue, which is

normally influenced by the sex hormones, cannot be directly compared with the tissues used in other work. Testosterone and androsterone have also been shown to be toxic to most cells at low concentrations compared to the corticosteroids (151 ,173), although Lasnitzki (175), using organ culture, has maintained the differentiation of young rat prostate glands. Older glands display edepithelial hypertrophy and abnormal mitoses which raised the question of testosterone acting as a carcinogen to senile glands *in vivo*, a point which might be remembered when elderly patients are under treatment with the drug.

Such work, however, borders on the mass of study which has been undertaken, using cell and organ culture, on the physiological actions and relationships of the steroids and associated hormones. The line of demarcation between pharmacology and physiology is at best tenuous and ill-defined. Nevertheless, an account of this work must fall outside the scope of this review.

Thyroid—As in the case of steroids, there are conflicting reports here too, some finding stimulation and some finding inhibition. This difficulty has been mentioned in a general review on the mechanism of action of thyroid hormone by Barker (176). Much of the work involving thyroid has dealt with the development of embryonic bone in culture. Although originally undertaken as work on embryology, this type of work could serve as a basis for assay or as a means of comparing related substances. One early established fact (177) in work resulting from the observation of bone changes in hyper- and hypothyroidism was that different embryonic chick bones, in the same experimental conditions, showed different susceptibilities. For example, radii and humeri responded to the growth promoting activity of thyroxine, while to femora and tibiae a harmful effect was observed. This could well be one factor accounting for conflicting reports. An interesting later work by the same authors (178) compared the effects of L-triiodothyronine and of thyroxine on the same tissue, reporting that both substances inhibited growth, but that the former was about four times as potent as the latter. Both, however, showed more effect on the more rapidly growing bones. A further factor reported to affect the result is the age of the chick embryo, stimulation changing to retardation with increasing age, considering radii and ulnae. Different effects on different bones or on the same bones at different stages in development are noted also by Dieterlin-Lievre (133), who mentions that increase in dose can even change stimulation to inhibition. Thus, in any quantitative experiments investigating the effects of thyroid on bone, the bone used, its age, and its growth rate would have to be considered.

The effect of thyroid on tissues other than bone has been investigated less, although stimulation of nerve tissue has been reported (179) and also retardation of embryonic lung and kidney tissue (180). This report, however, mentions that no retardation was observed in lines of cells that had been long in culture, indicating again that these may change in metabolism and therefore be of less value in observing and measuring drug effect than are primary explants.

Parathyroid—There are reports too of bone resorption experiments in connection with parathyroid. One comprehensive and mathematically sound paper (181) lists the various factors affecting the result, which would have to be kept constant in a quantitative assay. The tissue culture method is compared with the rat assay method and found to be more sensitive and to require less material, but to be less precise and to take longer. However, the author cautions that even fuller investigations into the factors affecting the result by tissue culture are required since changes in sera in the media affected it, with no reason for this being evident. Another report (182) suggests that constituents in the medium which bind protein may affect the results, and a further report (183) indicates that sulfated polysaccharides may stimulate bone resorption by parathyroid—though it could not be determined whether it was by virtue of the sulfate *per se*.

Insulin—A hormone which has received much attention from a tissue culture point of view is insulin. It is in fact fairly often included in tissue culture media for a growth-promoting effect. As will be seen, however, many cell types have been used in investigations of insulin, and again contradictory results of stimulation are found in these reports, some of which are difficult to evaluate for want of adequate information.

Organ culture of chick bones has been used (184) to demonstrate the ability of insulin to inhibit longitudinal growth of the bones while the epiphyses became abnormally large. A curious phenomenon was described whereby a second shaft formed alongside the original bone shaft. The histological differentiation and maturation of the bones was retarded, with poorer staining of cartilage. The level of 0.16 I.U. insulin per ml. of medium is however far in excess of any therapeutic dose which tissues *in vivo*, other than the subcutaneous tissues at the site of injection, are likely to encounter. Further work on bone (133) indicated that previously

reported micromelia was in fact directly due to insulin and not an indirect effect of hypoglycemia.

The same organ culture technique has been used (185) to study the effects of insulin on brown fat. Both glycogen and lipid contents of the cells showed an increase, although the glycogen fell after 3 days while the level of intracellular lipid remained high. The response was most marked in a medium of serum, but such results could be explained by the presence of insulin in the serum itself in addition to the added hormone, or to selective adsorption as suggested by Waymouth (186). She concluded from her own work and the examination of that of numerous others that, since insulin is adsorbed onto glass especially in the absence of other protein, in media containing protein the effect of insulin would probably be seen at lower levels.

An attempt to observe cellular uptake of fluorescein-labeled insulin (187) was unsuccessful. Failure was attributed to differing sensitivities of cell types (those used here being hamster kidney, both normal and tumor and Landschütz ascites cells) since Paul (188) had noted a greatly increased rate of pinocytosis (*i.e.*, uptake) in HeLa cells. This he conjectured to be due to either more energy made available to the cell by insulin for this kind of activity or a direct action of insulin on the cell membrane. On the other hand, Danes and Freshney (189) did not find insulin increasing pinocytosis, their measure of pinocytosis being not vacuole counts but uptake of iron–dextran.

This sensitivity difference of different cell types toward insulin and variation with media used was again recorded (190), insulin being found to promote growth of human fetal skin fibroblasts in maintenance medium but having no effect on their growth rate in growth-promoting medium. HeLa cells, on the other hand, increased their cell material but not cell number under the influence of insulin in maintenance medium, and their growth rate in growth-promoting medium was also significantly increased in the presence of the hormone. Insulin has also been found to have a significant effect on cell numbers in chick heart explants. The increase in the rate of cell division was coupled with a rise in RNA phosphate per cell (191). Waymouth (186) reported also an elongating effect of insulin on L cells. Since this took place after a few hours, it is considered a direct effect on existing cells and not selective survival of long cells.

The metabolic effects of insulin have been studied, using fresh chick embryo and L cells (188). Carbohydrate metabolism was stimulated, with a rise in glucose utilization and lactate production, while pyruvate levels in the medium fell. Stimulation of synthetic processes was found to be erratic, especially with fresh explants. The explanation of this unpredictable reaction was not forthcoming, but the suggestion was made that it might be associated with the ability of the cells to produce high energy compounds dependent on the previous treatment of the cells. Glucose utilization increase by HeLa cells in growth-promoting medium, was reported by Leslie *et al.* (190), and the rate of incorporation of various amino acids into protein has also been reported (192).

Briefly, the effect of insulin is most marked at a metabolic level, stimulating carbohydrate, lipid, and protein metabolism. The effects of insulin are due solely to its hormonal action since the concentrations of the hormone were normally too low for it to be utilized by the cells as a normal protein.

Gonadotropic Hormones—Much work has been done on these also in tissue culture (193). Human chorionic gonadotropin or prolactin separately were almost inactive in incorporating acetate-^{14}C into cholesterol in normal rat corpus luteum *in vitro*, but together they increased the cholesterol labeling by 90%. Such synergism would need to be taken into account if either was being assayed *in vitro*. Follicles and stromal cells of rat ovary are also reported (194) to be stimulated by gonadotropic hormone in culture, but this work comments that species of origin of tissue may be important in assessing these substances, different results having been obtained with mouse tissue.

Alkaloids—These substances and other weak bases, although differing widely in their pharmacological action *in vivo*, mostly seem to produce similar morphological change, vacuolization, in cells in culture. Tissue culture could not so far be used to distinguish many alkaloids from one another, although it could distinguish them from toxins or metabolic inhibitors whose effect is irreversible. There is one extremely comprehensive article on substances producing vacuolization (195) showing that this is an easily observed cell change and the extent of it varied with concentration. The article goes on to show that changes with concentration are in fact caused by this and not by osmotic pressure changes. From the point of view of making a quantitative assay the occurrence or nonoccurrence of vacuolization would be preferable as an end point to a rating system for amount of vacuolization.

Alkaloids and other weak bases producing vacuolization include procaine hydrochloride and amide, cocaine, atropine, ephedrine, pilo-

carpine, and ammonium chloride. However, dibucaine and quinidine, in similar concentrations, did not produce vacuoles in similar cells, although the cells did die (195). A further report of Buchsbaum and Kuntz (196) also refers to vacuolization, and makes the very useful contribution of an excellent design of equipment for such study. Another useful article on drug-induced vacuolization (197) describes similar reversible effects produced by various autonomic drugs in malignant but not in normal cells, and only if the cells were initially undamaged. Structure of the drug molecule could not be correlated with production of vacuoles, and some drugs antagonistic *in vivo* had additive effects in respect of vacuolization.

The present authors have never observed, or seen illustrations of, drug-induced vacuolization as extensive as the state produced by vacuolating virus. The actual cell size does not seem to enlarge in the former. It may be as Yang, Strasser, and Pomerat (195) reported that the vacuole is an attempt to dilute out the drug, and if this is so, it may be that the cell is overcome ultimately by lethal effects of the drug setting in before vacuolization becomes as pronounced as with virus. None of the above experiments, however, was continued to cell death, since the reversibility of this effect was one of the objectives of this investigation. Vacuole production is not specific to alkaloids and chemically similar substances, having been observed also from plant polysaccharides (197). Nevertheless, its nonspecificity does not prevent its being a useful index of toxicity. A more fundamental investigation of precise causes of vacuolization and nature of vacuole contents is difficult owing to the intangible nature of the vacuoles. Morphine sulfate also produced vacuoles (198) and in fact the cells developed a tolerance to it, becoming able to withstand doses which would have been lethal to fresh cells. In addition, the cells exhibited withdrawal symptoms, adopting morphological characteristics of unhealthy cells. Another alkaloid inducing vacuolization is nicotine (199, 200), but unlike the experiments with morphine, those with nicotine showed neither dependence nor withdrawal symptoms. Another effect of nicotine on cells has also been reported (201). It depressed ciliary activity in ciliated cells, doing this to a greater extent in the presence of influenza infection than when alone. Nevertheless, these works show that ciliary activity is a useful change to observe in cells, and that it can be observed with normal cinemicrographic apparatus, high speed photography of the cilia not being necessary. Another work (202) on inhibition of cilia by nicotine unfortunately used amphibian cells growing at room temperature. The effect of berberine has also been observed (17). The cells rippled, frothed, and bubbled violently, similar to the effects produced by the dibucaine and quinidine mentioned above.

One alkaloid with a very characteristic effect on cells is, of course, colchicine, which arrests mitosis in the metaphase. This effect and its inhibition have been studied (17) using phase contrast cinemicrography, and a method has been developed (203) for measuring movements of isolated cells under the influence of colchicine or other substances. Experiments on combinations of colchicine and other substances showed that narcotine, bulbocarpine, and some apomorphine derivatives exerted a synergistic effect on the action of colchicine and related compounds (204), while tropolone and myo-inositol specifically antagonized its action (205). Such results with mixtures would have to be borne in mind in assays for any of these substances, just as in the case of chorionic gonadotropic hormone and prolactin mentioned above.

Other Drugs—No other drug or group of drugs has been studied nearly so extensively as the above in respect to its effects on cells.

Some antihistamine drugs have been studied (206) since they may be applied directly to nasal mucosa cells. These cells unfortunately were not used in the experiments, but in all the types of cells that were used (heart, intestine, and lung fibroblasts) clinical concentrations of the drugs produced no inhibition of growth, although the cells were vacuolated, however. On the other hand, the same workers (1) comment on the high toxicity of various antihistamines toward outgrowth from primary explants of normal adult human skin. Inhibition of tumor cells *in vitro* has also been reported (207), the authors speculating on the relation of this to reduced histamine found in cancer tissue.

One drug, sodium fluoride, has been used in experiments which have received more publicity than was perhaps expected. While the effects of sodium fluoride on cells are of interest to cytologists, they are of interest also to those concerned with adding the substance to water supplies deficient in it, to prevent dental decay in young children. There has been controversial correspondence on whether growth was slowed by the concentrations advocated for drinking water or only by higher concentrations (208–213). A further report (214) deals with inhibition of oxygen uptake and glycolysis but not inhibition of phagocytosis by sodium fluoride. So far it

can be said that inhibition does occur at the various concentrations reported on the cell types used, but it is too early to correlate this with any effect *in vivo*.

Salicylate analogs, cinchophen and chloroquine derivatives, and phenylbutazone and related compounds were examined by Whitehouse (215) using his technique of culturing and assaying cartilage. Anomalies between his results and *in vivo* findings were encountered and probably point to intermediate metabolism of the drugs into active forms by other organs. Sodium aurothiomalate and saligenin, for example, were inactive, but thiomalic acid and salicylate were effective.

Chloroquine has been further investigated for cell-inhibiting properties (62, 216) using chick embryo cells. Vacuolization and decreased growth were observed at 1/40,000, although lower concentrations stimulated growth. The cells also disaggregated to individual cells, like trypsinized cells. A detailed work on chloroquine (217) was undertaken, in view of its use in some conditions with abnormalities of the immune response, to find exactly what its mode of action in such cases might be. It was concluded that it "stabilized" lysosome membrane preventing enzyme release which would start lymphocyte derepression. It appeared to act only on lymphocytes responding to a stimulus. This paper throughout seems logically reasoned and mathematically sound, and for these reasons, as well as its topic, it is of interest.

Organophosphorus substances have been studied (218), their amount being estimated by the effect on ciliary activity of cells *in vitro*. Decrease of ciliary activity is not of course a specific effect of these substances, having been observed also in connection with local anesthetics (219) and nicotine (201).

An interesting use has been made of isolated, beating, chick embryo heart cells to compare digoxin, quinidine, and procaine amide (220). The action of digoxin was to produce arrhythmias, and this is in keeping with the view that digitalis preparations have an intracellular action. Quinidine and procaine amide had a depressant action on beating, and the potentiating effect of quinidine on digitalis recorded *in vivo* was reflected in tissue culture, indicating the potential usefulness of tissue culture model in studying cardiac drugs. Very little use has been made of this so far. In fact, the comment made in 1954 (1) is still applicable: "Similar (i.e. tissue culture) screening may be made of the action of cardiac glucosides on beating heart fragments. This possibility has not yet been adequately explored, but it offers many promising opportunities for fruitful observations."

Acetylcholine has also been used (221) in a study of the sensitivity to the drug of rat diaphragm muscle fibers when grown by organ culture methods. It was concluded that muscle fibers themselves produced changes in the fiber membrane, once nervous connection had been lost, to enable it to react to cholinergic drugs, thus confirming previous *in vivo* findings.

The irritant action of a number of substances, including podophyllin, croton oil, turpentine, and peptone was studied (222), and their effect on the motility of leucocytes was observed.

Anticoagulants have not been widely studied (223, 224). The former studies compared the effect of clinical concentrations of heparin, polyanetholsulfonic acid, and sodium citrate on leucocyte migration and phagocytosis. Only the heparin did not affect these. However, the author found no correlation between migration and phagocytosis, though later work usually describes a cessation of movement during pinocytosis. The other work involving heparin was with hamster sarcoma cells where effects were seen on the morphology, contents, mitotic index, and chromosomes, leading the authors to wonder if these were caused by a combination of sodium citrate with the proteins of the mitotic spindle. Further evidence on a relation between heparin and cell division was described by Lippman (225), who considered that, if mucopolysaccharides were removed from the cell surface, Ca^{2+} could then penetrate, increase cytoplasmic viscosity, and initiate chromosome condensation, and thence cell division. This paper includes a list of many sulfated polysaccharides reported to block cell division in many types of cells.

The tissue culture method offers scope for the development of assay methods for some immunological preparations. As is well known (23), there are still several such products for which there is no assay which correlates well with clinical results. The group of immunological products most obviously and directly lending itself to this assay method is the antisera, whose protective capacity against the relevant toxin may be assessed on cells. There are of course already some officially recognized tests of this nature, *e.g.*, the Biological Assay of Poliomyelitis Neutralising Antibody of the "British Pharmacopoeia," where the content of this antibody in a sample of serum is determined by comparing the dose of serum necessary to protect tissue cultures against infection from a test dose of poliomyelitis virus with the dose of a standard serum necessary to give the same protection (226). The cells

used are usually monkey kidney and the index of toxicity is cell damage as seen by light microscope. Tissue culture work has included also work on antibody production *in vitro* (227) performed with a view to gathering further knowledge on the mechanisms of antibody production and therefore irrelevant to this paper.

The application of tissue culture in active immunity preparations would be in testing toxoids and vaccines for freedom from toxicity and, where appropriate, freedom from live viruses. There are five recent works on a tissue culture assay for diphtheria preparations. The indices of toxicity investigated have been demyelination of fetal rat cord ganglion cells (154) or inhibition of protein synthesis in KB cells (228), a result being obtainable here in 90 min., which is usefully quick. Also the cellular method has been reported (229) to be quicker and cheaper than the use of guinea pigs. However, one important point still to be cleared up is whether different cell types affect the result. There are reports both for and against this (*References 230* and *231*, respectively).

Staphylococcal toxins have also been investigated in tissue culture (232, 233) on various cell lines, using both morphological and biochemical indices of toxicity. Although the work was done to gain knowledge on the relation between pathogenicity and the production of various toxins, the method is equally applicable to assay, the basis being there already in the mathematical detail quoted in these papers.

In connection with diagnostic immunological preparations, a proliferative effect of tuberculin purified protein derivative on human peripheral macrophages has been reported (234), but no correlation was established between this effect and the donor's skin sensitivity state toward ordinary tuberculin testing.

In the field of nonmicrobiological immunologicals, spider venom has been reported (235) to produce degenerative changes in HeLa and L cells within a few hours, the changes not occurring if the venom was neutralized with antiserum. This again could serve as a basis for assay of the antivenom.

It seems then that the most promising "growth points" of tissue culture as applied to immunological preparations are the quantitative assays of antisera and the testing for freedom from toxicity of viral vaccines and bacterial toxoids.

Drugs acting on nerve cells are probably the most difficult to investigate by tissue culture (236), since these cells in culture, if normal, probably move and divide less than most other cell types. A biochemical rather than a microscopical index of effect is therefore indicated. However, other nervous system cells have been used—for example, oligodendrocytes (237)—to study the effect of chlorpromazine, an increase in contraction rate being the effect observed. The toxicity of barbiturates toward outgrowths from embryonic chick spinal cord and heart tissues has also been measured (238). It was noted that heart tissue was more resistant to the range of barbiturates tested. The toxicity of convulsant barbiturates was in keeping with their *in vivo* toxicity, but anomalies were blatant in the case of hypnotic barbiturates. Such anomalies would probably indicate an *in vivo* metabolic pathway synthesizing a more or a less toxic molecule.

When the discovery was being investigated that the antiepileptic drug phenytoin (B.P.) aided wound healing, it was found (239) that it stimulated the growth of a line of human gingival fibroblasts, although experiments with analogs failed to clarify which part of the molecule was responsible. The mode of action was not cleared up by a later comprehensive work (240), using primary explants from dental surgery from 15 patients to set up 596 test experiments and 533 controls.

Finally, the tragedy of thalidomide stimulated work into its effects on various tissues grown *in vitro*, resulting in the report (241) that the soluble hydroxy derivative of the drug was capable of inhibiting the synthesis of protein by embryonic cells. Other work (242) has endeavored to find the mechanism of action whereby thalidomide inhibited small lymphocytes in culture using the two racemates and various degradation products, all in concentrations similar to those teratogenic in animals. It was hoped that this might give a clue to the teratogenic mechanism. However, more work is required for any proof, and only a theory could be put forward, that thalidomide might be antagonistic to glutamic acid or glutamine.

CONCLUSION

The use of tissue culture techniques in the study of drug action and toxicity is as yet in its infancy. The bulk of the work presented in this publication has dealt with the toxicity of materials toward explants of tissues, often embryonic avian tissues whose metabolism cannot be comparable in every respect to the metabolism of human tissues.

Generally, toxicity is recognized by failure of a tissue or cell culture to grow. However, growth in tissue culture systems is difficult to define. It may be taken to mean an increase in cell number,

increase in cell size, or increase in metabolic rate. These criteria, however, may be completely independent and affected by unrelated factors. It has been repeatedly emphasized that the different indices of growth are not necessarily synonymous. Cunningham and Kirk (32) found area of explant, cell size, and cell number may vary independently, and Ritter (243) found that protein and cell counts could also vary independently. The authors feel confident that, as the effect of more drugs in tissue culture are investigated, more, and more specific, effects will be observed. For example, in their own work, a curious arcing of H.Ep. 2 cells has been observed with spermine (22). Effects on stages of cell division are the group of effects investigated in greatest detail as yet, leaving much to be done on all the other aspects of cell biology.

The advent of time-lapse cinemicrography and the sophistication of many techniques in cytology and biochemistry have led to the possibilities of investigation into the detailed action of medicinal substances on tissues and on cells, and of the metabolism of the drugs by the cells. For too long, this has been a subject where isolated workers scratch at the outside of a particular problem when the possibilities of reaching a fundamental solution have been numerous. Fortunately, in the laboratories of the world, attention is now being paid to those basic phenomena essential to the life of the cell. Ultimately there will be increased knowledge of the effect of drugs in their widest sense on those phenomena, a logical sequence to the more elementary gross toxicity tests which have been hitherto carried out. The rewards of such a study are potentially great, and tissue culture techniques have clearly an increasing part to play in the study of the interaction between the organism and pharmacologically active substances.

SUMMARY

This review investigates the effects of drugs on animal cells grown *in vitro*. The cells include separated individual cells, tissues, and small organs, both primary explant material and serially propagated lines, and also material from various species. The techniques used to examine the effects of the drugs on the cells include simple microscopy, time-lapse cinemicrography, electron microscopy, and many biochemical estimations.

It is shown that only a small fraction of available drugs have as yet been examined for direct cellular effect. Also it is shown that the method can, with value, be included in routine examination of new drugs. The advantages and limitations of this technique are listed and compared with other pharmacological techniques.

Comparative Hydrolytic Rates of *N*-Substituted 6-Amino-thiouracils

By TING-FONG CHIN, WEN-HUNG WU, and JOHN L. LACH

A study has been carried out on the acid and base-catalyzed hydrolysis of *N*-substituted 6-amino-thiouracils. Two series, aliphatic and halogenated aromatic *N*-substituted 6-amino-thiouracils, have been synthesized and investigated. The experimental results, obtained in this hydrolytic study, indicate that a number of factors may be involved and are rationalized in terms of steric and electronic effects.

INTEREST IN *N*-substituted 6-amino-thiouracils relative to their antitumor activity prompted this preliminary investigation of the influence of *N*-substitution on the stability of the C=S function. Although a survey of the literature indicates that a number of such compounds have been prepared (1, 2), their stability aspects are less known (3), although it would be expected that the *N*-substituted compound should be less stable than the parent unsubstituted thiouracils. Therefore, a systematic study concerning the effect of substituents on 6-amino-thiouracil upon the relationship of hydrolysis in acid and in base would be of value in the design and synthesis of sufficiently stable thiouracils for biological evaluation.

EXPERIMENTAL

Synthesis—Two series, aliphatic and halogenated aromatic *N*-substituted 6-amino-thiouracils, have been prepared by a modification of the condensation method of Carstens (4). The *N*-substituted thiourea and ethyl-cyanoacetate were added to absolute ethanol containing sodium ethoxide. The solution was refluxed with constant stirring for 4–5 hr., and then diluted with water and neutralized with acetic acid. On cooling a 60–80% yield was obtained. It was then purified by recrystallization and chromatographic techniques. The final products were identified by I.R. spectra and elemental analysis. Physical constants and analyses for all thiouracils synthesized are listed in Table I.

Kinetic Studies—Spectra of each thiouracil were taken in 0.3 *N* HCl and 0.3 *N* NaOH solution using a Beckman DB spectrophotometer equipped with a Sargent recorder. The $\lambda_{max.}$ and ϵ and hydrolytic rate constants are listed in Table II. The hydrolysis was carried out at 70° ± 0.1 in a 6 *N* HCl or 6 *N* NaOH solution, and the reaction course was followed by measuring the decrease in absorbance at $\lambda_{max.}$ utilizing a Beckman DU spectrophotometer. An accurate weight of the thiouracil was placed in a 100-ml. volumetric flask and brought to the volume with 6 *N* HCl or 6 *N* NaOH solution (previously warmed to 70°) to obtain an approximate concentration of 3×10^{-5} mole/L. The hydrolysis was carried out in a 100-ml. glass-stoppered volumetric flask which was immersed in a "Haake-Thermostate Unitherm" water bath, regulated at 70° ± 0.1. Aliquots were withdrawn periodically and diluted with water to 100 ml. and the absorbance read at $\lambda_{max.}$ In the same manner, hydrolysis at three temperatures, 70° ± 0.1, 60° ± 0.1, 50° ± 0.1, was carried out for the *N*-phenyl 6-amino-thiouracil in acid and base in order that additional data be obtained concerning the degradative pathway of these compounds.

RESULTS AND DISCUSSION

Prior to the hydrolytic study, ultraviolet absorption spectra of each thiouracil was obtained. Since the spectrum of the corresponding uracil exhibits a $\lambda_{max.}$ at approximately 260 mμ and shows little or no absorption at $\lambda_{max.}$ of the thiouracil, as shown in Fig. 1, all measurements were made at $\lambda_{max.}$ of the thiouracil. Uracil absorption causes no interference in thiouracil systems when the concentration of these thiouracils undergoing degradation is 3×10^{-5} mole/L. or less. In cases where this uracil interference is significant, particularly at higher concentration of the thiouracil, the use of two component analysis can be satisfactorily applied.

The degradation product of the *N*-substituted 6-amino-thiouracil in 6 *N* HCl or 6 *N* NaOH at 70° has been identified as the corresponding 6-amino-uracil using the thin-layer chromatographic technique. No ring cleavage was indicated in this case under the experimental condition employed.

Data obtained in this preliminary investigation indicate that the hydrolysis of these thiouracils follows a pseudo first-order rate law as shown in Figs. 2 and 3. A straight line relationship is obtained of a plot of log concentration against time. Kinetic data (Fig. 2) indicate that the aliphatic *N*-substituted 6-amino-thiouracils hydrolyze at a substantially faster rate than the corresponding

parent unsubstituted 6-amino-thiouracils, as was expected. This greater stability of the unsubstituted 6-amino-thiouracils can be attributed to a resonance structure effect since this resonance structure no longer exists after *N*-substitution. It is also interesting to note (Fig. 2) that an increase in the carbon number of the aliphatic substituent increases the stability of these compounds, probably due to steric hindrance. A bulky molecule in the *N*-position would certainly hinder the nucleophilic attack (5) of water on the partially positive carbon of the C=S reaction center resulting in a slight increase in stability. Although this aliphatic effect was not studied beyond C_4, it is reasonable to believe that extension of the chain length or branching of the chain would further increase the stability of these thiouracils.

As shown in Fig. 3, the introduction of a phenyl substituent at this *N*-position also results in a significant decrease in the stability. This increase in hydrolytic rate is due probably to a diminished resonance structure of the thiouracil and an electron delocalization to the phenyl ring. The electron pair on the *N*-nitrogen can be delocalized to the benzene ring system making the reaction center more positive, increasing the rate of water molecule attack in the rate-determining step. In the absence of phenyl *N*-substitution, this electron pair can be delocalized to the reaction center making it less positive, resulting in an increase in the stability of the compound as discussed in the aliphatic series. Introduction of a halogen in the *para*-position of the phenyl group increases the stability of the thiouracils somewhat. This slight increase in stability may be attributed to a decrease of the positive charge of the reaction center by a resonance contribution of the halogenated phenyl, resulting in a push of the electron pair on the nitrogen toward the reaction center.

The kinetic data (Table II) show that rate of hydrolysis of these *N*-substituted thiouracils is considerably greater in acid than in base. This suggests that the reaction centers of the 6-amino-thiouracils in the protonated form are more positive and favor this water molecule attack in the mechanism involved. Calculation of the apparent energy of

activation, E_a, from the slope of the Arrhenius plot (Fig. 4) for *N*-phenyl-6-amino-thiouracil in acid and in base yielded 23.5 Kcal./mole and 29.7 Kcal./mole, respectively. Since this apparent energy of activation includes the heat of ionization of water (approximately 11.5 Kcal./mole), the energy of activation for the acid and base hydrolysis is 13.1 Kcal./mole and 18.2 Kcal./mole, respectively, which is a reasonable value for hydrolytic reactions of this type (6).

As previously pointed out, the protonated thiouracil species undergo a faster rate of hydrolysis suggesting that specific acid catalysis is involved. This aspect was studied by an investigation of the hydrolytic rates of *N*-phenyl-thiouracil at various acid and base concentrations. Data for acid hydrolysis are shown in Fig. 5, A. Scheme I is a possible mechanism for this acid catalyzed hydro-

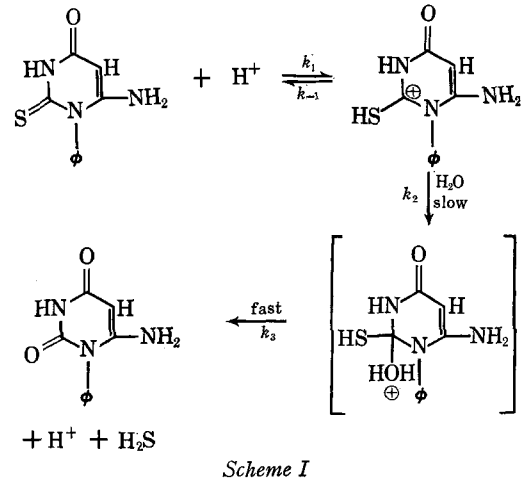

Scheme I

lytic reaction. This mechanism suggests that the thiouracils readily pick up a proton to form an intermediate which undergoes water attack and rapidly collapses to form the corresponding uracils.

Since the kinetic and mathematical aspects of such a system are adequately covered by Laidler (7), the final rate equation is listed here only for discussion purposes.

$$\text{rate} = \frac{k_1 k_2\,(\text{thiouracil})\,(H^+)}{k_1(H^+) + k_2 + k_{-1}} \qquad \text{(Eq. 1)}$$

An examination of this equation indicates that at high acid concentration the rate of hydrolysis reaches a limiting value and the rate equation becomes,

$$\text{rate} = K\,(\text{thiouracil}) \qquad \text{(Eq. 2)}$$

This is verified in Fig. 5, A, and illustrates specific hydrogen ion catalysis. At low (H^+) the rate is dependent on the equilibrium concentration of the protonated and nonprotonated thiouracil species in solution. Although only the acid hydrolysis of *N*-phenyl-thiouracil was studied, it is reasonable to assume that the other *N*-substituted derivatives would undergo a similar behavior.

At low acid concentration k_2 is small, and the rate equation then can be expressed as:

$$\text{rate} = \frac{k_2 k_1\,(\text{thiouracil})\,(H^+)}{k_1(H^+) + k_{-1}} \qquad \text{(Eq. 3)}$$

Rearrangement gives the following relationship:

$$\text{rate} = \frac{k_2\,(\text{thiouracil})}{1 + \dfrac{k_{-1}}{k_1(H^+)}} = \frac{k_2\,(\text{thiouracil})}{1 + \dfrac{K}{(H^+)}}$$

$$1 + \frac{k}{(H^+)} = \frac{k_2\,(\text{thiouracil})}{\text{rate}} \qquad \text{(Eq. 4)}$$

From Eq. 4 a straight line relationship would be obtained by plotting $1/(H^+)$ against $1/(\text{rate})$. This is shown in Fig. 5, B, suggesting specific acid catalysis.

Data for base catalysis of the *N*-phenyl-thiouracil are given in Fig. 6. No limiting of the hydrolytic rate was observed at high hydroxyl-ion concentration (6 *N*) as was seen in acid hydrolysis, suggesting that the rate is proportional to hydroxyl-ion concentration. Although the limited data available do not permit the calculation of exact rate equations, a possible mechanism for this degradation is listed in Scheme II based on the information available.

Schemes I and II are mechanisms for both acid and base hydrolysis involving a rapid polarization of the C=S or thio-group followed by the rate-determining step (8) of a water molecule attack to form a tetrahedral intermediate which rapidly collapses to form the corresponding uracil. Since water attack is postulated to be the rate-determining step, the greater the positive character of the reaction center or C=S function the faster should be the rate of hydrolysis. No bonded electrons on the *N*-nitrogen should be capable of localization toward the reaction center, such as in halogenated phenyl-*N*-substitution, which decreases the positive charge of the carbon in C=S resulting in an increase in stability.

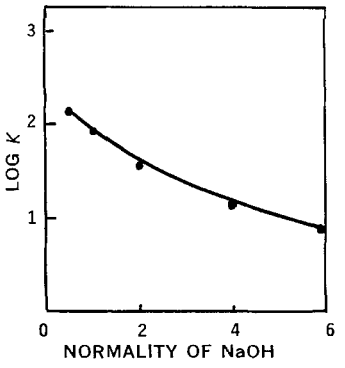

Fig. 6—Base hydrolysis of N-phenyl-6-amino-thiouracil.

Irreversible Enzyme Inhibitors LXXXII

Candidate Active-Site-Directed Irreversible Inhibitors of Dihydrofolic Reductase VII. Derivatives of 2,4-Diaminopyrimidine I

By B. R. BAKER, GRAHAM D. F. JACKSON, and RICH B. MEYER, JR.

Fusion of α-benzoyl-α-phenylazoacetonitrile (V) with guanidine carbonate gave 2,4-diamino-6-phenyl-5-phenylazopyrimidine (VII) in 52 per cent yield; catalytic reduction of VII to 6-phenyl-2,4,5-triaminopyrimidine (VI) proceeded smoothly. Condensation of the triaminopyrimidine (VI) with *p*-nitrocinnamaldehyde to an anil followed by a two-stage reduction afforded 5-(*p*-aminophenylpropylamino)-2,4-diamino-6-phenylpyrimidine (XI); selective bromoacetylation on the *p*-amino group gave the candidate irreversible inhibitor, 5-(*p*-bromoacetamidophenylpropylamino)-2,4-diamino-6-phenylpyrimidine (XII). When XII was incubated with dihydrofolic reductase in the presence or absence of TPNH, no inactivation occurred; the possible conformational differences in binding to dihydrofolic reductase between XII and other successful active-site-directed irreversible inhibitors are discussed.

TWO TYPES of active-site-directed irreversible inhibitors (1, 2) derived from 2-amino-4-pyrimidinol have been found for dihydrofolic reductase; once the hydrophobic bonding region of dihydrofolic reductase had been discovered and explored (3), irreversible inhibitors could be designed. For example, the 5-phenylbutyl group of I and II is complexed in the hydrophobic region; the 6-side-chain is then projected into a hydrophilic region of the enzyme where covalent bond formation occurs that leads to irreversible inhibition of the enzyme (4). Similarly, the 6-phenyl group of III is complexed in the hydrophobic region which allows the alkylating function on the 5-side-chain to attack a nucleophilic group on the enzyme surface (5).

Where 50% of the enzyme was in the form of a reversible complex with the inhibitor, *I*, dihydrofolic reductase was inactivated with a half-life of about 12 min. at 37°. The concentration of the inhibitor, *I*, necessary to form 50% reversible complex (4×10^{-5} *M*) was considered to be too high to be of practical use in an intact animal (4). Therefore, the design of candidate irreversible inhibitors of dihydrofolic reductase that could form 50% reversible complex at a concentration of 10^{-6}–10^{-8} *M* was initiated. Since it is well known that 2,4-diaminopyrimidines are 300 to 3000-fold more effective as inhibitors of dihydrofolic reductase than the corresponding 2-amino-4-pyrimidinols (3, 6–8), this design centered on finding active-site-directed irreversible inhibitors derived from 2,4-diaminopyrimidines; that this design would not necessarily be a simple problem was indicated by the possibility that a 2,4-diaminopyrimidine and the corresponding 2-amino-4-pyrimidinol might not bind to the active site of dihydrofolic reductase in the same rotomeric configuration (7, 9). The first such attempt to find an active-site-directed irreversible inhibitor of dihydrofolic reductase of the 2,4-diaminopyrimidine type—that took into consideration the hydrophobic bonding region—is the subject of this paper; earlier attempts, prior to knowledge of the complications created by the hydrophobic bonding region, have been described (10, 11).

DISCUSSION

6-Phenyl-2,4,5-triaminopyrimidine (VI) was selected as the carrier for the covalent forming group, since VI could be readily synthesized in three steps

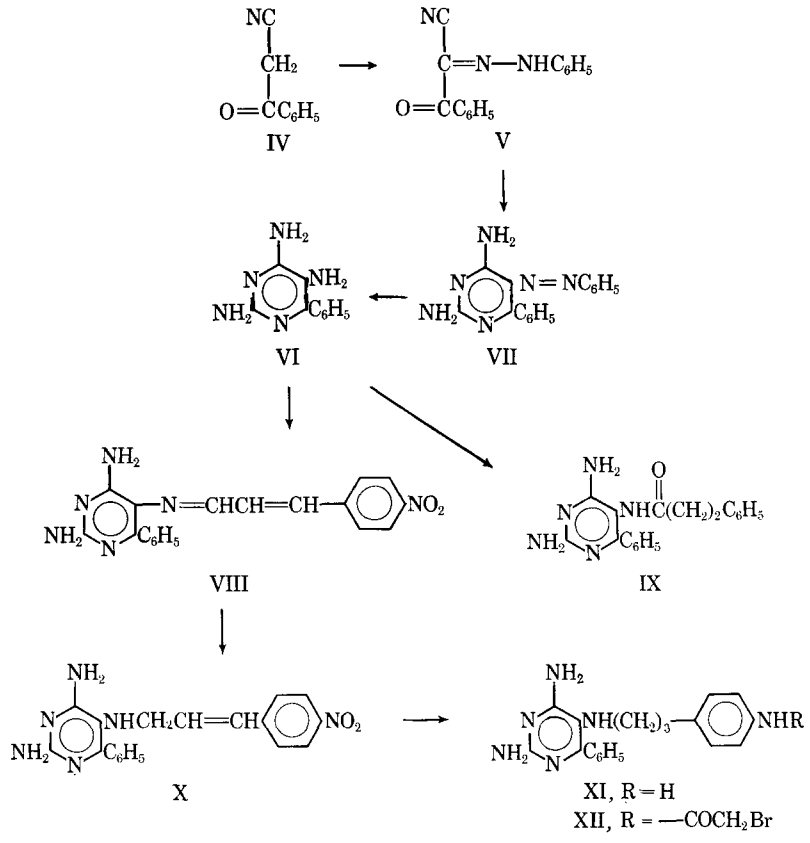

Scheme I

from benzoylacetonitrile (IV) (Scheme I). The latter smoothly coupled with diazotized aniline to the phenylhydrazone (V). When the ketonitrile (V) was fused with an excess of guanidine carbonate at 180°, the phenylazopyrimidine (VII) was obtained in 52% yield. Hydrogenation of VII with a Raney nickel catalyst afforded the desired triaminopyrimidine (VI)

2,4,5-Triamino-6-phenylpyrimidine (VI) was only one-seventh as effective a reversible inhibitor as the corresponding pyrimidine without the 5-amino group, namely, XIII (Table I); since the 5-amino group should not decrease the basicity of the 2,4-diaminopyrimidine (12), the poorer inhibition by VI than XIII may be due to repulsion of the 5-amino group from a hydrophobic area on the enzyme.

Conversion of the triaminopyrimidine (VI) to the 5-phenylpropionyl derivative (IX) with phenylpropionyl chloride resulted in a slight increase in inhibition (Table I); however, the effectiveness of IX was far less than the previously reported (9, 13) 5-anilinopropylpyrimidine (XIV). Thus, a 5-acylamido group on the pyrimidine is not well tolerated, as previously noted in the 2-amino-6-methyl-4-pyrimidinol series (14). Therefore, the triaminopyrimidine (VI) was converted to the 5-(*p*-aminophenylpropyl) derivative (XI), since 2-amino-6-methyl-5-phenylpropylamino-4-pyrimidinol was previously observed to be as good a reversible inhibitor as 2-amino-6-methyl-5-anilinopropyl-4-pyrimidinol (15).

Condensation of the triaminopyrimidine (VI) with *p*-nitrocinnamaldehyde gave the anil (VIII) in 93% yield. Reduction of the anil with sodium borohydride in methanol afforded a 76% yield of X; further reduction of X catalytically afforded the desired 5-(*p*-aminophenylpropyl)pyrimidine (XI). Attempts to reduce VIII directly to XI by catalytic methods were unsuccessful. As anticipated, XI was as good a reversible inhibitor of dihydrofolic reductase as the corresponding 5-anilinopropyl pyrimidine (XIV).

Treatment of XI with bromoacetic anhydride in acetone, containing acetic acid to protonate the diaminopyrimidine system (16), gave the desired candidate active-site-directed irreversible inhibitor (XII); XII could be isolated as a crystalline picrate or as an amorphous hydrobromide.

The candidate irreversible inhibitor (XII) was an excellent reversible inhibitor of dihydrofolic reductase. When XII was incubated with dihydrofolic reductase in the presence of 12 μM TPNH, no inactivation of the enzyme occurred with a concentration of XII sufficient to complex 90% of the available enzyme; similar results were obtained in the absence of TPNH. In contrast, it was previously reported (5) that the corresponding 4-pyrimidinol (III) gave 50% inactivation of the enzyme in 50 min. when a concentration of III was employed that complexed 25% of the available enzyme, but in the absence of TPNH.

These contrasting results between III and XII

The technical assistance of Maureen Baker, Susan Lakatos, and Karen Smith is acknowledged. [a] Dihydrofolic reductase was a 45–90% saturated ammonium sulfate fraction from pigeon liver that was prepared and assayed with 6 μM dihydrofolate and 12 μM TPNH at pH 7.4 as previously described (18). [b] Dihydrofolic reductase was incubated with the inhibitor at 37° in 0.05 *M* Tris buffer (pH 7.4) containing no mercaptoethanol and no TPNH as previously described (19) unless otherwise indicated; in each case an enzyme control showed 0–4% inactivation. [c] Estimated from $K_i = I \times K_m/S$, where I = inhibitor concentration giving 50% inhibition (20); this equation is usually valid when $S > 4K_m$ and in this case $S = 6K_m$. [d] Calculated from $[EI] = E_t/(1 + K_i/I)$, where E_t = the total concentration of active enzyme and $[EI]$ = fraction of E_t reversibly complexed by I (1,21). [e] Data from *Reference 9*. [f] The same results were obtained in the presence of 12 μM TPNH in the incubation mixture. [g] Data from *Reference 5*.

clearly show that the terminal bromoacetamido group of the two compounds is positioned differently within the enzyme–inhibitor reversible complex. This different positioning of the bromoacetamido group can be rationalized in at least two different ways: (*a*) the pyrimidines may be complexed in the same way, but the allowable ground-state conformations of the 5-side-chains of III and XII are different, or (*b*) the 2,4-diaminopyrimidine (XII) may be complexed as a rotomer (7) different from the 2-amino-4-pyrimidinol (III), as previously suggested (9). Explanation (*a*) has been eliminated by synthesis of the analog of III where the 4-hydroxyl group has been replaced by 4-amino and both have identical side-chains; this diamino analog of III also failed to show irreversible inhibition of dihydrofolic reductase (17).

EXPERIMENTAL

Melting points were determined in capillary tubes on a Mel-Temp block and those below 230° are corrected. Infrared spectra were determined in KBr pellet with a Perkin-Elmer 137B spectrophotometer. Ultraviolet spectra were determined in 10% ethanol with a Perkin-Elmer 202 spectrophotometer. Thin-layer chromatograms (TLC) were run on silica gel GF and spots were detected by visual examination under ultraviolet light.

α-Benzoyl-α-phenylazoacetonitrile (V)—A solution of 5.6 Gm. (60 mmoles) of aniline in 20 ml. of concentrated hydrochloric acid and 67 ml. of water and was treated at 0° with 4.2 Gm. of sodium nitrite in 8 ml. of water in the usual manner. The solution was carefully neutralized at −5° with a solution of 7.2 Gm. of anhydrous sodium carbonate in 72 ml. of water. To a solution of 6.05 Gm. (41.8 mmoles) of benzoylacetonitrile in 500 ml. of ethanol was added 40 ml. of 50% aqueous sodium acetate and 25 Gm. of solid sodium acetate; to this stirred suspension at 10° was added 150 ml. of above diazonium solution over a period of about 2 min. The product precipitated within a few minutes. The thick suspension was stirred at ambient temperature for 30 min., then cooled to 0° in an ice bath. After addition of 40 ml. of ether, the mixture was stirred an additional 30 min. at 0°, then filtered. The product was washed with 60% aqueous ethanol; yield, 8.28 Gm. (80%) of yellow needles, m.p. 137–138°. Recrystallization from petroleum ether gave yellow crystals, m.p. 137–138°; $\nu_{max.}$ 2200 (C≡N); 1640 (C=O), 1590, 1540 (C=C, C=N); 750, 718, 685, 670 cm.$^{-1}$ (C_6H_5).

Anal.—Calcd. for $C_{15}H_{11}N_3O$: C, 72.3; H, 4.44; N, 16.9. Found: C, 72.5; H, 4.46; N, 16.9.

2,4-Diamino-6-phenyl-5-phenylazopyrimidine (VII)—A well-ground mixture of 2.49 Gm. (10 mmoles) of V and 1.80 Gm. (10 mmoles) of guanidine carbonate was heated in an oil bath; at 130° gas evolution began and the bath was brought to 170–180° over a period of 30 min. with occasional manual stirring. After 30 min. at 170–180°, gas evolution subsided and the mixture solidified. The cooled residue was digested with 30 ml. of boiling petroleum ether (b.p. 60–110°) and the solvent decanted. The residue was extracted with five 50-ml. portions of boiling ethanol. The combined extracts were heated to boiling, then filtered. The filtrate was heated to boiling and water was added to turbidity. After several hours at 0°, the mixture was filtered and the product was washed with 50% aqueous ethanol; yield, 1.51 Gm. (52%) of orange crystals, m.p. 236–237°. Recrystallization of a sample from aqueous ethanol afforded orange needles, m.p. 238–239°; $\nu_{max.}$ 3250 (NH); 1610, 1590, 1520 (NH, N=N, C=C, C=N); 760, 695, 680 cm.$^{-1}$ (C_6H_5);

$\lambda_{max.}$ (pH 1): 238, 285, 357; (pH 7): 230, 280, 379; (pH 13): 280, 378 mμ.

Anal.—Calcd. for $C_{16}H_{14}N_6 \cdot 1/2\ H_2O$: C, 64.2; H, 5.02; N, 28.1. Found: C, 64.6; H, 5.10; N, 28.1.

2,4-Diamino-6-phenylpyrimidine—Fusion of 725 mg. (5 mmoles) of IV with 900 mg. (5 mmoles) of guanidine carbonate was performed as described for the preparation of VII. The cooled melt was extracted with five 20-ml. portions of boiling petroleum ether (b.p. 60–110°). The combined decantates deposited 132 mg. (13%) of white crystals, m.p. 162–163°. This compound was identical with a sample prepared from 6-phenylisocytosine (22, 23).

6-Phenyl-2,4,5-triaminopyrimidine (VI)—A solution of 600 mg. (2 mmoles) of VII in 100 ml. of 2-methoxyethanol was shaken with hydrogen at 2–3 Atm. in the presence of 0.5 Gm. of No. 28 Raney nickel (W. R. Grace Co.) for 3 hr. When 4 mmoles of hydrogen was absorbed, the solution had changed from orange to pale yellow. The mixture was filtered through a pad of diatomaceous earth.[1] The filtrate was spin-evaporated *in vacuo*. Trituration of the residual oil with benzene gave nearly white crystals, m.p. 196–198°; yield, 320 mg. (80%). A portion was recrystallized from ethanol–benzene to give white crystals, m.p. 197–198°; $\nu_{max.}$ 3400, 3300 (NH); 1650–1550 (multiple peaks of NH, C=C, C=N); 760, 695 cm.$^{-1}$ (C_6H_5); $\lambda_{max.}$ (pH 1): 315; (pH 13): 322 mμ.

Anal.—Calcd. for $C_{10}H_{11}N_5$: C, 59.7; H, 5.51; N, 34.8. Found: C, 60.0; H, 5.38; N, 34.5.

2,4-Diamino-6-phenyl-5-phenylpropionamidopyrimidine (IX) Sulfate—To a stirred solution of 201 mg. (1 mmole) of VI in 10 ml. of reagent pyridine cooled in an ice bath was added 168 mg. (1 mmole) of hydrocinnamoyl chloride. After 30 min. at 0°, the solution was spin-evaporated *in vacuo* and the residue triturated with ethyl acetate. Recrystallization of the solid from 5 ml. of water gave 182 mg. (55%) of VII free base, m.p. 232–233°. A hot solution of 80 mg. of the free base in 4 ml. of water was quickly cooled to about 25°, then 0.2 ml. of 96% sulfuric acid was added with stirring. The sulfate salt was collected; yield, 80 mg. (84% conversion) of white crystals, m.p. 208–213°. Recrystallization from water gave the analytical sample, m.p. 204–206°.

Anal.—Calcd. for $C_{19}H_{19}N_5O \cdot 1/2H_2SO_4 \cdot H_2O$: C, 57.0; H, 5.49; N, 17.5. Found: C, 56.9; H, 5.18; N, 17.5.

2,4-Diamino-5-(p-nitrocinnamalamino)-6-phenylpyrimidine (VIII)—To a solution of 100 mg. (0.50 mmole) of VI in 5 ml. of hot ethanol was added a hot solution of 89 mg. (0.50 mmole) of *p*-nitrocinnamaldehyde in 5 ml. of hot ethanol. After the addition of 2 drops of glacial acetic acid, the mixture was heated 10 min. on a steam bath, then cooled to 0°. The product was collected on a filter and washed with cold ethanol; yield, 168 mg. (93%), m.p. 205–207°. Recrystallization of a portion from 2-methoxyethanol–ethanol gave red crystals, m.p. 206–207°; $\nu_{max.}$ 3500, 3400–3350 (NH); 1610, 1590, 1540 (NH, C=C, C=N); 1500, 1330 (NO_2); 830 (*p*-C_6H_4); 745, 695 cm.$^{-1}$ (C_6H_5).

Anal.—Calcd. for $C_{19}H_{16}N_6O_2$: C, 63.3; H, 4.48; N, 23.3. Found: C, 63.4; H, 4.60; N, 23.4.

[1] Marketed as Celite by the Johns-Manville Corp., New York, N. Y.

2,4-Diamino-5-(p-nitrocinnamylamino)-6-phenylpyrimidine (X)—A hot solution of 540 mg. (1.5 mmoles) of VIII in 250 ml. of methanol was cooled to 25°, then 0.1 ml. of glacial acetic acid was added. Over a period of 30 min., the stirred solution was treated with 650 mg. of sodium borohydride. After a further 30 min., TLC showed only one component was present. The solution was concentrated to about 25 ml. *in vacuo*, then cooled. The product was collected on a filter and washed with cold methanol, then water; yield, 412 mg. (76%), m.p. 214–215°. Recrystallization from ethanol–ethyl acetate gave orange crystals, m.p. 214–215°; $\nu_{max.}$ 3500, 3400 (NH); 1610, 1590, 1555 (NH, C=C, C=N); 1500, 1330 (NO_2); 770, 742, 695 cm.$^{-1}$ (C_6H_5).

Anal.—Calcd. for $C_{19}H_{18}N_6O_2$: C, 63.0; H, 5.01; N, 23.2. Found: C, 63.0; H, 5.20; N, 23.0.

5-(p-Aminophenylpropylamino)-2,4-diamino-6-phenylpyrimidine (XI)—A hot solution of 362 mg. (1 mmole) of X in 150 ml. of boiling ethanol was stirred with 250 mg. of decolorizing carbon for about 20 min. The filtered solution was shaken with hydrogen at 2–3 Atm. in the presence of 20 mg. of platinum oxide until 4 mmoles of hydrogen had been absorbed. The filtered solution was spin-evaporated *in vacuo*. The residue was crystallized by solution in 2 ml. of ethyl acetate, addition of 15 ml. of benzene, then finally petroleum ether to turbidity; yield, 296 mg., m.p. 72–80°, which showed two spots on TLC. Several recrystallizations from benzene gave 102 mg. (31%) of white crystals, m.p. 91–94°, that were uniform on TLC and had $\nu_{max.}$ 3500, 3300, 3200, 3100 (NH); 1620, 1550 (NH, C=C, C=N); 768, 700 (C_6H_5); no NO_2 near 1500 or 1330 cm.$^{-1}$.

Anal.—Calcd. for $C_{19}H_{22}N_6$: C, 68.2; H, 6.63; N, 25.1. Found: C, 68.4; H, 6.80; N, 24.9.

5-(p-Bromoacetamidophenylpropylamino)-2,4-diamino-6-phenylpyrimidine (XII) Picrate—To a solution of 100 mg. (0.30 mmole) of XI in 2 ml. of acetone and 0.55 ml. of 3.6% aqueous acetic acid (0.66 mmole) at 0° was added 90 mg. (0.34 mmole) of bromoacetic anhydride in 0.5 ml. of acetone. After being stirred for 30 min. in an ice bath, the solution was treated with 0.5 ml. of saturated ethanolic picric acid; a picrate immediately separated. The mixture was warmed to complete solution, then allowed to cool slowly. The picrate was collected and washed with acetone; TLC showed the presence of one major component with two minor impurities. Four recrystallizations from aqueous 2-methoxyethanol and drying at room temperature in high vacuum gave 50 mg. (25%) of yellow crystals, m.p. 150–151° dec. TLC in 1:4 ethanol–chloroform showed one moving spot (viewed at 350 mμ) with the picric acid staying at the origin; the moving spot gave a positive 4-nitrobenzylpyridine test (16) for active halogen. The compound had $\nu_{max.}$ 3330 (NH); 1640 (C=O); 1530, 1420, 1330–1310 (NO_2); 1270, 1075 cm.$^{-1}$ (C—O—C).

Anal.—Calcd. for $C_{27}H_{28}BrN_9O_9 \cdot H_2O$: C, 47.2; H, 4.11; N, 18.4. Found: C, 47.3; H, 4.05; N, 18.1.

An amorphous hydrobromide was also prepared by adding 30% hydrogen bromide in acetic acid, then ether, to the reaction solution. The hydrobromide moved as a single spot on TLC, the spot giving a positive 4-nitrobenzylpyridine test; this hydrobromide was used for enzyme assays.

Irreversible Enzyme Inhibitors LXXXIV

Candidate Active-Site-Directed Irreversible Inhibitors of Dihydrofolic Reductase IX. Derivatives of 2,4-Diaminopyrimidine III

By B. R. BAKER and RICH B. MEYER, JR.

The candidate active-site-directed irreversible inhibitor, 5-(*p*-bromoacetamidophenoxypropyl)-2,4-diamino-6-phenylpyrimidine (VI) has been synthesized *via* the key intermediate, 2-amino-5-(*p*-nitrophenoxypropyl)-6-phenyl-4-pyrimidinol (XI*c*). Although VI was a better reversible inhibitor than the corresponding 4-pyrimidinol, 2-amino-5-(*p*-bromoacetamidophenoxypropyl)-6-phenyl-4-pyrimidinol (IV), VI failed to inactivate dihydrofolic reductase when incubated in the presence or absence of TPNH. The fact that IV in the absence of TPNH could inactivate the enzyme, but VI at the same concentration showed no inactivation of the enzyme, clearly demonstrated that IV and VI had different conformations when complexed to dihydrofolic reductase. Evidence for the possible binding conformations of IV and VI is presented.

THE SUCCESS of the 5-phenylbutyl-4-pyrimidinol (II) (1) and the 6-phenyl-4-pyrimidinol (IV) (2) as active-site-directed irreversible inhibitors (3, 4) of dihydrofolic reductase was predicated on a knowledge of (*a*) the strength and location of the hydrophobic bonding region on the enzyme (5–10), and (*b*) the probability that one of several possible rotomers of the pyrimidine ring could be complexed in the active-site (7) which was determined by the position of the hydrophobic group on the pyrimidine carrier (10). The substrate, dihydrofolate (I), must have some given conformation of the pteridine ring when complexed to the enzyme, which is arbitrarily depicted as indicated in I; other rotomeric conformations of the pyrimidines to be discussed below are in relation to the conformation depicted in I. Thus, the active-site-directed irreversible inhibitor of dihydrofolic reductase derived from a 4-pyrimidinol with a hydrophobic 5-phenylbutyl group (II) probably has its hydrophobic group projected vertically as indicated; the 4-pyrimidinol (II) is believed to complex in configuration II*A* which projected the 6-group into a hydrophilic region where covalent bond formation to the enzyme rapidly occurred within the enzyme-inhibitor complex with a half-life of about 12 min. (1). Similarly, the 6-phenyl-4-pyrimidinol (IV) is believed to be complexed in the configuration indicated in IV which projects the 5-group into the same area of the enzyme as the 6-group of II*A* is projected (2).

Irreversible Enzyme Inhibitors LXXXIV

Candidate Active-Site-Directed Irreversible Inhibitors of Dihydrofolic Reductase IX. Derivatives of 2,4-Diaminopyrimidine III

By B. R. BAKER and RICH B. MEYER, JR.

The candidate active-site-directed irreversible inhibitor, 5-(*p*-bromoacetamidophenoxypropyl)-2,4-diamino-6-phenylpyrimidine (VI) has been synthesized *via* the key intermediate, 2-amino-5-(*p*-nitrophenoxypropyl)-6-phenyl-4-pyrimidinol (XI*c*). Although VI was a better reversible inhibitor than the corresponding 4-pyrimidinol, 2-amino-5-(*p*-bromoacetamidophenoxypropyl)-6-phenyl-4-pyrimidinol (IV), VI failed to inactivate dihydrofolic reductase when incubated in the presence or absence of TPNH. The fact that IV in the absence of TPNH could inactivate the enzyme, but VI at the same concentration showed no inactivation of the enzyme, clearly demonstrated that IV and VI had different conformations when complexed to dihydrofolic reductase. Evidence for the possible binding conformations of IV and VI is presented.

THE SUCCESS of the 5-phenylbutyl-4-pyrimidinol (II) (1) and the 6-phenyl-4-pyrimidinol (IV) (2) as active-site-directed irreversible inhibitors (3, 4) of dihydrofolic reductase was predicated on a knowledge of (*a*) the strength and location of the hydrophobic bonding region on the enzyme (5–10), and (*b*) the probability that one of several possible rotomers of the pyrimidine ring could be complexed in the active-site (7) which was determined by the position of the hydrophobic group on the pyrimidine carrier (10). The substrate, dihydrofolate (I), must have some given conformation of the pteridine ring when complexed to the enzyme, which is arbitrarily depicted as indicated in I; other rotomeric conformations of the pyrimidines to be discussed below are in relation to the conformation depicted in I. Thus, the active-site-directed irreversible inhibitor of dihydrofolic reductase derived from a 4-pyrimidinol with a hydrophobic 5-phenylbutyl group (II) probably has its hydrophobic group projected vertically as indicated; the 4-pyrimidinol (II) is believed to complex in configuration II*A* which projected the 6-group into a hydrophilic region where covalent bond formation to the enzyme rapidly occurred within the enzyme-inhibitor complex with a half-life of about 12 min. (1). Similarly, the 6-phenyl-4-pyrimidinol (IV) is believed to be complexed in the configuration indicated in IV which projects the 5-group into the same area of the enzyme as the 6-group of II*A* is projected (2).

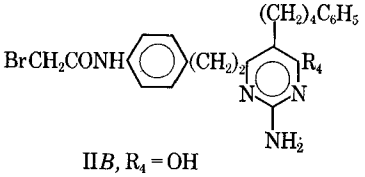
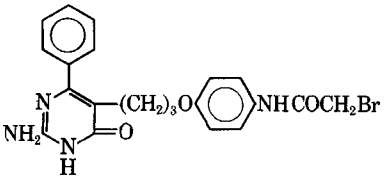
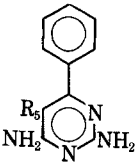
IIA, $R_4 = OH$
IIIA, $R_4 = NH_2$



IIB, $R_4 = OH$
IIIB, $R_4 = NH_2$



IV



V, $R_5 = BrCH_2CONH$  $(CH_2)_3NH-$

VI, $R_5 = BrCH_2CONH$  $O(CH_2)_3-$

Although success with these two active-site-directed irreversible inhibitors of dihydrofolic reductase was greatly encouraging in the chemotherapeutic approach, these two compounds suffered from the drawback that too high a concentration was needed for reversible complexing of the enzyme, since the rate of the inactivation is dependent upon the fraction of the enzyme being in a reversible complex, which in turn is dependent upon the dissociation constant, K_i (11, 12).

Since 2,4-diaminopyrimidines are complexed as much as 3000 times more strongly to dihydrofolic reductase than 4-pyrimidinols (5, 13, 14), the synthesis and evaluation of candidate active-site-directed irreversible inhibitors from this system was undertaken. That such an undertaking might be more difficult than merely converting a successful 4-pyrimidinol-type irreversible inhibitor such as II or IV to III or VI, respectively, was indicated by earlier studies (10) on the mode of reversible binding by pyrimidines; 4-pyrimidinols were believed to have conformations II*A* or IV, whereas their 2,4-diamino counterparts would probably have conformation III*B* and VI, which would project the alkylating function in the opposite direction. Unfortunately, these earlier fears were borne out with the candidate 2,4-diaminopyrimidine irreversible inhibitors, III*B* (15) and V (16), which failed to inactivate dihydrofolic reductase, although the two compounds were much better reversible inhibitors of dihydrofolic reductase than II or IV. Since V had a slightly different side-chain than IV which may have made V ineffective as an irreversible inhibitor due to differences in allowable ground-state conformations of the 5-side-chain, the synthesis and evaluation of the exact 2,4-diamino analog (VI) of the 4-pyrimidinol (IV) was undertaken; the results are the subject of this paper.

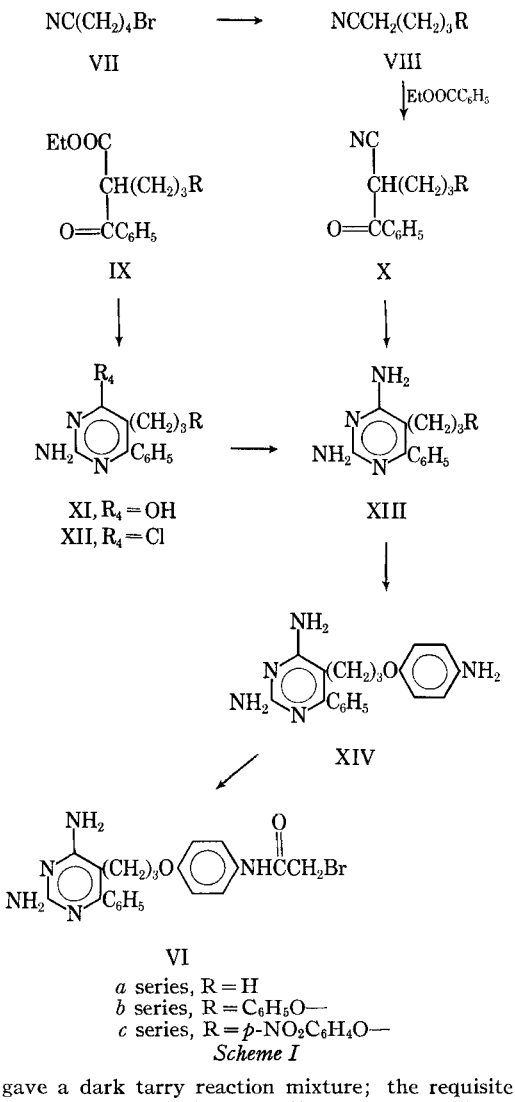
CHEMISTRY

Methods

Several routes to the key 2,4-diamino-5-(*p*-nitrophenoxypropyl)-6-phenylpyrimidine (XIII*c*) were investigated (Scheme I); the successful route will be discussed first. The previously described 5-(*p*-nitrophenoxypropyl)-4-pyrimidinol (XI*c*) (2) is readily synthesized by alkylation of ethyl benzoylacetate with bromopropyl *p*-nitrophenyl ether to IX*c*, followed by reaction with guanidine. Considerable difficulty was initially encountered in conversion of XI*c* to the 4-chloropyrimidine (XII*c*), then further amination to XIII*c*; the intermediate chloropyrimidine (XII*c*) could not be crystallized, and the diaminopyrimidine (XIII*c*) was less soluble in 10% aqueous acetic acid than previously encountered with 2,4-diamino-6-phenylpyrimidines (10, 17). By suitable modifications of the general procedures, as described under *Experimental*, XIII*c* was obtained pure as its hemisulfate salt in 15% yield for the two steps.

Hydrogenation of the nitro group of XIII*c* to give XIV in the presence of platinum oxide catalyst proceeded satisfactorily in aqueous ethanol only if excess hydrochloric acid was present; without the added acid, gummy products were obtained. Reaction of XIV with excess bromoacetic anhydride in acetone—in the presence of acetic acid to protonate the 2,4-diaminopyrimidine ring system (18)—afforded the candidate active-site-directed irreversible inhibitor (VI) isolated as its hemisulfate salt.

The 2,4-diamino-5-(phenoxypropyl)-6-phenylpyrimidine (XIII*b*), which was needed for reversible binding studies with dihydrofolic reductase, was synthesized by two routes previously used for related compounds (10, 15, 16). Reaction of 5-bromovaleronitrile (VII) with phenol and potassium carbonate in boiling acetone afforded the phenyl ether (VIII*b*) as an oil. Claisen condensation of VIII*b* with ethyl benzoate and sodium hydride in xylene afforded the keto nitrile (X*b*) as an oil that was estimated to be about 60% pure by thin-layer chromatography. Fusion of the crude keto ester (X*b*) with guanidine carbonate at 180° (10, 16)



Scheme I

gave a dark tarry reaction mixture; the requisite 2,4-diaminopyrimidine (XIII*b*) was readily isolated by extraction with 10% aqueous acetic acid, albeit in low over-all yield.

The second route to XIII*b* started with ethyl benzoylacetate which was alkylated with 3-bromopropyl phenyl ether to IX*b*; further reaction with guanidine carbonate in *tert*-butyl alcohol (19) afforded the 4-pyrimidinol (XI*b*) in 17% over-all yield for the two steps. Reaction of XI*b* with boiling phosphorus oxychloride gave the chloropyrimidine (XII*b*) as a gum which could not be crystallized; further reaction of the crude XII*b* with methanolic ammonia at 155° afforded the 2,4-diaminopyrimidine (XIII*b*).

Numerous attempts to prepare X*c* by condensation of 5-(*p*-nitrophenoxy)-valeronitrile (VIII*c*) with ethyl benzoate and sodium hydride in dimethylsulfoxide, benzene, or xylene gave dark tars; apparently the nitrophenyl group is incompatible with these Claisen conditions, as previously observed with *p*-nitrophenylacetonitrile (20). Although conversion of XIII*b* to XIII*c* by nitration might be a feasible reaction, it was not studied since the synthesis of XIII*c* *via* XI*c* was successful.

Synthesis

Melting points were taken in capillary tubes on a Mel-Temp block and those below 230° are corrected. Infrared spectra were determined in KBr pellet, unless otherwise indicated, with a Perkin-Elmer 137B or 337 spectrophotometer. Ultraviolet spectra were determined in 10% alcohol, unless otherwise indicated, with a Perkin-Elmer 202 spectrophotometer. Thin-layer chromatograms were run on Brinkmann silica gel GF and spots were detected by visual examination under ultraviolet light.

2-Amino-5-phenoxypropyl-6-phenyl-4-pyrimidinol (XI*b*)—To a stirred solution of 15.5 Gm. (81 mmoles) of ethyl benzoylacetate and 17.5 Gm. (81 mmoles) of 3-bromopropyl phenyl ether in 75 ml. of reagent dimethylsulfoxide was added 4.0 Gm. (81 mmoles) of sodium hydride (as a 50% dispersion in mineral oil) over a period of 45 min. (21). After being stirred for 24 hr., the mixture was acidified with glacial acetic acid, then poured into a stirred mixture of 150 ml. of benzene and 200 ml. of water. The separated aqueous layer was extracted with two 50-ml. portions of benzene. The combined benzene solutions were washed with two 100-ml. portions of water, dried with magnesium sulfate, then evaporated *in vacuo;* yield, 28 Gm. of crude IX*b* which showed two spots on TLC in 5:1 petroleum ether (b.p. 60–110°)–ethyl acetate, neither of which were starting materials.

To a solution of this crude IX*b* in 100 ml. of *tert*-butyl alcohol was added 6.5 Gm. (36 mmoles) of guanidine carbonate. After being refluxed with magnetic stirring for 72 hr., during which time the product separated, the mixture was cooled and filtered (21). The product was washed with ethanol; yield, 4.0 Gm. (17%), m.p. 264–267°, suitable for further transformation. A sample was recrystallized three times from aqueous 2-methoxyethanol: white crystals, m.p. 270–274°, that showed one spot on TLC in 4:1 ethanol–chloroform. The compound had $\lambda_{max.}$ (pH 1, 7): 279 mμ; (pH 13): 286 mμ; $\nu_{max.}$ 3350, 3100 (NH); 1640, 1580, 1480 (C=O, C=N, C=C); 755, 697, 688 cm.$^{-1}$ (C_6H_5).

Anal.—Calcd. for $C_{19}H_{19}N_3O_2$: C, 71.0; H, 5.96; N, 13.1. Found: C, 70.9; H, 5.88; N, 12.9.

2,4-Diamino-5-phenoxypropyl-6-phenylpyrimidine (XIII*b*) Hemisulfate—*Preparation A*—A mixture of 2.4 Gm. (15 mmoles) of 5-bromovaleronitrile (VII), 1.40 Gm. (15 mmoles) of phenol, 2.0 Gm. (15 mmoles) of anhydrous potassium carbonate, and 5 ml. of reagent acetone was refluxed with magnetic stirring for 8 hr. The mixture was spin-evaporated *in vacuo*, then the residue was extracted with 20 ml. of benzene. The benzene solution was washed with two 20-ml. portions of 0.1 *N* aqueous sodium hydroxide, then three 20-ml. portions of water. Dried with magnesium sulfate, the solution was evaporated to residue *in vacuo;* yield, 2.40 Gm. (89%) of crude VIII*b;* $\nu^{film}_{max.}$ 2260 (C≡N); 1600, 1490 (C=C); 1240 (C—O—C); 755, 690 cm.$^{-1}$ (C_6H_5).

To a magnetically stirred solution of 4.8 Gm. (27 mmoles) of similarly prepared crude VIII*b* in 50 ml. of xylene was added 1.20 Gm. (26 mmoles) of sodium hydride (as a 50% dispersion in mineral oil) followed by 3.75 Gm. (25 mmoles) of ethyl benzoate. The mixture, protected from moisture, was care-

fully brought to the b.p., then refluxed for 24 hr. The mixture, acidified with glacial acetic acid, was poured into a mixture of 100 ml. of benzene and 150 ml. of water. The separated organic layer was washed with three 100-ml. portions of water, then spin-evaporated *in vacuo;* yield, 9.0 Gm. of crude X*b* which showed one major spot and several minor spots on TLC in 1:10 ethyl acetate–petroleum ether (b.p. 60–110°).

A mixture of the above crude X*b* and 4.5 Gm. (25 mmoles) of guanidine carbonate was placed in a bath preheated to 180°; after 30 min. at 180°, gas evolution was essentially complete. The cooled melt was stirred with 100 ml. of 10% aqueous acetic acid for about 30 min., then the mixture was filtered through a diatomaceous earth[1] pad. To the filtrate was added 10 ml. of 20% aqueous sulfuric acid. After several hours, the mixture was filtered and the product was recrystallized from aqueous 2-methoxyethanol; yield, 0.68 Gm. (5.9% over-all based on VII), m.p. 235–240°; $\lambda_{max.}$ (pH 1): 287 mμ; (pH 13): 297 mμ; $\nu_{max.}$ 3350, 3200 (NH); 1630, 1490 (NH, C=C, C=N); 1240 (C—O—C); 755, 685 cm.$^{-1}$ (C_6H_5).

Anal.—Calcd. for $C_{19}H_{20}N_4O \cdot {}^1/_2H_2SO_4 \cdot H_2O$: C, 59.2; H, 5.97; N, 14.6. Found: C, 59.2; H, 6.11; N, 14.6.

Preparation B—A magnetically stirred mixture of 1.00 Gm. (3 mmoles) of XI*b* and 10 ml. of phosphorus oxychloride under a reflux condenser and protected from moisture was placed in a bath preheated to 110° and maintained at 110° for 1 hr. The cooled solution was poured into 60 ml. of petroleum ether (b.p. 60–110°), then allowed to stand until the supernatant liquid had cleared (1 hr.). The supernatant was then decanted from the gum. The gum was dissolved in chloroform and the solution washed with two 50-ml. portions of ice-cold 10% aqueous sodium acetate, then two 50-ml. portions of water; the layers readily emulsified, and separation was slow. Dried with magnesium sulfate, the chloroform solution was spin-evaporated *in vacuo* leaving about 1 Gm. of crude XII*b* which had $\lambda_{max.}$ (pH 1): 323 mμ; (pH 13): 308 mμ.

The crude XII*b* was heated with 40 ml. of methanol previously saturated with ammonia in a Parr bomb at 155° for 10 hr. The cooled mixture was spin-evaporated *in vacuo*. The residue was extracted with 50 ml. of 10% aqueous acetic acid on a steam bath. The decanted solution was clarified with carbon, then diluted with 20 ml. of 20% aqueous sulfuric acid. The cooled mixture was filtered and the product washed with water; yield, 0.223 Gm. (18%), m.p. 200–210°, that was identical with *Preparation A* as shown by U.V., I.R., and TLC in 5:1 chloroform–ethanol.

2,4-Diamino-5-(p-nitrophenoxypropyl)-6-phenylpyrimidine (XIIIc) Hemisulfate—The crude chloropyrimidine (XII*c*), prepared from 1.92 Gm. (5.11 mmoles) of XI*c* (10), as described for the preparation of XII*b*, was dissolved in 40 ml. of methanol previously saturated with ammonia at −10°. The solution was heated in a Parr bomb at 150–155° for 20 hr., then spin-evaporated *in vacuo*. The residue was extracted with 300 ml. of 10% aqueous acetic acid on a steam bath. The solution was clarified with decolorizing carbon by filtration through a diatomaceous earth pad. To the filtrate was added 20 ml. of 20% sulfuric acid. The cooled mixture was filtered and the product was washed with water; yield 1.15 Gm. (52%) of crystalline product, m.p. 239–256°, which showed two spots on TLC in 4:1 chloroform–ethanol. Six recrystallizations from aqueous 2-methoxyethanol gave pure product in 30% recovery, m.p. 261–263°; $\lambda_{max.}$ (pH 1): 293 mμ; (pH 13): 305 mμ; $\nu_{max.}$ 3300, 3100 (NH); 1660, 1620, 1500 (NH, C=C, C=N); 1250 (C—O—C); 1105 ($SO_4^=$); 890 (*p*-C_6H_4); 750, 695 cm.$^{-1}$ (C_6H_5).

Anal.—Calcd. for $C_{19}H_{19}N_5O_3 \cdot {}^1/_2H_2SO_4 \cdot H_2O$: C, 52.8; H, 5.15; N, 16.2. Found: C, 52.7; H, 5.47; N, 16.0.

5-(p-Aminophenoxypropyl)-2,4-diamino-6-phenylpyrimidine (XIV)—A solution of 300 mg. (0.70 mmole) of XIII*c* in 100 ml. of 85% aqueous ethanol and 0.20 ml. of 12 *N* hydrochloric acid was shaken with hydrogen at 2–3 Atm. in the presence of 50 mg. of platinum oxide for 30 min. when hydrogen uptake was complete. The solution was filtered through a diatomaceous earth pad, then evaporated *in vacuo*. The residual amine salt was dissolved in 20 ml. of boiling 50% aqueous ethanol; the solution was made alkaline with 2 ml. of 1 *N* aqueous sodium hydroxide, then water was added to turbidity. On cooling, the solution deposited 190 mg. (78%) of crystals that analyzed for a monohydrate, m.p. 158–159° dec.; $\nu_{max.}$ 3400 (H_2O); 3300, 3180–3050 (NH); 1620, 1550 (NH, C=C, C=N); 1245 (C—O—C); 820 (*p*-C_6H_4); 710 cm.$^{-1}$ (C_6H_5); $\lambda_{max.}$ (pH 1): 283 mμ; (pH 13): 297 mμ. After being dried at 80° for 1 day in high vacuum, the compound was still partially hydrated.

Anal.—Calcd. for $C_{19}H_{21}N_5O \cdot {}^1/_2H_2O$: C, 66.3; H, 6.44; N, 20.3. Found: C, 66.3; H, 6.65; N, 20.0.

3-(p-Bromoacetamidophenoxypropyl)-2,4-diamino-6-phenylpyrimidine (VI) Hemisulfate—To a magnetically stirred mixture of 17 mg. (0.050 mmole) of XIV, 2 ml. of acetone, and 0.165 ml. (0.055 mmole) of 3.3 m*M* aqueous acetic acid cooled in an ice bath was added a solution of 16 mg. (0.06 mmole) of bromoacetic anhydride in 0.5 ml. of acetone. After 30 min., the solution was treated with 0.5 ml. of 0.2 *N* aqueous sulfuric acid. The solution was concentrated to about 1 ml. *in vacuo*. The mixture was warmed on a steam bath, then just sufficient alcohol was added to give a clear solution. Water was added to turbidity, then the solution was allowed to cool; yield 15 mg. (58%), that was uniform on TLC in 5:1 chloroform–ethanol. Recrystallization from aqueous 2-methoxyethanol gave the analytical sample, m.p. 171–172° dec.; $\lambda_{max.}$ (pH 1, 7): 280 mμ; (pH 13): 291 mμ.

Anal.—Calcd. for $C_{21}H_{22}BrN_5O_2 \cdot {}^1/_2H_2SO_4 \cdot H_2O$: C, 48.1; H, 4.81; N, 13.4. Found: C, 48.2; H, 4.85; N, 13.3.

The compound gave a positive test for a reactive halogen with *p*-nitrobenzylpyridine (18) and negative Bratton-Marshall test for aromatic amine (18).

RESULTS AND DISCUSSION

Table I presents the results of the candidate 2,4-diamino active-site-directed irreversible inhibitor (VI) on inactivation of dihydrofolic reductase; the previous results with the corresponding 2-amino-4-pyrimidinol (IV) (2) are also presented. Note that

VI	NH_2	1.7		20	0	>13[e]	120	0

The technical assistance of Barbara Baine, Maureen Baker, and Susan Lakatos with the assays of Tables I and II is acknowledged. [a] The dihydrofolic reductase was a 45–90% saturated ammonium sulfate fraction from pigeon liver that was prepared and assayed with 6 μM dihydrofolate and 12 μM TPNH in 0.05 M Tris buffer (pH 7.4) containing 10 mM mercaptoethanol, as previously described (22). The K_i was estimated from $K_i = I \times K_m/S$, where I = inhibitor concentration giving 50% inhibition, $K_m = 1 \times 10^{-6}$ M, and $S = 6 \times 10^{-6}$ M; this equation is usually valid when $S > 4\ K_m$ (6, 23). [b] Dihydrofolic reductase was incubated with inhibitor at 37° in 0.05 M Tris buffer (pH 7.4) containing *no* mercaptoethanol as previously described (24); in each case an enzyme control was run and the per cent inactivation by inhibitor is corrected for the small amount of thermal inactivation in the enzyme control. [c] Calculated from $[EI] = E_t/[1 + K_i/I]$, where E_t = the concentration of total active enzyme, $[EI]$ = the fraction of E_t reversibly complexed by I, and I = the inhibitor concentration (3, 12). [d] Data from *Reference 2*. [e] The $[EI]$ concentration is unknown in the absence of TPNH, due to the ternary binding requirement for 2,4-diaminopyrimidines; see *Results and Discussion*.

VI gives no inactivation of the enzyme in the absence of TPNH or in the presence of 12 μM TPNH; in contrast, IV shows inactivation of the enzyme even at a concentration of 20 μM where IV reversibly complexes with only 13% of the total available dihydrofolic reductase.

Before discussion of these results, the recent experiments by Bertino *et al.* (25, 26) on measurement of binding to dihydrofolic reductase by tryptophan fluorescence spectra should be considered. They observed (25) that the 2,4-diamino-type inhibitor—2,4,7-triamino-6-phenylpteridine—could complex to dihydrofolic reductase in the absence of TPNH (binary binding), but binding was sixtyfold tighter in the presence of TPNH (ternary binding). In Table II are presented some of their results (26) on our 6-phenylpyrimidines.

Note that the 2,4-diamino-6-phenylpyrimidines with a 5-phenylbutyl (XXII) or 5-anilinopropyl (XXIII) show tighter binding in the presence of TPNH (ternary binding) than in the absence of TPNH (binary binding); the extent of this increased binding could not be measured due to the limit of detection of the ternary K_D, but the increase in binding was >fortyfold with XXII and >100-fold with XXIII. In contrast, a much less dramatic effect by TPNH was seen with the 2-amino-6-phenyl-4-pyrimidinols; with the 5-anilinopropyl (XXVII) and the 5-phenylbutyl side-chain (XXVI), only a 2.5-fold and twelvefold increase in ternary binding over binary binding being observed. Also note that the 2,4-diaminopyrimidines gave stronger binary binding than the corresponding 2-amino-4-pyrimidinols; with the 5-phenylbutyl side-chain, XXII was complexed sixtyfold better than XXVI and with the 5-anilinopropyl side-chain, XXIII was complexed thirtyfold better than XXVII.

Now let us return to experiment *C* in Table I. At a concentration of 20 μM, the diaminopyrimidine (VI) should complex more of the enzyme than the 2-amino-4-hydroxypyrimidine (IV) when TPNH is absent—although this exact number cannot be determined kinetically since TPNH is required for a kinetic experiment (25). The fact that 20 μM IV still shows inactivation of the enzyme, but 20 μM VI shows none, demonstrates unequivocally that IV and VI form complexes with dihydrofolic reductase that are conformationally different, since the terminal alkylating function is juxtaposed to a nucleophilic group on the enzyme in the case of IV, but not in the case of VI.

How can these conformations within the enzyme–inhibitor reversible complex be different? In Table II are listed reversible binding constants for five classes of compounds—determined kinetically in the presence of TPNH. There are at least three distinct modes of binding with respect to the side-chains.

In class *A* are listed the 5-(*p*-chlorophenyl)-2,4-diaminopyrimidines with varying substituents at the 6-position. It was previously noted that the *p*-chlorophenyl group gave a 5500-fold increment in binding due to hydrophobic bonding (6); this tremendous increase in binding was believed to be determinant (3, 10) on which rotomer (7) of the pyrimidine would complex to the enzyme. Note that there is less than a threefold difference in binding with small and large chains at the 6-position in class *A;* these results are best interpreted as indicating that the 6-side-chain is not in contact with the enzyme, but is projected into space.

Similar observations were made with the class *B* compounds containing a 5-phenylbutyl side-chain (except XX); the 5-phenylbutyl side-chain gives a 40,000-fold increment in binding (6), and presumably determines which rotomer (7) will complex to the enzyme (3,10); note again that small or large 6-side-chains have no more than a two fold effect on binding.

In class *E* are listed some 2-amino-4-pyrimidinols; note that with the 5-phenylbutyl side-chain a loss in binding occurs in proceeding from a 6-methyl (XXVIII) to a 6-*n*-propyl side-chain (XXIX); this result has been attributed to a repulsion of the propyl group from a hydrophilic area on the enzyme (10). Thus, the propyl group of XXIX would have to be in contact with the enzyme in order for this repulsion to occur, in contrast to the noncontact of the 6-group in series *A* and *B*.

A third type of binding is observed with the 2,4-diamino-6-phenylpyrimidines of class *C*. First, it should be noted that the 6-phenyl group of XXI gives only a sevenfold increment in binding (10) compared to the 6-methyl group of 2,4-diamino-6-methylpyrimidine (6)—much smaller than the 5500-fold increment observed with XV; thus the 6-phenyl group may not necessarily be determinant on which rotomer will bind even though most of the earlier data with 6-phenylpyrimidines could be rationalized on this basis (10). That the terminal phenyl group of a 5-side-chain in class *C* may not be complexed to the enzyme in the same place as a terminal phenyl group of class *B* is indicated by the following comparison; note that in class *B*, the phenylbutyl group of XVIII gives 85-fold tighter binding than the anilinopropyl group of XX, attributed to the terminal phenyl group being complexed in a hydrophobic region; in contrast, note in class *C* that the 5-phenylbutyl (XXII), 5-phenoxypropyl (XIII*b*), and 5-anilinopropyl (XXIII) side chains differ by no more than a factor of four in binding, indicating that the terminal phenyl group is in a more polar region. Similar results were previously observed in class *D* with XXVI and XXVII which should be compared with XXVIII, XXX, and XXXI in class *E*.

These reversible binding studies could indicate that the two candidate irreversible inhibitors, IV and VI (Table I), bind in a similar conformation; however, experiment *C* (Table I) indicates clearly that their conformations are different. A possible working hypothesis useful for further studies is the following.

The active-site-directed irreversible inhibitors of the 2-amino-4-pyrimidinol type such as II and XXXII are believed to have conformation *B* (Table III). This assignment is based on the decrease in binding when the 6-methyl group of class *E* compounds (XXVIII) (Table II) is extended to *n*-propyl (10), but the terminal phenyl group of XXXII gives a fourfold increase in binding (1); such a repulsion of an alkyl group by the enzyme is likely to take place if this alkyl group is complexed in the polar region that normally complexes the substrate, dihydrofolate, with assigned conformation I (10). Compound IV is believed to have conformation *A* (2, 10).

Since IV can inactivate dihydrofolic reductase, but the diaminopyrimidine (VI) does not, it follows that IV and VI must have different conformations when complexed to dihydrofolic reductase. That VI does not have a conformation *C* like that assigned to XVI is indicated by extra binding exerted by the phenoxyalkyl group of VI, whereas XVI shows no appreciable addition or loss of binding as the phenylalkyl group is varied (see class *A*, Table II).

A logical conformation for V and VI is *D* with the phenylalkyl group staggered to the right; it was pointed out above that the terminal phenyl group of class *B* compounds was complexed in a different area on the enzyme than class *C* compounds (Table II) since the side-chain binding of class *B* compounds such as XVIII and XX was considerably influenced when an NH group adjacent to the

XXV, R = —H

phenyl of XX was replaced by methylene as in XVIII.

Therefore, the conformations outlined in Table III will be used as a working hypothesis. The synthesis of compounds V and XXV (16) is quite adaptable to variation of side chain in order to determine the ideal bridge distance for irreversible inhibition (3, 4); such studies are currently being pursued. Such active-site-directed irreversible inhibitors, if successful, would give another parameter to the assignment of binding conformations, as noted in the comparison of IV and VI.

Application of Regression Analysis to Hypoglycemic Activities of 12 Piperidinesulfamylsemicarbazides and Activity Predictions for 12 Analogs

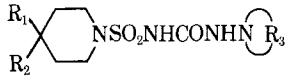
By W. RONALD SMITHFIELD and WILLIAM P. PURCELL

A regression analysis is applied to the hypoglycemic activity data for a series of 12 piperidinesulfamylsemicarbazides. The results are used to estimate the hypoglycemic activity for 12 untested analogs. The following seven untested compounds are predicted to have greater hypoglycemic activity than chlorpropamide: 1,1-pentamethylene-4-(4-ethyl-4-methyl-1-piperidinesulfamyl)semicarbazide; 1,1-pentamethylene-4-(4-methoxy-4-methyl-1-piperidinesulfamyl)semicarbazide; 1,1-pentamethylene-4-(4,4-diethyl-1-piperidinesulfamyl)semicarbazide; 1,1-pentamethylene-4-(4-ethyl-4-methoxy-1-piperidinesulfamyl)semicarbazide; 1,1-pentamethylene-4-(4,4-dimethoxy-1-piperidinesulfamyl)semicarbazide; 1,1-hexamethylene-4-(4-methoxy-4-methyl-1-piperidinesulfamyl)semicarbazide; 1,1-hexamethylene-4-(4-ethyl-4-methoxy-1-piperidinesulfamyl)semicarbazide.

THE POSSIBILITY of designing molecules for specific therapeutic uses by the application of regression analyses to structure-activity data (1–3) holds considerable interest for the authors. Recently, Free and Wilson's method (3) has been applied to an analogous series of cholinesterase inhibitors (4) synthesized in these laboratories.

Several prerequisites are necessary for the satisfactory application of regression analysis to structure-activity data: (*a*) the series to be studied should be composed of closely related analogs (thereby increasing the probability of having a similar mechanism of action), (*b*) accurate biological data measured under uniform conditions must be available, and (*c*) the activity parameter chosen must be intrinsically additive. Naturally, it is also desirable to have a maximum number of degrees of freedom and, therefore, to have a high ratio of the number of observations to the number of unknown terms in the linear equations.

McManus and Gerber (5) have recently reported activity data which appear suitable for the application of the regression analysis technique. They evaluated a series of 12 substituted piperidinesulfamylsemicarbazides (I) as possible hypoglycemic agents, and the activity data (Table I), including standard deviations, are presented as the maximum per cent fall in blood glucose at a dose level of 100 mg./Kg. in groups of 8–10 rats of the Sprague-Dawley strain. The authors analyzed these results using a method similar to that reported by Free and Wilson (3) with the purpose of (*a*) calculating and ranking group contributions to activity for the series of piperidinesulfamylsemicarbazides and (*b*) estimating the hypoglycemic activity of analogous molecules which have not been screened.



I

REGRESSION ANALYSIS

If one assumes that the substituents on the molecules evaluated by McManus and Gerber (5) make a constant and additive contribution to the over-all activity, a simultaneous equation may be written for each of the 12 observations (Eqs. 1–12).

$$a[\mathrm{H}] + b[\mathrm{H}] + c[\mathrm{C_5}] + \mu = 14.8 \quad \text{(Eq. 1)}$$

$$a[\mathrm{H}] + b[\mathrm{H}] + c[\mathrm{C_6}] + \mu = 11.1 \quad \text{(Eq. 2)}$$

$$a[\mathrm{H}] + b[\mathrm{Me}] + c[\mathrm{C_5}] + \mu = 26.1 \quad \text{(Eq. 3)}$$

$$a[\mathrm{H}] + b[\mathrm{Me}] + c[\mathrm{C_6}] + \mu = 33.9 \quad \text{(Eq. 4)}$$

$$a[\mathrm{Me}] + b[\mathrm{Me}] + c[\mathrm{C_5}] + \mu = 39.1 \quad \text{(Eq. 5)}$$

$$a[\mathrm{Me}] + b[\mathrm{Me}] + c[\mathrm{C_6}] + \mu = 34.9 \quad \text{(Eq. 6)}$$

$$a[\mathrm{Me}] + b[\mathrm{Et}] + c[\mathrm{C_6}] + \mu = 42.0 \quad \text{(Eq. 7)}$$

$$a[\mathrm{Et}] + b[\mathrm{Et}] + c[\mathrm{C_6}] + \mu = 34.4 \quad \text{(Eq. 8)}$$

$$a[\mathrm{C_2}] + b[\mathrm{C_2}] + c[\mathrm{C_5}] + \mu = 35.6 \quad \text{(Eq. 9)}$$

$$a[\mathrm{C_2}] + b[\mathrm{C_2}] + c[\mathrm{C_6}] + \mu = 30.8 \quad \text{(Eq. 10)}$$

$$a[\mathrm{C_{2.5}}] + b[\mathrm{C_{2.5}}] + c[C_6] + \mu = 25.0 \quad \text{(Eq. 11)}$$

$$a[\mathrm{H}] + b[\mathrm{OCH_3}] + c[\mathrm{C_6}] + \mu = 24.8 \quad \text{(Eq. 12)}$$

In Eqs. 1–12 the brackets indicate activity contributions, while the letters *a*, *b*, and *c* refer to positions R_1, R_2, and R_3, respectively. Therefore, $a[\mathrm{H}]$ is the activity contribution of a hydrogen atom at position R_1; $a[\mathrm{C_2}]$ is the activity contribution of half of a tetramethylene group at position

[a] The 4,4-tetramethylene group is denoted by two units of $(CH_2)_2$, and the 4,4-pentamethylene group is denoted by two units of $(CH_2)_{2.5}$. [b] Activities are reported (5) as maximum per cent blood glucose lowering at dose of 100 mg./Kg. McManus and Gerber (5) found chlorpropamide to have an activity of 35 ± 3.3%. [c] Observed values are reported with standard deviations.

R_1 and is necessarily paired with $b[C_2]$; $a[C_{2.5}]$ is the activity contribution of half of a pentamethylene group at position R_1 and is paired with $b[C_{2.5}]$; $c[C_5]$ is the activity contribution of a pentamethylene group at position R_3; $c[C_6]$ is the activity contribution of a hexamethylene group at position R_3, *etc.*; μ represents the activity contribution of the parent structure. In each equation the sum of the appropriate group contributions and μ are set equal to the maximum per cent fall in blood glucose at a dose level of 100 mg./Kg. as reported by McManus and Gerber (5).

If one assumes that positions R_1 and R_2 are equivalent in the substituted piperidinesulfamylsemicarbazides, the following six simplifying equations may be written:

$$a[H] = b[H] \quad \text{(Eq. 13)}$$

$$a[Me] = b[Me] \quad \text{(Eq. 14)}$$

$$a[Et] = b[Et] \quad \text{(Eq. 15)}$$

$$a[C_2] = b[C_2] \quad \text{(Eq. 16)}$$

$$a[C_{2.5}] = b[C_{2.5}] \quad \text{(Eq. 17)}$$

$$a[OCH_3] = b[OCH_3] \quad \text{(Eq. 18)}$$

Substitution of these relationships into Eqs. 1–12 results in 12 equations with nine unknowns. In addition, two restrictions (Eqs. 20, 21) result from the summation to zero (3) of the group contributions at positions R_1 and R_2 and position R_3:

$$5a[H] + 2b[H] + 3a[Me] + 4b[Me] + a[Et] + 2b[Et] + 2a[C_2] + 2b[C_2] + a[C_{2.5}] + b[C_{2.5}] + b[OCH_3] = 0 \quad \text{(Eq. 19)}$$

or, from Eqs. 13–18,

$$7a[H] + 7a[Me] + 3a[Et] + 4a[C_2] + 2a[C_{2.5}] + a[OCH_3] = 0 \quad \text{(Eq. 20)}$$

and

$$4c[C_5] + 8c[C_6] = 0 \quad \text{(Eq. 21)}$$

The 14 simultaneous equations with nine unknowns were solved by the method of least squares by employing the program Scrap and the IBM 1620 computer.

RESULTS AND DISCUSSION

Simultaneous solution of the 12 linear equations gives the calculated activity contribution for each group (Table II) and the value for the constant, μ (35.25%).

The appropriate group contributions and μ may be used in Eq. 22 to calculate hypoglycemic activities (Table I) and

$$\text{hypoglycemic activity} = \mu + \Sigma \text{ group contributions} \quad \text{(Eq. 22)}$$

the agreement between calculated and observed values may be used as a test for the analysis.

From Table II one can rank[1] the groups at positions R_1 and R_2 in order of decreasing contribution to hypoglycemic activity as follows: $CH_3 > C_2H_5 > OCH_3 > (CH_2)_2 > (CH_2)_{2.5} > H$. The hydrogen substituent has a deleterious effect on activity (−8.99%), while the methyl group contributes most to activity (3.56%). It is interesting to note that the addition of one methylene group produces a substantial reduction in contribution between the tetramethylene group, $(CH_2)_4$ (2 ×

[1] Free and Wilson have emphasized that "The rank order of related substituents within a position would be expected to have meaning" (3).

TABLE II—SUBSTITUTENT GROUP CONTRIBUTION TO HYPOGLYCEMIC ACTIVITY

Position(s)	Group[a]	Contribution[b]
R_1 and R_2	H	−8.99
R_1 and R_2	CH_3	3.56
R_1 and R_2	C_2H_5	2.20
R_1 and R_2	OCH_3	1.17
R_1 and R_2	$(CH_2)_2$	0.38
R_1 and R_2	$(CH_2)_{2.5}$	−3.54
R_3	$(CH_2)_5$	−2.47
R_3	$(CH_2)_6$	−3.17

[a] See *Footnote a*, Table I. [b] See *Footnote b*, Table I.

0.38% = 0.76%), and the pentamethylene group, $(CH_2)_5$ (2 × −3.54% = −7.08%). At the R_3 position, both the pentamethylene and hexamethylene groups have a negative contribution (−2.47% and −3.17%, respectively).

It is apparent from Table I that reasonable agreement exists between the calculated and observed hypoglycemic activities. The *F*-ratio between the variance of the estimated activity and the variance of the observed activity is significant at the 99% level. The coefficient of the multiple correlation is 0.977. In four of the 12 compounds (No. *2*, *4*, *10*, and *12*), however, the differences between the calculated and observed values are greater than the standard deviations reported by McManus and Gerber (5).

The primary interest in this type of study is the selection of untested molecules which have a high probability of possessing useful therapeutic activity. The seven untested molecules which are predicted to be more active than chlorpropamide [activity as determined by McManus and Gerber (5), 35 ± 3.3%], are 1,1-pentamethylene-4-(4-ethyl-4-methyl-1-piperidinesulfamyl)semicarbazide; 1,1 - pentamethylene - 4 - (4 - methoxy - 4 - methyl-1 - piperidinesulfamyl)semicarbazide; 1,1 - hexamethylene - 4 - (4 - methoxy - 4 - methyl - 1 - piperidinesulfamyl)semicarbazide; 1,1-pentamethylene-4-(4,4-diethyl - 1 - piperidinesulfamyl)semicarbazide; 1,1-pentamethylene-4-(4-ethyl- 4 - methoxy-1-piperidinesulfamyl)semicarbazide; 1,1-hexamethylene-4-(4-ethyl-4-methoxy-1-piperidinesulfamyl)semicarbazide; 1,1-pentamethylene-4-(4,4-dimethoxy-1-piperidinesulfamyl)semicarbazide (No. *11*, *13*, *14*, *15*, *17*, *18*, and *19*, respectively). These compounds appear to be worthy of synthesis and testing as possible hypoglycemic agents.

Kinetics of Reaction of Dehydroacetic Acid I

Reaction with Primary Amines I

By SHIGERU GOTO, SADAO IGUCHI, AKIRA KONO, and HIDEKO UTSUNOMIYA

Dehydroacetic acid (DHA), one of the officially recognized food preservatives in Japan, has been found in some instances to readily react with amino compounds under mild and physiological conditions to produce Schiff's base type compounds. The kinetic study of the reaction between DHA and β-phenethylamine (PE-NH), with the formation of 3-(1-phenethylamino)ethylidene-6-methyl-3H-pyran-2,4-dione, was investigated in various water–ethanol mixtures, and a linear relationship was observed between the reciprocal of the dielectric constant of the solvent and log *k*. The *k*–pH profiles for the reaction in 80 per cent ethanol solution at 40 and 60° were completed in the acetate buffer regions. No general acid-base catalysis was observed but salt effects were not negligible. The rate-determining step in 80 per cent ethanol solution was probably the attack of free PE-NH on the protonated carbonyl carbon atom in free DHA.

DEHYDROACETIC ACID (DHA) (I) has been accepted as one of the officially recognized food preservatives in Japan and is at present being used widely not only in some foodstuffs and refreshing drinks but also in pharmaceutical preparations as an antiseptic. It has been pointed out that one of the most remarkable chemical behaviors of DHA is its affinity toward compounds possessing an amino radical. When they coexist in solution, Schiff's base type compounds (II) are initially readily produced by the reaction between DHA and amino compounds, and then finally transformed, in some cases, to lutidone derivatives (V). This has been reported in the preceding papers (1, 2) and the mechanism described in Scheme I was proposed.

In some instances the conversion proceeds under mild and physiological conditions.

Other similar qualitative and synthetic investigations (3–5) have been published, but no

Kinetics of Reaction of Dehydroacetic Acid I

Reaction with Primary Amines I

By SHIGERU GOTO, SADAO IGUCHI, AKIRA KONO, and HIDEKO UTSUNOMIYA

Dehydroacetic acid (DHA), one of the officially recognized food preservatives in Japan, has been found in some instances to readily react with amino compounds under mild and physiological conditions to produce Schiff's base type compounds. The kinetic study of the reaction between DHA and β-phenethylamine (PE-NH), with the formation of 3-(1-phenethylamino)ethylidene-6-methyl-3H-pyran-2,4-dione, was investigated in various water–ethanol mixtures, and a linear relationship was observed between the reciprocal of the dielectric constant of the solvent and log *k*. The *k*–pH profiles for the reaction in 80 per cent ethanol solution at 40 and 60° were completed in the acetate buffer regions. No general acid-base catalysis was observed but salt effects were not negligible. The rate-determining step in 80 per cent ethanol solution was probably the attack of free PE-NH on the protonated carbonyl carbon atom in free DHA.

DEHYDROACETIC ACID (DHA) (I) has been accepted as one of the officially recognized food preservatives in Japan and is at present being used widely not only in some foodstuffs and refreshing drinks but also in pharmaceutical preparations as an antiseptic. It has been pointed out that one of the most remarkable chemical behaviors of DHA is its affinity toward compounds possessing an amino radical. When they coexist in solution, Schiff's base type compounds (II) are initially readily produced by the reaction between DHA and amino compounds, and then finally transformed, in some cases, to lutidone derivatives (V). This has been reported in the preceding papers (1, 2) and the mechanism described in Scheme I was proposed.

In some instances the conversion proceeds under mild and physiological conditions.

Other similar qualitative and synthetic investigations (3–5) have been published, but no

Proposed Route for Reaction of Dehydroacetic Acid with β-Phenethylamine

Scheme I

kinetic data on this transformation have been reported. It seems natural, based on the unique chemical behavior of DHA, especially from a kinetic viewpoint, to extend studies to cover the re-estimation of its practical usages in Japan.

In this experiment the authors selected β-phenethylamine (PE-NH) as a representative primary amine because of its easiness of treatment. Reactions of DHA were kinetically studied in water–ethanol mixtures.

This paper considers the kinetics in the first step of the transformation reaction, the formation of 3-(1-phenethylamino)-ethylidene-6-methyl-3H-pyran-2,4-dione (NR-DHA).

EXPERIMENTAL

Materials—Ethanol of superior special grade for precision analysis was used. PE-NH (Wako pure reagent) was redistilled twice (b.p. 178–179°). DHA (Taito Pfizer Co.) was recrystallized from ethanol–water, m.p. 109–110°. Commercial acetic acid was redistilled, and sodium acetate and sodium chloride of pure reagent grade were used for the kinetic studies.

Determination of DHA—A 1-ml. sample was diluted with 9 ml. of cold distilled water. Three drops of a 10% hydrochloric acid solution and 0.1 ml. of a 17% titanium chloride solution were added to the sample solution. The observed pH of the final sample solution was in the range of 1.5 to 2.0. The absorbance of the sample was measured against a blank solution at 550 mμ using 1-cm. cells in a Hitachi photoelectric spectrophotometer of the EPU 2A type. A plot of absorbance *versus* concentration gave a straight line graph over the range 1×10^{-4} to 2×10^{-3} *M*. The percentage standard deviation for repeated determinations was ±1.0%. The coexistences of NR-DHA (II), lutidones (V), 2,6-bis(phenethylamino)-2,5-heptadien-4-one (IV), and PE-NH did not interfere with DHA determinations.

Kinetic Studies—The rates were measured by following the decrease of DHA. Twenty-five milliliters of a 2×10^{-2} *M* DHA solution in an appropriate acetate buffer was mixed with 25 ml. of a 2×10^{-2} *M* PE-NH solution in a 50-ml. glass volumetric flask, and thermostated at the temperature of the prospective kinetic study. The pH of the reaction mixture was measured over the entire period of a kinetic run, and the average of these pH values was used for further kinetic calculations. The ionic strengths of the reactions were generally constant at 0.1. The effect of change in the ionic strength on the reaction was studied by changing the ionic strength of the solutions with sodium chloride, and the effect of the general acid-base catalysis was evaluated in eightfold ranges of acetate buffer concentration at the constant ionic strength ($\mu = 0.1$). Aliquots (1 ml.) were pipeted out at regular time intervals, and the above for the DHA assay was used. Verification of the fact that the spectrophotometric absorption band at 550 mμ characterized the intact DHA was obtained by thin-layer chromatographic determination of an aliquot of the residual DHA and the reaction product, NR-DHA, in 99.7% ethanol at 40°. Calibration curves of known concentrations (1×10^{-5} to 2×10^{-4} *M*) for the two components in ethanol were prepared by spectrophotometric absorbances at 305 mμ for DHA and 314 mμ for NR-DHA. The thin-layer plates (20 × 20 cm.) were coated with a 0.4-mm. layer of silica gel B-5 (Wako pure reagent), and a 100-μl. sample solution was spotted on the plate. The plates were developed with benzene–acetic acid–water (1:1:2) twice. The solvent front was allowed to advance 13 cm. Detection for DHA and NR-DHA was performed under ultraviolet light at 253.6 mμ. Each spot was cut off and extracted with warm ethanol in a small glass apparatus for about 5 min. The extracts were filtered through filter paper (Toyo Roshi Co.). The residues on the paper were washed twice by warm ethanol. The washings were added to the filtrates, and the total solutions were adequately diluted by ethanol and measured by the spectrophotometric method. The results of the analysis from colorimetric and thin-

layer chromatographic methods coincided well. Since the sum of the mole concentrations of DHA and NR-DHA at each time interval was equal to the initial mole concentration of DHA, the reaction was terminated at the formation of the Schiff's base type compounds.

RESULTS AND DISCUSSION

Reaction in 99.73 Per Cent v/v[1] Ethanol Solution—A mixture of DHA and an equivalent mole of PE-NH ($1 \times 10^{-2}M$) was placed in the constant-temperature bath, and the proceeding reaction was studied by estimating the concentration of DHA by means of the color assay developed with titanium chloride. The reaction rate was expressed as:

$$v = k_1 (\text{DHA})(\text{PE-NH}) \qquad \text{(Eq. 1)}$$

and satisfied the rate equation,

$$dx/dt = k_1 (a - x)^2 \qquad \text{(Eq. 2)}$$

and the integrated form is

$$1/(a - x) = k_1 t + 1/a \qquad \text{(Eq. 3)}$$

where a is the initial concentration for DHA and PE-NH, x represents the consumed concentration at t for DHA and PE-NH, and k_1 is the apparent second-order rate constant. The second-order plots for the reaction are given in Fig. 1.

Effect of Addition of Water—The addition of water retarded the apparent rate constant, k_1, and accelerated the hydrolysis of NR-DHA (k_2).

$$\text{PE-NH} + \text{DHA} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \text{NR-DHA} + \text{H}_2\text{O}$$

The observed apparent equilibrium constant, K, in the presence of an excess amount of water is

$$K = \frac{(\text{NR-DHA})}{(\text{DHA})(\text{PE-NH})} \qquad \text{(Eq. 4)}$$

and the apparent rate constants for the forward and the reverse reactions, k_1 and k_2, are calculated by means of the following equations:

$$k_1 = \frac{1}{t} \frac{2.303\, x_e}{a^2 - x_e^2} \log \frac{x_e (a^2 - x x_e)}{a^2 (x_e - x)} \qquad \text{(Eq. 5)}$$

$$k_2 = \frac{1}{K} k_1 = \frac{(a - x_e)^2}{x_e} k_1 \qquad \text{(Eq. 6)}$$

where x_e is the concentration of consumed DHA and PE-NH at equilibrium. The values of k_1 are calculated from the slope of $2.303\, x_e/(a^2 - x_e^2) \log x_e(a^2 - x x_e)/a^2(x_e - x)$ *versus* t.

It was observed that the rate constant for forward reaction, k_1, decreased with a decrease of concentration of ethanol in solvent. This fact may be due to an increase in ionizing power of solvent by the addition of water to solvent. The plot of log k_1 *versus* the reciprocal of dielectric constants,[2] 1/D, is an approximate straight line (Fig. 2). This phenomenon may be ascribed to the degree of ionization of both DHA and PE-NH at initial stage, namely, the relative concentration of free DHA and free PE-NH.

[1] Measured by titrimetric (Karl Fischer) method.
[2] Dielectric constants of ethanol–water mixtures were obtained from Akerlöf, G., *J. Am. Chem. Soc.*, **54**, 4125(1932).

TABLE I—OBSERVED RATE CONSTANT ($10^3 k_1$ IN M^{-1} sec.$^{-1}$) FOR THE REACTION OF DHA WITH PE-NH IN 80% ETHANOL[a]

Observed pH	Observed Rate Constant
40° C.	
6.37[b]	0.97
6.57[b,c]	1.44
6.98[b,c]	2.25
7.50	2.90
8.13	2.80
60° C.	
6.58[b,c]	5.01
6.84[b]	6.45
7.07	7.17
7.19[c]	7.80
8.10[c]	7.67
8.63	5.00

[a] Initial concentration: DHA, 1×10^{-2} *M*; PE-NH, 1×10^{-2} *M* ($\mu = 0.1$). [b] When the ionic strength was changed, a significant difference in the apparent rate constant was observed (see Fig. 4). [c] When the concentration of acetate buffer solution was at eightfold ranges, no significant differences in the apparent rate constants were observed.

the concentration of acetate buffer solution (μ = 0.1) was changed at eightfold ranges, no significant difference in the apparent rate constants was observed. But a significant ionic strength effect was observed for the reaction at the same pH and buffer (Fig. 4); therefore, the ionic strength was adjusted to 0.1 by the addition of sodium chloride. As the concentration of the protonated PE-NH increases with a decrease in pH, the ability of PE-NH to act as a nucleophilic agent is lost, and thus a decrease in the rate constant is observed. On the other hand, in alkaline media where the concentration of the protonated PE-NH is at a minimum, a reduction in the rate is again observed. This is attributed to a decrease in the concentration of free DHA. Since a maximum of the pH-profile occurred at about a pH of 7.5 (Fig. 3 and Table I), these results suggest that a probable mechanism would be the attack of a nucleophilic reagent such as free undissociated PE-NH onto the protonated carbonyl carbon atom in free undissociated DHA. Assuming that the relative species are free PE-NH and DHA, the forward rate v_f is expressed as:

TABLE II—APPARENT pKa VALUES[a] IN ETHANOL–WATER MIXTURES AT 40°C.

Vol. % of Ethanol[b]	pKa
β-Phenethylamine	
97.5	8.00
88.2	8.37
78.4	8.61
68.6	8.71
49.0	8.80
Dehydroacetic Acid	
98.5	7.55
89.3	7.25
79.2	6.80
69.5	6.40
59.2	6.25

[a] The titrations were conducted on 40-ml. sample solutions with 0.1 *N* HCl and 0.1 *N* NaOH aqueous solutions and pKa values were calculated by Shima's method (see Shoji, R., and Yoshimura, H., "Theory and Measurement of pH," Maruzen, Tokyo, Japan, p. 130.). Estimated pKa values for β-phenethylamine and dehydroacetic acid in 80% ethanol were 8.58 and 6.83, respectively. [b] The per cent ethanol at each pKa was calculated from the known volume in the original solution and the known volume of aqueous titer added to achieve the apparent pH corresponding to that pKa value.

$$v_f = k_f (\text{DHA})_f (\text{PE-NH})_f \quad \text{(Eq. 7)}$$

$$= k_f \frac{K_1}{K_1 + (\text{H}^+)} \frac{(\text{H}^+)}{K_2 + (\text{H}^+)} (a - x)^2 \quad \text{(Eq. 8)}$$

where k_f is the true rate constant for the forward reaction. The K_1 and K_2 are the dissociation constants of the protonated PE-NH and DHA, respectively. The apparent rate constant, k_1, for the forward reaction can be written:

$$k_1 = k_f \frac{K_1}{K_1 + (\text{H}^+)} \frac{(\text{H}^+)}{K_2 + (\text{H}^+)} \quad \text{(Eq. 9)}$$

Moreover, k_f is expressed as:

$$k_f = k_0 + k_{\text{H}^+} (\text{H}^+) \quad \text{(Eq. 10)}$$

where k_0 may be the rate constant for the solvent catalyzed, and k_{H^+} is the bimolecular rate constant for hydrogen ion. A plot of k_f against the hydrogen-ion concentration estimates k_{H^+} from the slope and k_0 from the intercept. The values of k_0 and k_{H^+} were calculated to be 2.2×10^{-1} mole^{-1} sec.$^{-1}$ and 5.5×10^4 mole^{-1} sec.$^{-1}$ at 40°, 6.0×10^{-1} mole^{-1} sec.$^{-1}$ and 8.0×10^5 mole^{-1} sec.$^{-1}$ at 60°, respectively. The values of K_1 and K_2 in 80% ethanol were calculated by titration in various ethanol concentrations at 40°. The results are shown in Table II. The values of K_1 and K_2 in 80% ethanol at 40° applied to Eqs. 8 and 9.

In conclusion, it has been suggested that the rate-determining step for the reaction between DHA and PE-NH in 80% ethanol is the attack of free PE-NH on the protonated carbonyl carbon atom in free DHA.

Behavior of Erythrocytes in Various Solvent Systems IV

Water–Dimethylsulfoxide

By DONALD E. CADWALLADER and JOHN P. DRINKARD*

Hemolytic behavior of human erythrocytes in water–DMSO solutions was investigated. Complete hemolysis of erythrocytes took place in all DMSO solutions, with discoloration and precipitation occurring at DMSO concentrations greater than 35 per cent. The addition of 0.9 per cent NaCl or isotonic concentrations of other compounds ($CaCl_2$, dextrose, lactose, KBr, Na citrate, NaBr, NaI, and Na salicylate) prevented hemolysis in solutions containing 0.0 to 40 per cent DMSO. The addition of these compounds to solutions containing more than 40 per cent DMSO did not prevent hemolysis, discoloration, or precipitation of human red blood cells. When possible, the data were used to calculate van't Hoff *i* values for sodium chloride in various aqueous DMSO solutions. The DMSO concentration which afforded the greatest protection to erythrocytes against osmotic hemolysis was 26–27 per cent. In aqueous ternary solvent systems, DMSO did not affect the concentrations at which propylene glycol and polyethylene glycol 300 damage erythrocytes.

To PREPARE a safe, stable, and efficacious injection, it is sometimes necessary to employ a mixed solvent system consisting of water and a nonaqueous cosolvent. With this in mind, the hemolytic behavior of rabbit and human erythrocytes in aqueous solutions of glycerin, propylene glycol, and liquid polyethylene glycols has been investigated (1–3).

The solvent system selected for this investigation was water–dimethylsulfoxide (DMSO). In recent years, DMSO has been the subject of many research articles concerning its effect on biological systems and its unusual and numerous medicinal properties. In addition, a great deal of interest has been expressed in the excellent solvent properties of DMSO. Of the aprotic solvents, DMSO has one of the highest dielectric constants, 48.9 at 20°. Thus, DMSO is completely miscible in all proportions with water and most common organic solvents, including glycerin, acetone, and ethanol (4). DMSO has been found to be an unusually effective solvent for a variety of compounds, including proteins (5), glycogen (6), cellulose and related substances (7, 8), steroids (9), sugar and sugar esters (10), and alphaglucochloralose (11).

Results of preliminary pharmacological tests indicate that drugs dissolved in DMSO and administered systemically do not differ significantly in their lethality or cellular penetration (12). Willson *et al.* (13) carried out toxicity studies to determine if DMSO would be useful as a vehicle for the intravenous administration of water-insoluble antitumor agents. His and other reports (14, 16) indicate that DMSO has a very low toxicity; however, it appears that blood cells are hemolyzed in the presence of high concentrations of this vehicle.

The purpose of this investigation was to study the behavior of red blood cells in aqueous DMSO solutions. The hemolytic method was employed, and the experiments were designed so that standard hemolysis curves obtained for human blood in experiments using aqueous saline solutions could be compared to hemolysis curves obtained from experiments using sodium chloride–water–DMSO solutions. From these data it was possible to calculate *hemolytic* isotonic coefficients for sodium chloride in various water–DMSO solutions. Experiments were also carried out to observe what effect the addition of isotonic quantities of various compounds had in preventing hemolysis of erythrocytes in water–DMSO systems.

EXPERIMENTAL

Materials—Reagent grade dimethylsulfoxide supplied by the J. T. Baker Chemical Co. was used. All electrolytes and nonelectrolytes employed in this study were reagent grade.

Blood Samples—Human blood was used in all experiments and was obtained from several 20–25 year old male Caucasian donors just prior to each experiment. Approximately 10 ml. of blood was obtained from the forearm vein and placed in a 50-ml. round-bottom flask containing 10–15 glass beads. After gently rotating the flask for approximately 5 min., the defibrinated blood was decanted into a 50-ml. conical flask and aerated by gently swirling the flask for about 5 min.

Received October 10, 1966, from the School of Pharmacy, University of Georgia, Athens, GA 30601

Accepted for publication December 15, 1966.

Previous paper: Smith, L. B., and Cadwallader, D. E., *J. Pharm. Sci.*, **56**, 351(1967).

Presented to the Basic Pharmaceutics Section, A.PH.A. Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

* Student participant in a 1965–1966 Mead Johnson undergraduate research award.

Preparation of Solutions—Dimethylsulfoxide solutions were calculated and prepared as volume–volume percentage solutions. Solutions containing glycerin, polyethylene glycol, and propylene glycol were prepared on a weight-volume basis. Concentrations of electrolytes and solid nonelectrolytes in solution were based on weight-in-volume calculations. Solutions containing isotonic concentrations of various compounds were prepared using data from an earlier paper [*viz.*, Table I (2)].

Quantitative Determination of Per Cent Hemolysis—The method used to determine the amount of hemolysis of erythrocytes in various solutions was described in earlier papers in this series (1, 2). Hemolysis experiments were carried out at 25 ± 1 and 37 ± 1°.

To determine the effect of time on hemolysis, several rate studies were carried out in which the blood-test solution mixtures were removed at 10-min. intervals, during a period of 60 min., centrifuged, and the amount of hemolysis determined colorimetrically. These rate experiments were carried out at 37 ± 1, 25 ± 1, and 20 ± 1° so that the effect of temperature on rate could be ascertained.

Calculation of i Values—An objective of this paper was to calculate *apparent i* values for sodium chloride when the salt was present in a water–DMSO system, *e.g.*, sodium chloride in 20% DMSO. When the concentrations of sodium chloride in water and water–DMSO solutions causing the same degree of hemolysis are known, the value of i (isotonic coefficient) for sodium chloride in aqueous DMSO solutions can be calculated according to a previously described equation (1) modified as follows:

$$\begin{pmatrix} i \text{ value for} \\ \text{NaCl in water} \end{pmatrix} \begin{pmatrix} \text{Gm. of NaCl} \\ \text{in 100 ml. water} \end{pmatrix} = \begin{pmatrix} i \text{ value for} \\ \text{NaCl in DMSO soln.} \end{pmatrix} \begin{pmatrix} \text{Gm. of NaCl in} \\ \text{100 ml. DMSO soln.} \end{pmatrix} \quad \text{(Eq. 1)}$$

The value of i for sodium chloride in water was taken as 1.86.

Curves showing the degree of hemolysis in sodium chloride–water solutions and sodium chloride–water–DMSO solutions were plotted on rectangular coordinate paper. From these curves the concentrations of sodium chloride in Gm./100 ml. of water and the other solvent, causing 25, 50, and 75% hemolysis were determined. These values were inserted into Eq. 1, and the values of i for sodium chloride in a particular water–DMSO solution, at concentrations giving 25, 50, and 75% hemolysis were determined. The various i values for sodium chloride in aqueous DMSO solutions are shown in Table I.

Preparation of Hemolysis Curves—Twenty experiments employing human blood were carried out. The average readings of these experiments were used to construct a standard hemolysis curve (left-hand side of Fig. 1.) Hemolysis curves of the various DMSO solutions shown in Fig. 1 were prepared in the same manner as described in previous papers (1, 3).

To determine DMSO concentrations that offered greatest protection to red blood cells, hemolysis experiments were carried out in various water–DMSO–sodium chloride solutions and the data portrayed on rectangular coordinate paper as described above. From these hemolysis curves the amounts of sodium chloride preventing hemolysis of 50% of the erythrocytes (or where 50% hemolysis occurred) in various DMSO solutions were determined and the results are shown in Fig. 2.

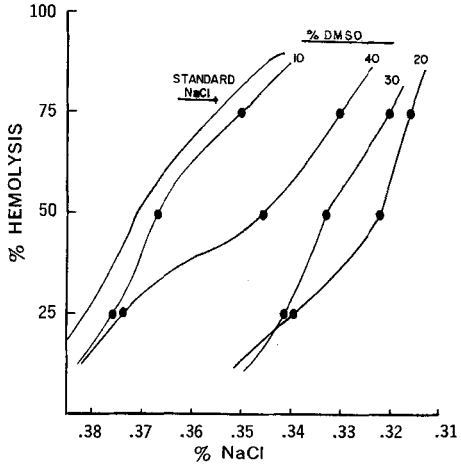

Fig. 1—Hemolysis of human erythrocytes after 45 min. at 37° in various DMSO–saline solutions.

RESULTS AND DISCUSSION

Complete hemolysis of human erythrocytes occurred in 0.0 to 100% DMSO solutions after 45 min. at 25 or 37°. Hemolysis in aqueous solutions containing 0.0 to 30% DMSO gave normal, clear red solutions; however, in solutions containing 35 to 45% DMSO, red-brown solutions were observed. Red-brown solutions containing a brown precipitate resulted when blood was placed in solutions containing 50% or more of DMSO. Precipitation became very heavy when the DMSO concentration reached 75 to 100%. These observations were

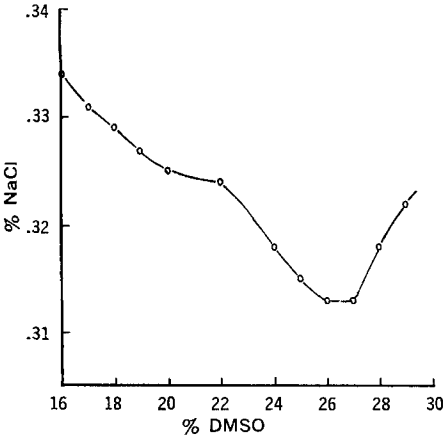

Fig. 2—Amount of sodium chloride preventing hemolysis of 50% of erythrocytes in various DMSO solutions at 37°.

similar to those reported by Ansel and Leake for rabbit blood (17).

Time studies showed that hemolysis and/or damage of red blood cells occurred immediately upon the addition of blood to aqueous DMSO solutions. The rate of hemolysis and cell damage was independent of experimental temperatures (20, 25, and 37°).

The addition of 0.9% sodium chloride prevented hemolysis of human erythrocytes in solutions containing 0.0 to 40% DMSO, however, in experiments where the concentration of DMSO was greater than 25%, trace hemolysis (less than 10%) occurred with several blood samples. Increased hemolysis was observed in solutions containing 40–45% DMSO, and brown-green solutions containing a dark brown precipitate resulted when blood was added to saline solutions containing between 46 and 49% DMSO. Discoloration and precipitation occurred in solutions containing higher concentrations of DMSO. This phenomenon was not prevented by the addition of 2 or 3% sodium chloride.

Aqueous DMSO solutions containing isotonic concentrations of various substances (1.15% calcium chloride, 9.39% dextrose, 8.16% lactose, 1.91% potassium bromide, 1.96% sodium citrate, 1.51% sodium bromide, 2.20% sodium iodide, and 2.45% sodium salicylate) gave results similar to those described above for DMSO–saline solutions. These compounds prevented hemolysis in 0.0 to 40% DMSO solutions but not in the more concentrated solutions.

The fragility of human erythrocytes in various water–DMSO solutions was modified by the addition of hypotonic quantities of sodium chloride. Typical sigmoid hemolysis curves (*viz.*, Fig. 1) resulted when blood was added to saline solutions containing 0.0 to 40% DMSO. These curves were constructed in the manner described under *Experimental* utilizing the data presented in Table I.

Hemolysis in 0.0 to 40% DMSO solutions is an osmotic phenomenon since addition of 0.9% sodium chloride to these solutions prevents hemolysis, and addition of hypotonic quantities of saline allows partial hemolysis to occur.

It was possible to calculate i values for sodium chloride in various water–DMSO solutions. The average i values for sodium chloride in these systems (Table I) were slightly greater than 1.86, the accepted value for 0.9% sodium chloride in water. This indicated that DMSO contributed very little to the tonicity of the extracellular aqueous solutions; however, it did not have a negative effect until, of course, the DMSO concentration became greater than 40%. This slight increase in i values can probably be attributed either to some effect of DMSO on the red cell membrane or to increased activity of sodium chloride in DMSO solutions. Sears *et al.* (18) determined the equivalent conductances in DMSO of a number of sodium and potassium salts including halides, but not sodium chloride, and found them to be completely dissociated in DMSO.

The i values at 37° were consistently slightly greater (approximately 1–3%) than the corresponding values at 25°. In previous studies (1, 2) with glycerin and propylene glycol systems, slightly greater i values were found at 37° than at 25°.

Although the range of hemolytic i values of sodium chloride in DMSO solutions was narrow, there was an optimum DMSO concentration which gave the most protection to erythrocytes against osmotic hemolysis. As can be seen in Fig. 2 the amount of sodium chloride needed to protect 50% of the erythrocytes against hemolysis decreased as the concentration of DMSO increased from 16 to 26–27%; the protective concentrations then increased with further increases in DMSO concentrations.

Kinetic studies were carried out in DMSO solutions (10, 20, and 30%) containing between 0.32 and 0.37% sodium chloride. Hypotonic concentrations of sodium chloride were used so that partial hemolysis of erythrocytes would occur in DMSO test solutions. Hemolysis did not appreciably increase from the first 10-min. reading to the 60-min. reading; final hemolysis readings were about 5% greater than initial readings. Essentially the same results were obtained for all experimental temperatures (20, 25, and 37°). These rate studies showed that complete or partial hemolysis in DMSO solutions occurs rapidly and is independent of time and temperature, indicating simple diffusion. The slight increases in hemolysis which did occur with time were probably due to some effect of DMSO on the red cell membrane.

Throughout this investigation it was observed that high concentrations of DMSO caused damage to red blood cells and that diluting the DMSO solutions with saline lowered the *in vitro* toxicity. This damage was not inhibited or prevented by the addition of sodium chloride or isotonic concentrations of various electrolytes and nonelectrolytes. DiStefano and Klahn (15) have shown that DMSO is a potent hemolytic agent when administered intravenously to cats. However, when DMSO was injected in a diluted form, it was far less hemolytic, and hemolysis was almost negligible when DMSO was diluted 8 times in isotonic saline. Willson *et al.* (13) reported that perivascular inflammation and local thrombosis resulted from repeated intravenous administration of undiluted DMSO into dogs, but that these reactions did not occur when the material was diluted adequately before use. In this current study the authors have found that the addition of 0.9% sodium chloride to solu-

tions containing more than 40% DMSO does not prevent damage to erythrocytes and/or the precipitation of blood components. It appears that aqueous solutions containing more than 40% DMSO would be unsafe as a vehicle for intravenous preparations.

To determine the effect of a ternary solvent system on erythrocytes, hemolysis experiments were run at 37° in solutions containing 20% DMSO, 0.9% sodium chloride, and various amounts of either propylene glycol or polyethylene glycol 300 (PEG 300). Solutions containing 0.0 to 30% propylene glycol did not hemolyze red blood cells, however, complete hemolysis with slight discoloration took place in those solutions containing more than 30% propylene glycol. Hemolysis did not take place in solutions containing 0.0 to 20% PEG 300; however, when blood was placed in solutions containing 25% or more PEG 300, the solutions became green-brown, and a brown precipitate formed. In these ternary solvent systems, the addition of DMSO did not alter the critical concentrations (in 0.9% saline) (2, 3) at which propylene glycol and PEG 300 have been reported to hemolyze red blood cells. The damaging effect of the glycols appeared to be solely dependent on their concentration in solution, and there was no additive effect contributed by the DMSO present.

Fallacy in Concluding There are Zero-Order Kinetics from Blood Level and Urinary Excretion Data

By JOHN G. WAGNER

During the past several years there have been a number of reports in which the authors concluded their data proved zero-order formation of a metabolite or zero-order absorption of a drug in the animal or human body. For two of these reviewed in this paper—namely, the conjugation of benzoate with glycine in the rabbit following doses of 500 mg./Kg. of benzoic acid and the conversion of salicylate to salicyluarate in rats at doses above 20 mg./Kg.—the evidence is very convincing. However, the principal evidence in the remainder of the reports is the apparent linearity of a segment of a cumulative urinary excretion curve and/or the curvature of semilogarithmic plots of drug blood levels or of amounts of drug not excreted against time. Model studies and simulations presented here show that neither of the latter is sufficient evidence for concluding there is zero-order rate of formation of a metabolite or zero-order absorption of a drug. The simulations of pharmacokinetic data have far-reaching implications which go much beyond the zero-order–first-order problem. They show one cannot disregard first-order rate constants of relatively large magnitude in many cases; that graphical fitting of pharmacokinetic, and even chemical kinetic, data may often lead to serious misinterpretations; and that "Lineweaver-Burk" plots, which are artifacts, are produced by plotting the reciprocal of excretion rate of a metabolite against the reciprocal of the amount of metabolite remaining in the body.

To illustrate how one may erroneously conclude that there are parallel zero-order and first order kinetics when, in fact, all kinetics are first order, a model simulating the real situation is presented. Assume there is a catenary chain with branching of parallel paths at one point in the chain and that all rate constants are first-order rate constants. Then we may write the model as shown in Scheme I.

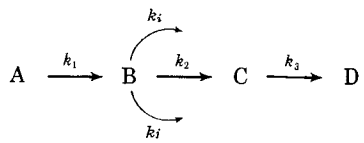
Fallacy in Concluding There are Zero-Order Kinetics from Blood Level and Urinary Excretion Data

By JOHN G. WAGNER

During the past several years there have been a number of reports in which the authors concluded their data proved zero-order formation of a metabolite or zero-order absorption of a drug in the animal or human body. For two of these reviewed in this paper—namely, the conjugation of benzoate with glycine in the rabbit following doses of 500 mg./Kg. of benzoic acid and the conversion of salicylate to salicyluarate in rats at doses above 20 mg./Kg.—the evidence is very convincing. However, the principal evidence in the remainder of the reports is the apparent linearity of a segment of a cumulative urinary excretion curve and/or the curvature of semilogarithmic plots of drug blood levels or of amounts of drug not excreted against time. Model studies and simulations presented here show that neither of the latter is sufficient evidence for concluding there is zero-order rate of formation of a metabolite or zero-order absorption of a drug. The simulations of pharmacokinetic data have far-reaching implications which go much beyond the zero-order–first-order problem. They show one cannot disregard first-order rate constants of relatively large magnitude in many cases; that graphical fitting of pharmacokinetic, and even chemical kinetic, data may often lead to serious misinterpretations; and that "Lineweaver-Burk" plots, which are artifacts, are produced by plotting the reciprocal of excretion rate of a metabolite against the reciprocal of the amount of metabolite remaining in the body.

To illustrate how one may erroneously conclude that there are parallel zero-order and first order kinetics when, in fact, all kinetics are first order, a model simulating the real situation is presented. Assume there is a catenary chain with branching of parallel paths at one point in the chain and that all rate constants are first-order rate constants. Then we may write the model as shown in Scheme I.



Scheme I

Received November 16, 1966, from the Medical Research Division, The Upjohn Co., Kalamazoo, MI 49001
Accepted for publication January 10, 1967.

Let k be the first-order rate constant for over-all loss from the B compartment. Hence, as written, we have $k = k_2 + k_i + k_j$. If there are no parallel paths, then $k = k_2$. If there is an additional parallel path initiating at B, with rate constant k_p, then $k = k_2 + k_i + k_j + k_p$. The kinetics of the catenary chain depend only on the values of k, k_1, k_2, and k_3; hence, it is necessary only to know k and not its components k_i, k_j, k_p, *etc.* The solutions below are applicable in all cases where no two or more of the constants k, k_1, k_2, and k_3 are exactly equal.

In the model, A represents a drug at the absorption site and B represents the drug in blood and other fluids of distribution. In the real world, the A → B process may be quite complicated and the process may only be approximated by first-order kinetics. However, it is well documented (1–7) that the over-all effects of dissolution of solid drug, stomach emptying, and absorption of the drug through the stomach and/or small intestinal barriers may be represented, usually by a first-order rate constant with or without a small lag time. In the case of acetylsalicylic acid (ASA) in tablet form, A would represent ASA in tablets, and B would represent salicylate in blood and other fluids of distribution. The over-all effects of tablet disintegration, dissolution of ASA from the resulting granules, stomach emptying, absorption of ASA from the stomach and small intestine, and hydrolysis of the ASA to salicylate have been shown (2, 5) to be represented by a combination of a first-order rate constant and a small lag time.

In the model, C represents a metabolite which is formed from B, and D represents the cumulated metabolite excreted in the urine. Interpretation of blood level and urinary excretion data has revealed that *usually* the apparent rate constant for absorption (k_1 in the model) and the rate constant for urinary excretion of metabolites (k_3 in the model) are greater in magnitude than the rate constant for over-all loss of drug from the body (k in the model). To simulate the usual kinetic situation the numerical values of k_1 and k_3 have been made larger than the numerical value of k in the examples. The rate constant for formation of metabolite (k_2 in the model) will always be less than k if there are parallel paths, and the ratio k_2/k gives the fraction of the total drug reaching the circulation which is converted to the metabolite. Hence, the ultimate amount in D will be this fraction multiplied by total amount of drug reaching the circulation. It is assumed that the amounts in compartments A, B, C, and D are all in the same mass units and in terms of one of the substances, since the substance in C and D is different than the substance in A and B.

The principal purpose of the model and the examples is to show that even when k_1 and k_3 are relatively large they become important in the kinetics in those situations when $1 < k_1/k < 100$ and/or $1 < k_3/k < 100$. Also, neither k_1 nor k_3 can be ignored, without appreciable error, when $1 < k_1/k < 10$ and/or $1 < k_3/k < 10$! These statements are valid when k_1 and k_3 are both greater than k. Since k_1 is usually in the range 0.5–2 hr.$^{-1}$, as estimated from actual data (1–7), and k_3 is usually in the range 0.07–2 hr.$^{-1}$ as estimated from actual data (8–11), then k_1 and k_3 cannot be ignored, without appreciable error, with drugs (simulated by B) whose k values range from 0.007 to 2 hr.$^{-1}$ or whose $t_{1/2}$ values ($0.693/k$) range from 0.3 to 99 hr.! This includes the vast majority of drugs which the author has been privileged to investigate and read about during the past 15 years. Another purpose of the examples is to show, as stated above, how one may erroneously conclude there are parallel zero-order and first-order processes when, in fact, all processes are first order. This error can be made readily when $1 < k_1/k < 10$ and $1 < k_3/k < 10$ since, in such cases, plots of both the cumulative amount of B converted to C *versus* time and the cumulative excretion plot are only slightly curved for a considerable period of time and may be erroneously interpreted as being linear. But this interpretation is incorrect. Following the assumption of linearity the conclusion can be made that the formation step, B → C, is obeying zero-order kinetics and, hence, this leads to the conclusion that there are parallel zero-order and first-order kinetics for loss of the drug from the body. Proof of zero-order rate of formation of a metabolite or zero-order rate of absorption of a drug requires, for any given drug, more evidence than just the appearance of the cumulative urinary excretion and semilogarithmic blood level plots. The experiments needed to provide the necessary additional data are usually feasible and have been performed with specific drugs by some investigators.

EXPERIMENTAL

Refer to Scheme I. Let X_A, X_B, X_C, and X_D be the amounts in compartments A, B, C, and D, respectively, at time t. Let X_A^0 be the initial amount in compartment A at time zero. Assume that $X_B = X_C = X_D = 0$ at time zero.

The differential equations and their solutions for the model are as follows:

$$\frac{-dX_A}{dt} = k_1 X_A \qquad \text{(Eq. 1)}$$

and

$$X_A = X_A^0 e^{-k_1 t} \quad \text{(Eq. 2)}$$

$$\frac{dX_B}{dt} = k_1 X_A - k X_B \quad \text{(Eq. 3)}$$

and

$$X_B = X_A^0 \left(\frac{k_1}{k_1 - k}\right)[e^{-kt} - e^{-k_1 t}] \quad \text{(Eq. 4)}$$

$$\frac{dX_C}{dt} = k_2 X_B - k_3 X_C \quad \text{(Eq. 5)}$$

and

$$X_C = X_A^0 \left(\frac{k_2}{k}\right)\left[\frac{-k_1 k e^{-k_1 t}}{(k_1 - k)(k_3 - k_1)} + \frac{k_1 k e^{-kt}}{(k_1 - k)(k_3 - k)} + \frac{k_1 k e^{-k_3 t}}{(k_3 - k_1)(k_3 - k)}\right] \quad \text{(Eq. 6)}$$

$$\frac{dX_D}{dt} = k_3 X_C \quad \text{(Eq. 7)}$$

and

$$X_D = X_A^0 \left(\frac{k_2}{k}\right)\left[\frac{-k k_3 (1 - e^{-k_1 t})}{(k_1 - k)(k_3 - k_1)} + \frac{k_1 k_3 (1 - e^{-kt})}{(k_1 - k)(k_3 - k)} + \frac{k_1 k (1 - e^{-k_3 t})}{(k_3 - k_1)(k_3 - k)}\right] \quad \text{(Eq. 8)}$$

For computational and instructional purposes, it is best to let $t = n/k$. Hence, n is the number of time constants where the time constant is $1/k$. Also, if we let $t_{1/2} = 0.693/k$, then $1/k = 1.44 t_{1/2}$. Since, in both examples below, $k = 0.25$ hr.$^{-1}$, then $t = 4n$ and $6n$ represents 24 hr. All graphs have been drawn with two abscissa scales; one scale is in terms of n, the other in terms of t. With k the smallest of the rate constants appearing in the exponential terms of Eqs. 4, 6, and 8, the n scale indicates it requires about 6 time constants or 8.6 half-lives of the drug to clear essentially all of the drug and metabolite from compartments B and C, respectively, and to reach essentially the asymptotic amount in compartment D.

Levy (11) has implied that the critical ratio is k_3/k_2; that is, the ratio of the excretion rate constant to the formation rate constant of the metabolite. This ratio is *not* critical unless $k_2/k \to 1$, *i.e.*, unless $k_2 \to k$. This can be seen by substituting n/k for t in the exponential e^{-kt} which yields e^{-n}; similar substitutions change $e^{-k_1 t}$ to $e^{-(k_1/k)n}$ and change $e^{-k_3 t}$ to $e^{-(k_3/k)n}$. Hence, the critical ratios are k_1/k and k_3/k, not k_3/k_2. The ratio k_2/k is equivalent to the fraction of B converted to C and which ultimately appears in D. In the case of the salicylurate–salicylate system $k_2/k \simeq 0.6$ and the ratios k_1/k and k_3/k become quite critical due to the order of magnitudes of the rate constants.

Example 1—Assignments made were $k_1 = 0.5$ hr.$^{-1}$, $k = 0.25$ hr.$^{-1}$, $k_2 = 0.15$ hr.$^{-1}$, and $k_3 = 0.75$ hr.$^{-1}$. Hence, $k_1/k = 2$, $k_2/k = 0.6$, and $k_3/k = 3$. For these numerical values, Eqs. 2, 4, 6, and 8 are reduced to Eqs. 9, 10, 11, and 12, respectively, if we let $X_A^0 = 100$ units.

$$X_A = 100e^{-2n} \quad \text{(Eq. 9)}$$

$$X_B = 200[e^{-n} - e^{-2n}] \quad \text{(Eq. 10)}$$

$$X_C = 60[e^{-n} - 2e^{-2n} + e^{-3n}] \quad \text{(Eq. 11)}$$

$$X_D = 60[1 - 3e^{-n} + 3e^{-2n} - e^{-3n}] \quad \text{(Eq. 12)}$$

Also, the rate of formation of C is given by

$$k_2 X_B = 30[e^{-n} - e^{-2n}] \quad \text{(Eq. 13)}$$

And the rate of appearance of C in D is given by

$$\frac{dX_D}{dt} = k_3 X_C = 45[e^{-n} - 2e^{-2n} + e^{-3n}] \quad \text{(Eq. 14)}$$

The cumulative amount of B converted to C in time T is given by

$$k_2 \int_0^T X_B \cdot dt = \left[\left(\frac{1}{k_3} \cdot \frac{dX_D}{dn}\right) + X_D\right] \quad \text{(Eq. 15)}$$

It should be clear that in Eqs. 9 through 14 terms with exponent $[-n]$ are associated with k, terms with exponent $[-2n]$ are associated with k_1, and terms with exponent $[-3n]$ are associated with k_3 in this example. The constants 2 and 3 in these terms are just the ratios k_1/k and k_3/k, respectively. As n increases, the order of magnitudes will always be $e^{-n} > e^{-2n} > e^{-3n}$. Also, as t increases, the order of magnitudes will be $e^{-kt} > e^{-(k_1/k)t} > e^{-(k_3/k)t}$ if $k_3 > k_1 > k$, and the order will be $e^{-kt} > e^{-(k_3/k)t} > e^{-(k_1/k)t}$ if $k_1 > k_3 > k$. Hence, the ratios k_1/k and k_3/k are critical as indicated above. If the numerical values of these ratios are very close, there will be very little curvature in a large segment of the X_D, t plot.

Equations 9 through 15 were solved for $n = 0.05$, 0.1, 0.15, 0.2, 0.25, 0.3, 0.4, 0.5, 0.55, 0.6, 0.65, 0.7, 0.8, 0.9, 0.95, 1, 1.125, 1.25, 1.375, 1.5, 1.75, 2, 2.5, 3, 3.5, 4, 4.5, 5, 5.5, and 6. In addition, values of $\Delta X_D/\Delta t$ were calculated corresponding to midpoint times of 0.2, 0.6, 1, 1.6, 2.2, 2.6, 3.2, 3.8, 4.5, 5.5, 7, 10, 14, 18, and 22 hr. The latter were intended to simulate the estimation of urinary excretion rates from analysis of fractional urine collections made at $t = 0.4$, 0.8, 1.2, 2, 2.4, 2.8, 3.6, 4, 5, 6, 8, 12, 16, 20, and 24 hr.

Example 2—Assignments made were $k_1 = 1.25$ hr.$^{-1}$, $k = 0.25$ hr.$^{-1}$, $k_2 = 0.15$ hr.$^{-1}$, and $k_3 = 1.0$ hr.$^{-1}$. Hence $k_1/k = 5$, $k_2/k = 0.6$, and $k_3/k = 4$. For these numerical values of the constants, Eqs. 2, 4, 6, and 8 become Eqs. 16, 17, 18, and 19, respectively, if $X_A^0 = 100$ units.

$$X_A = 100e^{-5n} \quad \text{(Eq. 16)}$$

$$X_B = 125[e^{-n} - e^{-5n}] \quad \text{(Eq. 17)}$$

$$X_C = 60[0.416e^{-n} - 1.66e^{-4n} + 1.25e^{-5n}] \quad \text{(Eq. 18)}$$

$$X_D = 60[1 - 1.66e^{-n} + 1.66e^{-4n} - e^{-5n}] \quad \text{(Eq. 19)}$$

RESULTS

Example 1—The time course of the amounts in compartments A, B, C, and D is shown in Fig. 1. The amount, X_A, drops rapidly with increase in time so that after 4 hr. only 13.5% of the initial amount remains in A. The amount, X_B, reaches a peak in the 2.5–3-hr. region then falls off without a great deal of curvature until 12 hr. The X_C curve rises slowly, reaches a peak of about 8.9 units at 4.5 hr., then falls off with little curvature until about 12 hr. The low peak of the X_C curve illustrates why it is often very difficult to measure blood levels of a metabolite. The X_D curve rises very slowly during the first 2 hr., but from 2 to 7 hr. has only *slight* curvature; during the latter period

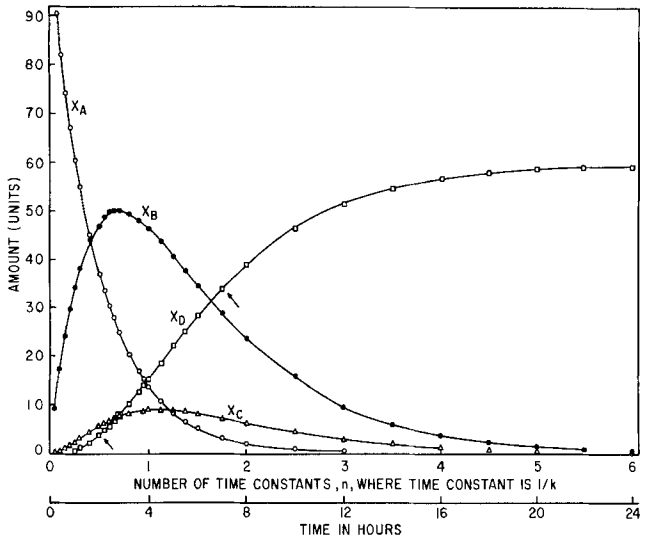


Fig. 1—The time course of the amounts X_A, X_B, X_C, and X_D in compartments A, B, C, and D, respectively, for the model shown as Scheme I and the constants of Example 1.

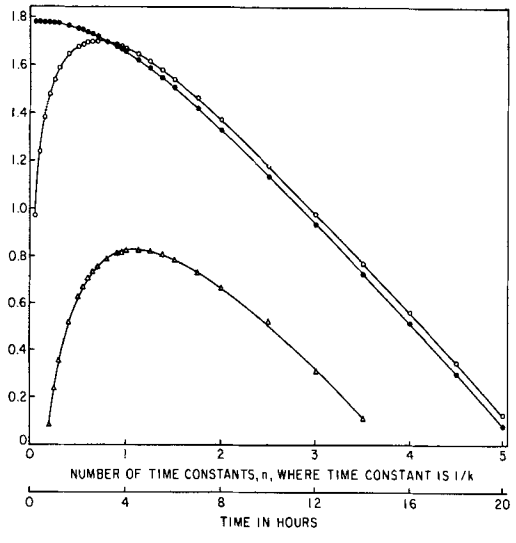

Fig. 2—Plots of $\log_{10}(60-X_D)$, $\log_{10}(X_B)$, and $\log_{10}(k_3 \cdot X_C)$ against time. These correspond to plots of the logarithm of the amount of metabolite not excreted, the logarithm of the plasma concentration of drug, and the logarithm of the excretion rate of metabolite against time. The constants of Example 1 were used. Key: ●, logarithm of amount not excreted = $\log_{10}(60 - X_D)$; ○, logarithm of amount in "B" = $\log_{10}(X_B)$; Δ, logarithm of excretion rate = $\log_{10}(K_3 \cdot X_C)$.

about 30 units or 50% of the C destined for the D compartment is contributed. It is not difficult to see how such a segment of a cumulative urinary excretion curve could be interpreted as being linear, particularly when analytical error, incomplete urine collections due to bladder retention, and other factors are contributing scatter to the points in the case of actual biological data.

Figure 2 is a plot of $\log_{10}(60 - X_D)$, $\log_{10}(X_B)$, and $\log_{10}(k_3X_C)$ *versus* time. These are comparable to plots of the logarithm of the amount of metabolite not excreted, the logarithm of the plasma concentration of drug, and the logarithm of the excretion rate of a metabolite. The curvature of the plots and the "plateau" in the excretion rate plot from about 3 to 6 hr. are noteworthy since proponents of zero-order formation have used these observations to support their claims.

Plots of the cumulative amount of B converted to C and the cumulative amount in D *versus* time are compared in Fig. 3. The first curve mentioned (the formation curve) could be interpreted, erroneously, as being linear in the region from 1 to 6 hr., while the excretion curve could be interpreted, also erroneously, as being linear in the region from 2 to 7 hr. The proper curve to resolve is the formation curve, not the excretion curve. The excretion curve was used by Levy (11), although Eq. 15 was published (12) for a different purpose; namely, to estimate absorption rate from measurement of unchanged drug in the urine and Levy (2) has made use of the equation.

Figure 4 is a plot of k_3X_C (the rate of excretion of metabolite) against k_2X_B (the rate of formation of metabolite). If formation rate were equal to excretion rate, all points would lie on the 45° line drawn through the origin; but, of course this is not true. Cummings and Martin (13) pointed out that in respect to drugs which are excreted predominantly as metabolites, the rate of excretion of a metabolite in urine will only parallel the rate of formation some time after the attainment of the maximum plasma concentration of the metabolite which is about 4 hr. in this example. This time corresponds to the change-over from diamonds to squares on the graph. One can estimate the relationship between rate of formation and rate of excretion if $k < k_3$ since at later times

$$k_2X_B \simeq \left(1 - \frac{k}{k_3}\right) k_2X_C \qquad \text{(Eq. 20)}$$

Substituting the values of k and k_3 for Example 1 into Eq. 20 yields

$$k_2X_B \simeq 0.67k_2X_C \qquad \text{(Eq. 21)}$$

The average ratio, k_2X_B/k_2X_C is 0.686 based on eight pairs of values in the 10–24-hr. interval.

The "mathematical error" involved in fractional urine collections may be gauged by the ratios $(\Delta X_D/\Delta t)/(dX_D/dt)$ where the derivatives are those at the midpoints of the Δt intervals. For the 15 "fractional collections" simulated the average value of this ratio was 0.99 with a range of 0.62 to 1.30. The extremes of the range were those corresponding to the midpoints of 0.4 and 0.2 hr., respectively. For the 13 "fractional collections" made in the 1.2–24-hr. range, the average ratio was 1.0 with a range of 0.95 to 1.17. It is heartening to know that, except at the very early times, $\Delta X_D/\Delta t$ estimates dX_D/dt within a reasonably small error.

Figure 5 is a "Lineweaver-Burk" (14) type plot of the reciprocal of $\Delta X_D/\Delta t$ against the reciprocal of X_B taken at the midpoints of the $\Delta X_D/\Delta t$ intervals. The midpoints used were those at 7, 10, 14, 18, and 22 hr. Levy (15) and Nelson *et al.* (16) interpreted such a plot as indicating a metabolite was being formed according to Michaelis-Menton kinetics (17). But the apparent "$V_{max.}$" and apparent "K_m" one calculates from the intercept and slope in the conventional manner (14) are purely artifacts. From the intercept one estimates an apparent "$V_{max.}$" of 19 units/hr. which is higher than the maximum excretion rate of about 6.67 units/hr. Hence, if one assumes that the maximum excretion rate is "$V_{max.}$," as Levy did, then this type of plot overestimates "$V_{max.}$" exactly as Levy found (15). The reciprocal of the slope of the line in Fig. 5, also equivalent to apparent "$V_{max.}$/apparent 'K_m'," since apparent "K_m" = slope x apparent "$V_{max.}$," is a meaningless number in the context of the model. As a result of the method of plotting and Eq. 21, the value of the reciprocal, 0.238, multiplied by 0.67,

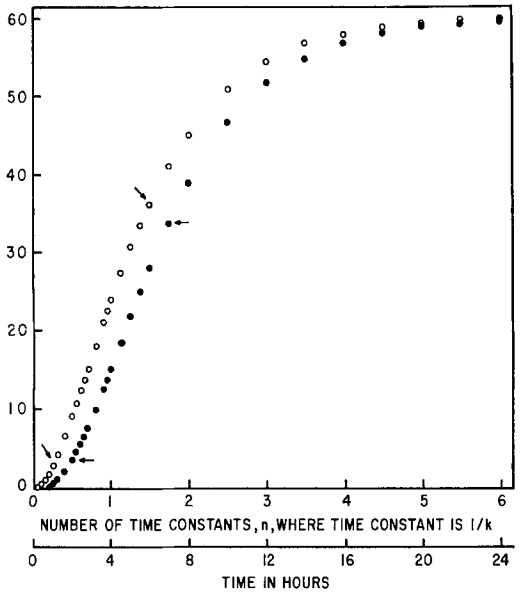

Fig. 3—Plots of the cumulative amount of B converted to C and the cumulative amount in D against time. These correspond to plots of the cumulative amount of drug converted to metabolite and the cumulative urinary excretion of the metabolite against time. The constants of Example 1 were used. Key: ○, cumulative amount of B converted to C; ●, cumulative amount in D.

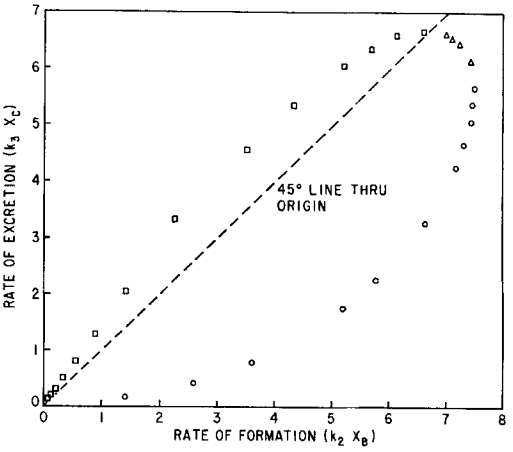

Fig. 4—A plot of the rate of excretion of metabolite (k_3X_C) against the rate of formation of metabolite (k_2X_B). Key: ○, values in the range $0 < n < 0.7$ and $0 < t < 2.8$; Δ, values in the range $0.8 < n < 1$ and $3.2 < t < 4$; □, values in the range $1.125 < n < 6$ and $4.5 < t < 24$. The plot shows that initially excretion rate underestimates formation rate then, beyond the time of occurrence of the peak metabolite concentration in blood, excretion rate overestimates formation rate. If excretion rate equalled formation rate, all points would lie on the 45° line drawn through the origin; but it is obvious this is not the case. The constants of Example 1 were used.

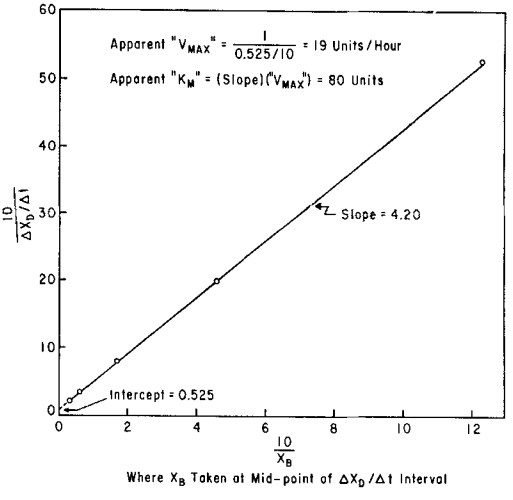

Fig. 5—Showing how a "Lineweaver-Burk" plot, which is an artifact, results from plotting the reciprocal of the excretion rate, $1\ \frac{\Delta X_D}{\Delta t}$, against the reciprocal of the amount of B, $1/X_B$, where X_B is taken at the midpoints of the excretion intervals. The constants of Example 1 were used.

is 0.16; the resultant number is essentially the same as the value of 0.15 obtained for k_2 from the correct plot shown in Fig. 6.

If Michaelis-Menton kinetics apply, one must use the reciprocal of the formation rate, *i.e.*, $1/k_2X_B$, rather than the reciprocal of the excretion rate for making a Lineweaver-Burk plot. From Eq. 20 can be calculated the approximate error in the ordinate value of such a plot if $1/k_2X_C$ is used in place of $1/k_2X_B$. If the kinetics are truly those of Michaelis and Menton (17), use of the reciprocal of the excretion rate causes rotation of the true line, so that the slope of the line drawn from excretion rate data has a slope which is less, and an intercept which is greater, than those of the true line. In such a case $V_{max.}$ is not estimated accurately, but K_m is estimated accurately since K_m = (slope) ($V_{max.}$). However, K_m will not have the same significance as it has usually (18). This is discussed in more detail under *Discussion*.

The proper plot employing $1/k_2X_B$ and $1/X_B$ is shown in Fig. 6. As expected, the reciprocal of the slope is k_2.

Example 2—The time course of the amounts in compartments A, B, C, and D is shown in Fig. 7. Since $k_1 = 1.25$ hr.$^{-1}$ in this example, compared with 0.5 hr.$^{-1}$ in the first example, X_A drops more rapidly in Example 2 than in Example 1, so that after only 1.6 hr. 13.5% of the initial amount remains in A. Hollister and Levy (19) reported an average k of 0.258 hr.$^{-1}$, an average k_2 of 0.153 hr.$^{-1}$, and Levy (11) reported an average k_3 of 1.1 hr.$^{-1}$ for the salicylate–salicylurate system in man. Hence, except for k_1, which Levy ignored, and the initial value $X_A{}^0$, the values of the constants in this example are very similar to those actually calculated for a specific drug–metabolite system as a result of the analysis of biological samples obtained from man.

Plots of the cumulative amount of B converted to C and the cumulative amount in D *versus* time are compared in Fig. 8. It should be noticed that the effect of increasing k_1 and k_3, but keeping k constant, is to cause the curves to rise more steeply and to become almost linear at an earlier time. One could interpret the formation curve as being linear in the 0.4 to 4.0-hr. period and the excretion curve similarly in the 1.2 to 5-hr. period. As in the previous example, during the latter period about 50% of the total metabolite is excreted.

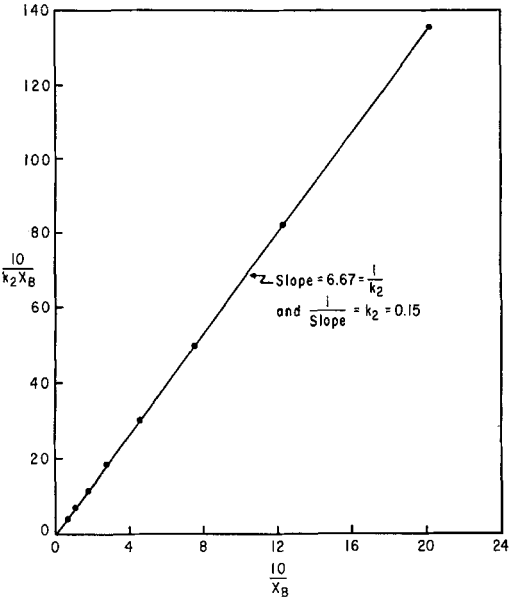

Fig. 6—A plot of the reciprocal of the formation rate, $1/k_2X_B$, against the reciprocal of the amount of B, $1/X_B$. The constants of Example 1 were used.

DISCUSSION

The implications of the simulations and equations presented above are as follows.

(*a*) The conclusion of Cummings *et al.* (20), Levy (11, 15), Nelson *et al.* (16), and Elliott (8) that the formation of salicylurate from salicylate becomes a zero-order process for some period of time following administration of either single oral doses of 1.5 or 2 Gm., or multiple oral doses of about 1 Gm., of acetylsalicylic acid to *adult humans* is most

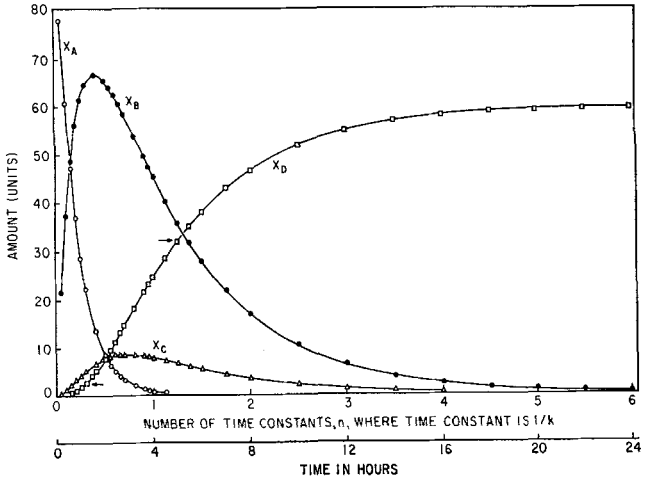

Fig. 7—The time course of the amounts X_A, X_B, X_C, and X_D in compartments A, B, C, and D, respectively, for the model shown as Scheme I and the constants of Example 2.

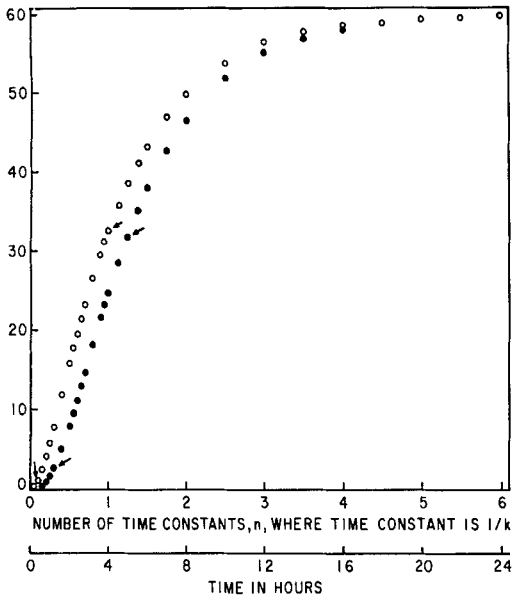

Fig. 8—Plots of the cumulative amount of B converted to C and the cumulative amount in D against time. These correspond to plots of the cumulative amount of drug converted to metabolite and the cumulative urinary excretion of the metabolite against time. The constants of Example 2 were used. Key: O, cumulative amount of B converted to C; ●, cumulative amount in D.

probably in error. Most probably only first-order rate constants are involved at all times. The data of Levy (11) are fit quite well by Eq. 8 based on Scheme I.

(*b*) The conclusion of Nelson (21) that the absorption of tetracycline becomes a zero-order process for some period of time following oral administration of tetracycline mucate in a special dosage form is most probably in error.

(*c*) Large errors can be made in estimating the half-life of a drug (*i.e.*, $0.693/k$) if the estimation is made in a time period when more than one exponential term is making a significant contribution. The wide variability of the reported half-life of salicylate (11) is explained better on this basis than the explanations presented by Levy (11) and Cummings *et al.* (20).

(*d*) When analyzing such pharmacokinetic data by graphical methods using semilogarithmic graph paper one tends to underestimate the over-all rate constant for loss from the body (k) if it is the smallest rate constant appearing in Eqs. 7, 9, and 11 or, in the case of other models, in equations similar to these. This in turn means one tends to overestimate the half-life of the drug. This is due to the fact that the semilogarithmic plots are actually gently curving when one assumes they are linear. Hence, when residuals are taken by extrapolating the terminal line drawn, one also obtains biased residuals. This ultimately results in estimates of the other rate constants, like k_1 and k_3, which are different from their real or "best" values. The best approach is to treat the graphical estimates of the rate parameters as "purely estimates" which are used as input data to a digital computer; with the proper iterative procedure programmed into the computer, the data may be fit by the method of least squares so that "least squares" estimates of all the rate constants may be obtained simultaneously. Such sets of rate constants are readily shown to be better estimates than the graphical ones since, in almost all cases, there is a significant reduction in the variance associated with the fit.

(*e*) The method of subtracting amounts of unchanged drug and metabolite excreted to 4 hr. postadministration from the total amounts excreted and elaborating a pharmacokinetic model from the residuals, as practiced by Nelson and O'Reilly (9), may introduce significant errors into the estimates of the rate constants from some, but not necessarily all, subjects' data. The magnitude of the errors depends upon the effective first-order rate constant for absorption (k_1), and this will vary widely from subject to subject (2, 3, 6).

(*f*) The conclusion of Levy (15) and Nelson *et al.* (16) that a plot of the reciprocal of the excretion rate against the reciprocal of the amount of total drug left in the body is a "Lineweaver-Burk" plot, in the accepted sense, is spurious. It has been shown above that when formation rate of the metabolite is first order, such a plot yields an intercept and a slope, but the plot is an artifact in the Michaelis-Menton sense. If the disappearance of B is truly describable by the extended Michaelis-Menton equation (18), namely

$$\frac{-dC_B}{dt} = \frac{V_{max.} \cdot C_B}{K_m + C_B} \qquad \text{(Eq. 22)}$$

where C_B is the concentration in compartment B at time t, and the system is as in Scheme II, where

$$E + B \underset{K_2}{\overset{K_1}{\rightleftarrows}} EB \xrightarrow{K_3} E + C \xrightarrow{K_4} D$$

Scheme II

E denotes the enzyme, EB the enzyme–drug complex, and K_i ($i = 1, 2, 3, 4$) are first order-rate constants, then the K_m obtained would have a different significance than in the classical case. In the classical case, the system is as shown in Scheme III,

$$E + B \underset{K_2}{\overset{K_1}{\rightleftarrows}} EB \xrightarrow{K_3} E + C$$

Scheme III

and the "extended Michaelis constant," $K_m = (K_2 + K_3)/K_1$ (18). The application of the Michaelis-Menton equation to metabolite data derived from the intact animal or human will always be complicated by the C → D step unless $K_4 > 100K_3$ in Scheme II; in addition, there may be additional errors if the application is made in a time period when B is being supplied from a reservoir such as the absorption site or from a precursor.

A Critique of History—Bray *et al.* (22) showed that in the conjugation of benzoic acid with glycine to form hippuric acid the availability of glycine for conjugation controlled the rate of hippuric acid formation and that formation of hippuric acid apparently proceeded at a constant rate when rabbits were given relatively high doses of 500 mg./Kg. This was a significant contribution. However, these authors made the following statement: "Hippuric acid formation takes place at a constant rate and *the acid is excreted immediately*

up to a limiting rate which appears to vary considerably between different rabbits." In their mathematical treatment they completely ignored the rate constant for urinary excretion of hippuric acid. This reference, which has been cited extensively, may be the source of the problem. Some scientists seem to have reached the conclusion that if a rate constant is relatively large, say 1.0 hr.$^{-1}$, it can be ignored. The presentation in this paper should dispel this idea.

Nelson *et al.* (16) showed that following 20, 40, and 60 mg./Kg. doses of salicylic acid *to rats*, the rate of excretion of the metabolite, salicyluric acid, was the same, within error, at all three doses. In addition, they showed that salicyluric acid, administered intraperitoneally at doses of 200 mg./Kg. to rats, was rapidly excreted; the excretion obeyed first-order kinetics with an excretion rate constant of 1.15 hr.$^{-1}$ which is essentially the same as Levy (11) reported for one human given 2 doses of salicyluric acid, but considerably higher than the average value of 0.654 hr.$^{-1}$ reported by Elliott (8) for five humans. The additional rat study showed that saturation of the active secretory pathway in the kidney could not have occurred for salicylurate in the rats dosed with sodium salicylate. Hence, their evidence is very convincing that saturation of the enzyme system which converts salicylate to salicylurate occurred *in rats* at the dose of 20 mg./Kg. and above. One should not conclude, however, that a comparable dose, *i.e.*, about 1.4 Gm. of salicylic acid in a 70-Kg. man, will produce the same effect!

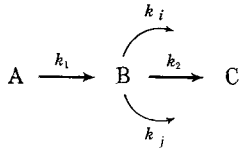
In the same paper (16) the conclusion was reached that the cumulative salicylurate excretion plots were linear following doses 1.5 and 2.0 Gm. of acetylsalicylic acid administered to two humans. Careful analysis of these plots reveals that the data points form a *curve;* the points start below the straight line drawn through them, then the points go above the line, then they go below the line again as time increases. The same result would be obtained if one were to draw a straight line through the points of the apparently linear segments of the X_D, t curves of Figs. 1 and 7! Levy (11) had previously drawn the conclusion that salicylurate was being formed at a constant rate from the same sets of experimental data. Later he (15) constructed "Lineweaver-Burk" plots from the same sets of data. He utilized the reciprocals of the salicylurate *excretion* rates, not the formation rates, in the time period 15 to 27 hr. postadministration. In light of the above presentation it appears that there is convincing proof of zero-order formation of salicylurate from salicylate in the rat, but the same type of proof has not been presented for man. It is obvious that there must be some critical dose level of acetylsalicylic acid or salicylate for man above which there will be zero-order formation of salicylurate for some time postadministration; such levels, for example, could be reached in poisoning cases when children ingest large quantities of acetylsalicylic acid. However, the administration of doses of up to 4 Gm. of sodium salicylate to adult subjects provided no data which supported zero-order formation of salicylurate from salicylate (23). Unfortunately, Levy (11) completely misinterpreted the data of Schachter and Manis (23).

Cummings and Martin (24) made some erroneous statements about metabolite formation which should be corrected. They stated that one could estimate the maximum rate constant for renal excretion of a metabolite from the volume of distribution (V) and the maximum renal clearance (R) employing the equation of Butler (25). But this is not so. The Butler equation, transferred into the terminology of this paper, is

$$R = Vkf = Vk_2 \qquad \text{(Eq. 23)}$$

where f is the fraction of B converted to C (*i.e.*, $f = k_2/k$). Hence, from renal clearance one can only estimate k or k_2 and not k_3. They also stated that the slope of the terminal segment of a plot of the logarithm of the excretion rate of metabolite would yield an estimate of k_2 when $k_2 < k_3$. But this is not true. The constant determined by this method of plotting will be k, providing k is less than k_1 and k_3. This is so because k, and not k_2, appears in the exponents of exponential terms of the solutions of the differential equations. Later, these authors (26) stated that if there was zero-order formation of one metabolite and first-order formation of another metabolite, then a plot of the logarithm of formation rate of total metabolites *versus* time would be a straight line having the same slope as if the latter metabolite were being formed alone. Their equations on which this conclusion is based are in error, and their own plots show this is not true!

The same type of error with respect to linearity of cumulative excretion curves, as discussed above for metabolities, can lead to the conclusion that constant rate (zero-order) absorption is operative, when, in fact, all rate constants are first-order rate constants. If a drug is partly metabolized and partly excreted unchanged in the urine and one measures unchanged drug in the urine, then one pertinent model may be written as in Scheme IV



Scheme IV

where A represents the solid drug administered, B represents the drug in blood and other fluids of distribution, and C represents the drug in urine. If k has the same meaning as for Scheme I, and k_2 is the rate constant for urinary excretion of unchanged drug, then a plot of the cumulative amount of unchanged drug in the urine (*i.e.*, X_C *versus* t) will be apparently linear, but actually slightly curved, during some time period if $1 < k_1/k < 10$. An example is shown in Fig. 9 for the case when $k_1 = 0.5$ hr.$^{-1}$, $k = 0.25$ hr.$^{-1}$, and $k_2 = 0.15$ hr.$^{-1}$. It may be seen that if a smooth line was drawn through the points, the line would be only slightly curved in the period 1.2 to 6 hr. postadministration. This region is marked off by the arrows on the graph. If one assumed linearity of the plot in this time period, one would conclude the A $\rightarrow$ B step was zero order—*i.e.*, that absorption was proceeding at a constant rate. This probably explains the results of Nelson (21) obtained with tetracycline mucate. The writer once made a similar interpretation from data derived following administration of a different drug and lived to regret it. As in Scheme I, the critical ratio for Scheme IV is k_1/k and not k_1/k_2.

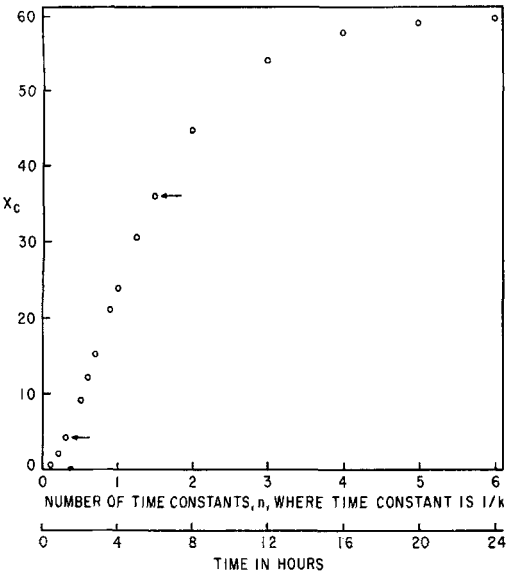


Fig. 9—A plot of the cumulative amount of unchanged drug in the urine, X_C versus time for the model shown as Scheme IV and the constants given in the text.

Pharmacokinetic Model for Nalidixic Acid in Man III

Effect of Repeated Oral Dosage

By E. W. MCCHESNEY, G. A. PORTMANN, and R. F. KOSS

In studies which involved the administration of 1-Gm. doses of nalidixic acid to human volunteers four times daily for a period of 10 days, it has been shown that the resulting plasma levels of nalidixic and of hydroxynalidixic acid could be predicted reasonably well from a model derived from single-dose studies. More satisfactory blood levels are obtained if the doses are taken at least 1 hr. before meals. Repeated dosage results in no important change in the absorption-excretion-metabolism patterns of the drug.

IN PREVIOUS communications (1, 2) a model describing the absorption and elimination of nalidixic acid[1] (NA) in man was presented. This model was derived from observations in seven subjects following the ingestion of single 1-Gm. doses of NA in several physical forms. There remained, however, the question of how well such a model would describe the situation in which the drug is given as a standard therapeutic course, *i.e.*, 1 Gm. four times daily. In particular there was the problem of whether such a dosage regimen would result in a significant carry-over of the drug and its metabolites from one day to another [it was already known (3) that following single 1-Gm. doses the excretion is usually not quite complete within 24 hr.], and whether the repeated administration of 4 Gm. per day would result in significant changes in the way the body handles

Pharmacokinetic Model for Nalidixic Acid in Man III

Effect of Repeated Oral Dosage

By E. W. MCCHESNEY, G. A. PORTMANN, and R. F. KOSS

In studies which involved the administration of 1-Gm. doses of nalidixic acid to human volunteers four times daily for a period of 10 days, it has been shown that the resulting plasma levels of nalidixic and of hydroxynalidixic acid could be predicted reasonably well from a model derived from single-dose studies. More satisfactory blood levels are obtained if the doses are taken at least 1 hr. before meals. Repeated dosage results in no important change in the absorption-excretion-metabolism patterns of the drug.

IN PREVIOUS communications (1, 2) a model describing the absorption and elimination of nalidixic acid[1] (NA) in man was presented. This model was derived from observations in seven subjects following the ingestion of single 1-Gm. doses of NA in several physical forms. There remained, however, the question of how well such a model would describe the situation in which the drug is given as a standard therapeutic course, *i.e.*, 1 Gm. four times daily. In particular there was the problem of whether such a dosage regimen would result in a significant carry-over of the drug and its metabolites from one day to another [it was already known (3) that following single 1-Gm. doses the excretion is usually not quite complete within 24 hr.], and whether the repeated administration of 4 Gm. per day would result in significant changes in the way the body handles

[1] Nalidixic acid is 1-ethyl-1,4-dihydro-7-methyl-4-oxo-1,8-naphthyridine-3-carboxylic acid. Marketed as NegGram by Winthrop Laboratories, New York, N.Y.

the drug. To answer these questions three separate studies have been conducted as outlined in studies *A*, *B*, and *C*.

Study A—The results of giving 1-Gm. doses four times daily for 3 consecutive days have been determined.

Study B—A comparison of the results obtained when the drug (single 1-Gm. dose) is taken on a full *versus* an empty stomach has been made.

Study C—The results of giving 1-Gm. doses four times daily for 10 consecutive days have been determined, at intervals during the course of this dosage regimen. (*Note:* the daily time schedules for studies *A* and *C* were not identical; see under *Experimental*.)

METHODS OF ANALYSIS

The methods used in the present work have been described (2, 3) and no further details are given here except as noted below.[2]

THEORETICAL

The equation used for calculating the theoretical NA plasma levels following the first 3 doses (in studies *A* and *C*) was that derived by Dost (4) for the case where equal doses are taken at equal time intervals. The average rate constants and apparent volumes of distribution which had been determined previously for another set of seven volunteers (2) were used in making the present calculations. For hydroxynalidixic acid (HNA) the general equation given below was derived by methods similar to those of Dost and of Wiegand *et al.* (5). The model, the basic equations, and the applicable constants have been presented (2). The urinary outputs of NA and of its several metabolic products were calculated in the same manner as the plasma levels.

The elimination rate constants for NA and HNA are designated as k_d and k_{d_2}, respectively. The availability rate constant for NA is designated as k_A, and the rate constant for the oxidation of NA to HNA as k_{M_1}. A_0 represents the total amount absorbed (in this case A_0 = dose administered) and n the number of doses given. The time interval between doses is designated as T, and the time elapsed after the administration of each dose as t. Division of the term HNA-B (that is, HNA in the body) by the apparent volume of distribution gives the plasma concentration:

$$\text{HNA-B} = \frac{k_{M_1}k_A A_0}{k_A - k_d} \times \left[\frac{(k_A - k_d)\, e^{-k_{d_2}t}}{(k_d - k_{d_2})(k_A - k_{d_2})}\left(\frac{1 - e^{-nk_{d_2}T}}{1 - e^{-k_{d_2}T}}\right) + \frac{e^{-k_A t}}{(k_A - k_{d_2})}\left(\frac{1 - e^{-nk_A T}}{1 - e^{-k_A T}}\right) - \frac{e^{-k_d t}}{(k_d - k_{d_2})}\left(\frac{1 - e^{-nk_d T}}{1 - e^{-k_d T}}\right)\right]$$

The average values for the various constants are as follows: k_d = 0.0112^{-1} min.; k_{M_1} = 0.00453 min.$^{-1}$; k_{d_2} = 0.00746 min.$^{-1}$; k_A = 0.0180 min.$^{-1}$; V_d for NA = 34% of body weight; V_d for HNA = 49% of body weight; mean body weight for study *A* = 74 Kg., for study *C* = 65.5 Kg.; lag time = 18 min. There is an almost perfect correlation between the values for V_d and per cent protein-bound: per cent protein-bound NA/HNA = 93/63 = 1.48 (2) V_d(HNA)/V_d(NA) = 49/34 = 1.45.

EXPERIMENTAL

Study A—Four male human volunteers took 1-Gm. doses of NA four times daily for 3 consecutive days, without control of the timing of the meals, or of the amounts eaten. The doses were taken, as 0.5-Gm. tablets, at 8:15 a.m., 1:15 p.m., 6:15 p.m., and at bedtime (about 11:15 p.m.). Oxalated plasma samples were obtained at 8:15 a.m. on each of the 3 days, at 2-hr. intervals thereafter until 4:15 p.m., and at 8:15 a.m. on the fourth day. Urine samples were collected for the interval 8:15 a.m.–4:15 p.m. for the first 4 days, and for the 4:15 p.m.–8:15 a.m. interval of the first 3 nights, (*i.e.*, for 80 hr. following the first dose). The compounds determined in these samples were NA and HNA in both free and ester glucuronide forms.

Study B—Three human volunteers took 1-Gm. doses of NA on an empty stomach, and were provided breakfast 75 min. later, while three other volunteers took 1-Gm. doses immediately after a full breakfast. Three days later the groups of subjects were reversed, to complete the experimental cross-over design. Oxalated plasma samples were obtained from each subject just prior to medication and at intervals of 0.5, 1, 2, and 3 hr. thereafter. These samples were analyzed for free NA and HNA.

Study C—Six human volunteers (four males, two females) took 1-Gm. doses of NA four times daily for 10 consecutive days. On days 1, 7, and 10 a strict schedule of dosage and meals was followed, with the drug being taken at 7:30 and 11:30 a.m., 3:30 and 9:00 p.m., and the meals being eaten at 8:30 a.m., 12:30 p.m., and 6–7 p.m. On the other 7 days the subjects were permitted a wider latitude of choice in the timing of their meals and of the medications, but record cards which they were required to fill out showed that the greatest deviation from the dosage schedule in any case was 1 hr. On days 1, 7, and 10 of this regimen oxalated plasma samples were obtained at 7:30, 9:00, and 11:30 a.m., and at 1:00, 3:30, and 5:00 p.m. Quantitative urine collections were made under toluene for the intervals 7:30 a.m.–4:30 p.m. and 4:30 p.m.–7:30 a.m. of each of these days. The plasma samples were analyzed for free, (*i.e.*, extractable) NA and HNA; the urine samples were analyzed for both free and conjugated NA and HNA, and for the dicarboxylic acid metabolite (3). (Analysis for the last-named is somewhat nonspecific, and is subject to some interference from other drugs which the volunteers may take; *e.g.*, salicylates.)

RESULTS AND DISCUSSION

The data obtained in study *A* are presented in Tables I and II. The plasma levels observed for NA and HNA and their glucuronides are presented in Table I, as are the values for NA and HNA which were calculated from the model (2). Table II pre-

[2] In *Reference 2*, p. 73, the volume ratio of buffer solution (pH 5.63) to toluene was inadvertently not stated. The ratio used is 45/30.

TABLE I—PLASMA LEVELS OF NA AND HNA, FREE AND CONJUGATED, IN FOUR HUMANS TAKING 1 GM. OF NA 4 TIMES DAILY FOR 3 CONSECUTIVE DAYS[a]

Substance Determined[b]	Day of Expt.	hr. After Morning Dose[c] 0	2	4	6	8
NA	1	...	15.6 ± 7.2 (17.3)	13.7 ± 3.4 (6.6)	8.1 ± 5.1 (17.2)	9.6 ± 2.7 (12.0)

Total		243 ± 37	—	9979 ± 125[d] (10618)[d]

[a] Doses given at 0, 5, 10, and 15 hr. of each day; initial dose at 8:15 a.m. [b] For definition of terms see Table I. [c] Values given as mg. ± S.E., and in terms of NA equivalents. Figures in parentheses are the calculated values derived from the model. [d] Total for 80 hr.

sents the corresponding urinary excretion data for NA, HNA, and their glucuronides, along with the values for each which were calculated from the model. The results obtained in study *B* are presented in Table III, while the results obtained in study *C* are presented in Tables IV and V. The latter tables are quite comparable to Tables I and II, the principal difference being that Table V includes data on the actual and calculated excretion of the dicarboxylic acid metabolite. The following comments may be made on the data.

There are numerous time schedules which might be followed in taking 1-Gm. doses of any drug four times daily. In the case of a drug which has a half-life of about 60 min., it is especially desirable to use a regimen which will maintain the maximum possible plasma levels over the longest period of time, within the limits of safety. [In this connection it should be noted that the antibacterial spectrum of HNA both *in vitro* and *in vivo* is very similar to that of NA (3, 6, 7); therefore, the biologically effective plasma level is a function of the sum of the concentrations of free NA plus HNA.] As a practical matter, however, there are essentially only two schedules of dosage which are likely to be prescribed: (*a*) 1 Gm. after meals and at bedtime, and (*b*) 1 Gm. between meals and at bedtime. Study *A* was based on the former schedule and the data obtained suggested that, as a result of the absence of any control of the amount of food in the stomach when the doses were taken, some variation in the rate (and possibly completeness) of absorption had occurred. Nevertheless, certain general conclusions could be drawn from the study, as follows.

(*a*) The plasma levels of free NA were generally about equal to those of conjugated NA (Table I). For the 15 separate intervals studied the ratio of free to conjugated NA averaged 1.0 ± 0.3 (S.D.),

TABLE III—PLASMA LEVELS OF NA AND HNA[a] IN MAN AT 4 INTERVALS AFTER INGESTION OF 1-GM. DOSES OF NA

Subject	State of Stomach[b]	Time After Medication, hr. 0.5 NA	0.5 HNA	1.0 NA	1.0 HNA	2.0 NA	2.0 HNA	3.0 NA	3.0 HNA

[a] Values given as mcg./ml.; zero-hr. blank values (0.1–0.2 mcg./ml.) subtracted. [b] When dose was ingested. The term "full stomach" means that the subjects were allowed as big a breakfast as they wished. The dose was taken immediately after the meal was finished.

TABLE IV—PLASMA LEVELS OF NA AND HNA IN SIX HUMANS TAKING 1 GM. OF NA 4 TIMES DAILY FOR 10 CONSECUTIVE DAYS[a]

Substance Determined[b]	Day of Expt.	hr. After Morning Dose[c] 0	1.5	4	5.5	8	9.5
NA	1	...	12.1 ± 2.6 (21.8)	4.3 ± 0.8 (7.7)	13.5 ± 3.1 (24.5)	10.9 ± 2.3 (8.1)	16.4 ± 5.8 (25.1)
HNA	1	...	5.0 ± 1.5 (2.9)	2.8 ± 0.4 (4.7)	3.7 ± 0.5 (6.8)	7.3 ± 1.2 (6.2)	9.5 ± 1.7 (7.6)
NA	7	1.1 ± 0.7 (0)	21.7 ± 2.8 (21.8)	4.3 ± 0.8 (7.7)	21.0 ± 7.1 (24.5)	7.9 ± 1.2 (8.1)	32.2 ± 6.1 (25.1)
HNA	7	4.5 ± 0.6 (0.9)	12.2 ± 1.6 (3.2)	8.2 ± 1.3 (4.7)	8.4 ± 1.8 (6.8)	8.5 ± 1.3 (6.2)	17.0 ± 1.9 (7.6)
NA	10	1.1 ± 0.2 (0)	17.5 ± 2.9 (21.8)	3.6 ± 1.0 (7.7)	32.2 ± 3.2 (24.5)	6.6 ± 2.0 (8.1)	24.2 ± 4.1 (25.1)
HNA	10	2.9 ± 1.0 (0.9)	11.9 ± 4.1 (3.2)	5.8 ± 1.1 (4.7)	12.6 ± 3.6 (6.8)	10.8 ± 1.9 (6.2)	14.6 ± 2.4 (7.6)

[a] Doses taken at zero (7:30 a.m.), 4, 8, and 13.5 hr. each day. The subjects had breakfast at 1 hr., lunch at 5 hr., and dinner at approximately 11 hr. of each day, based on this time schedule. [b] NA, nalidixic acid; HNA, hydroxynalidixic acid. [c] Values given as mcg./ml. ± S.E.; those values given in parentheses were calculated on the basis of rate constants derived from a panel which included one of the same subjects (2).

and no individual subject showed any consistent change in these ratios as related to time of day or the number of days on medication.

(*b*) There was a small but definite carry-over of naphthyridine in the plasma from one day to another, although the equations derived from the earlier single-dose studies (see under *Theoretical*) suggested that the only carry-over should be a small amount of HNA. The mean carry-over at 24 hr. in all forms determined, for example, was 6.9 mcg./ml.; at 48 hr. it was 7.6 mcg./ml. and at 72 hr. it was 10.6 mcg./ml. Free naphthyridine represented about half of the carry-over and in this category HNA predominated over NA in a ratio of about 3/2 (Table I).

(*c*) The urinary output of free naphthyridine (NA + HNA) per hour was greatest in the 8–24-hr. period of the first day, but otherwise fluctuated according to no obvious pattern. The per hour outputs of this item for the seven successive periods of observation were: 10.0, 15.6, 8.5, 12.8, 9.5, 9.4, and 3.7 mg. The 8–24-hr. period of the first day was also characterized by the largest output of total naphthyridine, for any of the periods studied. The ratio of free naphthyridine to total naphthyridine also varied from one period to another, from a low of 0.065 to a high of 0.119, but according to no consistent pattern.

(*d*) With allowance for the excretion of 4% of the dose in the feces (3) and 8% as the dicarboxylic acid[3] (2), the daily urinary output of total naphthyridine should have averaged 3540 mg. This rate of excretion was not achieved for any one of the 3 days studied, reflecting the fact that in two of the subjects the over-all recoveries were only 84 and 93% of the expected amounts. The subject who gave the lowest total recovery of naphthyridine in the urine also generally gave the lowest plasma levels. (NA + HNA = 29.4 mcg./ml. at 4 hr. and 27.2 mcg./ml. at 26 hr.; otherwise there was no level above 18. The expected peak level for a subject of his body weight, following a single 1-Gm. dose of NA would be about 32.) This subject, considered reliable, was very positive that he had taken all of the doses.

The reasons for the somewhat erratic results obtained in study *A* were revealed in part in study *B*,

[3] In terms of NA equivalents an output of 8 mg. as dicarboxylic acid would be reduced to 7 mg.

TABLE V—URINARY EXCRETION OF NALIDIXIC ACID AND FOUR METABOLIC PRODUCTS IN SIX HUMANS TAKING 1-Gm. DOSES OF NA 4 TIMES DAILY FOR 10 CONSECUTIVE DAYS[a]

Substance Determined[b]	Day of Expt.	Interval After Morning Dose[c] 0–9 hr.	9–24 hr.	0–24 hr.

DCA		104 ± 25	166 ± 70	270 ± 63 (328)
Total		1553 ± 178	2314 ± 218	3867 ± 90 (3880)

[a] Doses taken at 0, 4, 8, and 13.5 hr. of each day (zero hr. = 7:30 a.m.). The subjects had breakfast at 8:30 a.m., lunch at 12:30 p.m., and dinner at approximately 6:30 p.m. each day on which samples were to be taken. One subject failed to take the fourth dose on the first day and is not included in the means for that day. [b] For definition of terms see Table I; DCA, dicarboxylic acid. [c] Values given as mg., in terms of NA equivalents.

which showed definitely that the presence of food in the stomach delays the absorption of NA. In the "full stomach" part of the experiment, one subject gave a peak plasma level at 0.5 hr., and another subject at 1 hr., but in half of the subjects the 3-hr. level was the highest observed (Table III). In contrast, when in the postprandial state the mean plasma level for the same six subjects at 0.5 hr. postmedication exceeded any which was attained when they ingested the dose immediately after a full breakfast, and in this state only one of the subjects reached his peak level as late as 2 hr. postmedication.

In study *C* the expected urinary excretion rate of about 3860 mg./day (including the dicarboxylic acid) was fully realized, as is evident in Table V. The mean outputs of the items determined, as per cent of the total amount excreted, were approximately as follows, for the 3 days studied: conjugated NA, 51; conjugated HNA, 31; free HNA, 11; dicarboxylic acid, 6.5; free NA, 0.5 (all values given in terms of equivalents of NA). On the basis of the single-dose studies (2) the expected partition of these excretory products, listed in the same order, was: 56, 24, 11, 8, 1. Thus, the only important difference between the present and the earlier set of values would be the shift of about 6% of the output from the conjugated NA to the conjugated HNA fraction. This shift was also reflected in the smaller than expected output of free NA. No consistent change in the fraction of the total output represented by any of these compounds becomes evident in a comparison of the results for days 1, 7, and 10. For example, free HNA remained constant throughout at 11.2% of the total, while conjugated NA increased from 48.7 to 54% and then decreased to 49.4% on day 10, and conjugated HNA decreased from 32.9 to 28.6% on day 7 and then increased again to 32.1% on day 10. Meanwhile the per cent of the output represented by DCA varied within the narrow limits of 5.2 and 7%.

With regard to the plasma level curves for the 3 days which were studied, the following generalizations may be made.

(*a*) On the first day the levels for NA deviated considerably from the expected course. Generally the observed values were lower than the calculated, one possible reason being that as a result of the very rapid absorption-elimination kinetics of the drug, the true peak level for each individual could only have been established by multiple blood sampling at times around the expected peak. Practical considerations rendered it impossible to do this. Other contributing factors might be the small number of subjects used relative to the complexity of the pharmacokinetic model, and the fact that only one of the experimental subjects was included in the panel from which the model was derived. The last-named option was deliberate, in the hope that the results obtained on the panel would be sufficiently representative to permit a prediction of what would be observed in the general population. This hope was only partially realized in the present experiments, but in kinetic studies such as those of Engberg-Pedersen (8) and of Krüger-Thiemer and Bunger (9) the possibility of predicting plasma levels of a chemotherapeutic agent from a kinetic model has been well established.

(*b*) Also on the first day, the observed values for HNA never coincided exactly with the calculated values, although the means of the two sets of figures were about equal. In general, therefore, the expected peaks and valleys developed, but these peaks and valleys did not invariably occur at the predicted times, for reasons set forth above.

(*c*) On the seventh and tenth days of the experiment the observed values for NA followed the calculated path quite closely.

(*d*) On the seventh and tenth days of the experiment the observed values for HNA exceeded the calculated values by rather large amounts (exception: day 10, 4 hr.). This discrepancy was due in part to the fact that the daily lows for HNA were considerably higher than the calculated 0.9 mcg./ml. However, in each of the six subjects the carryover of HNA from day 9 was actually less than that from day 6, indicating that there was not a progres-

sive accumulation of the drug in the plasma. For days 7 and 10 the overnight lows for NA in the six subjects ranged from 0.1 to 1.7 mcg./ml., and those for HNA ranged from 1.6 to 12.1 mcg./ml.[4]

(*e*) HNA represented a more constant constituent of the plasma than NA. Evidence for this is the fact that at practically every low point in the NA curves, the level of HNA was higher than that of NA, and *vice versa*. Thus, following each dose of NA the ratio NA/HNA increased to a peak of about 3/1, and then gradually decreased, so that by the time the next dose was taken the ratio was less than 1. (*Note:* at the equilibrium high the calculated plasma levels for subjects of the average weight used in this study would be: NA = 25 mcg./ml.; HNA = 7.5 mcg./ml.)

SUMMARY

The absorption and elimination of nalidixic acid have been studied in subjects receiving the drug four times daily on two different dosage schedules: "after meals" and "between meals." More satisfactory and predictable results were obtained when the doses were given at least 1 hr. before meals, rather than at variable times after meals. Plasma levels and excretion patterns of nalidixic and hydroxynalidixic acids resulting from the administration of 1 Gm. of the former four times daily for 10 days followed quite closely a model derived from single-dose studies. This dosage regimen did not result in any important change in the characteristics of the absorption, excretion, or metabolism of the drug, as based on a comparison of the data for the first, seventh, and tenth days of medication. The multiple dosage regimen resulted in some carry-over of naphthyridine in the plasma from one day to another, but the carry-over did not appear invariably to increase or decrease with the number of days on medication. Sensitivity of the plasma levels to small changes in the rate constants has been shown. The inverse relationship of plasma levels and body weights suggests that dosage should be adjusted to individual body weights, with the initial adult dosage regimen being approximately 15–16 mg./Kg. four times daily.

[4] Since the number of metabolic and excretion processes involved in the over-all picture is considerable, relatively small changes in the rates of several of these could grossly alter the overnight values. For example, a 30% decrease in the mean elimination rate constant for HNA (k_{H2}) would increase the overnight low from 0.8 to 1.9 mcg./ml., and would increase the 9.5-hr. value from 7.6 to 10 mcg./ml. A 1.5-fold increase in the average rate constant for NA → HNA (k_{M1}) without a corresponding change in k_d would increase HNA 1.5 times. Such differences in rate constants have been observed (2).

Effects of the Ratio of Calcium to Potassium in the Nutrient Medium on the Growth and Alkaloid Production of *Atropa belladonna*

By STANISLAUS J. SMOLENSKI, FRANK A. CRANE, and RALPH F. VOIGT

The increase of calcium/potassium ratios in nutrient solutions reduces growth of belladonna plants. This is evident in the reduced elongation of all stems, particularly the sympodial flowering branches, and in the fresh and dry weights of all plant parts. There appears to be a concurrent increase in the proportion of leaf to total plant at the expense of stem and root. The increase in calcium/potassium ratio results in higher yields of total nitrogen and alkaloids.

THE IMPORTANCE of calcium and potassium in the nutrition of plants is well established (1–4). The authors' interest was directed to the effect of varying ratios of calcium/potassium concentration on the metabolic reactions in the alkaloid-producing plant *Atropa belladonna* L. The influence of the concentration of one of these cations on the other has been expressed in connection with: (*a*) their being bound on soil particles (5–7), (*b*) their absorption from the soil solution by roots (7), (*c*) their translocation through the plant (8), and (*d*) the rate of a number of metabolic reactions within the plant (9, 10).

Brown (11) reported that interactions involving nutrient elements may directly or indirectly affect all of the major metabolic pathways in plants and animals. The ratio of iron/phosphorus may drastically alter the ability of cells to grow by controlling oxidative mechanisms.

Effects of the Ratio of Calcium to Potassium in the Nutrient Medium on the Growth and Alkaloid Production of *Atropa belladonna*

By STANISLAUS J. SMOLENSKI, FRANK A. CRANE, and RALPH F. VOIGT

The increase of calcium/potassium ratios in nutrient solutions reduces growth of belladonna plants. This is evident in the reduced elongation of all stems, particularly the sympodial flowering branches, and in the fresh and dry weights of all plant parts. There appears to be a concurrent increase in the proportion of leaf to total plant at the expense of stem and root. The increase in calcium/potassium ratio results in higher yields of total nitrogen and alkaloids.

THE IMPORTANCE of calcium and potassium in the nutrition of plants is well established (1–4). The authors' interest was directed to the effect of varying ratios of calcium/potassium concentration on the metabolic reactions in the alkaloid-producing plant *Atropa belladonna* L. The influence of the concentration of one of these cations on the other has been expressed in connection with: (*a*) their being bound on soil particles (5–7), (*b*) their absorption from the soil solution by roots (7), (*c*) their translocation through the plant (8), and (*d*) the rate of a number of metabolic reactions within the plant (9, 10).

Brown (11) reported that interactions involving nutrient elements may directly or indirectly affect all of the major metabolic pathways in plants and animals. The ratio of iron/phosphorus may drastically alter the ability of cells to grow by controlling oxidative mechanisms.

Received August 15, 1966, from the Department of Pharmacognosy and Pharmacology, College of Pharmacy, University of Illinois, Chicago, IL 60680
Accepted for publication February 16, 1967.

Likewise, the calcium/boron ratio can markedly influence development of meristems and metabolism of sugars in all living cells.

James (12), in 1945, detailed a factorial experiment, involving additions of nitrogen, calcium, potassium, and phosphate to potted plants of belladonna. He reported that the application of nitrogen increased the total plant yield to its greatest magnitude. The addition of potassium and calcium increased the yield of alkaloids. Calcium was present at 40 Gm. of lime per plant, and potassium at 8 Gm. of potassium sulfate. This implies that a relationship of the two (Ca–K) exerted an effect on the plant in addition to that stimulated by the other nutrients.

Olsen (13) studied the effects of calcium and potassium on the growth and production of dry matter on *Sinapis* and *Hordeum* in nutrient solutions. He found the accumulation of dry weight greatest when the plants received Ca–K in a ratio of approximately 10:1.

It was the purpose of this study to determine what effects the ratios of concentrations of calcium to potassium have on the growth of the belladonna plant and its alkaloid production. In order to eliminate effects of soil binding of ions, plants were grown in nutrient solutions. Thus, concentrations of each of the ions available to the plant could be controlled.

EXPERIMENTAL

Plants and Containers—Seeds of a selected strain of *A. belladonna* were scarified by exposure to concentrated sulfuric acid for 1 min., followed by vigorous rinsing with tap water. They were then germinated in a sand–vermiculite mixture (1:1) maintained at 70°F. Germination occurred within 3 weeks. Following germination, the young seedlings were transferred to a full nutrient solution (14) for 3 weeks. They had developed 5 leaves, 2–3 cm. tall, averaging 2 Gm. fresh weight. The plants were then transferred to the experimental treatments.

Plants were grown in the greenhouse in glazed crocks which contained 12 L. of nutrient solution. The plants, which were supported on specially prepared Masonite covers, were lightly fastened by plant ties to a heavy wire frame. Four plants were grown in each of the four crocks used, making a total of 16 plants for each treatment.

Nutrient Solutions[1]—Solutions were prepared from reagent grade chemicals and distilled water on a milligram-equivalent per liter basis. All solutions contained the following ions in milligram-equivalents per liter: magnesium, 4 ml.; phosphate, 1 ml.; nitrate, 20 ml.; sulfate, 4 ml.; iron as EDTA, 1 ml.; and trace elements,[2] 1 ml. Experimental solutions contained, in addition to these, quantities of calcium and potassium in mg.-equivalents/liter, as adapted for each of the treatments.

Distilled water was added periodically to maintain the crock volumes at the same level as that at the beginning of the experiments. The pH of the solutions was adjusted weekly to 5.8 by the addition of dilute hydrochloric acid.

Nutritional Treatments—Three experiments were performed. In the first, the ratio of calcium to potassium was varied by maintaining the potassium concentration at the same level as that of the full nutrient solution. The following seven treatments were selected: Ca–K: 30:4, 20:4, 10:4, 5:4, 4:4, 2:4, and 1:4.

In the second experiment, the ratio was varied by maintaining the calcium level but by introducing a wide range of potassium concentration. The following eight treatments were chosen: Ca–K: 10:0, 10:1, 10:2, 10:4, 10:5, 10:10, 10:20, and 10:30

In the third experiment, five ratios were selected. Based on the observations of the preceding two experiments, it was found that they would support growth satisfactorily. They were, as follows: Ca–K: 1:10, 1:4, 4:10, 4:4, and 10:4.

Measurement and Sampling—Measurements of the length of the primary shoot and of the first sympodial flowering shoot were made weekly during the growth period. Plants were harvested 35 to 42 days after having been transferred to the nutrient solutions. Fresh weights of separated parts were made at harvest; dry weights were recorded after the parts were air-dried and then oven-heated at 100°C. for 1 hr.

All of the dried leaves of a single treatment were combined and made into a homogeneous powder (20 mesh). Three-gram samples of these were taken and prepared for total nitrogen (Kjeldahl) determinations. Two separate determinations were conducted, and agreed within 3%.

In order to determine the total alkaloids, the authors followed the method of Brown, Kirch, and Webster (15), which involved aliquot portions from an extract of a 10-Gm. sample. However, they modified it by utilizing only 2-Gm. sample extractions for each determination, and chromatographing the total extract.

RESULTS

Growth Responses

Shoot Elongation—(Table I)—With an increase of the calcium/potassium ratio, there was a progressive reduction of primary shoot length. In experiment *A*, the growth of plants was greatest at the lowest ratios of Ca–K: 1:4 and 2:4. In experiment *B*, ratios of 10:20 and 10:4 produced optimum growth. In experiment *C*, selected ratios of 1:10 and 1:4 resulted in the best growth. Otherwise, fairly uniform growth was observed.

Sympodial Flowering Branches—(Table I)—Differences in elongation of the sympodial flowering branches were of greater magnitude than those of the primary shoot, with the greatest elongation occurring at the intermediate ratio of 5:4 in experiment *A*.

[1] These nutrient solutions were prepared from gram-equivalent stock solutions of the following salts: calcium nitrate, potassium nitrate, potassium acid phosphate (Sorensen's), magnesium sulfate, and iron ethylenediaminetetraacetate. The final solutions were made by adding 1.0 ml. of the stock solution per liter to a large volume of distilled water, and then filling each crock to the desired level with distilled water.

[2] The trace elements were prepared according to the Hoagland and Arnon (14) formula and added weekly.

In experiment *B*, due to the low potassium concentration (1 or 2 mg. equivalent/liter), the growth of the sympodial flowering branches was not so great as that of the primary shoot.

TABLE I—EFFECT OF CALCIUM/POTASSIUM RATIOS ON SHOOT LENGTH IN THE NUTRIENT MEDIUM

Expt.	Ratio Ca:K	Length of Main Erect Primary Stem, cm.	Length of First Sympodial Flowering Branch, cm.
A[a]	1:4	61.5[b] ± 1.7[c]	63.4[b] ± 9.1[c]
	2:4	60.9 ± 2.2	86.4 ± 16.7

	5:4	57.6 ± 4.3	94.6 ± 8.4
	10:4	54.6 ± 1.6	93.3 ± 8.8
	20:4	53.7 ± 1.7	69.3 ± 11.7
	30:4	49.5 ± 2.4	65.6 ± 9.6
B[d]	10:30	55.4 ± 6.0	39.3 ± 6.2
	10:20	61.5 ± 4.8	39.6 ± 9.7
	10:10	60.8 ± 3.0	43.3 ± 10.3
	10:5	61.5 ± 6.3	54.4 ± 7.3
	10:4	62.0 ± 2.3	53.7 ± 12.5
	10:2	57.5 ± 2.6	59.5 ± 15.2
	10:1	54.5 ± 1.7	34.0 ± 9.1
	10:0	22.3 ± 3.4	...
C[e]	1:10	54.2 ± 1.6	48.2 ± 5.9
	1:4	53.6 ± 1.3	43.1 ± 7.0
	4:10	51.7 ± 2.2	52.3 ± 11.0
	4:4	50.2 ± 1.6	44.4 ± 7.6
	10:4	51.4 ± 1.6	32.0 ± 5.8

[a] Experiment *A*, 6 weeks of growth. [b] Shoot lengths are mean of 16 plants. [c] Standard error of the mean. [d] Experiment *B*, 5 weeks of growth. [e] Experiment *C*, selected ratios.

In experiment *C*, the length of the sympodial flowering branches at the intermediate ratio of Ca–K 4:10 was significantly greater than the others ($p = 0.001$).

Fresh Weight—(Table II)—Increase of the Ca–K ratio resulted in decreased growth as measured by fresh weight of leaves, stems, and total plant at harvest. This was especially noted in experiment *C*, when selected ratios were used.

Fresh weights of roots appeared to be less responsive to the effect of this environmental ratio. The heaviest root systems were obtained at the intermediate ratios.

Dry Weight—(Table III)—In experiment *C*, increased Ca–K ratios produced less reduction in dry weights than was observed in fresh weights. On a percentage basis, the decrease in dry weights and in fresh weights was essentially the same.

Ratios of Plant Parts to Each Other—Increase in the Ca–K ratio resulted in a greater proportion of leaf to total plant with a corresponding decrease in stem. The ratio of shoot to root increased slightly, but none of the results were statistically significant.

Total Nitrogen (Kjeldahl) of Leaves—(Table IV)—Increase of the ratio of calcium/potassium resulted in a distinct rise in the total nitrogen content in the leaves of the plant, except in the case of the lowest ratio, 1:10. This increased amount of nitrogen per gram of dry tissue was in direct contrast

to the amount of growth obtained with the same ratios.

Total Alkaloids—(Table IV)—The pattern of alkaloid yield in general followed that of the total nitrogen synthesized in leaves. The 1:10 ratio revealed an alkaloid yield similar to that of the 10:4. It should be noted that on a mg./Gm. dry weight basis, the amount of alkaloids at the lowest ratio was similar to that produced at the highest ratio.

DISCUSSION

The use of nutrient solutions for growing plants for this type of study is advantageous. It eliminates the problem of binding of solute ions on soil particles which affects their availability to the plant. Soluble salts were used in this work because absorption of calcium by roots in the soil is slower than that of potassium. Except where noted, ratios were unreasonably low in calcium or potassium ions. No morphological deficiency symptoms were observed in any of the plants.

The upper sympodial flowering shoots were more responsive to the different nutrient treatments than were the main primary shoots. This might be partially explained on the basis that the primary shoot had already begun its elongation pattern at the beginning of the experimental treatment, whereas the sympodial branches had not yet been initiated. However, many experimental treatments were so drastic that the few centimeters of shoot length at the beginning of an experiment were not significant, considering the results. Lack of responsiveness of the main primary shoot would then indicate a certain inherent genetic quality which to a large extent operated independently of environmental nutritional stimuli. By the time sympodial branches were in the process of developing, growth had been more profoundly influenced by the nutritional supply.

Elongation of both primary and secondary stems appeared to be somewhat retarded by increased ratios of calcium/potassium. Percentage increases which occurred in the second, third, and fourth weekly measurements were greater at the higher ratios. This is in contrast to the general tendency of the shoot which would normally approach its maximum length at progressively slower rates.

Effects attributed to the ratio of concentrations might be considered in terms of one of the following: (*a*) the result of the calcium concentration irrespective of the potassium concentration, or *vice versa;* (*b*) the difference between hydration of the tissue at the lower ratios, or less hydration and more woodiness at higher ratios; or (*c*) the result of total concentration of solutes in the solution.

In experiment *A* when plants were grown at varying calcium concentrations but with potassium constant, the differences in succulence *versus* woodiness were not apparent even at high concentrations of calcium. Likewise in experiment *B*, where the potassium concentration was varied, differences in succulence were not apparent. This indicated that the effect was due to the ratio of these ions to each other, rather than to either ion by itself.

When considering the water content in the tissue, the total range from the lowest to the highest ratio indicated a variation of less than 0.5%. Likewise, the effect of total ion concentration on hydration of the tissue resulted in a difference of 0.6% between the lowest and the highest ratios of calcium/potassium.

Except for the samples determined at the lowest ratio (Ca–K 1:10), the total nitrogen and the alkaloids present in the leaves of the plants resulted in a higher yield, as the ratio of calcium/potassium increased. Because the results of determinations were surprisingly high at the low ratio, they were redetermined and verified. High percentages of nitrogen and total alkaloids were also found by Schermeister in work done in this laboratory (16).

Ratios of leaf to stem, and shoot to root, showed that higher calcium/potassium ratios favored leaf development and decreasing stem. They also tended to favor shoot over root. The smaller plant at the higher calcium/potassium ratio produced more leaf or photosynthetic material, and less stem and root structure.

CONCLUSIONS AND SUMMARY

Growth of belladonna is affected by the ratio of calcium to potassium in the nutrient medium. Production of all plant parts is reduced as the ratio of calcium/potassium is increased. Reduced elongation occurred in the sympodial flowering shoots to a more marked extent than in the primary erect stems. Fresh and dry weights of all plant parts were lower as the ratio increased.

As the calcium/potassium ratio increased, the yield of total nitrogen and alkaloids was higher. There was one exception: the 1:10 ratio.

Tumor Inhibitors XXI

Active Principles of *Acer negundo* and *Cyclamen persicum*

By S. MORRIS KUPCHAN, RICHARD J. HEMINGWAY, JOHN R. KNOX, STANLEY J. BARBOUTIS, DIETER WERNER, and MAUREEN A. BARBOUTIS

An alcoholic extract of leaves and stems of *Acer negundo* L. was found to show significant inhibitory activity against sarcoma 180 in mice. Systematic fractionation of the extract led to concentration of the activity and separation of two chromatographically homogeneous active acidic saponin fractions. One of the latter saponin fractions also showed significant inhibitory activity against the Walker intramuscular carcinosarcoma 256 tumor in rats. An alcoholic extract of the tubers of *Cyclamen persicum* Mill. was found to show significant inhibitory activity when tested *in vitro* against cells derived from human carcinoma of the nasopharynx (KB). Systematic fractionation led to separation of a chromatographically homogeneous saponin fraction with significant inhibitory activity against the Walker 256 tumor in rats. Preliminary characterization of the active saponin fractions is described.

In the course of the continuing search for tumor inhibitors from plant sources, an alcoholic extract of *Acer negundo* L.[1] (*Aceraceae*) was found to show significant inhibitory activity against sarcoma 180 in mice,[2] and an alcoholic extract of *Cyclamen persicum* Mill.[3] (*Primulaceae*) was found to show significant cytotoxic activity when tested *in vitro* against cells derived from human carcinoma of the nasopharynx (KB).[2] The present report describes the systematic fractionation and the isolation and preliminary chemical characterization of growth-inhibitory saponin fractions from each extract. The observations confirm and extend earlier reports of the tumor-inhibitory (1, 2) and cytotoxic (3) activity of saponins.

The fractionation of the alcoholic extract of *Acer negundo* is summarized in Schemes I and II. Fraction H material, dissolved in 10% methanol in chloroform, was subjected to chromatography on adsorbent magnesium silicate,[4] and the active fractions from this column were further purified on silicic acid columns, to yield two one-spot but noncrystalline acidic saponin materials. Attempts to further purify these materials by chromatography and countercurrent distribution were unsuccessful.

The *in vivo* assay data for fractions obtained in a typical experiment are reported in Table I. The evaluation of assay results by the CCNSC on a statistical basis in sequential testing is such that a material is considered active if it causes reduction of tumor weight to 42% or less.[2] The inhibitory activity of fraction P against the Walker carcinosarcoma 256 tumor in rats over a wide dosage range is noteworthy.

The preliminary fractionation of the alcoholic extract of *Cyclamen persicum* is summarized in Scheme III. Fraction X material dissolved in 10% methanol in chloroform was subjected to chromatography on silicic acid columns, to yield a one-spot but noncrystalline saponin material. Attempts to further purify this material by chromatography and countercurrent distribution were unsuccessful.

The cytotoxicity data are reported in Table II. Evaluation of the tissue culture assay results by the CCNSC is such that a material is considered active if the ED_{50} (dose inhibiting growth to 50% of control growth) equals or is less than 4 mcg./ml.[2] The Walker 256 assay data for fraction E′ are reported in Table III. It is noteworthy that the homogeneous saponin fraction E′ showed significant inhibitory activity against the Walker 256 tumor system *in vivo*, even though the cytotoxicity against KB cells was not marked; no explanation is readily apparent.

EXPERIMENTAL

Melting points were determined on a Hoover Uni-Melt melting point apparatus and were corrected. Infrared spectra were determined in chloroform solution on a Beckman IR5A infrared spectrophotometer. Specific rotations were measured on a Zeiss-

Scheme I

Winkel polarimeter. The petroleum ether used was Skellysolve B (b.p. 60–68°). Diatomaceous earth[5] was used for chromatography.

Extraction and Preliminary Fractionation of A. negundo—Coarsely ground leaves and twigs of *A. negundo* (2.8 Kg.) were twice extracted continuously with 95% ethanol for 5 hr., and the ethanol extract was concentrated under water pump pressure to a thick dark syrup (A, 370 Gm.). A portion of the extract (23.26 Gm.) was partitioned between petroleum ether (600 ml.) and 10% aqueous methanol (400 ml.); the petroleum ether solution and one seventh of the 10% aqueous methanol layer were evaporated under reduced pressure (B, 3.27 Gm., and C, 2.06 Gm., respectively). The remaining 10% aqueous methanol layer was treated with a methanol solution of neutral lead acetate (25% w/v) to complete precipitation. The precipitate was removed by centrifuging and washed with a little methanol before suspending in methanol and bubbling in hydrogen sulfide. The lead sulfide was filtered after precipitation had been completed, and the filtrate was concentrated to dryness under reduced pressure (D, 3.39 Gm.). The supernatant liquid from lead acetate precipitation was also treated with hydrogen sulfide, filtered, and evaporated (E, 6.08 Gm.). The material not precipitated by neutral lead acetate (after removal of an assay sample) was partitioned between water (30 ml.) and ethyl acetate (150 ml.) and the aqueous layer continuously extracted for 20 hr. with ethyl acetate. The two layers were concentrated under reduced pressure (F, 3.50 Gm., and G, 1.84 Gm., respectively).

A larger batch of fraction G (245 Gm.) was prepared from the crude extract (1450 Gm.) and a portion (170 Gm.) was dissolved in methanol (1500 ml.) and treated with a saturated methanolic solution of basic lead acetate to complete precipitation. The precipitate was removed by centrifugation and washed with a little methanol before suspending in methanol (1400 ml.) and bubbling in hydrogen sulfide. The lead sulfide was filtered after precipitation had been completed, and the filtrate was evaporated (H, 58.53 Gm.). The supernatant liquid from basic lead acetate precipitation was also treated with hydrogen sulfide, filtered, and evaporated (I, 69.59 Gm.).

Chromatography of Active Fraction H—Trial chromatographies on adsorbent magnesium silicate and silicic acid indicated that two materials giving

Flow Sheet for Final Fractionation and Chromatography of Active Principles of A. negundo *L.*

Scheme II

a brown color with 3% ceric sulfate in 3 *N* sulfuric acid were responsible for the activity of fraction H.

Fraction H (58.53 Gm.) was dissolved in methanol (100 ml.) and diluted with chloroform (900 ml.). The solubles (51.43 Gm.) were added to a column of acid-washed adsorbent magnesium silicate (3 Kg.) in chloroform. The material was eluted with 10% methanol in chloroform, and fractions were collected and examined by thin-layer chromatography on Silica Gel G using ethyl acetate–acetic acid–water (3:1:3) upper phase as developing solvent and ceric sulfate spray reagent. Fraction J (13.31 Gm.) was eluted before the first active material. Fraction K (4.29 Gm.) contained the first active material. Fraction L (1.18 Gm.) contained a mixture of the two active materials. Fraction M (3.97 Gm.) contained the second active material. The solvent was changed to 20% methanol in chloroform, fraction N (2.97 Gm.) was collected, and the remaining material was finally removed with methanol (O, 24.32 Gm.).

Fraction K (4.28 Gm.), dissolved in 25 ml. of 25% methanol in chloroform, was added to a column of silicic acid–diatomaceous earth (3:1, 800 Gm.) and the column was eluted with 7% methanol in chloroform (2.5 L.). The solvent was changed to 10% methanol in chloroform (12 L.), and fractions were collected and examined by TLC, using ethyl acetate–acetic acid–water (3:1:3) upper phase as solvent, and ceric sulfate as spray reagent. The fractions richest in the first active material were combined (P, 1.56 Gm.). Elution was continued with 20% methanol in chloroform (2 L.) and the remaining material was finally removed with methanol. Fraction P accounted for the activity of fraction K, and was essentially one-spot material on TLC.

Fraction M (3.9 Gm.), dissolved in 25 ml. of 25% methanol in chloroform, was added to a column of silicic acid–diatomaceous earth (3:1, 750 Gm.) and the column was eluted with 8.5% methanol in chloroform (2 L.). The solvent was changed to 10% methanol in chloroform (9 L.), fractions were collected and examined by TLC using ethyl acetate–acetic acid–water (3:1:3) upper phase as solvent, and ceric sulfate as spray reagent. The fractions richest in the second active material were combined (Q, 1.41 Gm.). Elution was continued with 20% methanol in chloroform (2 L.) and the remaining material was removed with methanol. Fraction Q accounted for the activity of the fraction M, and was one-spot material on TLC.

Fractions P and Q were also tested against Walker carcinosarcoma 256 (see Table II); only fraction P showed activity.

Fraction P was a yellow powder, m.p. 198–205° dec., $[\alpha]_D^{28} = +28.5°$ (c 1.79, MeOH).

Fraction Q was a beige powder, m.p. 230–237° dec., $[\alpha]_D^{27} = +8.6°$ (c 1.45, MeOH).

The acidic nature of fractions P and Q was indicated by their solubility properties. Both were readily soluble in dilute aqueous sodium bicarbonate, from which they were precipitated upon acidification with dilute hydrochloric acid.

Extraction and Preliminary Fractionation of C. persicum—Coarsely ground tubers of *C. persicum* (500 Gm.) were twice extracted continuously with 95% ethanol for 5 hr., and the ethanol extract was concentrated under water pump pressure to a brown resinous solid (R, 175 Gm.). A portion of the extract (60 Gm.) was partitioned between *n*-butanol (1 L.) and water (500 ml.), and the two solutions were evaporated separately under reduced pressure (S, 45.76 Gm., and T, 13.10 Gm., respectively). The *n*-butanol extract was further partitioned between

petroleum ether (1 L.) and 10% aqueous methanol (500 ml.), and the petroleum ether solution and one twenty-fifth part of the 10% aqueous methanol were evaporated under reduced pressure (U, 2.69 Gm., and V, 1.47 Gm., respectively). The remaining 10% aqueous methanol layer was treated with a saturated

Chromatography of Active Fraction X—Fraction X (6.0 Gm.) dissolved in methanol (20 ml.) was diluted with chloroform (180 ml.) and the solution was introduced onto a column of silicic acid (600 Gm.) in chloroform. The column was eluted with 10% methanol in chloroform until the yellow bands were eluted (fraction Y, 472 mg.). The solvent was changed to 20% methanol in chloroform, and fractions were collected and examined by thin-layer chromatography on Silica Gel G using 50% methanol in chloroform as solvent and ceric sulfate as spray reagent. Fraction Z (607 mg.) was eluted before a one-spot active material. Fraction A′ (933 mg.) contained the one-spot active material and fraction B′ (1.77 Gm.) was eluted after the active material. The solvent was changed to 30% methanol in chloroform, when fraction C′ (1.09 Gm.) was eluted. The remaining material was removed with 50% methanol in chloroform, to yield fraction D′ (929 mg.).

TABLE III—ACTIVITY OF THE ACTIVE FRACTION FROM *C. persicum* MILL. AGAINST THE WALKER INTRAMUSCULAR CARCINOSARCOMA 256

Fraction	Dose, mg./Kg.	Survivors	Animal Wt. Change, Gm. Diff. (T-C)	Tumor Wt., mg. (Test/Control)	T/C × 100
E′	50	2/4	−14	1400/7400	Toxic
	40	4/4	−11	1900/7100	26%
	30	4/4	−7	4400/7100	61%

A larger batch of fraction A′ (9.67 Gm.), prepared from crude extract (84 Gm.), was dissolved in 5% methanol in chloroform (400 ml.) and introduced onto a column of silicic acid (1 Kg.) in chloroform. The column was eluted with 5% methanol in chloroform (4 L.), 7% methanol in chloroform (6 L.), and with 10% methanol in chloroform (10 L.), to yield fractions which were examined by TLC as before. The fractions richest in the one-spot active material were combined (E′, 4.84 Gm.) and tested in the Walker carcinosarcoma 256 assay (see Table III).

Fraction E′ was a white amorphous powder, (m.p. 229–233°); $[\alpha]_D^{28}$ = +0.8° (c 1.20 MeOH), I.R. (Nujol) 3.04 μ, 5.81 μ, 6.10 μ.

Determination of the Hemolytic Index of Fractions P, Q, and E′—The determination was performed by the method outlined in the Swiss Pharmacopoea (4) using a 1:20 dilution of blood with normal saline and Fisher standard saponin as reference. Using these conditions, fraction P had a hemolytic index of 0.8; fraction Q, 0.5; and fraction E′, 316; with reference to standard saponin at 100. Hence the *Acer negundo* active principles have low hemolytic activity.

Test for the Glycosidic Nature of Fractions P, Q, and E′—Fractions P, Q, and E′ (5 mg. of each, separately), when heated for 2 min. with a 0.5% aqueous solution of triphenyltetrazolium chloride (2 drops) and 0.5 *N* sodium hydroxide (1 drop), gave no pink color or precipitate.

Further 5 mg. portions of fractions P, Q, and E′ were hydrolyzed by refluxing for 30 min. with 0.5 *N* hydrochloric acid in 50% aqueous alcohol (0.2 ml). Each hydrolyzate was neutralized and the triphenyltetrazolium chloride test performed. The deep red solutions and red precipitates indicated the presence of reducing sugars in each of the hydrolyzates (5).

Molecular Orbital Calculations on Sulfonamide Molecules

By E. C. FOERNZLER* and A. N. MARTIN†

The LCAO-MO method has been used to compute the electronic characteristics for a series of 50 sulfonamide derivatives. The results of the calculations have been compared with experimental parameters through correlation with pKa. For those compounds where the substituent R group was an alternate ring, the correlation of pKa and the electronic charge at the ionizing (N^1) nitrogen atom was considered significant. However, it was necessary to classify the compounds by type of R group, plotting each class separately. The simple Hückel MO treatment was inadequate for those molecules where the substituent R group attached to the N^1 nitrogen atom was a nonalternate ring or a straight chain.

IN RECENT YEARS it has become possible to study the electronic structure of large organic molecules by using the principles of quantum mechanics. This field is known as quantum chemistry, and when applied to molecules of biological interest, has been called quantum biology or quantum biochemistry (1–4). The molecular orbital (MO) method, involving a linear combination of atomic orbitals (LCAO), is ordinarily used for calculating the energies of the π or delocalized electrons in a molecule, and the abbreviation LCAO-MO is used to designate this type of calculation. In this study, a modification of the LCAO-MO method, the simple Hückel molecular orbital (HMO) approximation (3–6), has been employed.

Actually, the reactivity of drug molecules should be discussed in terms of their dynamic

Determination of the Hemolytic Index of Fractions P, Q, and E′—The determination was performed by the method outlined in the Swiss Pharmacopoea (4) using a 1:20 dilution of blood with normal saline and Fisher standard saponin as reference. Using these conditions, fraction P had a hemolytic index of 0.8; fraction Q, 0.5; and fraction E′, 316; with reference to standard saponin at 100. Hence the *Acer negundo* active principles have low hemolytic activity.

Test for the Glycosidic Nature of Fractions P, Q, and E′—Fractions P, Q, and E′ (5 mg. of each, separately), when heated for 2 min. with a 0.5% aqueous solution of triphenyltetrazolium chloride (2 drops) and 0.5 *N* sodium hydroxide (1 drop), gave no pink color or precipitate.

Further 5 mg. portions of fractions P, Q, and E′ were hydrolyzed by refluxing for 30 min. with 0.5 *N* hydrochloric acid in 50% aqueous alcohol (0.2 ml). Each hydrolyzate was neutralized and the triphenyltetrazolium chloride test performed. The deep red solutions and red precipitates indicated the presence of reducing sugars in each of the hydrolyzates (5).

Molecular Orbital Calculations on Sulfonamide Molecules

By E. C. FOERNZLER* and A. N. MARTIN†

The LCAO-MO method has been used to compute the electronic characteristics for a series of 50 sulfonamide derivatives. The results of the calculations have been compared with experimental parameters through correlation with pKa. For those compounds where the substituent R group was an alternate ring, the correlation of pKa and the electronic charge at the ionizing (N^1) nitrogen atom was considered significant. However, it was necessary to classify the compounds by type of R group, plotting each class separately. The simple Hückel MO treatment was inadequate for those molecules where the substituent R group attached to the N^1 nitrogen atom was a nonalternate ring or a straight chain.

IN RECENT YEARS it has become possible to study the electronic structure of large organic molecules by using the principles of quantum mechanics. This field is known as quantum chemistry, and when applied to molecules of biological interest, has been called quantum biology or quantum biochemistry (1–4). The molecular orbital (MO) method, involving a linear combination of atomic orbitals (LCAO), is ordinarily used for calculating the energies of the π or delocalized electrons in a molecule, and the abbreviation LCAO-MO is used to designate this type of calculation. In this study, a modification of the LCAO-MO method, the simple Hückel molecular orbital (HMO) approximation (3–6), has been employed.

Actually, the reactivity of drug molecules should be discussed in terms of their dynamic

behavior in going into a transition state along with a specific receptor or reagent (7). However, where such an approach is either impossible or too complex, useful information may be obtained by considering various static properties of the molecules, such as the electronic charge densities relative to the total π or mobile electron systems of the molecules in their ground states. Calculation of the distribution of electronic charge indicates the average density of mobile electrons present on different atoms in the molecule. The higher the calculated charge, the greater the π electron density associated with a particular atom. It is also possible to compute bond orders, free valence, and the relative values of the highest occupied (homo) and lowest empty (lemo) molecular orbitals. This information, together with other chemical knowledge may be useful for predicting various physical-chemical properties and even biological activities of drug molecules.

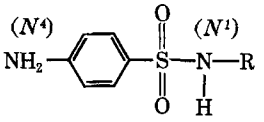
During the past two and one-half decades, a number of theories have been advanced on the mechanism of sulfonamide action. Bell and Roblin (8), Kumler and associates (9–11), Klotz and Bordwell (12–13), and Krüger-Thiemer *et al.* (14) have proposed possible modes of action. Although these theories present different explanations of the mechanism of sulfonamide action, they are all based on the original suggestion of Woods (15) and Fildes (16) that the sulfonamides interfere with the utilization of *p*-aminobenzoic acid in enzyme systems through competitive enzyme inhibition.

In this study the authors have computed the electronic charge densities for 50 sulfonamide compounds. The results of the computations have allowed an examination of the utility of HMO calculations applied to complex drug molecules, and have resulted in additional knowledge which may be useful for further elucidating the mechanism of sulfonamide action.

TREATMENT OF SULFONAMIDE MOLECULES

Compounds Studied—The 50 sulfonamide molecules selected for the calculations were those studied by Bell and Roblin (8). These molecules are all N^1-substituted sulfanilamide type compounds of the general structure I, and are listed in Table I according to nomenclature and numbering used by Bell and Roblin. The chemical structures of these compounds are given in a text by Northey (17). The experimental data, including the acid dissociation constants and the *in vitro* activities, C_R, were taken from the published results of Bell and Roblin.

The activity index, C_R, in Table I represents the minimum molar concentration of drug necessary to cause bacteriostasis of *E. coli* in a buffered (pH 7) synthetic medium under standardized conditions. The smaller the number, the greater the activity. As pointed out by Bell and Roblin, it is difficult to obtain a high degree of precision in such tests and small differences in bacteriostatic activity (a factor of 2) are within experimental error.



I

Sulfanilamide type compounds are weak acids because the amide (N^1) nitrogen atom of these molecules is sufficiently negative in solution to liberate a proton. Due to their high electronegativity, the oxygen atoms of the sulfonyl (SO_2) group greatly attract electrons. The resulting electron deficiency of the sulfur atom results in the electrons of the N:H bond being held more closely to the nitrogen atom. The hydrogen, therefore, is bound less firmly and readily ionizes to liberate a proton in solution. In addition to the acid dissociation constants, Bell and Roblin also measured the basic dissociation constants which are due to the ionization of the *p*-amino group or amino (N^4) nitrogen atom. These values were found to be approximately constant [$(0.5–2.3) \times 10^{-12}$]. A striking difference was thus observed between the acid and basic dissociation constants.

The R group is the only variable involved in the N^1-substituted sulfonamide derivatives, and it must be the factor controlling the acid dissociation constants of these compounds (8). In other words, the greater the electronegativity of the R group, the more R attracts electrons from the adjacent amide (N^1) nitrogen so that the hydrogen escapes more easily as a proton in solution leaving the anion form of the molecule. However, according to Bell and Roblin, as the electron-attracting power of different R groups increases, the SO_2 group should become less negative (thereby decreasing activity), because under these conditions a greater part of the ionic charge of the amide (N^1) nitrogen will be taken by the R group which will be competing more strongly with the SO_2 group for the ionic charge. As the SO_2 group becomes less negative, its ion should be less active than an ion whose R group is a weaker electron-attracting group. Similar conclusions are obtained by applying the same reasoning to the molecular form.

By calculating the electronic charge densities of the sulfanilamide type compounds, we would expect to find a relationship between the pKa and the electronic charge at the ionizing (N^1) nitrogen atom. The relationship of pKa to electronic charge has been discussed by Daudel *et al.* (3, 18–20), Longuet-Higgins (21), the Pullmans (22–24), and others (25).

Calculations—The linear combination of atomic orbitals-molecular orbital (LCAO-MO) method was employed for the calculations, using the Hückel molecular orbital (HMO) approximation with neglect of overlap (3–6). For the heteroatom (or substituent group) X, the Coulomb integral (α_X) and resonance or bond integral (β_{CX}) were given the usual forms shown in Eqs. 1 and 2:

$$\alpha_X = \alpha_C + \delta_X\beta_{CC} \qquad \text{(Eq. 1)}$$

[a] S = Sulfanilamido.

$$\beta_{CX} = \eta_{CX}\beta_{CC} \qquad \text{(Eq. 2)}$$

where δ_X (heteroatom Coulomb integral coefficient) and η_{CX} (heteroatom bond integral coefficient) are the adjustable, semiempirical parameters of the HMO treatment. The δ and η values used in this study were similar to those which have been suggested by the Pullmans (24). A complete listing of these parameters is given in Table II.

For each molecule, the appropriate δ_X and η_{CX} values must be selected. The HMO matrix (A) must then be set up and solved for the eigenvalues and eigenvectors. The electronic charges may then be computed from the coefficients contained in the eigenvectors. Although a number of different procedures may be employed to manipulate such matrices, the most reasonable approach for large molecules as those studied here is through the use of a digital computer. To solve the matrices on a computer, a program is required which will determine the eigenvalues (x) and eigenvectors (v) of a real symmetric matrix (A) for an eigenvalue problem which has the form $Av = xv$ (26). Initial calculations were made using a Jacobi routine (27) and an IBM 1620 computer. However, this method was too slow, and the procedure was changed to a modified Givens routine (28) written for an IBM 7090. In this case a subroutine for the Gram-Schmidt orthogonalization procedure (29) was added to the main program in order to insure an orthonormal basis for the eigenvectors computed by the Givens method. A second subroutine was also added to the main program which computed the electronic charges directly according to Eq. 3, thereby eliminating most of the hand computations. In Eq. 3, q_J is the electronic charge density of atom J,

$$q_J = \sum_{i=1}^{n} e_i c_{iJ}^2 \qquad \text{(Eq. 3)}$$

and c_{iJ} is the LCAO coefficient of atom J in the i^{th} molecular orbital which is occupied by e_i electrons. The sum is taken over all molecular orbitals, $i = 1, 2, \ldots, n$, however, only the occupied MO's contribute to the charge, since for the unoccupied orbitals, $e_i = 0$. For the HMO matrix, A, the roots (x) of the characteristic equation of A, *i.e.*, $|A - xI| = 0$, were obtained in the form shown in Eq. 4, where E_i is the energy level of the i^{th} molecular orbital, α is the Coulomb integral, β is the resonance integral, and x_i is the molecular orbital energy coefficient of the i^{th} MO.

$$E_i = \alpha + x_i\beta \text{ or } x_i = \frac{\alpha - E_i}{\beta} \qquad \text{(Eq. 4)}$$

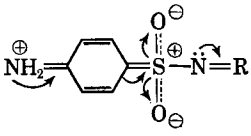
The molecular form of the sulfonamide molecules was used as a model for the LCAO-MO calculations.[1] In order to consider the lone pair of electrons at the N^1 nitrogen atom as part of the mobile electron system, the resonance structure (II) was assumed.



II

The number of molecular orbitals and the number of π electrons considered for each molecule are given in Table III. The HMO matrix A for any particular compound listed in Table I may be set up by referring to Northey (17) for the structure of the R group, by allocating to the molecule the number of π electrons shown in Table III, and by using the δ and η values given in Table II. An example of the HMO matrix is given in Table IV for sulfapyridine (sulfa No. *15*). The numbering of the rows and columns in the matrix corresponds to the numbering of the atoms shown in structure III.[2] All other molecules were treated in the same manner as the sulfapyridine example, with exception of the δ and η values for the R groups. The δ and η values for the sulfanilamido part of the molecule in each case were the same as those given for the sulfapyridine example, that is, up to and including δ_{11} and η_{11-12}.

Results—The results of the LCAO-MO calculations on 30 of the sulfonamides studied are given in Table V. The tabulation includes the electronic charges at the amide nitrogen (q_{N1}), the *p*-amino nitrogen (q_{N4}), the SO_2 group oxygen atoms (q_{oxy}), and the sulfur atom (q_S). The formal π charges at these atoms may be computed by subtracting the tabulated electronic charges (the q's) from 2, 2, 1, and 2, respectively, according to Eq. 5, where f_J denotes the net or formal charge on atom J, atom J contributing e_J π electrons to the π electron pool.

[1] Calculations on the ionic forms did not differ appreciably from the molecular forms, and the authors were not able to improve the correlations by accounting for the ionic species in the calculations. Also, the omega technique (5, 30) was used for another series of compounds; however, it did not change the results significantly. The authors have found more success in accounting for ionic forms by moderately adjusting the δx parameter rather than by using the iterative process of the omega method.

[2] The *d*-orbitals of sulfur have been neglected. There is some controversy in the literature about the contribution of these orbitals (34). However, an article by Cammarata [*J. Pharm. Sci.*, **55**, 1469(1966)] suggests that if the effects of the *d*-orbital overlap are taken into account (using $\delta x = -2.60$ and $\beta CX = 0.99$ for the entire SO_2 group), small variations in the electronic charge at the *p*-amino position of the sulfonamides could be noted.

$$f_J = (e_J - q_J) \qquad \text{(Eq. 5)}$$

The results of the MO calculations on the sulfanilamide type compounds generally agree with chemical facts. In terms of the formal charge for sulfanilamide, for example (sulfa No. *2*), the electronic configuration shown in structure IV is found. The results indicate: (*a*) a deficiency (+) of π electrons at the *p*-amino group due to the fact that this group has donated its electrons to the adjacent benzene ring; (*b*) that due to their high electronegativity, the sulfonyl oxygen atoms have withdrawn electrons from the sulfur atom and also from the N^1 nitrogen atom, resulting in an excess (−) of electrons at these atoms; and (*c*) that the N^1 nitrogen atom is deficient (+) in π charge with

respect to its original contribution of 2π electrons to the π electron pool.

Now looking at the derivative whose R group is a phenyl radical, N^1-phenylsulfanilamide (sulfa No. 7) (V), the results change accordingly. In this case, the electronegative phenyl group as well as the SO_2 group oxygen atoms withdraw electrons from the sulfanilamide system. A much greater deficiency of π charge results at the N^1 nitrogen atom. The phenyl group has also reduced the charge on the oxygen atoms, further indicating its effect as an electron acceptor.

An even greater deficiency of π charge results at the N^1 nitrogen atom where the R group is pyridine with the pyridine nitrogen at the *ortho* position in sulfapyridine (sulfa No. *15*) (VI). The greater electronegativity of this R group is thereby accounted for. A still greater change occurs for sulfadiazine (sulfa No. *23*) (VII). The excess π charge at the oxygen atoms reacts accordingly when these atoms as well as the electronegative R group compete for the available delocalized electrons. For the compound 5-sulfanilamidopyrimidine (sulfa No. *28*) (VIII), the electron attracting effect of the R group is less than that for sulfadiazine, apparently because the electronegative nitrogen atoms in this substituent group are further removed from the point of attachment at the N^1 nitrogen.

Table V also shows that for all of the sulfonamide derivatives studied, the electronic charge at the N^4 nitrogen atom is constant, $q_{N^4} = 1.848$ (formal π charge $= +0.152$). Although this group seems to be necessary for biological activity, it appears that no correlation exists between the degree of activity and the electronic charge density calculated by the HMO method for this position of the compounds studied. This seems to agree with Bell and Roblin's finding of constant basic dissociation; however, it is possible that differences in the charges at the N^4 nitrogen atom of various sulfonamide derivatives would become evident if a more refined method of calculation were established.[2]

CORRELATION AND DISCUSSION OF RESULTS

A plot of pKa *versus* the electronic charge at the ionizing N^1 nitrogen atom (q_{N^1}) for the 50 sulfanilamide type compounds indicated considerable scatter. The correlation expected in this case would be a linear relationship between pKa and q_{N^1}. The scatter was due, at least in part, to the effect of solvation energy which was not included in the calculations. More important, however, is the fact that the R groups of the 50 sulfonamide derivatives are of widely varying types, such as alternate rings, nonalternate rings, rings with and without substituent groups, and straight chains with and without heteroatoms. The correlation of pKa and electronic charge depends upon whether certain partition functions cancel (3, 19, 20). If this is not the case, the relationship may be much less direct, especially in the case of changing molecular skeletons. Also, the Hückel approximation does not provide equally good results in all of these cases. It is known, for instance, that the simple Hückel treatment gives a better account of alternate than nonalternate hydrocarbons because in the latter case the presence of a nonself-consistent field really requires that the Coulomb integral of each atom be corrected for the charges on neighboring atoms (3, 4). Also, the treatment of straight chains requiring the use of hyperconjugation is often less reliable. The R groups of those compounds which were poorly accounted for by the simple Hückel method were all of the nonalternate or straight chain types (types *D*, *E*, and *F* as defined below), and hence, less reliable results were to be expected in these cases.

In order to examine the relationship between pKa and electronic charge in more detail, the 50 sulfonamide derivatives were classified into groups dependent on the type of substituent R group attached to the N^1 nitrogen atom. The classes are given in Table VI. Following this classification, individual plots were constructed for each type of R group. The results are shown in Figs. 1–3, for the *A*, *B*, and *C* type substituents. Accordingly, the categorization by the type of R group seems to be an important factor in explaining the correlation of

the pKa–electronic charge relationship. The results illustrate that if one anticipates using the electronic charge at the ionizing atom of sulfanilamide type compounds (or similarly complex drug molecules) for theoretically predicting pKa, it will probably be necessary to employ a more exact treatment in the cases of nonalternate R groups and hyperconjugation than the simple Hückel approximation. Procedures for the treatment of hyperconjugation and nonalternate molecules are available (5, 30, 31); however, the problems involved become increasingly difficult with the number and types of heteroatoms.

A knowledge of the electronic characteristics of a molecule may also allow prediction of drug activity. This would be possible even for compounds which have never been synthesized, once a basic relationship has been established by pharmacological testing of a representative sample of compounds. Table VII shows the relationship between sulfonamide activity and the charge $q_N{}^1$. The trend exhibited by the data indicates that, in general, a decrease in bacteriostatic activity may be associated with a decrease in the formal π charge at

N^1 (or an increase in $q_N{}^1$). A better correlation of these parameters is probably dependent upon a more complete calculation procedure, including the use of partition coefficients as substituent constants (32, 33) in order to account for the polar characteristics of the molecules. Further work is being performed to correlate the electronic characteristics of the sulfonamide molecules with biological activity.

Hemolysis of Erythrocytes by Antibacterial Preservatives IV

Hemolytic Activity of Chlorhexidine Diacetate

By HOWARD C. ANSEL

Chlorhexidine diacetate has been shown, *in vitro*, to be destructive to rabbit erythrocytes in a range of concentrations similar to that required for its antimicrobial effect, with total hemolysis and bacteriolysis occurring at similar dosage levels. It appears that the mode of action of chlorhexidine diacetate against microorganisms and erythrocytes is similar; that is, through the disruption of the structure and function of the cellular membrane. The hemolytic activity of chlorhexidine diacetate was reduced by the presence of polyethylene glycols of various molecular weights and by dimethylsulfoxide. This interference in the activity of chlorhexidine diacetate was considered from two possible modes: (*a*) chemical interaction between the chlorhexidine diacetate and the added substances, and (*b*) cellular effects of the added substances and chlorhexidine diacetate, making the hemolytic activity of the latter less pronounced. The latter mode of interference by the added substances is more strongly suspected.

CHLORHEXIDINE is a potent antibacterial compound, the properties of which were first described in 1954 (1). Since that time, investigations conducted mainly in Great Britain have been directed at determining the mode of action of chlorhexidine and its efficacy as a preservative agent particularly for ophthalmic preparations (2–10).

The present investigation represents a continuation of studies (11–14) to determine the hemolytic activity of antibacterial preservatives alone and in the presence of pharmaceutical adjuncts. Thus far, the work in the series has demonstrated a similarity between the drug concentrations required of certain preservatives to act effectively as antibacterial and hemolytic agents. Also, certain pharmaceutical adjuncts as the polyethylene glycols and dimethylsulfoxide (DMSO) have been shown to interfere with the hemolytic activity of certain preservatives. The information gathered in this series is expected to contribute both to the understanding of the cellular effects of preservative agents and to the effective preservation of pharmaceutical products, including those intended for intravenous administration. Chlorhexidine was selected for inclusion in the over-all study principally because its chemical structure, 1,6-di(4-chlorophenyldiguanido)hexane, is sufficiently diverse from those antibacterial agents already examined for hemolytic activity. Also, the bacteriological data for chlorhexidine, as reported in the current literature, provided a ready means for the comparison and possible correlation between the effects of the compound on microorganisms and on red blood cells.

Received December 19, 1966, from the School of Pharmacy, University of Georgia, Athens, GA 30601

Accepted for publication February 9, 1967.

Presented to the Basic Pharmaceutics Section, A.PH.A. Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

This investigation was supported in part by the office of General Research, University of Georgia, Athens.

Previous paper: Ansel, H. C., and Leake, W. F., *J. Pharm. Sci.*, **55**, 685(1966).

EXPERIMENTAL

Materials—The chlorhexidine diacetate employed in this investigation was pharmaceutical grade obtained through the courtesy of Ayerst Laboratories, Inc., New York, N. Y., and the dimethylsulfoxide was reagent grade obtained commercially.

Blood Samples—Rabbit blood, obtained by heart puncture and defibrinated in the manner previously described (15), was used throughout the study. Washed erythrocytes, prepared as reported in an earlier communication (14), were employed in certain experiments to reveal the influence of serum proteins on the hemolytic activity of chlorhexidine diacetate.

Each blood sample was collected just prior to its use and was verified for osmotic normalcy (11) during the course of each experiment.

Quantitative Determination of Per Cent Hemolysis—The colorimetric method employed for the determination of the degree of hemolysis occurring in each test solution has recently been described (11). In brief, it involved the addition of 0.05 ml. of defibrinated blood to duplicate pairs of colorimeter tubes, each containing 5 ml. of test solution. The test mixtures were incubated in a water bath for 45 min. at 37° after which the unhemolyzed cells were settled by centrifugation and the absorbance readings of the hemolysate determined with a Klett-Summerson photoelectric colorimeter. Each absorbance reading was compared with a total hemolysis reading obtained by laking red cells in distilled water. The degree of hemolysis occurring in each test solution was calculated as a per cent of total hemolysis. The data reported represent the average of a minimum of two like experiments. During and after the 45-min. incubation period each test mixture was macroscopically observed for color changes, precipitation, and other signs of denaturation.

Experimental Solutions—Aqueous solutions were employed throughout the investigation. Chlorhexi-

dine diacetate test solutions of varying concentration were prepared in 0.6% sodium chloride. The sodium chloride afforded the erythrocytes protection against osmotic hemolysis, and therefore any hemolysis occurring in the test solutions could be attributed to the cytotoxic effects of the preservative agent (11). The data thus obtained established the minimum concentrations of chlorhexidine diacetate required to induce trace and total hemolysis of rabbit erythrocytes. The latter concentration, producing the optimum effect, was subsequently employed in experiments designed to determine the influence of polyethylene glycols of various molecular weights and of DMSO on the hemolytic activity of chlorhexidine diacetate.

Test solutions were prepared to contain the optimum hemolytic concentration of chlorhexidine diacetate in 0.6% sodium chloride and varying concentrations of polyethylene glycols 400, 1540, and 4000, or dimethylsulfoxide. The ability of the polyethylene glycols or of DMSO to interfere with the hemolytic activity of chlorhexidine diacetate would be reflected by decreased hemolytic response. The test solutions were equilibrated overnight at room temperature prior to conductance of hemolysis experiments at 37°. Appropriate control solutions were employed concurrently to affirm the effects attributed to the presence of the polyethylene glycols and DMSO.

The concentration of chlorhexidine diacetate in the various test solutions is expressed in terms of mcg./ml., in keeping with the precedent established by other investigators of the properties and activities of this preservative agent. In doing so, a direct comparison was facilitated between the data obtained in this study employing erythrocytes and that of previous studies employing microorganisms.

Kinetic Studies—The general experimental design of the research series is such that the hemolytic effects of the preservative agents and the influences of the pharmaceutical adjuncts are determined after a constant 45-min. incubation period. In the current project the hemolytic activities of certain representative test solutions were also determined at incubation intervals of from 5 to 20 min., during periods up to 120 min.

RESULTS AND DISCUSSION

Hemolytic Activity of Chlorhexidine Diacetate—Chlorhexidine diacetate at concentrations as low as 20 mcg./ml. induced trace hemolysis of both washed and unwashed rabbit erythrocytes (Fig. 1). As the concentrations of the test solutions were increased, hemolysis increased and at a concentration of 110 mcg./ml., total hemolysis first occurred. As can be seen in Fig. 1, the washed cells appeared slightly more sensitive to the lytic effects of chlorhexidine diacetate than did the unwashed cells. The absence of serum proteins and the mechanical effects of the repeated washings during the preparation of the washed cell samples could account for the increased cellular fragility and sensitivity to chlorhexidine diacetate.

It is interesting to note that in various studies (4, 5, 10) involving the application of chlorhexidine to the preservation of ophthalmic solutions, the successful concentrations (depending on such conditions of the experiment as: cell count, micro-

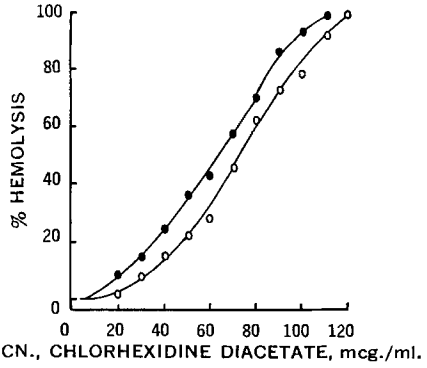

Fig. 1—Hemolytic activity of chlorhexidine diacetate in the presence of 0.6% NaCl. Key: ○, using unwashed erythrocytes; ●, using washed erythrocytes.

organism tested, temperature, and duration of incubation) ranged between 20 and 100 mcg./ml., a range which is nearly identical to that determined in the present investigation for trace to total destruction of erythrocytes. In practice, the most popular concentration of chlorhexidine employed as a preservative in ophthalmic solutions is reported to be 50 mcg./ml. (10).

Hugo and Longworth (2, 4) have investigated the mode of action of chlorhexidine diacetate against *Escherichia coli* and *Staphylococcus aureus*. They found chlorhexidine to be rapidly adsorbed by the cells. This adsorption was accompanied by cytological changes involving the permeability of the cells and their optical properties. The two microorganisms responded similarly to the effects of various dosage levels of chlorhexidine diacetate. At concentrations of 20 mcg./ml., the cells showed little damage to biochemical properties as well as an unchanged appearance as revealed by electron microscopy. At concentrations of 90 mcg./ml., chlorhexidine caused cytological damage resulting in widespread cellular leakage and in the formation of cellular ghosts devoid of cytoplasmic constituents. At concentrations of 200 and 500 mcg./ml., which greatly exceeded that required for cellular damage, the cells failed to exude their cytoplasmic constituents; however, compared to the controls, the cytoplasm appeared granular to electron microscopy and the cellular membranes appeared altered. They concluded from their studies that chlorhexidine exerts its bactericidal action by combining with the cell surface in a manner which lethally affects its structure and function thereby causing a disruption in its permeability barriers and over-all integrity. The release of cellular constituents by the bacterial cells was related to the level of drug adsorption. However, cellular release was not necessarily the sign of cellular death. This was demonstrated with highly bactericidal concentrations of chlorhexidine diacetate which as a consequence of their high concentration failed to induce bacteriolysis.

In the present study in which erythrocytes rather than microorganisms were exposed to various concentrations of chlorhexidine diacetate a similar pattern of cell response was noted (Fig. 1) with one exception. At high (500 mcg./ml.) chlorhexidine diacetate concentrations, which affected the bacterial cell membrane without inducing bacteriolysis, the

erythrocytes hemolyzed completely as they had at drug levels as low as 110 mcg./ml. In general, however, the red blood cells behaved similarly to the microorganisms, an observation which had been made before in this laboratory for other preservative agents (11–14). It is not unlikely that the mode of action suggested for chlorhexidine diacetate against microorganisms is similar against erythrocytes, that is, the disruption and disorganization of the structure and function of the cell membrane.

Kinetic Study of Chlorhexidine Diacetate—As depicted in Fig. 2, the hemolytic effects of chlorhexidine diacetate are manifest after a lag time apparently required for drug adsorption and consequent disruption of the permeability barriers of the cell. Gross cytolytic damage supported by cellular leakage proceeds rapidly, providing that the appropriate level of drug is present. In their observations on the effects of chlorhexidine diacetate on *E. coli*, Hugo and Longworth (4) concluded that of the two parmeters, time and concentration, the latter was the more important with respect to induced cytological damage.

Influence of Polyethylene Glycols and DMSO on the Hemolytic Activity of Chlorhexidine Diacetate—As noted in previous communications (12, 14), the presence of pharmaceutical adjuncts including the polyethylene glycols and dimethylsulfoxide interfere with the hemolytic activities of certain preservative agents suggesting like interference with preservative function.

The hemolytic activities of solutions containing 110 mcg./ml. of chlorhexidine diacetate, an amount sufficient to induce total hemolysis of erythrocytes (Fig. 1), in 0.6% sodium chloride and varying amounts of polyethylene glycols 400, 1540, and 4000 were determined along with the appropriate control solutions. As can be seen in Fig. 3, the presence of polyethylene glycols in increasing amounts and in increasing molecular weights was increasingly effective in preventing chlorhexidine-induced hemolysis. A similar influence of the polyethylene glycols in preventing hemolysis induced by antimicrobial preservatives was noted for phenolic compounds and was reported in an earlier communication (12). In that study a chemical interaction between the phenolic compound and the various polyethylene glycols was demonstrated titrimetrically and verified through the literature. In the current study, the possibility of a chemical interaction between the polyethylene glycols and the chlorhexidine diacetate, thereby rendering the preservative agent ineffective in its hemolytic capability, should be considered especially in light of the incompatible nature of both the polyethylene glycols (12) and chlorhexidine (5, 10) with other chemical materials. No visible signs of incompatibility were seen during the study. A second possibility for the protective action of the polyethylene glycols is a cellular effect of this chemical which interferes in some manner with the adsorption of chlorhexidine diacetate onto the erythrocytic membrane. This interference will be explored to a greater extent in a subsequent presentation.

The controversial chemical dimethylsulfoxide has been the subject of conflicting reports concerning its ability to act as a penetrant carrier of drugs through biologic membranes (16–20). Although DMSO freely penetrates the erythrocytic membrane

and, in high concentrations, is destructive to red blood cells, it was shown (14) to greatly reduce, not enhance, the phenol-induced hemolysis of both washed and unwashed erythrocytes. It was suggested that this interference may be manifest through chemical interaction with the phenol or through a direct cellular effect. The present experiment involving the combination of DMSO and chlorhexidine diacetate was an outgrowth of the prior study. As can be seen in Fig. 4, the presence of DMSO reduced the hemolytic capability of an otherwise hemolytic concentration of chlorhexidine diacetate (110 mcg./ml.). All test solutions contain-

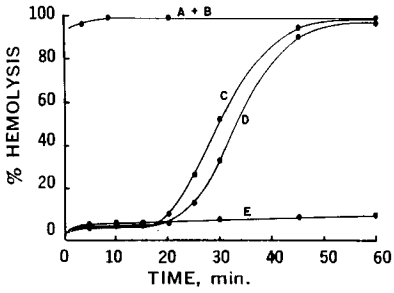

Fig. 5—Kinetic study of the hemolytic activity of various test solutions. Key: A, water; B, 15% DMSO; C, 110 mcg./ml. chlorhexidine diacetate in 0.6% NaCl; D, 110 mcg./ml. chlorhexidine diacetate, 0.6% NaCl, and 1% DMSO; E, 110 mcg./ml. chlorhexidine diacetate, 0.6% NaCl, and 15% DMSO.

ing concentrations of DMSO exceeding 35% caused the denaturation of blood, as noted in an earlier report (14).

As can be seen in Fig. 5, both distilled water and 15% DMSO induced total hemolysis within the first 5 min. of the study. Hemolysis occurring in the 15% DMSO test solution can be largely attributed to osmotic hemolysis resulting from the penetration of this hygroscopic material through the erythrocytic membrane (14). The addition of 0.6% sodium chloride to DMSO solutions of less than 35% concentration prevents osmotic hemolysis (14); hemolysis occurs in solutions containing greater amounts of DMSO due to the cytotoxic action of the more concentrated solutions. The addition of 1% DMSO to a solution containing 0.6% sodium chloride and 110 mcg./mg. of chlorhexidine diacetate slowed the rate of hemolysis induced by the latter and the addition of 15% DMSO all but prevented the chlorhexidine diacetate-induced hemolysis. The suspicion that DMSO exerts an independent cellular effect such as to prevent the preservative from exerting its own cellular activity has been bolstered by recent data obtained in this laboratory (21) showing a similar influence of DMSO on the hemolytic activities of such chemically diverse preservatives as phenylethyl alcohol, benzalkonium chloride, *p*-chlorophenol, benzyl alcohol, phenylmercuric acetate, and *m*-cresol. In each instance, the concentration of DMSO required to all but eliminate the hemolysis normally induced by the hemolytic concentrations of these preservatives was between 7 and 15%. Spectrophotometric analysis failed to reveal complexation between the DMSO and the chlorhexidine diacetate, further adding support to interference by DMSO by a cellular mechanism.

Drug Standards

Determination of Phenylephrine in Combinations with Other Drugs

By JOSEPH LEVINE and THOMAS D. DOYLE

Phenylephrine combines with di-(2-ethylhexyl) phosphoric acid to form an ion-pair which can be extracted with immiscible solvents. Application of this means of extraction in conjunction with partition chromatography provides a method for the analysis of phenylephrine in its various combinations with other drugs.

THE ISOLATION and determination of phenylephrine by the usual methods for the analysis of alkoids[1] is not feasible because of the highly unfavorable extraction characteristics of the compound. Most of the published procedures for its analysis are not applicable in the presence of the drugs with which it is compounded in many formulations. Pratt (2), applying the acetylation procedure of Welsh (3), converted phenylephrine in aqueous solution to the diacetyl derivative, which is readily extracted with im-

Determination of Phenylephrine in Combinations with Other Drugs

By JOSEPH LEVINE and THOMAS D. DOYLE

Phenylephrine combines with di-(2-ethylhexyl) phosphoric acid to form an ion-pair which can be extracted with immiscible solvents. Application of this means of extraction in conjunction with partition chromatography provides a method for the analysis of phenylephrine in its various combinations with other drugs.

THE ISOLATION and determination of phenylephrine by the usual methods for the analysis of alkoids[1] is not feasible because of the highly unfavorable extraction characteristics of the compound. Most of the published procedures for its analysis are not applicable in the presence of the drugs with which it is compounded in many formulations. Pratt (2), applying the acetylation procedure of Welsh (3), converted phenylephrine in aqueous solution to the diacetyl derivative, which is readily extracted with im-

[1] Because alkaloids and many pharmaceutically important synthetic organic bases present identical analytical problems, and since the word "alkaloid" is reserved for the natural product, it has been proposed (1) that the word "alkoid" be used to encompass the entire group.

miscible organic solvents. Clark and Rosenberg (4) and Hyatt (5) modified the acetylation procedure to permit its application to combinations containing various antihistamines. In these procedures, an alkaline solution of the sample is used as the immobile phase in a chromatographic column. A preliminary chloroform elution removes the antihistamines only. A chloroform solution of acetic anhydride passed over the column acetylates the phenylephrine *in situ*, and the resultant diacetyl compound is readily eluted. This procedure is inapplicable to samples containing acetaminophen, with which phenylephrine is frequently combined. Smith (6) separated phenylephrine from a number of other drugs by eluting them with chloroform from a partition chromatographic column in which the ratio of diatomaceous earth[2] to immobile phase is much higher than that usually employed; he then washed off the phenylephrine with ethanol. He reported the method to be unsuccessful for mixtures containing several accompanying drugs, including sodium benzoate and potassium guaiacolsulfonate. Hiskey and Levin (7) described a colorimetric procedure applicable directly to solutions without prior isolation of the phenylephrine. Reaction with 4-aminoantipyrine and potassium ferricyanide in sodium bicarbonate solution produces a red color, which can be measured directly. This method must be applied with great care, since the intensity of the color developed varies significantly with the concentration of each of the reagents, and both the intensity of the color and the wavelength of maximum absorbance change rapidly with time. Acetaminophen also produces a color with the reagent, while phenolphthalein is converted to its red salt; therefore, this method is inapplicable in the presence of these drug materials.

Phenylephrine may be extracted readily by converting it to an ion-pair with di-(2-ethylhexyl) phosphoric acid (DEHP).[3] Use of this reagent is based upon a report by Temple and Gillespie (8) that chloroform solutions of this "liquid ion-exchanger" will extract physiologically active amines from aqueous solutions at pH 4–8; in turn, the amines will be re-extracted by aqueous solutions at low pH levels. However, the procedure as described by Temple and Gillespie is not directly applicable to the determination of phenylephrine in pharmaceutical combinations, since other alkoids will be extracted together with that substance. Also, the unfavorable partition coefficient of ion-pairs formed with phenolic amines would require multiple extractions for complete recovery of phenylephrine.

Quantitative extraction of the phenylephrine–DEHP complex is readily achieved through the application of partition chromatography. A solution of the sample itself adjusted to a pH of 5–6 constitutes the immobile phase of the system. An ether solution of DEHP passed over the column elutes the phenylephrine; this is quantitatively extracted from the eluate with dilute sulfuric acid and determined spectrophotometrically. Because alkaline solutions of phenylephrine absorb more strongly and with a maximum at a longer wavelength than acid solutions, the extract is made alkaline prior to measurement.

This partition system is effective in the analysis of phenylephrine in combination with other drugs. A chloroform or ether wash of the column prior to the elution of phenylephrine with the DEHP solution will remove a variety of substances, including acetaminophen, sulfonamides, aspirin, phenolphthalein, glyceryl guaiacolate, dextromethorphan, dihydrocodeinone, and the antihistamines, as well as flavoring matter present in syrups.

Phenylpropanolamine is not completely removed by this treatment. This compound is separated from phenylephrine by passing the DEHP complex of both compounds through a sodium hydroxide column. This will trap only the phenylephrine, which will subsequently be released when the column is neutralized.

EXPERIMENTAL

Chromatographic Columns—Attach a 50-mm. length of 6 or 8-mm. tubing to a 25 × 250-mm. test tube. Use a tamping rod consisting of a disk of stainless steel, aluminum, or glass, of a diameter 1 mm. less than that of the column, attached to a rod 12 to 18 in. long. Pack fine glass wool[4] in the base of the column as support.

Buffers—*pH 5.8 Buffer*—Mix 1 vol. of 1 *M* dibasic potassium phosphate with 9 vol. of 1 *M* monobasic potassium phosphate. Adjust to pH 5.80 ± 0.05, using a pH meter.

pH 5.1 Buffer—Mix 2 vol. of 1 *M* dibasic potassium phosphate with 1 vol. of 1 *M* citric acid. Adjust to pH 5.10 ± 0.05.

Preparation of Samples—*Syrups*—For samples containing the usual concentration of 5 mg. of phenylephrine HCl per 5 ml., measure 10.0 ml. of pH 5.8 buffer into a 25-ml. volumetric flask. Add syrup to volume, being careful to avoid wetting the flask above the graduation mark.

Tablets—Weigh a ground sample containing about 2 mg. of phenylephrine into a 50-ml. beaker. If components of tablet are water-soluble, add 2 ml. of water, warm slightly to dissolve, and add 1 ml. of pH 5.8 buffer. If some components are not water-soluble (*e.g.*, acetaminophen), add 1 ml. of dimethyl-

[2] Marketed as Celite 545 by the Johns-Manville Corp., New York, N. Y.

[3] Listed in some catalogs as bis-2(ethylhexyl) phosphate.

[4] Pyrex Filtering Fibre, Corning Glass catalog No. 3950.

sulfoxide, warm to dissolve, and then add 2 ml. of pH 5.8 buffer. For tablets containing antacids such as magnesium and aluminum hydroxides, heat the powdered sample with 5 ml. of ethanol and 1 ml. of concentrated HCl to dissolve the alkaline material; add 10 ml. of *n*-butanol and evaporate to dryness.[5] Dissolve residue in 1 ml. of dimethylsulfoxide and add 2 ml. of pH 5.8 buffer.

Procedure

Use water-saturated solvents throughout.

A—*Samples Without Phenylpropanolamine*—Transfer mixture of 1 Gm. of acid-washed diatomaceous earth with 0.8 ml. of pH 5.1 buffer to column containing a pledget of glass wool, and tamp to a uniform mass. Mix 4 Gm. of diatomaceous earth with 3 ml. of syrup sample or with tablet preparation and transfer to column directly above pH 5.1 layer. Dry-wash beaker with 1 Gm. of diatomaceous earth, add to column, and tamp. Cover with wad of glass wool.

Pass 75 ml. of $CHCl_3$ over column, followed by 100 ml. of ether. Evaporate final 10 ml. of eluate separately; if residue remains, pass additional ether over column.

With a rubber bulb, draw DEHP[6] into a graduated 1-ml. pipet to a level estimated to provide a total of about 1.2 ml.[7] Transfer DEHP into 50 ml. of ether; then flush the pipet several times with the ether. Avoid contact with the reagent.

Place a separator containing about 20 ml. of approximately 0.1 *N* H_2SO_4, as a receiver under the column. Elute the column with the DEHP–ether solution, then follow with 25 ml. of ether. Shake the separator, and transfer aqueous layer to 50-ml. volumetric flask containing 4 ml. of 1 *N* NaOH. Re-extract ether with 15 ml. of 0.1 *N* H_2SO_4, transfer extract to the flask, and adjust to volume with water. (If sample contains magnesium hydroxide, gel will separate from this solution; remove by filtration or centrifugation.) Determine absorbance with a spectrophotometer at maximum at about 291 mμ, and compare with that of a standard solution containing about 2 mg. of phenylephrine HCl in 50 ml. of approximately 0.01 *N* NaOH.

B—*Samples Containing Phenylpropanolamine*—Prepare sample column, and wash with $CHCl_3$ and ether as under *A*. Mount a second column, prepared with 3 Gm. of diatomaceous earth and 2 ml. of 0.5 *N* NaOH, directly below sample column. Elute phenylpropanolamine with a solution of 0.1 ml. of DEHP in 50 ml. of ether, followed by 25 ml. of ether. Finally, elute the phenylephrine from the column train with 1.2 ml. of DEHP in ether exactly as described above.

RESULTS AND DISCUSSION

Standard quantities of phenylephrine, both alone and combined with other drugs, were analyzed by the procedure as described. Recoveries are presented in Table I. The analysis of phenylephrine in commercial samples of various combinations is presented in Table II. In several cases, analyses of selected accompanying materials were made as outlined below. The ultraviolet spectra of these were identical with those of the pure material, and the recoveries were in accord with the label claims. Since no standard recovery data were collected for these compounds, the results of the analyses are not included.

In accord with their distribution coefficients and dissociation constants, the majority of pharmaceutically important bases can be completely eluted from chromatographic columns at pH levels ranging down to about pH 3, using moderate volumes of ether or chloroform; the rate of elution increases rapidly with increase of pH up to the pKa value of the base. At pH 5.8 alkoids such as most of the antihistamines are readily removed; phenylpropanolamine is eluted slowly with chloroform and phenylephrine very slowly with ether at this pH level. The latter two compounds are retained on the pH 5.1 trap while the others pass through.

Phenylpropanolamine is separated from phenylephrine by passing the ether solution of their DEHP complexes over a diatomaceous earth–sodium hydroxide column. Phenylephrine is retained as its phenol salt while the phenylpropanolamine complex is eluted. For this separation, the quantity of DEHP used initially must be sufficient to remove the phenylpropanolamine completely while being insufficient to neutralize the entire NaOH column. This column must, in turn, be completely neutralized by the DEHP used to elute the phenylephrine. The proper balance is achieved with the concentrations specified under *Experimental*. It can be noted that phenylephrine can be quantitatively determined with procedure *A* even though the phenylephrine fraction is not free of phenylpropanolamine, since solutions of the latter

do not absorb at 291 mμ, the wavelength at which phenylephrine is measured.

With minor modification, the procedure as described can be adapted to the concurrent determination of many of the drugs which accompany phenylephrine in commercial preparations. Phenylpropanolamine, for example, can be extracted from the initial DEHP eluate with sulfuric acid in the same manner as phenylephrine. To compensate for the low absorbance of phenylpropanolamine, smaller volumes of acid may be used for the extraction. To determine acetaminophen, the initial chloroform and ether eluates from the sample column are passed over a diatomaceous earth–1 *N* NaOH column, which will retain the acetaminophen while alkoids, together with flavoring material, pass through. The acetaminophen is eluted after acidification of the column *in situ* with acetic acid, as previously described (9). For syrups containing dextromethorphan, a diatomaceous earth–2 *N* HCl column is placed in series with the sample column, and 100 ml. of ether is passed over the columns. This will elute the greater part of the dextromethorphan, together with flavoring matter, from the sample column; the dextromethorphan alone will be retained on the HCl column. Then 75 ml. of chloroform is passed over both columns to elute the total quantity of dextromethorphan. The eluate can be received directly in a volumetric flask containing a small amount of acidified methanol (1) and its absorbance measured directly. Chlorpheniramine, if present in this same combination, will be retained on the HCl column, and it can be eluted with ammoniacal chloroform by the procedure described for other alkoids (10). Finally, the phenylephrine is eluted with DEHP as above.

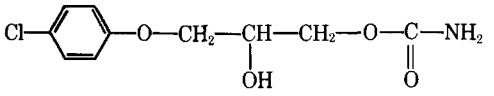
Qualitative and Quantitative Tests for Chlorphenesin Carbamate

By EDWARD F. SALIM* and ROGER E. BOOTH†

Provisional, unofficial monographs are developed by the Drug Standards Laboratory, in cooperation with the manufacturers of the drug concerned, for publication in the *Journal of Pharmaceutical Sciences*. The ready availability of this information affords discriminating medical and pharmaceutical practitioners with an added basis for confidence in the quality of new drug products generally, and of those covered by the monographs particularly. Such monographs will appear on drugs representing new chemical entities for which suitable identity tests and assay procedures are not available in the published literature. The purity and assay limits reported for the drugs and their dosage forms are based on observations made on samples representative of commercial production and are considered to be reasonable within expected analytical and manufacturing variation.

3-(P-CHLOROPHENOXY)-2-HYDROXYPROPYL CARBAMATE; $C_{10}H_{12}ClNO_4$; mol. wt. 245.67. The structural formula of chlorophenesin carbamate may be represented as:



Physical Properties—Chlorphenesin carbamate occurs as a white to off-white, odorless powder, m.p. 86–92° (U.S.P. class Ia). It is very slightly soluble in water, freely soluble in alcohol, and sparingly soluble in chloroform.

Identity Tests—Mix 500 mg. of chlorphenesin carbamate with 1 ml. of acetic anhydride, add 1 drop of sulfuric acid, stir until solution is effected, and allow the solution to stand at room temperature for 30 min., stirring occasionally. Pour the solution into 50 ml. of water while stirring the mixture vigorously, and allow to crystallize. Filter off the crystals, wash with water until the odor of acetic acid is no longer perceptible, and dry at about 60°: the acetyl chlorphenesin carbamate so obtained melts at about 133°.

A 1 in 100,000 solution of chlorphenesin carbamate in alcohol exhibits ultraviolet absorbance maxima at about 227 mμ [absorptivity (*a*) about 53], 280 mμ, and 288 mμ and absorbance minima at about 245 mμ and 284 mμ. The spectrum is shown in Fig. 1.

The infrared spectrum of a chlorphenesin carbamate dispersion in liquid petrolatum is shown in Fig. 2.

Purity Tests—Dry about 2 Gm. of chlorphenesin carbamate, accurately weighed, over silica gel and at a pressure not exceeding 5 mm. of mercury for 6 hr.: it loses not more than 0.5% of its weight.

Char about 1 Gm. of chlorphenesin carbamate, accurately weighed, cool the residue, add 1 ml. of sulfuric acid, heat cautiously until evolution of sulfur trioxide ceases, ignite, cool, and weigh: the residue does not exceed 0.5%.

Received October 28, 1966, from the *Drug Standards Laboratory, AMERICAN PHARMACEUTICAL ASSOCIATION, Washington, DC 20037

Accepted for publication December 19, 1966.

The Drug Standards Laboratory gratefully acknowledges the assistance of Miss Carolyn Damon and Miss Hannah Klein.

Weigh accurately about 600 mg. of chlorphenesin carbamate and transfer to a Kjeldahl flask with 20 ml. of sulfuric acid, 200 mg. of selenium, and 15 Gm. of anhydrous sodium sulfate. After the mixture has become colorless, digest for 1 hr., cool, and dilute to about 300 ml. with water. Cool, make alkaline with sodium hydroxide solution (1 in 2), and distil the liberated ammonia into 40.0 ml. of 0.1 *N* sulfuric acid. Add methyl red T.S. and titrate the excess acid with 0.1 *N* sodium hydroxide. Each milliliter of 0.1 *N* sulfuric acid is equivalent to 1.401 mg. of nitrogen (N). The amount of nitrogen found is not less than 5.50% and not more than 5.90% calculated on the dried basis.

Using about 20 mg. of chlorphenesin carbamate, accurately weighed, proceed as directed under "Oxygen Flask Combustion," U.S.P. XVII, p. 884, using a mixture of 1 ml. of sodium hydroxide T.S., 5 ml. of hydrogen peroxide T.S., and 15 ml. of water as the absorbing liquid. After the combustion is complete, rinse the stopper and sample holder with water and boil the solution for about 5 min. Cool, acidify with diluted nitric acid adding 2 ml. in excess, add 10.0 ml. of 0.05 *N* silver nitrate, 2 ml. of nitrobenzene, and 2 ml. of ferric ammonium sulfate T.S. Shake well, and titrate the excess silver nitrate with 0.05 *N* ammonium thiocyanate. Each milliliter of 0.05 *N* silver nitrate is equivalent to 1.773 mg. of chlorine (Cl). The chlorine content is not less than 13.9% and not more than 14.9%, calculated on the dried basis.

Assay—Dissolve about 125 mg. of chlorphenesin carbamate, accurately weighed, in 25 ml. of chloroform in a 50-ml. volumetric flask, add the solvent to volume, and mix. Similarly, dissolve an accurately weighed quantity of chlorphenesin carbamate reference standard in chloroform to obtain a standard solution having a concentration of about 2.5 mg./ml. Concomitantly determine the absorbances of both solutions in 1.0-mm. cells at the wavelength of maximum absorbance at about 5.80 μ, with a suitable infrared spectrophotometer, using chloroform as the blank. Calculate the quantity, in milligrams, of $C_{10}H_{12}ClNO_4$ in the portion of chlorphenesin carbamate taken by the formula $50C \times (A_u/A_s)$, in which C is the concentration, in milligrams per milliliter, of chlorphenesin carbamate reference standard in the standard solution, and A_u and A_s are the absorbances of the solution of chlorphenesin carbamate and the standard solution, respectively. The amount of chlorphenesin carbamate found is

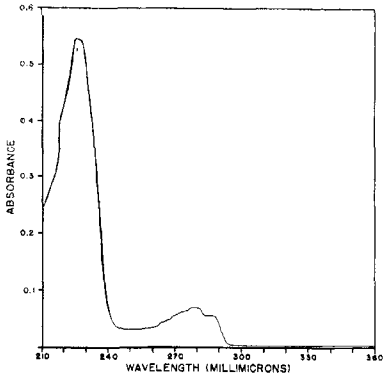

Fig. 1—Ultraviolet absorption spectrum of chlorphenesin carbamate in alcohol (10 mcg./ml.); Beckman model DK-2A spectrophotometer.

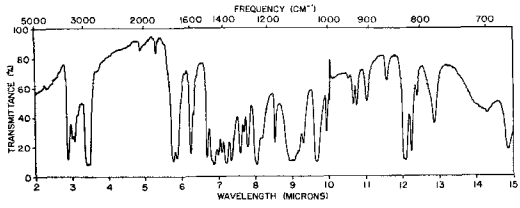

Fig. 2—Infrared spectrum of a chlorphenesin carbamate dispersion in liquid petrolatum; Perkin-Elmer model 21 spectrophotometer, sodium chloride prism.

not less than 97.0% and not more than 103.0%, calculated on the dried basis.

DOSAGE FORMS OF CHLORPHENESIN CARBAMATE

Chlorphenesin Carbamate Tablets

Identity Test—Triturate a quantity of finely powdered chlorphenesin carbamate tablets, equivalent to about 400 mg. of chlorphenesin carbamate, with 50 ml. of chloroform, and filter. Evaporate the clear filtrate on a steam bath to dryness: a liquid petrolatum dispersion of the residue exhibits infrared absorption maxima only at the same wavelengths as that of a similar preparation of chlorphenesin carbamate shown in Fig. 2.

Assay—*Standard Preparation*—Transfer 50.0 mg. of chlorphenesin carbamate reference standard to a glass-stoppered, 50-ml. conical flask and dissolve in 20.0 ml. of chloroform.

Assay Preparation—Weigh and finely powder not less than 10 chlorphenesin carbamate tablets. Weigh accurately a portion of the powder, equivalent to about 50 mg. of chlorphenesin carbamate, and transfer to a glass-stoppered, 50-ml. conical flask. Add 20.0 ml. of chloroform, stopper, and shake mechanically for 15 min. Filter a portion through paper into a glass-stoppered flask.

Procedure—Determine the absorbance of the *Assay Preparation* and that of the *Standard Preparation* in 1.0-mm. cells at the wavelength of maximum absorbance at about 5.80 μ, with a suitable infrared spectrophotometer, using chloroform as the blank. Calculate the quantity, in milligrams, of $C_{10}H_{12}ClNO_4$ in the portion of the tablets taken by the formula $50 \times (A_u/A_s)$, in which A_u is the absorbance of the *Assay Preparation* and A_s is the absorbance of the *Standard Preparation*. The amount of chlorphenesin carbamate found is not less than 92.5% and not more than 107.5% of the labeled amount.

DISCUSSION

U.S.P. and N.F. terminology for solubility, melting range, reagents, *etc.*, has been used wherever feasible.

Chlorphenesin carbamate[1] is an orally active skeletal muscle relaxant useful in the relief of discomfort associated with skeletal muscle trauma and inflammation.

Purity Tests—The synthesis of chlorphenesin carbamate involves the opening of a cyclic carbonate intermediate (1). An isomeric secondary carbamate is also formed in the reaction and constitutes a possible impurity in the final product. The limit of 3-(*p*-chlorophenoxy)-1-hydroxypropyl carbamate as a contaminant in chlorphenesin carbamate is controlled by quantitative nuclear magnetic resonance (NMR) spectroscopy (2) and should not exceed 1.5% of the weight of the bulk material.

Quantitative Methods—The nitrogen content of chlorphenesin carbamate as determined by the Kjeldahl procedure and the chlorine content by oxygen flask combustion gave average values of 5.61 ± 0.05%[2] and 14.2 ± 0.1%,[2] respectively.

Analyses for bulk chlorphenesin carbamate and the tablet formulation are based on infrared absorption properties of the carbonyl group in the molecule. Commercial tablets (400 mg.) gave an average recovery value of 99.7 ± 0.4%[2] of the labeled amount. Infrared analysis of the bulk drug yielded assay results of 100.2 ± 0.2%[2] which compares favorably to the recoveries (100.3 ± 0.3%[2]) obtained by the assay procedure reported for tybamate (3). A 500-mg. sample of chlorphenesin carbamate is subjected to sodium methoxide cleavage in a nonaqueous medium and the excess alkali determined by back titration with standard acid.

Selective Colorimetric Determination of Microgram Amounts of Quinestrol and Ethinyl Estradiol in Dosage Forms

By DIMITRI C. TSILIFONIS and LESTER CHAFETZ

Ethinyl estradiol and its 3-cyclopentyl ether, quinestrol, react with a methanol–sulfuric acid reagent of critical composition to form a stable color with $\lambda_{max.}$ 540 mμ and ε 36,000. The chromogenic reaction appears to be specific for these estrogens and the related steroid, mestranol. Separations required utilize only simple solvent extraction, and the use of the nonpolar solvent, petroleum ether, affords additional selectivity in the assay of dosage forms. Application of the method for the assay of quinestrol and ethinyl estradiol in representative dosage forms is described. The assay has sensitivity, precision, and accuracy suitable for its use in content uniformity testing of dosage forms declaring 10 mcg. or more without resort to micro techniques.

A NEED FOR a facile and accurate means for assaying microgram amounts of quinestrol in the numerous formulations produced in the course of process evaluation, stability testing, and clinical studies led to the examination of procedures for isolating and quantitating the estrogen from individual dosage units. Work on the assay of quinestrol, the 3-cyclopentyl ether of ethinyl estradiol, led to a superior assay for ethinyl estradiol itself. The procedure appears equally applicable to assay of mestranol, the 3-methyl ether of ethinyl estradiol.

The Iron-Kober assay for ethinyl estradiol used in U.S.P. XVII (1) is equally applicable to quinestrol, but the procedure requires meticulous technique for satisfactory results, and it is insufficiently rapid and precise for the analysis of single tablets. The azo dye method for phenolic estrogens (2) is a general chromogenic reaction for phenols, inapplicable to quinestrol determination and lacking in sensitivity adequate for process control studies. Gas-liquid chromatographic assays for ethinyl estradiol and mestranol (3–7) provide both sensitivity and specificity, but the procedures suffer from excipient interference, and the precision reported (7) was unsatisfactory for our purposes. Thin-layer chromatography (3, 8) and paper chromatography (9) were less suitable from the standpoints of time, convenience, and accuracy than the colorimetric method reported here.

Treatment of many estrogens with concentrated sulfuric acid results in a red color with green fluorescence (10), a procedure used in U.S.P. as an identification reaction for ethinyl estradiol. Reaction of ethinyl estradiol or quinestrol with the ethanol–sulfuric acid reagent described by Heusghem and Jehotte (11) affords an intense red color with green fluorescence, but the color fades rapidly with detriment to the precision and accuracy of the method. Study of this reaction led to the development of a methanol–sulfuric acid chromogenic reagent of definite and critical proportions which provided a stable and intense color suitable for measurement of microgram amounts of the estrogens.[1] The reaction was found surprisingly specific for ethinyl estradiol and its 3-ethers among a number of representative estrogens, although noninterfering chromophores were produced with three other estrogenic steroids.

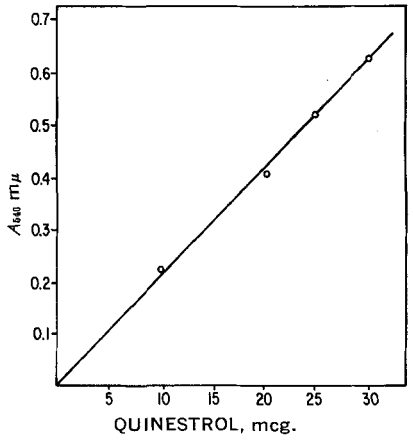

Fig. 1—Beer's law plot for the quinestrol chromophore.

EXPERIMENTAL

Equipment and Supplies—Absolute methanol and sulfuric acid were analytical reagent grade. The petroleum ether should give no color with concentrated sulfuric acid (Mallinckrodt's Nanograde was

Received October 28, 1966, from the Pharmaceutical Research and Development Laboratories, Warner-Lambert Research Institute, Morris Plains, NJ 07950
Accepted for publication February 16, 1967.
Presented at the Sixth Annual Conference on Pharmaceutical Analysis, Land O'Lakes, Wis., September 1966.

[1] Subsequent to presentation of this manuscript we learned that a similar method has been used for mestranol at Eli Lilly and Co. (12).

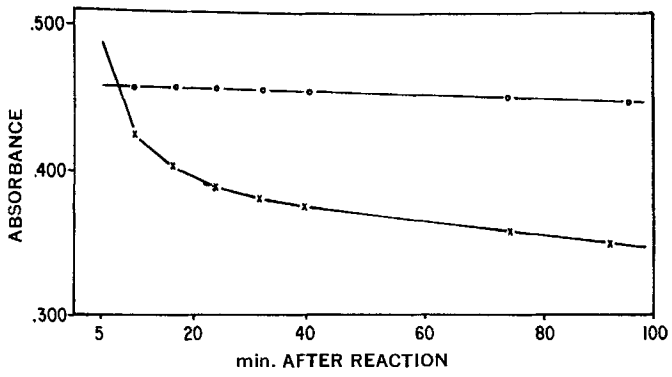

Fig. 2—Stability of color produced in the Heusghem and Jehotte and in this procedure for 20 mcg. of ethinyl estradiol. Key: ×, Heusghem and Jehotte; O, this procedure.

used). The separators used were fitted with Teflon stopcocks. A Beckman DU spectrophotometer and a Beckman DK-2 recording spectrophotometer were employed with 1-cm. silica cells for absorbance measurements.

The steroids used were official grades or comparable purity. These included reference standard quinestrol, ethinyl estradiol U.S.P., mestranol (Syntex), estrone N.F., estrone 3-cyclopentyl ether (Vismara Terapeutici, Casatenovo, Como, Italy), and β-estradiol N.F. α-Estradiol, equilin, 17-α-dihydroequilin, and equilinin were obtained from Ayerst Laboratories.

Chromogenic Reagent—Cautiously add concentrated sulfuric acid to 30.0 ml. of chilled absolute methanol in a 100-ml. volumetric flask. Adjust to room temperature and take the solution to the mark with acid. The reagent appears stable for at least 7 days.

Standard Preparation—Dissolve about 50 mg. of quinestrol or ethinyl estradiol, accurately weighed, in methanol and dilute to 100.0 ml. Further dilute 5.0 ml. to 50.0 ml. with absolute methanol to obtain a solution containing about 25 mcg. in 0.50 ml.

Assay of Tablets and Capsules—Determine the average unit weight of not less than 10 units for composite sample assay, and reduce the sample to a fine powder in a glass mortar. Transfer a weighed sample equivalent to about 25 mcg. of quinestrol or ethinyl estradiol to a 125-ml. separator containing 10 ml. of water, add 4–5 drops of concentrated hydrochloric acid, and extract the mixture with two 75-ml. vol. of petroleum ether, shaking vigorously for 2 min. during each extraction. Combine the solvent extracts in a second separator, and wash with one 10-ml. vol. of 1% sodium carbonate to remove colorants, if present. Discard the aqueous phase, and quantitatively transfer the combined extracts to a third, *scrupulously dry* separator through a cotton pledget filter with the aid of an additional 10 ml. of petroleum ether. Add exactly 0.5 ml. of anhydrous methanol, then add exactly 5.0 ml. of chromogenic reagent. Shake the mixture vigorously for 4 min., and allow the phases to separate. Discard the first few drops of the colored lower phase through the bore of the stopcock, and deliver about 4.5 ml. of the lower phase into a dry test tube. Withdraw exactly 4.0 ml. of the solution by pipet into a dry glass-stoppered centrifuge tube, add exactly 0.3 ml. of anhydrous methanol, mix well, and clarify if necessary by centrifugation. Determine the absorbance of the solution at the maximum, about 540 mμ, designating the absorbance A_u.

Concomitantly develop a color with the standard preparation, using 0.5 ml. of the standard preparation and 150 ml. of petroleum ether in a separator and following the procedure described above, beginning with "... add exactly 5.0 ml. of chromogenic reagent." Designating the concentration of the standard preparation in mcg./0.50 ml. as C and the absorbance of the color produced from it as A_s:

$$\text{estrogen, mcg./unit} = A_u/A_s \times C \times \text{mg. av. unit wt./mg. sample wt.}$$

Individual Unit-Dose Assay—Use the procedure described above with an individual intact tablet or the contents of one capsule as sample in place of the composite, adjusting the volumes of reagents appropriately for dosage forms containing more than 25 mcg. of estrogen.

Assay of Ethinyl Estradiol in a Complex Dosage Form—The example chosen was a tablet[2] declaring 5 mcg. of ethinyl estradiol, 2.5 mg. of methyltestosterone, and 16 mg. of thyroglobulin. Transfer an accurately weighed amount of pulverized tablet composite equivalent to about 15 mcg. of ethinyl estradiol to a 250-ml. separator containing 10 ml. of water, add 1-ml. of concentrated hydrochloric acid, and mix thoroughly. Extract the mixture with two 100-ml. vol. of petroleum ether, shaking about 2 min. during each extraction. Combine the extracts in a second 250-ml. separator, and wash the extract with three 5-ml. vol. of water, discarding the washings. Extract the organic phase with two 10-ml. vol. of 10% sodium hydroxide, shaking for 5 min. each time. Transfer the aqueous phases through a small cotton pledget into a third separator containing 7 ml. of concentrated hydrochloric acid. Discard the organic phase, then continue as described above for the general procedure, starting with "... extract with two 75-ml. vol. of petroleum ether. ..."

RESULTS AND DISCUSSION

Validity of Beer's Law at 540 mμ—Concentration was found to be proportional to absorbance for the chromophore produced by reaction of quinestrol or ethinyl estradiol with the chromogenic reagent. A typical Beer's law plot is shown in Fig. 1. It may be noted that assay of individual 10-mcg. tablets affords

[2] Marketed as Plestran Tablets by Warner-Chilcott Laboratories.

absorbance values at the low end of the optimum range for spectrophotometric accuracy. While the use of micro cells would have afforded better absorbance values by permitting smaller volumes of chromogenic reagent, this expedient was not resorted to in this study.

Color Stability—The stability of the color produced in the Heusghem and Jehotte procedure (11) and the color produced in the procedure reported here are compared in Fig. 2. The initial rapid fading of the color in the published procedure led to erratic results in routine assays. The difference in the methods was more marked with assay samples than with standards, for the petroleum ether solvent affords more selectivity than the more polar and hygroscopic diethyl ether used in the published method. Moreover, the new procedure obviates a solvent evaporation step.

Selectivity of the Color Reaction—The remarkable selectivity of the chromogenic reaction is illustrated in Table I. The absorptivity values reported are approximations obtained by assuming no volume changes on mixing reagents. Spectra of the ethinyl estradiol chromophore and the yellow chromophore from 17-α-dihydroequilin are shown in Fig. 3. The reaction is more selective than reactions using similar

TABLE I—VISIBLE SPECTRAL DATA FOR THE METHANOL–SULFURIC ACID CHROMOPHORE OF VARIOUS ESTROGEN STEROIDS

reagents, such as the Kober reaction to which all estrogens respond (13) and the Wintersteiner-Pfiffner green fluorescence in sulfuric acid (14). The lack of color formation in the reaction with estrone or its 3-ether suggests that the chromogenic reaction involves the groups at the 17-position of ethinyl estradiol and its ethers, but it is more difficult to adduce a structural feature common to the three other estrogens which results in the yellow chromophore. Elucidation of the apparent selectivity of the reactions of estrogens with methanol–sulfuric acid awaits characterization of the chromophores.

A possible, although not observed, degradation route for quinestrol in dosage forms is ether hydrolysis to form ethinyl estradiol. The latter might also be a by-product of quinestrol or mestranol synthesis. Extraction from alkaline solution, where any ethinyl estradiol would be retained as phenolate ion, would provide a selective assay for quinestrol or mestranol. As noted above, use of a nonpolar solvent in the isolation procedure confers a high degree of selectivity. No interference was encountered from red colorants used in tablet formulations, and spectrophotometric scans of the chromophore indicated absence of interferences in every formulation assayed.

Effect of Water on the Chromogenic Reaction—The necessity for employing dry reagents and glassware in the reaction was tested by adding varying amounts of water in the reaction of 20 mcg. of ethinyl estradiol with the chromogenic reagent. The effect is evident in Table II.

Recovery of Quinestrol Added to Placebo Tablets—Essentially quantitative recovery of added quinestrol was obtained. This was demonstrated by experiments using 20.0 mcg. of quinestrol and 150 mg. of excipients. These data are presented in Table III.

Table II—Effect of Added Water on the Color Obtained with 20 mcg. Ethinyl Estradiol

Water Added, ml.	0	0.05	0.10	0.15	0.20

	9.9	24.3
	Relative S. D., %	
	5.8	3.4

Assay of Quinestrol in Tablets—Seventeen trials on composites of tablets declaring 25 mcg. gave a mean of 24.4 mcg. (97.6%) with a relative standard deviation of 0.5 mcg. (2%). Fifteen trials on tablets declaring 10 mcg. provided a mean value of 9.6 mcg. Here the relative standard deviation from the mean was 0.28 mcg. or 2.9%.

Assay of Ethinyl Estradiol Tablets—Composite samples of two commercially available tablet formulations of ethinyl estradiol marketed by different reputable domestic manufacturers were assayed by the proposed procedure in sextuplicate. Table IV shows the results obtained. The precision compares quite favorably with that obtained in other procedures. Boughton *et al.* (7) reported over-all standard deviations of ±5.5% by the U.S.P. method and ±8.6% for their gas chromatographic procedure in assays of ethinyl estradiol tablets declaring 100 mcg. Heusser (8) reported a ±5% precision for assays of 20 mcg. tablets using colorimetry following a thin-layer chromatographic separation of the drug.

Content Uniformity Assays—Since process control studies require the assay of individual dosage units to insure uniform distribution of microgram amounts of drugs in mg. amounts of excipient matrix, the proposed procedure was applied to quinestrol tablets. The results of individual tablet assay on two typical quinestrol formulations are presented in Table V. Since the precision obtained in recovery

Table III—Recovery of 20.0 mcg. of Added Quinestrol

Trial	1	2	3	4	5	6	7
Found, mcg.	19.5	19.8	20.2	20.2	20.0	19.3	20.0

Av. recovery ± S.D. = 19.9 ± 0.34 mcg. or 99.5 ± 1.7%

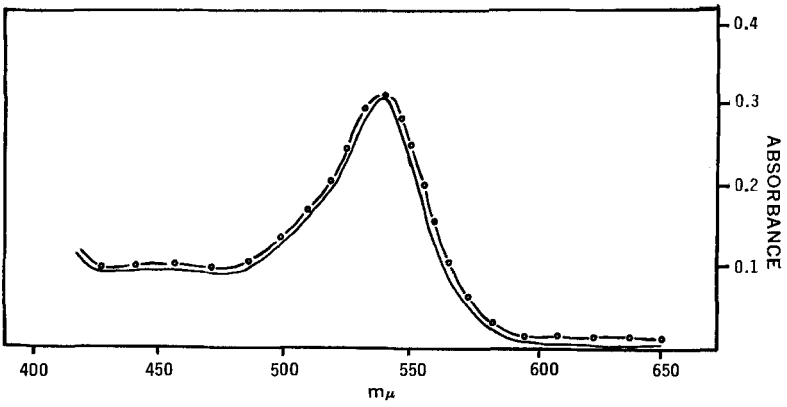

Fig. 4—Recovery of 15 mcg. of ethinyl estradiol from the tablets. (See Footnote 2). *Key: —, ethinyl estradiol standard; —·—·—·—, sample.*

experiments with quinestrol was 1.7%, the assay appears quite suitable for use in process control studies.

Ethinyl Estradiol Assay in the Estrogen–Androgen–Thyroglobulin Tablets—Recovery experiments for 10.0 mcg. of ethinyl estradiol added to the equivalent of two placebo tablets yielded values of 10.1 and 9.9 mcg.; for 15.0 mcg. added to the equivalent of three placebo tablets, a value of 15.6 mcg. was obtained. Assay of a production lot of tablets provided a value of 5.03 mcg./tablet or 102% of the declared amount. The absorption spectra of the sample and standard shown in Fig. 4 indicate the procedure provides clean separation from interferences.

SUMMARY AND CONCLUSION

Ethinyl estradiol, its 3-cyclopentyl ether, quinestrol, and its 3-methyl ether, mestranol, react with a methanol–sulfuric acid reagent of critical composition to form a stable chromophore with $\lambda_{max.}$ 540 mμ and ϵ 3.6 X 10^4. The chromogenic reaction appears to be specific for these estrogens among a number of others tested. A noninterfering yellow color with $\lambda_{max.}$ 452 mμ and varying absorptivities is produced by the reagent with α-estradiol, equilin, and 17-α-dihydroequilin, but no color is obtained with β-estradiol, estrone, estrone 3-cyclopentyl ether, and equilinin.

Examples are given of the use of the reaction for colorimetric assay of microgram amounts of quinestrol and ethinyl estradiol in dosage forms. The sensitivity, precision, accuracy, and manipulative ease of the method compare favorably with the U.S.P. colorimetric assay for ethinyl estradiol and the various chromatographic assays for it and mestranol in the literature. Solvent extraction with petroleum ether is used for isolation of the estrogens from dosage forms; this procedure itself affords considerable selectivity, since most excipients and many co-formulated drugs are excluded. An example of the selectivity of the procedure is presented in the assay of mcg. amounts of ethinyl estradiol in the presence of mg. amounts of methyltestosterone and thyroglobulin in a commercial dosage form.

Application of Reverse Phase Partition Chromatography to the Analysis of Testosterone Propionate in Oil Injectables

By EDWARD SMITH

In the analysis of testosterone propionate in oil injectables, reverse phase chromatography on silanized purified siliceous earth provides a convenient method for separating testosterone propionate from the bulk of the oil. The latter is retained on the column, while the steroid, together with the sterol and triterpenoid components of the oil, is eluted. The testosterone propionate is quantitatively separated from this mixture by direct phase chromatography, with nitromethane as immobile phase and heptane as eluant; the testosterone propionate is then determined spectrophotometrically.

THE ANALYSIS of steroid in oil solutions has been a problem for many years. Because of the lack of a suitable chemical analysis, the U.S.P. XIV (1) testosterone propionate injection monograph specified a biological assay for the solution in vegetable oil. The assay in the U.S.P. XV (2) and subsequent revisions has been a gravimetric measurement of the semicarbazone derivative, based on the procedure of Madigan *et al.* (3). For samples containing less than 10 mg./ml. of oil, a preliminary liquid–liquid extraction is used to separate the testosterone propionate from the bulk of the oil prior to the formation of the semicarbazone (3). The melting point of the semicarbazone is used as the criterion of identification.

Quantitative procedures have been described (4–6) based on colorimetric determination of the 2,4-dinitrophenylhydrazone after preliminary separation. Umberger (7) used an adsorbent magnesium silicate[1] to chromatographically separate testosterone propionate and progesterone from their oil solution prior to colorimetric determination of their isonicotinylhydrazones. Tappi *et al.* (8) also used the adsorbent magnesium silicate to separate steroids from olive oil.

The application of partition chromatography to the separation of drugs from oil dosage forms was investigated in these laboratories. Levine (9), Heftmann (10), Neher (11), and Bush (12) have reviewed the application of partition chromatography to the analysis of steroids. Jones and Stitch (13) used silicic acid–nitromethane partition columns to separate mixtures of steroids, with 3% $CHCl_3$ in petroleum ether as the mobile phase. Wolff (14) isolated progesterone from its oil injection with nitromethane as the stationary phase on purified siliceous earth[2] and *n*-heptane as the mobile phase. He found that the background ultraviolet absorbance due to the sterol fractions of the oil was thereby reduced to negligible proportions. This procedure was modified in our laboratory (15) and applied to the assay of chlorotrianisene capsules N.F.; the modified procedure is official in the N.F. XII (16). In these separations there is an interval of at least 40 ml. between the complete removal of the oil and the emergence of the desired substance.

Determination of testosterone propionate in oil injectables by this procedure proved to be difficult. The testosterone propionate follows the elution of the oil fraction so closely that sharp separation may not be achieved. The presence of such adjuvants as benzyl alcohol further interferes with this partitioning. No significant improvement was obtained by varying column dimensions or by substituting dimethylsulfoxide for nitromethane as the stationary phase.

Testosterone propionate can be separated from the bulk of the oil in these preparations by reverse phase partition chromatography. In this system, the hydrophobic support retains the nonpolar solvent as stationary phase and a polar solvent is used as the mobile phase. Silanized siliceous earth was first reported by Howard and Martin (17), who used it to separate C_{12} to C_{18} fatty acids. Other workers have used this type of silanized support to separate mixtures of adrenal steroids extracted from blood (18), to purify labeled steroids (19), and to separate these labeled steroids from urine (20). The application of silanized purified siliceous earth to the determination of steroids in oil dosage forms has not been previously described.

Silanized purified siliceous earth provides a convenient method for separating testosterone propionate from the glycerides, which constitute the major portion of the oil. The eluate from the

reverse phase column contains the testosterone propionate, together with the sterols and triterpenoids from the vehicle. It also contains any free testosterone which may be present. The testosterone propionate is separated from these materials by direct phase partition chromatography as previously described (14, 16).

EXPERIMENTAL

Materials—*Purified Siliceous Earth.*[2]

Redistilled n-Heptane—The absorbance *versus* ethanol in 1-cm. cells should be less than 0.500 in the range 250–360 mμ (limit of aromatic content). The residue from the evaporation of 25 ml. of distillate, dissolved in 10 ml. of ethanol, should have an absorbance not greater than 0.01 from 230 to 360 mμ (nonvolatile residue limit).

Nitromethane—Reagent grade.

Silanized Purified Siliceous Earth—Prepared essentially by the procedure of Howard and Martin (17). Place about 450 Gm. of purified siliceous earth in a large open glass crystallizing dish in a vacuum desiccator containing 30 ml. of silane.[3] Apply vacuum (water aspirator) intermittently for several hours until no liquid silane remains. Float the treated purified siliceous earth on distilled water and gently agitate to allow any uncoated particles to sink. Skim the coated purified siliceous earth off the surface, wash it on a sintered-glass funnel with warm methanol until the filtrate is no longer acidic, and dry at 110°.

Solvents—Shake 200 ml. of 90% ethanol with 100 ml. of redistilled *n*-heptane to equilibrate. Use the upper phase as the immobile phase on the reverse phase column and the lower phase as the eluant.

Assay Preparation—Dilute an accurately measured sample with *n*-heptane tc obtain a solution containing 0.5 mg. of testosterone propionate per ml.

Column I (Reverse Phase Column)—Pack a pledget of fine glass wool in the base of a chromatographic tube (25 × 250 mm. test tube to which is fused a 5-cm. length of 6 or 8-mm. tubing) with the aid of a tamping rod of stainless steel, aluminum, or glass at least 12 in. long and having a disk with a diameter about 1 mm. less than that of the chromatographic tube. To 3.0 Gm. of silanized purified siliceous earth in a 100-ml. beaker add 3 ml. of equilibrated *n*-heptane and incorporate by kneading thoroughly with a flexible spatula blade until the mixture is fluffy. Transfer to a chromatographic tube and tamp gently to compress the material to a uniform mass. In a like manner mix a 2-ml. aliquot of the diluted sample with 3.0 Gm. of silanized purified siliceous earth and pack above the lower layer. Dry-wash the beaker with about 1 Gm. of silanized purified siliceous earth and add this to the column. Place a small pad of glass wool above the column packing.

Colume II (Direct Phase Column)—Mix 8.0 Gm. of purified siliceous earth with 9.0 ml. of nitromethane and pack in a column as described above.

Procedure—Pass 35 ml. of equilibrated ethanol over column I, collecting the eluate in a 50-ml. beaker or conical flask. Evaporate the eluate just to dryness on a steam bath with the aid of a gentle stream of air. If the sample contains benzyl benzoate, wash down the side of the container with 5 ml. of methanol, add 5 ml. of distilled water, and re-evaporate. Repeat this evaporation step to insure complete removal of the benzyl benzoate.

Dissolve the residue in 5 ml. of *n*-heptane, heating on a steam bath and stirring to dissolve. Cool the solution to room temperature and transfer it quantitatively to column II. Wash the container with 5 ml., followed by 30 ml. of *n*-heptane and then continue the column elution with *n*-heptane. Discard the first 30 ml. of eluate. Collect the next 10-ml. fraction separately as a check[4] and then the next 150 ml. of eluate in a 250-ml. conical flask. Evaporate the 150-ml. fraction to dryness on a steam bath under a gentle stream of air. Dissolve the residue in small portions of 95% ethanol and transfer quantitatively to a 100-ml. volumetric flask. Add 95% ethanol to volume and mix. Concomitantly determine the absorbance of this solution and of a solution of the U.S.P. testosterone propionate reference standard in the same solvent at a concentration of about 10 mcg./ml. in 1-cm. cells at the absorbance maximum at about 240 and at 300 mμ in a suitable spectrophotometer, using 95% ethanol as the blank. Calculate the quantity of testosterone propionate, in milligrams, in the eluate by the formula $0.1\ C_s A_u / A_s$, where A_u is the absorbance of the sample at 240 mμ minus the absorbance of the sample at 300 mμ, A_s is the corresponding value for the standard, and C_s is the concentration of the standard solution in mcg./ml.

Identification Test—Evaporate the alcoholic solution of the isolated testosterone propionate to dryness in a suitable container. Transfer the residue obtained to a mullite mortar and prepare a potassium bromide disk in the usual manner. The infrared spectrum obtained should be identical with that obtained from a disk of testosterone propionate reference standard.

RESULTS AND DISCUSSION

For the application of reverse phase chromatography to the separation of the steroid from the bulk of the oil, several supporting media were investigated. Silanized purified siliceous earth was very effective in achieving the separation; no differences were shown by purified siliceous earth silanized with the combinations of several alkyl chlorosilanes. Nonsilanized purified siliceous earth cannot be used because it does not retain the *n*-heptane as the stationary phase. A fluorocarbon support did not give the desired separations.

During the reverse phase chromatographic partitioning, essentially all of the steroid is eluted in the first 10 ml. of eluate; however, 35 ml. of eluant is used to insure complete recovery of the steroid. Additional eluant up to 150 ml. does not remove any further quantities of ultraviolet-absorbing material from samples containing as low as 10 mg. of testosterone propionate per ml. of oil. This is the

[2] Various silanes used included 15 ml. each of dimethyldichlorosilane and trimethylchlorosilane or 30 ml. of Dow-Corning 1208 (a mixture of methyl trichlorosilane and dimethyldichlorosilane in the approximate weight ratio of 1:2).

[4] This fraction should be free of both testosterone propionate and oil. Evaporate it to dryness and dissolve the residue in 10.0 ml. of 95% ethanol. If the solution has any significant absorbance in the 230–240 mμ range, the column is not functioning properly.

[a] *A*, Five per cent benzyl alcohol in sesame oil; *B*, 3% benzyl alcohol in sesame oil; *C*, sesame oil: sample heated on water bath for 5 min. to dissolve testosterone propionate; *D*, sesame oil: sealed in ampul, heated at 100° for 2 hr.; *E*, sesame oil: sealed in ampul, heated at 160° for 2 hr.

lowest concentration found in commercial samples, and hence the concentration containing the greatest amount of oil in the aliquot analyzed.

About 99% of the oil, essentially fatty acid glycerides, is retained on the reverse phase column. The sterols and triterpenoid components of the oil are eluted together with the testosterone propionate, as are free testosterone and a number of the common adjuvants. Benzyl alcohol, chlorobutanol, and phenol are readily removed azeotropically during the evaporation of the ethanol eluate from the reverse phase column. Benzyl benzoate is partially removed in this step, but the subsequent evaporation of the 50% methanol added to the residue is necessary to completely volatilize this high boiling liquid. None of the testosterone propionate is lost during this evaporation. The parabens are not removed in this step, but are retained on the direct phase column in the ensuing step of the procedure.

The final separation of the testosterone propionate from the sterols and triterpenoids of the oil and any free testosterone on the purified siliceous earth—nitromethane column gives quantitative yields of pure testosterone propionate which is quantitated by its ultraviolet absorbance and identified by its infrared spectrum. The sterols are completely removed by the first 15 ml. of *n*-heptane. A distinct interval of about 30 ml. then follows before the appearance of testosterone propionate in the eluate. The triterpenoids, such as sesamin in sesame oil, are not eluted with *n*-heptane but are retained on the purified siliceous earth–nitromethane column. Testosterone is also retained on this column.

A series of standard samples were prepared to contain 10 to 50 mg. of testosterone propionate per ml. of sesame oil. The recoveries obtained by the column procedure are shown in Table I. Twelve commercial samples with concentrations ranging from 10 to 100 mg./ml. of oil were also analyzed by the column procedure (Table II).

The same commercial samples (Table II) and a number of standard samples (Table III) were also analyzed by the U.S.P. procedure. The results of these U.S.P. analyses were almost always higher than those obtained by the proposed method. Some of these standard samples (samples 1–11, Table III) were prepared by simply adding the weighed testosterone propionate to the measured volume of vehicle in the reaction flask, with no intermediate treatment prior to adding the reagents and completing the analysis. The analyses of these standards at the 50 mg./ml. level by the U.S.P. procedure averaged 3% higher than those by the proposed procedure, while those of the commercial samples averaged 8% higher. In order to resolve this anomaly the effects of the usual procedures used in the manufacturing of commercial samples were investigated.

[a] *A*, Three per cent benzyl alcohol, 0.5% chlorobutanol in sesame oil; *B*, 0.5% chlorobutanol in sesame oil; *C*, 0.08% methylparaben, 0.1% propylparaben in sesame oil; *D*, 1:4000 benzethonium octyloxyacetate in peanut oil; *E*, 0.5% phenol in sesame oil; *F*, 0.1% propylparaben, 3% benzyl alcohol in sesame oil; *G*, 10% benzyl alcohol, 0.08% methylparaben, 0.1% propylparaben in sesame oil; *H*, 25% benzyl benzoate, 0.5% chlorobutanol in sesame oil.

A standard sample (50 mg./ml.) was prepared by dissolving testosterone propionate in sesame oil by warming on a water bath. Portions were sealed in ampuls and subjected to dry heat sterilization. The U.S.P. method gave recoveries of 110 to 112.7% as compared with the average of 102% obtained with the unheated oil. The heating had no effect on recoveries obtained with the proposed procedure.

Blank samples of 1 ml. of sesame oil which were not heated and heated oil treated by the U.S.P. procedure yielded residues which corresponded to 1.4 and 4.1%, respectively, based on a 50-mg./ml. sample of the steroid. Greater amounts of material were contributed by the oil in the presence of testosterone propionate semicarbazone, due to coprecipitation. Weighed amounts of this derivative were dissolved in the reagent prior to the addition of the blank oil. After carrying through the U.S.P. procedure the increase contributed by the heated oil was 2 to 4 times that given by the unheated oil, paralleling the findings of the standard analyses.

The isolated derivatives from the U.S.P. assay were examined by thin-layer chromatography.[5] The material obtained from the blank oils gave a number of spots, several corresponding to the sterol and triterpenoid fractions of the oil. That from the heated oil gave more than that from the unheated oil. These same spots, as well as that of testosterone propionate semicarbazone, were ob-

[5] Samples dissolved in $CHCl_3$ were spotted on silica gel GF 0.25 mm. Solvent system: $CHCl_3$–methanol–H_2O, 90:7.5:0.5 (21). Spray the developed chromatogram with 50% H_2SO_4. Heat with heat lamp until spots are visible. Examine plate with long wavelength ultraviolet light.

tained from the standards and from the commercial samples. Several of the latter gave in addition a spot corresponding to free testosterone semicarbazone.

In contrast, the testosterone propionate isolated by the proposed procedure gives a single spot by thin-layer chromatography.

SUMMARY

Spectrophotometrically and chromatographically pure testosterone propionate is recovered quantitatively from its oil dosage forms by a combination of reverse phase and direct phase partition chromatography. The testosterone propionate, together with sterols and triterpenoids as well as any free testosterone, is separated from the bulk of the oil in the reverse phase process; it is then isolated free of these substances by direct phase partition. The procedure is applicable to samples containing such adjuvants as benzyl alcohol, benzyl benzoate, chlorobutanol, phenol, and the parabens.

Effects of Selected Variables on the Microencapsulation of Solids

By L. A. LUZZI* and R. J. GERRAUGHTY

The hypothesis that solid particles may be protectively encapsulated by coacervation led to the investigation of the extractability of microcapsules, which contained solids, by gastrointestinal fluids. Starting pH, starting temperature, ratio of solid to encapsulating materials, quantity of denaturant, and final pH were varied. The effects of the variables studied on microcapsules were determined by submitting samples to simulated gastrointestinal fluids for periods of up to 2.5 hr. and then comparing the extracts spectrophotometrically to known absorption spectra. Results showed that all variables effected some degree of change in microcapsules.

THE TERM "coacervation" has recently been used to describe the salting out of a lyophilic solid into liquid droplets rather than solid aggregates (1). The term was introduced into colloidal chemistry by Kruyt and Bungenberg de Jong (2) to describe the flocculation or separation of liquids from solution, where at least one of the liquids contained a colloidal solute.

Coacervation has been subdivided into simple coacervation and complex coacervation. Briefly,

Effects of Selected Variables on the Microencapsulation of Solids

By L. A. LUZZI* and R. J. GERRAUGHTY

The hypothesis that solid particles may be protectively encapsulated by coacervation led to the investigation of the extractability of microcapsules, which contained solids, by gastrointestinal fluids. Starting pH, starting temperature, ratio of solid to encapsulating materials, quantity of denaturant, and final pH were varied. The effects of the variables studied on microcapsules were determined by submitting samples to simulated gastrointestinal fluids for periods of up to 2.5 hr. and then comparing the extracts spectrophotometrically to known absorption spectra. Results showed that all variables effected some degree of change in microcapsules.

THE TERM "coacervation" has recently been used to describe the salting out of a lyophilic solid into liquid droplets rather than solid aggregates (1). The term was introduced into colloidal chemistry by Kruyt and Bungenberg de Jong (2) to describe the flocculation or separation of liquids from solution, where at least one of the liquids contained a colloidal solute.

Coacervation has been subdivided into simple coacervation and complex coacervation. Briefly,

Received November 18, 1966, from the College of Pharmacy, University of Rhode Island, Kingston, RI 02881
Accepted for publication February 23, 1967.
Presented to the Basic Pharmaceutics Section, A.PH.A. Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.
Abstracted in part from a thesis submitted by L. A. Luzzi in partial fulfillment of Doctor of Philosophy degree requirements.
* Present address: School of Pharmacy, University of Georgia, Athens, GA 30601

simple coacervation usually deals with systems containing only one colloidal solute, while complex coacervation usually deals with systems containing more than one colloid (3, 4).

Complex coacervation has been found to be primarily dependent on pH. It has been reported that in a gum arabic–gelatin system, complex coacervation into microcapsules occurred at pH values below the isoelectric point of the gelatin and would not occur above this pH regardless of how other factors were changed (5). The same was true of other systems containing two dispersed colloids of opposite electrical charge.

The optimum conditions for complex coacervation were achieved by adjusting the pH to a point at which equivalents of oppositely charged molecules of the two colloids were present, since, at this pH, the greatest number of salt bonds were formed (5). In such a system, the pH must be adjusted so that the gelatin particles are positively charged (below the isoelectric point), since gum arabic particles are always negative in colloidal dispersions (6). Therefore, the principal condition necessary for successful complex coacervation is pH. This factor is easily and precisely controlled and since the author had previous experience with this system, it was decided that encapsulation by way of complex coacervation would be suited to the purposes of this study.

Green and Schleiker made practical use of the process of coacervation in various patents (7–11). Two of the patents (7, 10) indicated that oils, some of which contained dissolved dyes, had been entrapped in gelatin–acacia microcapsules. No quantitative method to evaluate the strength of the capsules or the degree of encapsulation was given.

It appears that encapsulation through coacervation has great potential application in pharmacy. Some properties that might be especially useful include (*a*) prevention of vaporization of volatile substances (*e.g.*, volatile oils), (*b*) protection of moisture-sensitive or light-sensitive substances (*e.g.*, vitamins A and K), (*c*) separation of incompatible substances within a single system, (*d*) aid in the dispersion of water-insoluble substances in aqueous media and, (*e*) controlled release of encapsulated substances to the environment (*e.g.*, long acting medication).

Before such application could be explored, it was apparent that some methods should be available to predict necessary conditions to achieve good encapsulation. Luzzi and Gerraughty (12) examined some properties of oils used in pharmacy and found that the acid value and the surfactant properties of the oil affected the extraction of oils from microcapsules, whereas saponification values had little or no effect on extractability when subjected to ethyl ether.

With these considerations in mind, the system of Luzzi and Gerraughty (12) was examined. It was the intent of this study to develop a means to encapsulate solids through complex coacervation and to determine: (*a*) the effects of varying the starting pH, the starting temperature, the quantity of denaturant, the ratio of material to be encapsulated to encapsulating agents, and the final pH on the permeability of capsule shell when in contact with gastrointestinal fluids; and (*b*) to evaluate the effect of such variations on the system.

EXPERIMENTAL

Preparation of Microcapsules—The basic procedure employed by Luzzi and Gerraughty (12) for the preparation of microcapsules was used. The primary encapsulating solutions were made by dissolving 3.0 Gm. of acacia and 3.0 Gm. of gelatin separately in 100 ml. of purified water at 55°. The acacia used was powdered acacia U.S.P.; the gelatin used was 300 bloom pigskin gelatin[1] with an isoelectric point at pH 8.0.

A 20% sodium hydroxide solution was used to adjust the starting pH of the solution to 6.5. Acacia particles in solution are negatively charged and at this pH the gelatin particles are sufficiently negative so that they will not interact with the acacia.

A suspension was formed by adding the solid to be encapsulated to the solution of gelatin and acacia with gentle agitation. The pH of the mixture was then adjusted to 4.5 by the dropwise addition of diluted hydrochloric acid U.S.P., while stirring. At the pH, the gelatin particles were positively charged and were attracted to the negatively charged acacia particles. The combined particles coalesced about the suspended solid and isolated it from the rest of the system. At this point, 10 ml. of formaldehyde solution U.S.P. was added to the mixture and it was cooled to 10° by immersion in an ice bath.

The pH was then adjusted to a final pH of 9.0 by the dropwise addition of 20% sodium hydroxide solution. In order to remove solubilized drug and excess formaldehyde, the mixture was then diluted to approximately 400 ml. with distilled water and filtered. The wet mass was firmly wrapped in blotting paper to remove most of the remaining liquid. A coarsely granular material was obtained from the resulting soft rubbery mass by passing it through a 20-mesh screen and drying it at 50° for 24 hr.

To determine the effect of each variable all other variables were held at the values given in the above procedure. Each variable was studied within the following limits: (*a*) the starting pH was varied between 5.0 and 7.0; (*b*) the ratio of materials to be encapsulated to encapsulating materials (dry weight) was varied from 2/6 through 20/6; (*c*) the quantity of formaldehyde solution was varied from

[1] American Agricultural Chemical Co., Detroit, Mich.

1 ml. to 20 ml. for each 100 ml. of 3% gelatin dispersion; (*d*) the starting temperature was varied from 34° to 42°; and (*e*) the final pH was varied from 6.5 to 8.8.

Choice of Materials—The primary objective of the research was to determine whether a solid particle could be encapsulated by this particular process. Preliminary investigation showed that: (*a*) the solid to be encapsulated should be insoluble, or nearly so, in the system; (*b*) the solid particles should be readily dispersable in either gelatin or acacia solution; (*c*) the solid should contribute no surfactant properties; (*d*) the solid should be quickly soluble when exposed to the proper solvent; and (*e*) the solid should not degrade appreciably when exposed to aqueous systems for several hours.

The materials encapsulated for possible elucidation of one or more of the previously mentioned aims were: colloidal sulfur, special flowers of sulfur, aspirin anhydride (recrystallized from ethyl acetate solutions to a m.p. of 81°–83°), acetophenetidin U.S.P., barbituric acid, lycopodium spores, DDT, pentobarbituric acid (m.p. 127°–128°), and carbon black.

With one exception, difficulties in assay and stability precluded the use of all of these materials for use in these studies. The exception was pentobarbituric acid. The advantages in this case were those of relative insolubility in acid aqueous media and solubility, as a salt, in alkaline aqueous media. In addition, quantitative spectrophotometric determinations for sodium pentobarbital are easily accomplished.

METHOD OF EVALUATION OF MICROCAPSULES

The method used to evaluate the susceptibility of the coacervate shell to the action of U.S.P. simulated gastrointestinal fluids was based principally on the ability of the fluids to expose and/or extract the encapsulated material. In order to determine the degree of destruction or permeability, or both, caused by the gastrointestinal fluids, a spectrophotometric method of assay was used.

The microcapsules were prepared in the manner previously described and 0.25-Gm. samples of the dried capsules were exposed consecutively, then separately to 100 ml. of gastric fluid and 100 ml. of intestinal fluid, employing a Burrell wrist action shaker.[2]

In the first instance, the samples remained in contact with 100 ml. of gastric fluid for 0.5 hr., were filtered, and the filter paper and remaining sample were then transferred to 100 ml. of intestinal fluid; the filter paper was broken up prior to immersion in intestinal fluid. A 1.0-ml. sample of the intestinal fluid was withdrawn through a cotton pledget after 1 hr., and after 2 hr. the intestinal fluid was removed from the microcapsules by filtration.

The removal of the sample from gastrointestinal fluids was preceded in each instance by the adjustment of pH to 9.25. If the samples were to remain in a fluid for further extraction, the pH was again adjusted to official (U.S.P.) suggested values for that fluid using diluted hydrochloric acid U.S.P. or 20% sodium hydroxide solution.

[2] Burrell Corp., Pittsburgh, Pa.

Pentobarbituric acid has a pKa of 8.11 (13) and, therefore, at pH 9.1 the ratio of sodium pentobarbital to pentobarbituric acid becomes 10 to 1. Spectrophotometric studies of solutions of sodium pentobarbital indicated that absorption increased with increased pH values and that at pH 9.0, as may be predicted from theory, a gradual decrease in the slope of the curve occurred. Since pH values of 9.25 could be achieved with relative accuracy (±0.05 pH units) and ease, and since a great majority of the solute is in the salt form at this pH, this was the pH at which all liquid filtrates were compared.

The samples of filtered gastric fluid were assayed for content of active constituents, as were the filtered samples of intestinal fluids. The solutions were scanned for wavelength of maximum absorption using a recording spectrophotometer.[3] A broad peak was found with a maximum at 241 to 242 mμ. Beer's law plots were prepared using a Beckman spectrophotometer.[4] The concentration of the liquid filtrates, obtained by the extraction methods already described, were determined by comparing their respective Beer's law plots to the absorbance observed.

The total quantity of pentobarbituric acid in each sample was found by disintegrating a known weight of capsules in a Virtis blender[5] with a known volume of distilled water at pH 9.25, the sample was filtered and the resulting liquid adjusted, if necessary, to pH 9.25. Additional blending and maceration indicated that substantially all pentobarbituric acid had been released by the capsules. Aliquots were prepared and spectrophotometric data were collected which, when compared to the Beer's law plot yielded the information from which the calculations for total pentobarbituric acid content were carried out.

Microphotography of Microcapsules—It is the intent of this section to illustrate the typical formation and general appearance of microcapsules under various conditions.

Figure 1 shows a dispersion of pentobarbituric acid particles in a 3% gelatin solution. It can be seen that the particles are quite well dispersed.

Figure 2 is typical of groups of microcapsules found when there is nearly an optimum relationship between solid particles and encapsulating agents. The ratio of material to be encapsulated to encapsulating material was 8/6.

Figure 3 depicts both filled and unfilled microcapsules. The ratio of material to be encapsulated to encapsulating material was 4/6.

RESULTS

Effect of Starting pH on Microcapsules—A series of samples ranging from pH 5.0 to pH 7.0 was prepared and 0.25 Gm. of each was assayed in the manner previously described. Table I shows that, throughout the entire series, the maximum difference in per cent of total pentobarbituric acid released after 2.5 hr. of exposure to gastrointestinal fluids was only 4.8. The difference in per cent released was somewhat greater (9.9) after 0.5 hr. exposure to gastric fluid alone.

Fig. 2—Typical group of microcapsules found when there is nearly an optimum relationship between solid particles and encapsulating agents.

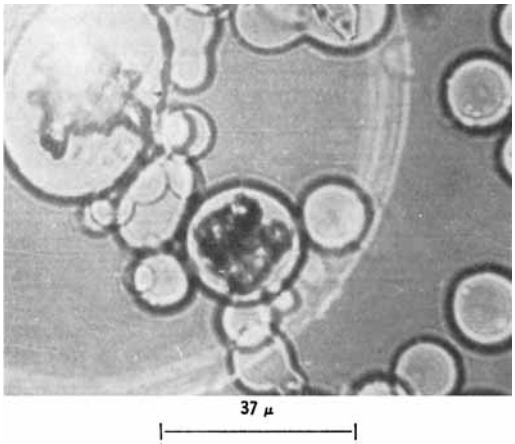

Fig. 3—Filled and unfilled microcapsules.

Effect of Starting Temperature on Microcapsules—Table II shows that the range of starting temperatures employed was between 34° and 42°. In all cases observed, except after 0.5 hr. in gastric fluid, the per cent of pentobarbituric acid that was released was found to be at a maximum at 34° starting temperature and reached a minimum at 37°.

Effect of Ratio of Solid to Encapsulating Materials—This series consisted of ratios ranging from 4.0 Gm. of pentobarbituric acid to 6 Gm. total dry weight of encapsulating materials (4/6), through 20.0 Gm. of acid to 6 Gm. total dry weight of encapsulating materials (20/6). Table III shows that the per cent of total acid which was released from the samples increased as the ratio of solid to encapsulating materials increased. Table III, it should be noted, also shows that the increase in per cent released, from 1 to 2 hr. exposures to intestinal fluid, decreased or the ratio increased.

Effect of Different Quantities of Denaturant on Microcapsules—Formaldehyde acts as a denaturant to harden and fix the wet gelatinous shell. In

TABLE I—EFFECT OF STARTING pH ON THE PER CENT OF PENTOBARBITURIC ACID EXTRACTED FROM MICROCAPSULES EXPOSED TO GASTROINTESTINAL FLUIDS[a]

[a] All values expressed as per cent of total pentobarbituric acid found in microcapsules. [b] After removal of gastric fluid, the samples were transferred to intestinal fluid.

TABLE V—EFFECT OF FINAL pH ON THE PER CENT OF PENTOBARBITURIC ACID EXTRACTED FROM MICROCAPSULES EXPOSED TO GASTROINTESTINAL FLUID[a]

Final pH	After 0.5 hr. in Gastric Fluid[b]	After 1 hr. in Intestinal Fluid	After 2 hr. in Intestinal Fluid	Total in Gastric and Intestinal Fluids
6.5	27.0	14.7	23.5	50.5
7.0	23.7	28.4	29.3	53.0
7.5	29.4	13.1	22.4	51.8
8.0	28.6	17.7	27.2	55.8
8.8	36.7	33.7	36.0	72.7

[a] All values expressed as per cent of total pentobarbituric acid found in microcapsules. [b] After removal of gastric fluid, the samples were transferred to intestinal fluid.

order to test this effect, concentrations of from 1 to 20 ml. of 37% formaldehyde solution were added to the microencapsulation process for each 100 ml. of 3% gelatin solution. Table IV shows that 1- and 2-ml. quantities of formaldehyde solution were insufficient to allow collection of samples. When 4 ml. of formaldehyde solution was used, the samples became collectable and continued so throughout the remainder of the series. An interesting observation was that during initial exposure to either gastric or intestinal fluids, the per cent of pentobarbituric acid released was greater in those samples to which the largest quantity of formaldehyde had been added.

Effect of Final pH on Microcapsules—A series of samples was prepared with final pH values ranging between 6.5 and 8.8. Table V shows that after initial exposure to gastric fluids, the per cent of acid released from samples prepared at pH 7.0 was less than the acid released from samples prepared at pH 6.5. In intestinal fluid, the per cent of acid released after initial exposure was less for samples prepared at pH 7.5 than for those prepared at pH 6.5. Thereafter, a gradual increase was noted throughout the remainder of the series.

Table V indicates that in assays carried out after 1- and 2-hr. periods, on samples transferred from gastric fluid to intestinal fluid, the per cent of pentobarbituric acid extracted was erratic, with a slight tendency to increase as the final pH was increased. Table V also shows, however, that the over-all per cent extracted increased with increasing final pH.

DISCUSSION AND CONCLUSIONS

Encapsulation of solids occurred when oppositely charged colloidal particles agglomerated about the solid particles to form a shell which may contain one or several solid particles.

There seemed to be little difference in the quantity of solid extracted over a 2.5-hr. period when the starting pH was the variable. It was expected that maximum amounts of solid would be extracted at the extremes and lesser quantities in the median ranges. Although this was the trend, a wider range of pH values would be necessary to establish this clearly.

The minimum in amount extracted at starting temperature 37° (Table II) may have been due to a combination of adequate fluidity on the part of the colloidal particles and the relative insolubility of the solid.

The study of ratio of solid to encapsulating material (Table III) seems to indicate that the smaller the ratio the greater the retaining power of the capsule. This could be due to multiple droplet thickness of the wall or to the attraction of empty capsules to filled capsules.

Although microscopic examination of samples prepared with little or no formaldehyde indicated that capsule formation did take place, the capsules seemed to disappear when the temperature of the mixture was raised from 10° through 25° to 40°. When the capsules did remain intact the increase in the per cent of solid released at lower formaldehyde concentrations (Table IV) was probably due to two factors, both of which could result from inadequate denaturization. First, the gelatin–acacia shell might not have been sufficiently denatured, thus promoting a partial solubilization of the capsule during washing. This may have made the shell less impervious to the action of gastrointestinal fluids through lack of adequate denaturization. The increased per cent of acid that was extracted when greater amounts of formaldehyde were added was probably due to a cracking, resulting from excessive denaturization, of the capsule shell on drying.

As the final pH of the encapsulating process was increased the quantity of pentobarbituric acid extracted increased (Table V). This was probably due to a solubilization of the acid at the higher pH values and the subsequent weakening of the capsule wall by the resulting increased salt content of the mixture.

Chemical Examination of *Clerodendron serratum*. Isolation and Characterization of D-Mannitol

By V. P. GARG and S. C. L. VERMA

D-Mannitol has been isolated from the root bark of *Clerodendron serratum* in a yield of 10.9 per cent and identified by mixed melting point, by analysis, chromatographic behavior, and by preparation of hexa-acetyl, hexanitro, hexabenzoyl derivatives, and benzaldehyde condensation product.

CLERODENDRON SERRATUM Spreng (N.O. *verbinaceae*) (1), popularly known in India as Bharangi, is a small flowering shrub found more or less throughout India, Ceylon, and the Malay peninsula. Various parts of the plant are credited in the Indian system of medicine with usefulness in bronchitis, asthma, eczema, catarrhal affections of lungs, febrile, and other manifestations. Aqueous extracts of the root bark of the plant have been found by Sachdev *et al.* (2) to block selectively the histamine-induced responses in isolated guinea pig ileum and on blood pressure in anesthetized dogs. The antihistaminic effects have been confirmed by Gupta *et al.* (3) in this department. Although it was considered by Sachdev *et al.* (2) that the active material could be precipitated from the aqueous extracts by addition of ethanol, a systematic chemical examination of the plant for its constituents has not been described before. During the course of fractionation of the aqueous extracts for isolating the antihistaminic principles, it has been found that the root bark contains a considerable amount (10.9%) of D-mannitol, whose isolation and identification are presently reported.

EXPERIMENTAL

Isolation of D-Mannitol

The dried root bark, freed from outer green skin and foreign matter, was reduced to about No. 20 mesh powder (500 Gm.) and was extracted with four changes of distilled water by boiling for 15 min. each. After filtering through muslin, the combined extract (3.5 L.) was allowed to stand for 3 days in an ice chest to allow complete deposition of the suspended matter. The clear supernatant was diluted 2.5 times with water and boiled briefly with active charcoal (108 Gm.). On concentrating the colorless filtrate to about 150 ml. and cooling, colorless crystalline needles of crude D-mannitol separated slowly over a number of days. The crystals were, however, collected after 3 days and further purified by passing, in aqueous solution, through a column of ion-exchange resin[1] (H) to remove traces of calcium salts that were found to be present. Yield, about 1%.

Better yield (10.9%) of D-mannitol was obtained by soxhleting the root powder with 95% ethanol for several hours, most of the extracted D-mannitol crystallizing during the extraction process. After final purification by treatment with the resin[1] and crystallization from hot 95% ethanol, the substance melted at 166° (corrected).

Anal.—Calcd. for $C_6H_{14}O_6$: C, 39.55; H, 7.74; mol. wt., 182. Found: C, 39.67; H, 7.67; mol. wt. (ebullioscopic), 188.9.

Characterization as D-Mannitol

Solubility—The isolated substance was very slightly soluble in hot 95% ethanol and insoluble in ether, chloroform, petroleum ether, benzene, and ethyl acetate. It was highly soluble in water, the solution being neutral to litmus.

Reactions—It did not reveal the presence of aromatic character or the aldehydic, ketonic, carboxyl, and phenolic groups or unsaturation. The substance, however, changed the color of ceric ammonium nitrate reagent to orange red and discharged the pink color of 1% borax solution due to phenolphthalein, the color reappearing on warming. Like D-mannitol, it prevented the precipitation of $Fe(OH)_3$ on addition of NaOH solution to a solution of $FeCl_3$ and gave a flocculent precipitate with an ammoniacal solution of copper sulfate. Its melting point on admixture with a pure authentic sample of D-mannitol was undepressed.

Optical Rotation—An aqueous solution (10%) of the substance gave no evidence of optical activity while 10% solution in 0.2 *N* borax gave $[\alpha]_D^{25}$ +30° after 3 hr.

Chromatographic Identification—The substance was found to be chromatographically homogeneous with the authentic sample on Whatman No. 1 filter paper using butanol–ethanol–water solvent (4:1.1:1.7). Its mobility was impeded on borated chromatographic strips, which is characteristic of D-mannitol.

Derivatives—The substance gave hexa-acetyl, hexanitro, hexabenzoyl derivatives, and a benzaldehyde condensation product. The properties of these derivatives agree with those given in literature for such derivatives of D-mannitol.

Hexa-acetate—Obtained readily by treatment with acetic anhydride and fused sodium acetate, m.p. 122° (corrected).

Anal.—Acetyl value: Calcd. for $C_6H_8O_6$ $(Ac)_6$: 59.47. Found: 61.5.

Hexanitrate—Prepared by treating this substance (1 part) dissolved in concentrated HNO_3 (5 parts) with concentrated H_2SO_4 (10 parts) in cold, m.p. 112° (corrected).

Received November 28, 1966, from the Pharmacology Department, Gandhi Medical College, Bhopal, India.

Accepted for publication December 30, 1966.

Anal.—Calcd. for $C_6H_8N_6O_{18}$: N, 18.59. Found: N, 18.50.

Hexabenzoate—Prepared by treating the substance with benzoyl chloride in presence of pyridine, m.p. 148° (corrected).

Benzaldehyde Condensation Product—The condensation (4) of D-mannitol (100 mg.) with benzaldehyde (200 mg.) was more satisfactorily achieved using phosphorus pentoxide (100 mg.) or concentrated sulfuric acid (2 drops), than with concentrated HCl. After shaking the mixture for 15 min., the product was washed with dilute sodium carbonate solution, water, and ether and crystallized from ethanol. The condensation product melted at 220° (corrected) (*cf.* m.p. 223–224°) (4).

Observations Concerning the Correlation of *In Vitro* Sulfonamide Activity with pKa and the Hammett Values

By ARTHUR CAMMARATA and RICHARD C. ALLEN*

Linear correlations of the *in vitro* bacteriostatic activity of sulfonamides with pKa provide little evidence in support of there being a definite pKa which a sulfonamide must possess in order to exhibit maximum activity.

Bell and Roblin (1) first reported a correlation between the *in vitro* bacteriostatic activity of a series of sulfonamides and their pKa values. They summarized their proposition in the statement: "the more negative the SO_2 group of a sulfonamide type compound, the greater the bacteriostatic activity of the compound . . . . .; the correlation between acid dissociation (pKa) and the activity is shown to be directly associated with the negative character of the SO_2 group." Seydel, Krüger-Thiemer, and Wempe (2, 3) obtained the polarizability of the SO_2 group by infrared spectrophotometric measurement of the S-O force constant. They reported that the SO_2 polarizability had no relation to the *in vitro* bacteriostatic activity of the sulfonamides, and the hypothesis of Bell and Roblin is thus cast into doubt. However, the experimental data which led to the Bell and Roblin hypothesis—namely, the correlation of activity with pKa is widely accepted (4, 5). Implications which are derived from the data of Bell and Roblin, and which are considered to be valid are: (*a*) a sulfonamide must possess a pKa which lies within a definite pKa region (6.0–7.5) in order to exhibit maximum activity; (*b*) sulfonamides having a pKa which lies to either side of this region exhibit decreasing activities.

Seydel (6) has recently shown that the *in vitro* bacteriostatic activities for an homologous series of N^1-phenylsulfanilamides are linearly correlated with their respective Hammett σ values. The correlation obtained provided a line of negative slope. In the present report, the authors present other correlations, obtained from the data of Bell and Roblin (1) and supplemented by the data of Seydel, Krüger-Thiemer, and Wempe (2, 3, 6, 7), whose activities correlate linearly with both pKa and with σ values[1] and for which lines of both positive and negative slopes are obtained. In light of these data, it is pointed out that there is little evidence to support the implications derived from the Bell and Roblin correlation; *i.e.*, that a sulfonamide must have a *definite* pKa (in the range of 6.0–7.5) in order to exhibit maximum activity.

If one classifies the activity-pKa data of Bell and Roblin in terms of homologous series it is noted that: (*a*) in the region where pKa = 6–11, the Bell and Roblin "curve" actually consists of a number of incomplete homologous series, each of which describes a straight line of negative slope; (*b*) in the region where pKa = 2–6, a limited number of homologous compounds can be found (we were able to find no more than three) to which a line of positive slope can be ascribed. In these terms, for the maximum in the Bell and Roblin curve to constitute a true maximum, it would be expected that one set of homologous series would afford lines of positive slope (pKa 2–6), another set of homologous series would afford lines of negative slope (pKa 6–11), and each set would intercept at the accepted maximum.

A search of the literature was made in an attempt to find results which would provide lines of positive slope to substantiate the Bell and Roblin maximum. Only a very limited number of antibacterial activity and pKa data could be found for use in this study. The compiled data (Table I) are presented graphically in Fig. 1; the curved dashed line is that originally reported in the work of Bell and Roblin (1). From the information at hand, only one very incomplete series, the 2-sulfanilamido-(substituted) thiadiazoles, could be said to support the ascending portion (pKa 2–6) of the Bell and Roblin plot.

Two other series appear to cast some doubt on the validity of the Bell and Roblin correlation; the N^1-(substituted) methylsulfanilamide series, which give a line of positive slope and which lies at the

[a] Minimum inhibitory concentration for bacteriostasis of *E. coli*. [b] The actual concentration was employed in evaluating $\log 1/C_R$. [c] This is the only ionic substituent in this series, which may, in part, account for its departure from the line.

very end of the Bell and Roblin curve (pKa 10–11); and, the *ortho*-substituted members of the N^1-benzoylsulfanilamide series, which yields an almost vertical line bisecting the Bell and Roblin curve at about pKa 5. These last two series have not been considered as reliable test series in our study, for there is reason to believe that the mechanism of action for these compounds may differ from that of the other series considered.

Figure 2 shows the correlation of activity with σ for the N^1-benzoylsulfanilamides.[2] It demonstrates a definite break in the line when the transition is made from *meta* and *para* substituted derivatives to the *ortho* substituted ones. If the analogy can be made between the Hammett equation and the equation which correlates activity with σ:

$$\log 1/C_R = \alpha\sigma + \log 1/C_R^\circ$$

[2] Hammett values were obtained from Jaffé's compilation (8); *ortho* values are those given by Bray and Barnes (9).

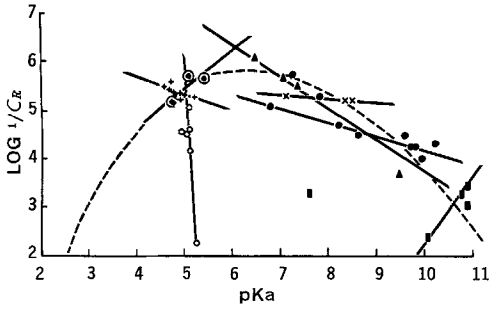

Fig. 1—Key: ⊙, *2-sulfanilamido (substituted) thiadiazoles;* +, meta *and/or* para-*substituted* N^1-*benzoylsulfanilamides;* O, ortho-*substituted* N^1-*benzoylsulfanilamides;* ▲, *2-sulfanilamido (substituted) pyrimidines;* ×, *2-sulfanilamido (substituted) pyridines;* ●, N^1-*(substituted) phenylsulfanilamides;* ■, N^1-*(substituted) methylsulfanilamides.*

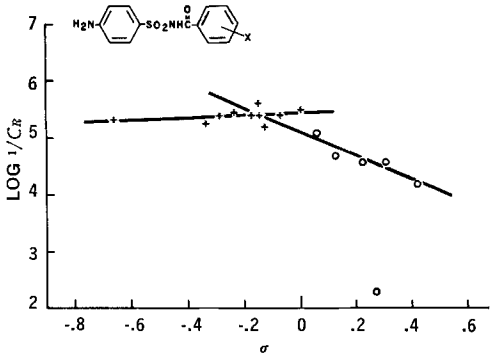

Fig. 2—Key: +, meta *and/or* para-*substituted* N^1-*benzoyl-sulfanilamides;* O, ortho-*substituted* N^1-*benzoyl-sulfanilamides.*

where α defines the "intrinsic" activity which may be associated with a given homologous series, and where log $1/C_R^\circ$ is an arbitrary reference activity, then the break in the line could be interpreted as a possible change in the mechanism of action. This would follow from similar considerations of the Hammett equation in relation to chemical reaction mechanisms (10).

It has been shown (11) that sulfonamides bearing an N^1-aromatic substituent are capable of binding at an enzyme site through each of their aromatic rings. Since all the series considered in this study possess an N^1-aromatic ring except the N^1-(substituted) methylsulfanilamides, the latter is not considered a reliable test series. It is quite conceivable that binding differences, coupled with diminished pKa values, may account for the divergent pattern in activities exhibited by *ortho*-substituted N^1-benzoyl-sulfanilamides.

The linear correlation of *in vitro* bacteriostatic activity with pKa, which is observed in this study for homologous series of sulfonamides, provides little evidence in support of there being a definite pKa which a sulfonamide must possess in order to exhibit maximum activity. Rather, from the data at hand, it appears that many sulfonamides lying outside of the "prescribed" Bell and Roblin maximum, notably those containing electron withdrawing substituents on an N^1-aromatic ring, are potentially capable of high *in vitro* activities, provided they can penetrate the bacterial cell wall.

Gas Chromatography of Alkyl Ether Derivatives of *p*-Hydroxybenzoate Esters

By MERRILL WILCOX

A procedure for the separation and estimation of mixtures of the four lower normal alkyl *p*-hydroxybenzoates as derivatives is described. The esters were converted to phenyl alkyl ethers by means of diazoalkanes. Diazoethane, diazo-*n*-propane, diazoisobutane, and diazo-*n*-butane, when catalyzed with 0.007 per cent boron trifluoride, alkylated essentially quantitatively in 30 min. at room temperature. Variable yields were noted in the absence of the catalyst for reaction times as long as 18 hr. Diazomethane did not alkylate quantitatively when catalyzed in the same manner. Derivatives prepared from mixtures of the four esters were resolved on the gas chromatograph regardless of the diazoalkane used.

THE ALKYL *p*-hydroxybenzoate esters are important food and pharmaceutical preservatives. Lach and Sawardeker (1) list several reviews of the role of these esters as preservatives. They also review the general methods of analysis which have been published. An additional general method of analysis has recently appeared (2). Higuchi *et al.* (3) developed an assay using column chromatography and U.V. spectrophotometry which could be used to resolve mixtures of the esters. Lach

and Sawardeker (1) and Donato (4) have separated and assayed the esters as their trimethylsilyl ethers by means of gas chromatography. Higher diazoalkanes have been found useful in gas chromatography of phenolic acids (5) because of their superior alkylating activity relative to diazomethane. The alkylating activity of diazomethane has been greatly increased by means of boron trifluoride catalysis (6). Alkyl ethers of phenolic acids have been demonstrated to be somewhat more stable than the corresponding trimethylsilyl ethers (7) in gas chromatography. This report describes the suitability of some higher diazoalkanes under boron trifluoride catalysis for preparation of derivatives of *p*-hydroxybenzoate esters for gas chromatography.

EXPERIMENTAL

Apparatus and Materials—A Perkin-Elmer 202 recording spectrophotometer having linear wavelength presentation was used. The gas chromatograph was a Barber-Colman 10c, equipped with a hydrogen flame ionization detector. The smallest detectable quantity of derivative was approximately 50 nanograms. Sample concentrations were chosen so that injection volumes ranged between 1 and 5 μl. Naphthalene was used as an internal standard. The injection heater and detector were maintained at a temperature 50° above that of the column.

Two columns were used. A stainless steel column 50 M. by 0.25 mm. i.d. coated internally with high vacuum paraffin grease[1] was operated isothermally at 200°, with column flow of 18 ml. argon per minute and inlet pressure of 60 p.s.i. A pre-column splitter allowed 23% of the sample to flow into the column and exhausted the remainder. In later experiments a glass column 2 M. by 4 mm. i.d. without the splitter was substituted. It was packed with 1.5% SE-30 polyester on 90–100 mesh Anakrom ABS and was operated isothermally at 135° with a column flow of 240 ml. argon per minute and an inlet pressure of 28 p.s.i.

Diazomethane was prepared without distillation from *N*-methyl-*N*-nitroso-*N'*-nitroguanidine (5) (Aldrich Chemical Co.). Higher diazoalkanes were prepared without distillation from *N*-alkyl-*N*-nitrosoureas (5). All were used within 30 hr. of their preparation. Alkyl *p*-hydroxybenzoates were provided by Tenneco Chemicals, Inc. Methanolic boron trifluoride (14%, Applied Science Laboratories) was diluted to 0.7% with anhydrous reagent methanol.

Methods—The *p*-hydroxybenzoate esters (usually 10 mg.) were dissolved in 0.5 ml. methanol and treated at room temperature with 3 ml. ethereal diazoalkane, or enough to retain a yellow color. One drop (.03 ml.) of 0.7% methanolic boron trifluoride was added to those samples where catalysis was desired. At the end of the reaction period, the excess diazoalkane was destroyed by bubbling carbon dioxide through the solution. These samples were either injected into the gas chromatograph without further treatment or were evaporated under nitrogen and made to volume in dichloromethane which gave a very narrow solvent peak. Samples used for alkylation assays were treated similarly except that they were made to volume in water rather than dichloromethane.

A phenolate difference spectrum assay was used to measure the remaining phenolic groups after alkylation. A 5-ml. sample aliquot was added to 5 ml. of 0.2 *M* phosphate buffer (pH 10) and read against a reference solution containing an identical aliquot of sample diluted with 5 ml. of 0.2 *M* phosphate buffer (pH 7). The pH values of the solutions were checked by means of a Photovolt model 110 meter after addition of buffer. A graphic method was used to measure the absorbance (*A*). A base line was drawn between the points at 270 and 340 mμ on the spectrum. The height of the curve was then read at 320 mμ relative to the base line, giving the absorbance directly. Since the instrument had linear wavelength presentation, this was equivalent to:

$$A_{\text{corrected}} = A_{320\ m\mu} - \frac{2}{7} A_{270\ m\mu} - \frac{5}{7} A_{340\ m\mu}$$

Calibration curves were prepared in this manner for concentrations which were equivalent to a range of from 0.1 to 10% unalkylated phenol. The data followed Beer's law throughout this range, which included all values of practical interest in this work.

RESULTS AND DISCUSSION

Alkylation—The alkylation activity among the diazoalkanes generally increased with chain length but was not consistently quantitative after uncatalyzed reaction periods as long as 18 hr. Catalysis with 0.007% boron trifluoride greatly increased yields. Alkylation yields following catalyzed reaction periods of 30 min. appear in Table I. The data are averages of single determinations from each of two alkylations in a typical experiment. Reaction times of 2.5 hr. were necessary for consistent alkylation of 95% or better by catalyzed diazomethane.

Chromatography—The relative retention times of the derivatives when chromatographed on the capillary column are listed in Table II. All gave single symmetrical peaks except the *n*-butyl ethers

TABLE I—PER CENT ALKYLATION OF *p*-HYDROXYBENZOATE ESTERS BY DIAZOALKANES CATALYZED WITH .007% BORON TRIFLUORIDE FOR 30 min. AT ROOM TEMPERATURE

	% Alkylation by Diazoalkane				
Ester	Methyl	Ethyl	*n*-Propyl	Iso-butyl	*n*-Butyl
Methyl	<90	97.0	99.8	99.5	99.9
Ethyl	<90	99.2	99.9	99.8	99.6
Propyl	<90	99.6	99.9	99.9	99.9
Butyl	<90	99.5	99.9	99.9	99.9

TABLE II—RELATIVE RETENTION TIMES OF ALKYL ETHERS OF *p*-HYDROXYBENZOATE ESTERS ON PARAFFIN GREASE CAPILLARY COLUMN

	Retention Time of Alkyl Ether Relative to Naphthalene[a] Internal Std.				
Ester	Methyl	Ethyl	*n*-Propyl	Iso-butyl	*n*-Butyl
Methyl	1.3	1.7	2.5	2.9	4.0
Ethyl	1.8	2.2	3.2	3.7	4.9, 5.4[b]
Propyl	2.6	3.4	5.0	5.5	7.2, 7.8[b]
Butyl	4.0	5.2	7.7	8.6	13.3

[1] Marketed as Apiezon L by the James G. Biddle Co., Philadelphia, Pa.

[a] The absolute retention time of naphthalene was 0.90 min. at 200°, 18 ml. argon carrier per min. [b] The second peak appeared to be due to decomposition on the column.

TABLE III—RELATIVE RETENTION TIMES OF ALKYL ETHERS OF *p*-HYDROXYBENZOATE ESTERS ON COLUMN PACKED WITH 1.5% SE-30 POLYESTER ON ANAKROM ABS

Ester	Retention Time of Alkyl Ether Relative to Naphthalene[a] Internal Std.		
	Ethyl	*n*-Propyl	*n*-Butyl
Methyl	2.0	2.5	3.8
Ethyl	2.4	3.2	4.8
Propyl	3.3	4.6	7.3
Butyl	5.0	7.0	11.2

[a] The absolute retention time of naphthalene was 1.0 min. at 135°, 240 ml. argon per min.

of ethyl and propyl *p*-hydroxybenzoate. These two derivatives each gave two overlapping peaks, the first being symmetrical, the second being lower with considerable tailing. The author suspects this effect was due to decomposition on the column. Single peaks without tailing were observed for the *n*-butyl ethers when the column temperature was lowered to 170°. For this reason selected derivatives were chromatographed on a column packed with 1.5% SE-30 polyester on 90-100 mesh Anakrom ABS at a temperature designed to give similar retention times. The data which appear in Table III indicate that this packed column under these conditions is more suitable than the capillary column. The four esters thus may be resolved within each set of ether derivatives under appropriate conditions. Quantitative work was restricted to diazoethane and diazopropane since they produced stable derivatives in good yields. Plots of peak height *versus* concentration were linear for the lower three esters, as were plots of peak area *versus* concentration for the butyl ester when using ethyl derivatives on the capillary column. Plots of peak height *versus* concentration were linear when using propyl derivatives of the four esters on the packed column. This was true whether the esters were alone or mixed on either column.

The results indicate that higher diazoalkanes, when catalyzed with boron trifluoride, are useful for preparation of derivatives for gas chromatography of *p*-hydroxybenzoate esters. Now that *N*-alkyl-*N*-nitroso-*N'*-nitroguanidine precursors of higher diazoalkanes are commercially available,[2] their use should be considered for gas chromatography of these or other phenolic acids.

SUMMARY

Methyl through butyl esters of *p*-hydroxybenzoic acid have been converted to alkyl ethers by means of diazoalkanes catalyzed with .007% boron trifluoride. These ethers were easily resolved on the gas chromatograph. Ethers prepared from diazoethane and diazopropane were found suitable for quantitative work. The method seems generally applicable among phenolic acids where alkylating activity greater than that of diazomethane is needed.

Syntheses of Some Hydroindolizines by Reductive Cyclization

By JOSEPH SAM and K. APARAJITHAN

The syntheses of dodecahydrobenzo[*b*] indolizine, octahydrocyclopenta[*b*] indolizine, decahydronaphth[2,1-*b*] indolizine, and 7-methoxydecahydronaphth[2,1-*b*]-indolizine are reported. The preparations of pyridylmethylene and pyridylmethyl derivatives of cyclopentanone, cyclohexanone, 1-tetralone, and 7-methoxy-1-tetralone also are described. Some preliminary pharmacological observations in mice are included.

THE SYNTHESIS of dodecahydrobenzo[*b*] indolizine (11-perhydroazafluorene) (II*b*) involving several steps was reported by Prelog and associates (1). Subsequently the authors reported (2) a two-step synthesis of II*b* by reductive cyclization of I at 200° and 2000 p.s.i. (Scheme I) and also the low pressure (50–60 p.s.i.) catalytic reductive cyclization of 2-pyridylmethylene-1-indanones (III) to the corresponding hydroindolizine (IV) (3, 4). (Scheme II.) The authors have now utilized the latter method for the synthesis of other hydroindolizines (II and XII) from 2-(2-pyridylmethylene)-cycloalkanones (IX and XI). The formation of IX*b* by the reaction of cyclohexanone (V*b*) with 2-pyridinealdehyde (VI) was investigated; however, only 2,6-bis-(2-pyridylmethylene) cyclohexanone (VII) was obtained. The synthesis of IX was accomplished by the reaction of 2-pyridinealdehyde with the morpholine enamine (VIII) (5, 6) of the cycloalkanone (V). The 3-, and 4-pyridylmethylenecycloalkanones also were prepared by this method using the appropriate pyridinealdehydes. The reaction of 2-pyridinealdehyde with 1-tetralones (X) occurred satisfactorily to yield the corresponding pyridylmethylene derivatives (XI). Some of the properties of the products from the reaction of pyridinealdehydes with various cycloalkanones are summarized in Table I.

A number of the unsaturated compounds (IX,

Syntheses of Some Hydroindolizines by Reductive Cyclization

By JOSEPH SAM and K. APARAJITHAN

The syntheses of dodecahydrobenzo[*b*] indolizine, octahydrocyclopenta[*b*] indolizine, decahydronaphth[2,1-*b*] indolizine, and 7-methoxydecahydronaphth[2,1-*b*]-indolizine are reported. The preparations of pyridylmethylene and pyridylmethyl derivatives of cyclopentanone, cyclohexanone, 1-tetralone, and 7-methoxy-1-tetralone also are described. Some preliminary pharmacological observations in mice are included.

THE SYNTHESIS of dodecahydrobenzo[*b*] indolizine (11-perhydroazafluorene) (II*b*) involving several steps was reported by Prelog and associates (1). Subsequently the authors reported (2) a two-step synthesis of II*b* by reductive cyclization of I at 200° and 2000 p.s.i. (Scheme I) and also the low pressure (50–60 p.s.i.) catalytic reductive cyclization of 2-pyridylmethylene-1-indanones (III) to the corresponding hydroindolizine (IV) (3, 4). (Scheme II.) The authors have now utilized the latter method for the synthesis of other hydroindolizines (II and XII) from 2-(2-pyridylmethylene)-cycloalkanones (IX and XI). The formation of IX*b* by the reaction of cyclohexanone (V*b*) with 2-pyridinealdehyde (VI) was investigated; however, only 2,6-bis-(2-pyridylmethylene) cyclohexanone (VII) was obtained. The synthesis of IX was accomplished by the reaction of 2-pyridinealdehyde with the morpholine enamine (VIII) (5, 6) of the cycloalkanone (V). The 3-, and 4-pyridylmethylenecycloalkanones also were prepared by this method using the appropriate pyridinealdehydes. The reaction of 2-pyridinealdehyde with 1-tetralones (X) occurred satisfactorily to yield the corresponding pyridylmethylene derivatives (XI). Some of the properties of the products from the reaction of pyridinealdehydes with various cycloalkanones are summarized in Table I.

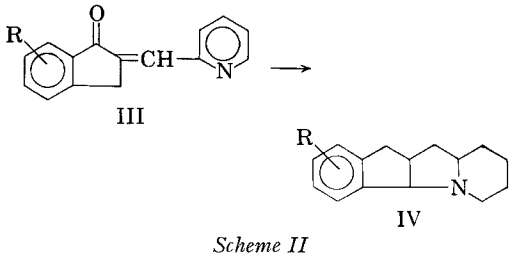

Scheme II

XI, and the corresponding 3- and 4-pyridyl derivatives) were catalytically (Pd-C) hydrogenated at 50–60 p.s.i. to the corresponding dihydro derivatives. The properties of the latter compounds are summarized in Table II.

The cyclization of IX and XI to the hydroindolizines (II and XII) was accomplished by low pressure catalytic (PtO_2) hydrogenation as described in earlier reports (3, 4). (Scheme III.) Elemental analysis and infrared spectrophotometry were used for the identification of the products. Gas–liquid chromatography of the hydroindolizines (Table III) indicated the presence of trace quantities of impurities. These, however, were readily removed during the recrystallization of the corresponding salts.

PHARMACOLOGY[1]

Acute effects after intraperitoneal administration to albino mice were observed for five of the pyridylmethylenecycloalkanones (Table I, compounds *13, 16, 17, 18, 20*), six of the pyridylmethylcycloalkanones (Table II, compounds *21, 22, 24, 27, 28, 33*) and three of the indolizines (Table III, compounds *38, 42, 46*). Gross symptomatology at toxic and subtoxic dosages was noted in a fashion similar to that described by Irwin (7) and approximate LD_{50}'s (48 hr.) were determined by the method of Horn (8) utilizing five mice per dosage level.

Most of the compounds showed LD_{50}'s in a moderate dosage range (147 to 562 mg./Kg.) with the exceptions of compound *20* which produced deaths only at greater than 1.0 Gm./Kg., and of the three indolizines which all had LD_{50}'s below 100 mg./Kg. (26 to 93 mg./Kg.). Excitation was prominent after compounds *13, 16, 17, 18, 20, 24, 27,* and *28*. Compound *20* differed in that it evoked convulsions which were delayed 2–3 hr. after administration. Muscular incoordination and/or tremors were prominent after compounds *21, 28, 33, 38, 42,* and *46*. Predominant symptoms of CNS depression were seen at all dosages of compounds *21* and *22*. Sedation seemed to occur at lower dosages of compounds *13* and *24*.

EXPERIMENTAL[2]

2-(Pyridylmethylene) Cycloalkanones (Table I)—*Method A*—A mixture of 0.4 mole of freshly distilled cycloalkanone, 40 Gm. (0.45 mole) of freshly distilled morpholine, 0.5 Gm. of *p*-toluenesulfonic acid, and 100 ml. of dry benzene was heated under reflux for 18 hr. with a Dean-Stark water separator. The benzene solution was distilled under reduced pressure (water-aspirator) to give the desired enamine (5) of cyclopentanone and cyclohexanone.

A solution of 0.3 mole of *N*-(1-cycloalkenyl)morpholine and 28 Gm. (0.26 mole) of pyridinealdehyde in 100 ml. of dry toluene or benzene was refluxed for 1 to 7 days with a Dean-Stark apparatus. The reaction mixture was cooled, treated with 120 ml. of 6 *N* hydrochloric acid, and thereafter stirred for 2 hr. The lower acid layer was separated, washed with ether, and then neutralized with sodium bicarbonate. The oil (or solid) that separated was extracted with benzene, washed with water, and dried (anhydrous magnesium sulfate). Distillation of the benzene solution under reduced pressure gave the desired product (Table I). The infrared spectrum showed strong absorption at about 5.75–5.9 μ.

2-(Pyridylmethylene)-1-tetralones—*Method B*—A mixture of 0.15 mole of the 1-tetralone, 4 ml. of acetic acid, 5 ml. of piperidine, and 0.15 mole of pyridinealdehyde was heated on a steam bath for 0.5 to 3 hr. The lower boiling materials were removed by distillation (water-aspirator). The residue was dissolved in benzene and extracted with dilute hydrochloric acid. The acid layer was separated and treated with dilute sodium hydroxide. The solid was removed by filtration and recrystallized from a suitable solvent (Table I). The infrared spectrum showed strong carbonyl absorption at about 5.95 μ.

2 - Pyridylmethylcycloalkanones—*Method C*—A solution of 0.1 mole of the 2-pyridylmethylene compound in 100 ml. of ethanol was hydrogenated at 50 p.s.i. at room temperature with 1 Gm. of 5% Pd/C catalyst in a Parr low pressure hydrogenator. The product was isolated in the usual manner and distilled (Table II). The infrared spectrum showed strong carbonyl absorption at about 5.95 μ.

Indolizines (Table III)—A solution of 0.025 mole of cycloalkanone in a mixture of 50 ml. of glacial acetic acid and 15 ml. of freshly distilled acetic anhydride was hydrogenated at 47 p.s.i. with 0.1 Gm. of platinum oxide catalyst. The absorption of hydrogen was rapid in the first hr. and was complete in 24 hr. The catalyst was removed by filtration; the filtrate was treated with 15 ml. of water and then allowed to remain at room temperature for 2 hr. The solvents were distilled; the residue was treated with 75 ml. of water and filtered. The filtrate was saturated with sodium bicarbonate and extracted with chloroform. The chloroform extract was washed with water and dried over anhydrous magnesium sulfate. The chloroform solution was distilled under reduced

[1] The authors are grateful to Dr. W. Marvin Davis, Department of Pharmacology, School of Pharmacy, University of Mississippi, University, for the pharmacological data.

[2] All melting points were taken on a Fisher-Johns apparatus and are uncorrected; boiling points are uncorrected. Infrared spectra were determined on a Perkin-Elmer model 137 Infracord spectrophotometer.

Potential Radiation Protective Agents V. Synthetic Approaches to 2-Aryl-2-mercaptoethylamines

By BENG-THONG HO and WALTER C. McCARTHY

β-Acetthiohydrocinnamoyl azide, through the Curtius degradation, gave 2-mercapto-2-phenylethylamine hydrochloride in low yield. Following the nitro-thiolacetate route to 2-aryl-2-mercaptoethylamines, two acetoxy-substituted β-nitrostyrenes were found to undergo an anomalous reaction with thiolacetic acid involving reduction of the nitro group, formation of elemental sulfur, and the isolation of products containing four more acetyl groups than the starting material.

THE CURTIUS degradation (1) route to 2-aryl-2-mercaptoethylamines was investigated. Cinnamic acid was converted through β-acetthiohydrocinnamic acid to the corresponding azide, which was rearranged and hydrolyzed to 2-mercapto-2-phenylethylamine hydrochloride. In view of the low yield, no attempt was made to extend this route to substituted members of the series.

The nitro-thiolacetate route (2, 3) to 2-aryl-2-mercaptoethylamines was studied to delineate further limitations of this synthetic sequence. Although several alkoxy-substituted β-nitrostyrenes had been shown to add thiolacetic acid to give the expected 1-aryl-1-acetthio-2-nitroethanes in good yield (3), two acetoxy-substituted β-nitrostyrenes were found to undergo a much more complex reaction under these conditions. The nitro group was reduced, elemental sulfur was formed, and the isolated products contained four more acetyl groups than the starting acetoxy-β-nitrostyrenes, as in structures I*a* and I*b*.

EXPERIMENTAL

β-Acetthiohydrocinnamoyl Chloride—β-Acetthiohydrocinnamic acid (4) was converted to its acid chloride by heating with thionyl chloride, followed by removal of the excess reagent under reduced pressure, and recrystallization from ligroin, in 99% yield, m.p. 81–82.8°.

2-Mercapto-2-phenylethylamine Hydrochloride—Activated sodium azide (5) (1.43 Gm., 0.022 mole) was added to a solution of 4.85 Gm. (0.02 mole) of β-acetthiohydrocinnamoyl chloride in 20 ml. of dry benzene, and the mixture was refluxed under nitrogen for 21 hr. After cooling, the solid matter was filtered, and the clear benzene filtrate was hydrolyzed by refluxing under nitrogen with 25 ml. of concentrated hydrochloric acid for 6 hr. Evaporation of the aqueous layer to dryness, followed by three recrystallizations from isopropyl alcohol gave 0.25 Gm. (7%) of 2-mercapto-2-phenylethylamine hydrochloride, m.p. 161–162.5°. The infrared spectrum was identical with that from the compound prepared *via* lithium aluminum hydride reduction of 1-phenyl-1-acetthio-2-nitroethane (2).

Upon cooling the separated benzene phase from the hydrolysis, a white solid crystallized, and subsequent recrystallization from a mixture of benzene and petroleum ether gave 0.56 Gm. of white crystals, m.p. 111.5–112.5°. The infrared spectrum of this product showed absorption peaks at 2565 cm.$^{-1}$ and 699 cm.$^{-1}$ characteristic of the mercapto group and at 1710 cm.$^{-1}$ characteristic of the carbonyl stretching vibration of the carboxyl group. The melting point is in agreement with that previously reported for β-mercaptohydrocinnamic acid (4, 6).

Evaporation of the benzene filtrate left 1.91 Gm. of gummy residue not further investigated.

N,O-Diacetyl-N-[β-(3,4-diacetoxyphenyl-)α,β-bis(acetthio)ethyl]hydroxylamine (Ia)—3,4-Diacetoxy-β-nitrostyrene (0.265 Gm., 0.001 mole) (7) was dissolved in 0.6 ml. (0.64 Gm., 0.008 mole) of thiolacetic acid by warming. After cooling, 5 drops of tri-*n*-butylamine was added. An exothermic reaction took place, and the mixture was allowed to stand overnight at room temperature. Filtration gave 0.295 Gm. of white solid, m.p. 166–167.5°, with a trace of yellow sulfur. (Addition of 10 ml. of 95% ethanol to the filtrate precipitated 26 mg. of yellow sulfur, m.p. 113–114.5°.) Successive recrystallization of the white solid from xylene, dioxane, and 95% ethanol raised the m.p. to 172–172.5°.

Anal.—Calcd. for $C_8H_5NO_3S_2Ac_6$: C, 49.48; H, 4.77; N, 2.88; O, 29.66; S, 13.21; acetyl, 53.2. Found: C, 49.40; H, 4.91; N, 3.01; O, 29.49; S, 13.07; acetyl, 54.0.

The infrared spectrum showed a carbonyl absorption peak at 1750 cm.$^{-1}$ and a thiolacetate peak at 1680 cm.$^{-1}$; the absorption peak of the nitro group at 1545 cm.$^{-1}$ was absent.

The NMR spectrum, in deuterochloroform at 60 Mc. with tetramethylsilane as internal reference, showed a 3-proton aromatic singlet at τ 2.84, two methine doublets centered at τ 3.67 and 4.86, J = 9.5 c.p.s., and six methyl singlets at τ 7.70, 7.74, 7.75, 7.79, 7.86, and 7.94.

3-Acetoxy-β-nitrostyrene—To a stirred solution of 10 Gm. (0.0608 mole) of *m*-acetoxybenzaldehyde, 8.2 ml. (0.152 mole) of nitromethane, and 60 ml. of 95% ethyl alcohol cooled to 5°, there was added 26 ml. of 10% (0.0604 mole) aqueous sodium hydroxide. The reaction time was limited to 30 sec. (8), after which the reaction was arrested by the addition of 200 ml. of 2% (0.067 mole) of aqueous acetic acid.

Received October 12, 1966, from the College of Pharmacy, University of Washington, Seattle, WA 98105
Accepted for publication February 28, 1967.
Part of this work was done under contract DA-49-193-MD-2048 with the U. S. Army Medical Research and Development Command, Office of the Surgeon General, Washington, D. C.

A yellow oil (10.7 Gm.) separated. (Increasing the reaction time to 1 min. gave only half this yield of yellow oil.) The infrared spectrum of this material was consistent with that expected for the nitro-alcohol condensation product, but this material was sufficiently labile that it was not convenient to purify a sample for analysis. This oil was dehydrated by mixing with 10.7 Gm. of powdered fused sodium acetate and 53.4 Gm. (0.523 mole) of acetic anhydride and boiling under reflux for 10 min. After cooling, the mixture was poured into 120 ml. of water. A yellowish brown solid was obtained, 8.25 Gm., m.p. 76–79°. Recrystallization from 95% ethanol gave 6.35 Gm. (51%) of yellow crystals, m.p. 83.5–84.5°.

Anal.—Calcd. for $C_{10}H_9NO_4$: C, 57.97; H, 4.38; N, 6.76; O, 30.89. Found: C, 58.12; H, 4.50; N, 6.82; O, 30.93.

N,O-Diacetyl-N-[β-(3-acetoxyphenyl-)α,β-bis-(acetthio)ethyl]hydroxylamine (Ib)—3-Acetoxy-β-nitrostyrene (0.193 Gm.) was dissolved in 0.5 ml. of thiolacetic acid. Addition of 5 drops of tri-*n*-butylamine caused an exothermic reaction. The resulting solution was allowed to stand at room temperature for 20 hr. Upon addition of 1 ml. of 95% ethanol followed by cooling and scratching, there was precipitated 75 mg. of white solid, m.p. 110–111°. Recrystallization from ethanol did not raise the m.p.

Anal.—Calcd. for $C_8H_6NO_2S_2Ac_5$: C, 50.57; H, 4.95; N, 3.28; S, 15.00; acetyl, 50.3. Found: C, 49.76; H, 5.03; N, 3.39; S, 14.89; acetyl, 49.9.

Oxidative Effect of Perbenzoic Acid on *N*-Methylated Pyrrole, Indole, and Carbazole

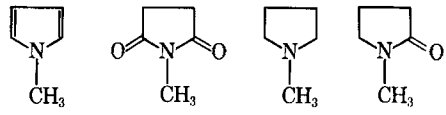
By I. NABIH and E. HELMY*

Perbenzoic has been shown to oxidize *N*-methylpyrrole to *N*-methylsuccinimide, *N*-methylpyrroline to *N*-methylpyrrolidone, and 2,3-dihydro-*N*-methylindole to *o*-dimethylaminobenzaldehyde. Under similar conditions *N*-methylcarbazole and 1,4-dihydro-*N*-methylcarbazole are not oxidized.

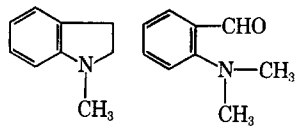
EXTENSIVE STUDIES have been carried out on the oxidation of pyrrole, indole, and carbazole using a variety of oxidizing agents (1–5).

In this work, the oxidative effect of perbenzoic acid on the *N*-methylated forms of pyrrole, indole, and carbazole is studied. Generally, peracids have been mostly used for the selective oxidation of the carbon-carbon double bond. As an electrophilic reaction, the rate is enhanced through the presence of an electron-donating group in the substrate (6). In systems where double bond is conjugated with other multiple bonds, this rate decreases since the delocalization of the π electrons reduces the electron density at all the double bonds.

Usually, the oxidation with peracids leads to the epoxide; however, the products may undergo subsequent rearrangements, as in the case of chloroolefins, where the over-all products are the chloroketones (7). Also, epoxidation of aliphatic enol-acetate leads after intermolecular rearrangements to α-acetoxy-ketones (8). By this route, the olefins *via* the epoxidation products can be converted after undergoing rearrangement to carbonyl compounds (9). In the present work, when *N*-methylpyrrole (I) was subjected to the oxidizing effect of perbenzoic acid in chloroform solution, the analytical measurements showed that two atoms of oxygen had been involved in the reaction. Preparative experiments showed that the reaction product was *N*-methyl succinimide (II) in 92% yield. It appears in this reaction that the initially formed epoxides at both double bonds, favored through the presence of the electron rich *N*-methyl group, undergo internal rearrangement to give the imide.



I II III IV



V VI

When *N*-methyl-3-pyrroline (III) was similarly treated, the product was *N*-methyl-α-pyrrolidone (IV) in 79% yield. The analytical data showed that only one oxygen atom had been consumed.

Under the same condition, 2,3-dihydro-*N*-methylindole (V) is oxidized with the fission of the pyrrole nucleus and *o*-dimethylaminobenzaldehyde (VI) is obtained in 81% yield. The analytical measurement indicated the consumption of one oxygen atom during the reaction.

N-Methylcarbazole and 1,4-dihydro-*N*-methyl carbazole could not be oxidized with the same oxidizing agent.

Received October 31, 1966, from the National Research Centre, Cairo, Egypt.
Accepted for publication January 20, 1967.

EXPERIMENTAL

All melting points were taken in open capillaries and are uncorrected.

Determination of the Number of Oxygen Atoms Needed for a Known Weight of the Organic Substance (10).—The organic substance (0.2 Gm.) was added to a known volume of perbenzoic acid in chloroform with known normality. The mixture was left for 6 hr. in a dark place with occasional shaking. Five milliliters of 10% KI solution as well as 2 drops of concentrated H_2SO_4 were added to the mixture. The liberated iodine was then titrated against sodium thiosulfate (0.1 *N*).

With N-Methylpyrrole (I)—The determination showed two oxygen atoms to be involved in the reaction.

N-Methyl Succinimide (II)—*N*-Methylpyrrole (2.0 Gm.) was added to 190 ml. 0.54 *N* perbenzoic acid in chloroform. The reaction mixture was left in a dark place for 12 hr. Then it was neutralized by sodium bicarbonate solution. The chloroform layer was then isolated, washed with water several times, dried over calcium chloride, and finally evaporated.

Two and one half grams of *N*-methylsuccinimide was left. Yield 92%. Crystallization from acetone as white needles gave m.p. 67–68°. [Lit. m.p. 66° (11).]

Anal.—Calcd. for $C_5H_7NO_2$: C, 53.09; H, 6.29; N, 12.30; O, 28.31. Found: C, 53.00; H, 6.18; N, 12.30; O, 28.30.

With N-Methyl-3-pyrroline (III)—The determination showed that one oxygen atom was involved with each mole of the compound.

N-Methyl-α-pyrrolidone (IV)—*N*-Methyl-3-pyrroline (2.0 Gm.) was added to 120 ml. of perbenzoic acid in chloroform 0.4 *N* (one oxygen atom). The whole mixture was left for 3 hr. in a dark place at room temperature, then neutralized by sodium bicarbonate solution. The chloroform layer was then isolated, washed with water, dried over calcium chloride, and evaporated.

A 1.9-Gm. (79.1%) quantity of *N*-methyl-α-pyrrolidone was collected as a colorless oil, b.p. 201°/740 mm. [Lit. 202°/760 mm. (12).]

Anal.—Calcd. for $C_5H_9NO.HCl$: C, 44.40; H, 7.40; N, 10.36; O, 11.84. Found: C, 44.38; H, 6.99; N, 10.30; O, 11.81.

With N-Methylindoline (V)—The determination showed one oxygen atom was consumed in the reaction.

o-Dimethylaminobenzaldehyde (VI)—*N*-Methylindoline (2.0 Gm.) was added to 104 ml. 0.29 *N* perbenzoic acid in chloroform (one oxygen atom). The reaction mixture was left at room temperature in a dark place for 24 hr. with occasional shaking, then neutralized by solution of sodium bicarbonate. The chloroform layer was then separated, washed with water several times, dried over calcium chloride, and finally evaporated.

A 1.8-Gm. (81%) quantity of *o*-dimethylaminobenzaldehyde was collected at 141/30 mm. as yellow oil. [Lit. 142°/30 mm. (13).]

Anal.—Calcd. for $C_9H_{12}N_2O$: C, 60.10; H, 6.66; N, 15.55. Found: C, 59.87; H, 6.29; N, 15.49.

Isolation of Matricin from *Artemisia caruthii*

By JEFFREY C. SPITZER and CORNELIUS STEELINK

The sesquiterpene lactone, matricin, has been isolated from *Artemisia caruthii* and is shown to be the precursor of chamazulene, previously reported in the steam distillate of this species.

THE COMMON SAGE brush *Artemisia caruthii* Wood, var. *Wrightii* (A. Gray), yields a blue oil upon steam distillation or upon simple brewing as a "folk" tea. The oil has been identified (1) as chamazulene (I). Because of the occasional use of the plant as a folk medicine by the Indians of Northern Arizona, and because of the wide distribution of sesquiterpene lactones in the *Artemisia* species, the authors were prompted to investigate the sesquiterpene lactone precursors of chamazulene (pro-chamazulenogens) in this species.

The isolation and characterization of matricin (II) in *A. caruthii* is reported. This compound exists in low concentrations in the plant, and is readily converted to chamazulene (I) by simple steam distillation or by heating in the presence of

All melting points were taken in open capillaries and are uncorrected.

Determination of the Number of Oxygen Atoms Needed for a Known Weight of the Organic Substance (10).—The organic substance (0.2 Gm.) was added to a known volume of perbenzoic acid in chloroform with known normality. The mixture was left for 6 hr. in a dark place with occasional shaking. Five milliliters of 10% KI solution as well as 2 drops of concentrated H_2SO_4 were added to the mixture. The liberated iodine was then titrated against sodium thiosulfate (0.1 *N*).

With N-Methylpyrrole (I)—The determination showed two oxygen atoms to be involved in the reaction.

N-Methyl Succinimide (II)—*N*-Methylpyrrole (2.0 Gm.) was added to 190 ml. 0.54 *N* perbenzoic acid in chloroform. The reaction mixture was left in a dark place for 12 hr. Then it was neutralized by sodium bicarbonate solution. The chloroform layer was then isolated, washed with water several times, dried over calcium chloride, and finally evaporated.

Two and one half grams of *N*-methylsuccinimide was left. Yield 92%. Crystallization from acetone as white needles gave m.p. 67–68°. [Lit. m.p. 66° (11).]

Anal.—Calcd. for $C_5H_7NO_2$: C, 53.09; H, 6.29; N, 12.30; O, 28.31. Found: C, 53.00; H, 6.18; N, 12.30; O, 28.30.

With N-Methyl-3-pyrroline (III)—The determination showed that one oxygen atom was involved with each mole of the compound.

N-Methyl-α-pyrrolidone (IV)—*N*-Methyl-3-pyrroline (2.0 Gm.) was added to 120 ml. of perbenzoic acid in chloroform 0.4 *N* (one oxygen atom). The whole mixture was left for 3 hr. in a dark place at room temperature, then neutralized by sodium bicarbonate solution. The chloroform layer was then isolated, washed with water, dried over calcium chloride, and evaporated.

A 1.9-Gm. (79.1%) quantity of *N*-methyl-α-pyrrolidone was collected as a colorless oil, b.p. 201°/740 mm. [Lit. 202°/760 mm. (12).]

Anal.—Calcd. for $C_5H_9NO.HCl$: C, 44.40; H, 7.40; N, 10.36; O, 11.84. Found: C, 44.38; H, 6.99; N, 10.30; O, 11.81.

With N-Methylindoline (V)—The determination showed one oxygen atom was consumed in the reaction.

o-Dimethylaminobenzaldehyde (VI)—*N*-Methylindoline (2.0 Gm.) was added to 104 ml. 0.29 *N* perbenzoic acid in chloroform (one oxygen atom). The reaction mixture was left at room temperature in a dark place for 24 hr. with occasional shaking, then neutralized by solution of sodium bicarbonate. The chloroform layer was then separated, washed with water several times, dried over calcium chloride, and finally evaporated.

A 1.8-Gm. (81%) quantity of *o*-dimethylaminobenzaldehyde was collected at 141/30 mm. as yellow oil. [Lit. 142°/30 mm. (13).]

Anal.—Calcd. for $C_9H_{12}N_2O$: C, 60.10; H, 6.66; N, 15.55. Found: C, 59.87; H, 6.29; N, 15.49.

Isolation of Matricin from *Artemisia caruthii*

By JEFFREY C. SPITZER and CORNELIUS STEELINK

The sesquiterpene lactone, matricin, has been isolated from *Artemisia caruthii* and is shown to be the precursor of chamazulene, previously reported in the steam distillate of this species.

THE COMMON SAGE brush *Artemisia caruthii* Wood, var. *Wrightii* (A. Gray), yields a blue oil upon steam distillation or upon simple brewing as a "folk" tea. The oil has been identified (1) as chamazulene (I). Because of the occasional use of the plant as a folk medicine by the Indians of Northern Arizona, and because of the wide distribution of sesquiterpene lactones in the *Artemisia* species, the authors were prompted to investigate the sesquiterpene lactone precursors of chamazulene (pro-chamazulenogens) in this species.

The isolation and characterization of matricin (II) in *A. caruthii* is reported. This compound exists in low concentrations in the plant, and is readily converted to chamazulene (I) by simple steam distillation or by heating in the presence of

II

Received November 1, 1966, from the Department of Chemistry, University of Arizona, Tucson, AZ 85721
Accepted for publication December 30, 1966.
Abstracted in part from a thesis submitted by Jeffrey C. Spitzer to the University of Arizona, Tucson, in partial fulfillment of Doctor of Philosophy degree requirements.

dilute mineral acid. Matricin is concentrated in the bitter leaves of the plant and exhibits its maximum concentration during July. By September, it is almost undetectable in the plant. It has been previously found only in *Matricaria chamomilla* (2); this is the first report of its occurrence in the *Artemisia* species.

EXPERIMENTAL

Dried ground leaves of *A. caruthii* (collected from the Graham Mountain region of Arizona at elevations above 6000 ft.) were soaked in chloroform overnight. The green slurry was filtered, evaporated to dryness, and taken up in 100 ml. of 95% ethanol. The addition of 300 ml. of water precipitated a tar. The supernatant liquid was filtered through a mat of diatomaceous earth[1] and activated carbon.[2] The filtrate was then shaken with chloroform, and the chloroform layer concentrated to a gum (yield, 1.1%). Preparative thin-layer chromatography (1 mm. thick Silica Gel G; solvent: 90:1 chloroform–methanol) proved to be the most efficient method for separating the prochamazulenogen from other lactonic materials. Methanol elution of the band at R_f 0.22 from a number of TLC plates yielded enough tan colored material for characterization.

The following physical constants were entirely consistent with structure II and with a sample of authentic matricin,[3] m.p. 152–156°. $[\alpha]_D^{30}$ −122° ($CHCl_3$); $\lambda_{max.}$ 242 mμ (ε, 11,200); ν, 3600 cm.$^{-1}$ (OH), 1780 cm.$^{-1}$ (γ-lactone), 1747 cm.$^{-1}$ (acetoxy). The NMR assignments are shown in Table I. Although the evidence is not unequivocal, one would deduce from the NMR data that 5, 6, and 7 protons are all *trans*.

In addition to the above evidence, co-chromatography of the prochamazulenogen and authentic matricin in four different solvent systems showed no differences. Matricin polymerizes readily on exposure to light or upon moderate heating; this creates some problems in handling.

Since the original interest in the plant was motivated by reports of its use as a folk medicine, the authors submitted certain fractions for physiological analysis. The chloroform extract (matricin-rich) exhibited minor depressant activity with cats.[4] Chamazulene, whose precursor is matricin, showed some antispasmodic activity. It also produced urination and emesis in cats, when given intraperitoneally.

TABLE I—NMR ASSIGNMENTS

p.p.m.[a]	Multiplicity	Assignment	No. Protons
1.36	2	C-13	6
1.43	1	C-14	
1.90	1	C-15	11 or 12
2.14	1	OAc	
2.0–3.3	...	C-5,7,9,11, —OH	
4.12	3	C-6	1
4.9	...	C-8	1
5.94	2	C-3	1
6.33	2	C-2	1

[a] Relative to tetramethylsilane.

CONCLUSION

The labile sesquiterpene matricin (II) has been found to be the precursor of the blue oil, chamazulene (I), in *A. caruthii*. This is the first report of the occurrence of matricin (II) in an *Artemisia* species; the taxonomic implication of this type of lactone in plants is discussed elsewhere (3). The activity of I as an emetic is interesting. The Navajo and Hopi Indians use *A. caruthii* as an emetic in cleansing ceremonies (4). Although chamazulene (I) does not exist in the plant as such, it can be obtained from matricin (II) by the simple steam distillation or tea-brewing process. The conversion of II to I is not only a remarkable example of dehydration and dehydrogenation, but is also the basis of an effective folk medicine.

Method of Estimating Relative Absorption of a Drug in a Series of Clinical Studies in Which Blood Levels Are Measured After Single and/or Multiple Doses

By JOHN G. WAGNER

Previously published methods of estimating relative absorption of a drug are primarily applicable to crossover studies in which a panel of subjects is administered one or more test formulations and a readily available form of the drug. The method described provides estimates of average relative absorption of a drug administered to different panels of subjects in a series of clinical trials in which blood levels are measured after either single and/or multiple doses of the drug. The method incorporates corrections for differences in dosage, body weight or surface area, and intra- and inter-subject variation in half-life of the drug. The method is illustrated by results of calculations made from 167 sets of serum concentrations of tetracycline hydrochloride activity including 112 sets obtained following administration of tetracycline to children and 55 sets obtained following administration of tetracycline to adults.

WAGNER AND NELSON (1) summarized seven methods of estimating per cent availability. These methods are primarily applicable to a crossover study in which a panel of subjects are administered one or more test formulations and a readily available form of the drug. Frequently, however, one may wish to compare the relative absorption of a drug in a series of clinical trials performed with different panels of subjects at different times. In such a case one must make corrections for differences in dosage, body weight, and intra- and inter-subject variations in half-life of the drug. The method to be described allows such corrections to be made and also allows comparison of blood levels observed after a single dose and during a dosage interval at the equilibrium state after multiple doses of drug administered at uniform time intervals.

EXPERIMENTAL

Following single doses of drug the basic material balance equation[1] as given by Wagner *et al.* (2) is:

$$F \cdot D = V \cdot K \cdot \int_0^\infty C(t)\,dt \qquad \text{(Eq. 1)}$$

where F is the fraction of the dose which is absorbed, D is the dose, V is the apparent volume of distribution of the drug, K is the first-order rate constant for over-all loss of drug from the body, and the integral represents the area under the blood (serum or plasma) concentration curve from zero to infinite time.

Substitution of $0.693/t^1/_2$ for K, where $t^1/_2$ is the half-life, and rearrangement gives

$$\frac{\int_0^\infty C(t)dt}{D \cdot t^1/_2} = \frac{F}{0.693V} \qquad \text{(Eq. 2)}$$

If $C(t)$ is expressed in micrograms per milliliter, D in milligrams per kilogram of body weight, t and $t^1/_2$ is similar units, then V will be in units of liters per kilogram of body weight which is equivalent to fraction of body weight, and F is dimensionless. The dose, D, could also be expressed in milligrams per square meter of body surface area in which case V will be in units of liters per square meter of body surface area.

Similarly, following multiple doses of a drug one can derive (2) the relationship

$$\frac{\int_{t_1}^{t_2} C_\infty(t)}{D \cdot t^1/_2} = \frac{F}{0.693V} \qquad \text{(Eq. 3)}$$

where the integral represents the area under the blood (serum or plasma) concentration curve during a dosage interval at the steady state after multiple doses of drug given at uniform time intervals, τ, such that $\tau = t_2 - t_1$, and F is the fraction of each dose which is absorbed; the other symbols have the same meanings as indicated above.

The half-lives, $t^1/_2$, may be estimated in the usual manner from the terminal $C(t)$, t values after a single dose of drug or following the last dose of a series of doses given at uniform time intervals; in the latter case, it may or may not be necessary to include values beyond the end of the last dosage interval. The infinite area of Eq. 2 may be estimated from the equation

$$\int_0^\infty C(t)dt = \int_0^T C(t) + \frac{\hat{C}_T}{K} \qquad \text{(Eq. 4)}$$

where $\hat{C}_T$ is the estimated serum concentration at the last sampling time, T, following the single dose of drug, the integral represents the area under the blood (serum or plasma) concentration curve from zero time to time T, and K is defined in Eq. 1. The integrals $\int_0^T C(t)dt$ and $\int_{t_1}^{t_2} C_\infty(t)dt$ may be estimated by trapezoidal rule from observed serum concentrations measured at appropriate time intervals after dosing. The value of $\hat{C}_T$ is obtained by substituting T for t in the equation of the least squares line used to estimate K.

The method of estimating relative absorption of a

The averages are based on 35 *different* subjects' data. [c] Marketed as Panalba KM by The Upjohn Co., Kalamazoo, Mich. [d] Marketed as Albamycin-T by The Upjohn Co., Kalamazoo, Mich. [e] Marketed as Panmycin by The Upjohn Co., Kalamazoo, Mich. [f] It is the author's experience that similarity in average ratios is not improved when surface area rather than body weight is used as the variable.

drug in a series of clinical studies utilizes calculation of the area/dose × half-life ratios shown in the left-hand side of Eqs. 2 and 3 for each subject administered a given dosage form in each study. The average value of the ratio for the panel of subjects administered a given dosage form of the drug in each study is calculated. If the assumption is made that the average apparent volume of distribution (expressed as a fraction of body weight or liters per $M.^2$ of body surface area) is the same from panel to panel of subjects, then the average ratios are indices of relative absorption efficiency.

RESULTS

The method has been applied by the author to estimate relative absorption efficiencies of several antibiotics administered in different dosage forms to different panels of subjects in dozens of clinical trials. As an example, results are presented of half-lives and area/dose × half-life ratios estimated from serum concentrations of tetracycline hydrochloride activity (in micrograms per milliliter) observed in several clinical trials in which children and adults were administered various novobiocin-tetracycline combinations and tetracycline hydrochloride alone in capsules. Results are summarized in Table I. Although there was wide variation in milligram dosage, body weight, and estimated half-life in these studies, the average area/dose × half-life ratios are amazingly similar. Appropriate statistical tests indicated that the difference between any pair of the averages of the ratios was not significant at the 5% level of confidence. If one assumes that the average volume of distribution expressed as a fraction of body weight was constant, these data indicate that the average efficiency of absorption of tetracycline was not significantly different in the six groups of subjects listed in Table I.

Determination of 17α-Ethynylestradiol-3-methyl Ether in Tablets by a Colorimetric Assay

By ARVIN P. SHROFF and RICHARD E. HUETTEMANN

A colorimetric method has been developed for assaying 17α-ethynylestradiol-3-methyl ether in tablets. The method is based on the formation of a colored complex with phenol–sulfuric acid reagent. This complex exhibits an absorption maximum at 550 mμ, obeys Beer's law, and is stable for a reasonable length of time. Optimum conditions for the color formation in the presence of a nonphenolic steroid have been determined and are reported herein.

ESTROGENS in combination with progestational agents have come into prominence as a contraceptive composition in the last decade. The most frequently used estrogen in these combinations is 17α-ethynylestradiol-3-methyl ether (mestranol). A rapid and sensitive colorimetric determination of mestranol in a tablet combination with norethindrone[1] stored under a variety of conditions is the subject of this paper.

Steroidal estrogens have been assayed by a number of methods. Of these ultraviolet spectrophotometric (1, 2) and spectrofluorometric (3–5) analyses have been preferred by a number of authors. The lack of sensitivity of the ultraviolet method of assay on aged tablets was shown by this laboratory (2).

Recently ion-exchange (6) and paper chromatographic methods (7) have also appeared in the literature. These methods are sensitive but they lack the specificity required in the presence of other steroids for a rapid analytical method. Specificity can be imparted to these methods through prior isolation of the estrogens by other techniques. However, because of the number of manipulations required, varied results may be obtained. Schulz (8) has discussed the difficulties of assaying mestranol by a paper chromatographic method.

Gas-liquid chromatography has also been considered to be a desirable technique (2, 8–10). It offers quantitation with concurrent fractionation. The GLC process developed for assaying mestranol by this laboratory (2), although efficient, was relatively slow for routine assay purposes.

A colorimetric technique was resorted to because of its rapidity and reproducibility. Estrogens have been determined by colorimetric methods using 2,6-dibromoquinone chlorimide (11) and various diazotized amines (12–18) as the color-producing reagents. The official U.S.P. procedure for the determination of estrone, estradiol, and ethynyl estradiol, is based on the Kober reaction.

In this investigation the color development of mestranol was carried out with a phenol–sulfuric acid reagent. The color formation was stable over a reasonable period of time and no interference by nonphenolic steroids was observed. As a result of these studies with extraction procedures and different commercial phenols, a rapid, accurate, and sensitive colorimetric procedure for mestranol in estrogen–progestin tablets was developed. A comparison of the results from the ultraviolet, gas-liquid chromatographic, and colorimetric methods is also presented.

EXPERIMENTAL

A Beckman model DU spectrophotometer was used to determine the absorbance values and a Cary model 11 recording spectrophotometer was used to obtain the spectrum in Fig. 1.

Reagents and Solutions—Freshly distilled phenol, methylene chloride, sulfuric acid (1:1), and methylcyclohexane (spectroquality) are used.

Phenol–Sulfuric Acid Solution—Add 40.0 Gm. of phenol to a 400-ml. beaker containing 100 ml. of 1:1 sulfuric acid solution. Bring the mixture to a boil with continuous stirring and until homogeneous. Store in a volumetric flask and in a dark place.

Mestranol Standard Solution—Weigh accurately 10.0 mg. of mestranol into a 100-ml. volumetric flask and dilute to mark with methylene chloride.

Procedure—Place a number of tablets equivalent to about 400 mcg. of mestranol in a 29.5 × 80-mm. vial. To this add 4.0 ml. of distilled water and shake until the tablets disintegrate. Add 4.0 ml. of methylcyclohexane and shake for 30–60 min. Centrifuge for approximately 2 min. and transfer 1.0 ml. of clear methylcyclohexane solution to a 21 × 50-mm. vial. Also transfer 1.0 ml. of the standard mestranol solution into another 21 × 50-mm. vial. Evaporate the solvent in each vial over a steam bath and under a stream of nitrogen. To each vial add 5.0 ml. of phenol–sulfuric acid solution. To a third 21 × 50-mm. vial add 5.0 ml. of phenol–sulfuric acid solution to serve as a reference. Shake the three vials thoroughly and place them in a 55° water bath for 5 min. Allow the solutions to come to room temperature in a dark place (about 15 min.) and determine the absorbance of the standard and the sample at 550 mμ, using the contents of the third vial as the reference solution.

DISCUSSION

The absorbance spectrum of mestranol resulting from the reaction with phenol–sulfuric acid is shown in Fig. 1. It exhibits broad absorption maxima at 470 mμ and 550 mμ. The stability of the color as measured at 550 mμ depended upon the phenol used. For example, a reagent made with May and Baker phenol gave a stable color over a period of 6 hr., whereas other reagents made from different phenols

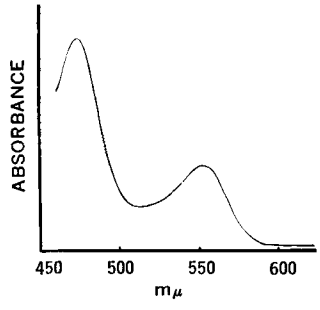

Fig. 1—Visible absorption spectrum of mestranol treated with phenol–sulfuric acid reagent.

Received November 3, 1966, from the Division of Organic Chemistry, Ortho Research Foundation, Raritan, NJ 08869

F	13 mo. R.T.	51.5	45.6	50.6	52.2
G	18 mo. R.T.	57.6	48.9	56.5	56.0

[a] Data obtained from *Reference 2*.

did not give so stable a color. However, in all instances the color intensity remained constant for a sufficient length of time (20–30 min.) to allow recording of the spectrophotometric readings.

The relationship between absorbance at 550 mμ and the quantity of mestranol was found to obey Beer's law. The standard deviation for accuracy and precision was found to be ± 1.6% and ± 1.52%, respectively.

The specificity of the method for mestranol in the presence of norethindrone and other tablet excipients is demonstrated by the results shown in Table I. The excipients used in the formulation of the tablets were lactose, cornstarch, magnesium stearate, and polyvinylpyrrolidine. The data in Table I include several samples of formulation stored under various conditions of temperature and humidity. A previous study (2) indicated that mestranol did not undergo any decomposition under these conditions. Hence, the selectivity and sensitivity of this colorimetric method appeared adequate for performing routine studies.

Table I compares the data obtained by the ultraviolet and gas chromatographic methods (2) with the present colorimetric results. It is evident that the color assay compares favorably with the gas chromatographic assay and is superior to the ultraviolet method. The mechanism by which phenol–sulfuric acid reacts with mestranol and other estrogens to give colored products is under investigation.

SUMMARY

A quantitative colorimetric procedure using phenol–sulfuric acid has been developed for the analysis of mestranol in estrogen–progestin tablets. The accuracy and precision of this method are ±1.6% and ±1.52%, respectively. The nonphenolic steroid and tablet excipients do not interfere in the determination.

Identity of Columbianadin and Zosimin

Sir:

Recently, Nikonov and Baranauskaite (1, 2) reported the isolation of a purportedly new coumarin, zosimin, from the roots of *Zosimia absinthifolia* (Vent) Link. This compound analyzed for the formula $C_{19}H_{20}O_5$ and, on alkaline saponification, yielded *cis*-1,2-dimethylacrylic acid (*i.e.*, tiglic acid) and a hydroxylactone, zosimol (m.p. 156–158°), with the formula $C_{14}H_{14}O_4 \cdot {}^1/_2CH_3OH$. It was recognized that zosimin was isomeric with columbianadin (3, 4), but the apparent divergence in optical activities between the two coumarins and the corresponding hydroxylactones led the authors to the conclusion that they were different and that zosimin was, in fact, a new coumarin. Their decision apparently was confirmed by the fact that zosimin yielded tiglic acid on alkaline saponification. The identity of the hydroxylactone was ascertained by Perel'son *et al.* (5) by both spectral and chemical studies, thus eliminating the several other possible structural candidates [*e.g.*, marmesin (6), lomatin (7), 3′-hydroxy-3′,4′-dihydroxanthyletin (8), *etc.*]. On this basis it was concluded originally that zosimin

[a] Data obtained from *Reference 2*.

did not give so stable a color. However, in all instances the color intensity remained constant for a sufficient length of time (20–30 min.) to allow recording of the spectrophotometric readings.

The relationship between absorbance at 550 mμ and the quantity of mestranol was found to obey Beer's law. The standard deviation for accuracy and precision was found to be ± 1.6% and ± 1.52%, respectively.

The specificity of the method for mestranol in the presence of norethindrone and other tablet excipients is demonstrated by the results shown in Table I. The excipients used in the formulation of the tablets were lactose, cornstarch, magnesium stearate, and polyvinylpyrrolidine. The data in Table I include several samples of formulation stored under various conditions of temperature and humidity. A previous study (2) indicated that mestranol did not undergo any decomposition under these conditions. Hence, the selectivity and sensitivity of this colorimetric method appeared adequate for performing routine studies.

Table I compares the data obtained by the ultraviolet and gas chromatographic methods (2) with the present colorimetric results. It is evident that the color assay compares favorably with the gas chromatographic assay and is superior to the ultraviolet method. The mechanism by which phenol–sulfuric acid reacts with mestranol and other estrogens to give colored products is under investigation.

SUMMARY

A quantitative colorimetric procedure using phenol–sulfuric acid has been developed for the analysis of mestranol in estrogen–progestin tablets. The accuracy and precision of this method are ±1.6% and ±1.52%, respectively. The nonphenolic steroid and tablet excipients do not interfere in the determination.

Identity of Columbianadin and Zosimin

Sir:

Recently, Nikonov and Baranauskaite (1, 2) reported the isolation of a purportedly new coumarin, zosimin, from the roots of *Zosimia absinthifolia* (Vent) Link. This compound analyzed for the formula $C_{19}H_{20}O_5$ and, on alkaline saponification, yielded *cis*-1,2-dimethylacrylic acid (*i.e.*, tiglic acid) and a hydroxylactone, zosimol (m.p. 156–158°), with the formula $C_{14}H_{14}O_4 \cdot {}^1/_2CH_3OH$. It was recognized that zosimin was isomeric with columbianadin (3, 4), but the apparent divergence in optical activities between the two coumarins and the corresponding hydroxylactones led the authors to the conclusion that they were different and that zosimin was, in fact, a new coumarin. Their decision apparently was confirmed by the fact that zosimin yielded tiglic acid on alkaline saponification. The identity of the hydroxylactone was ascertained by Perel'son *et al.* (5) by both spectral and chemical studies, thus eliminating the several other possible structural candidates [*e.g.*, marmesin (6), lomatin (7), 3′-hydroxy-3′,4′-dihydroxanthyletin (8), *etc.*]. On this basis it was concluded originally that zosimin

TABLE I—ROTATIONS OF COMPOUNDS

Compd.	M. p.	Specific Rotation in $CHCl_3$
Zosimin	119–120° (1, 2)	$[\alpha]_D^{16}$ +272° (c, 1.03)
Columbianetin angelate (*i.e.*, columbianadin)	117–119° (3)	$[\alpha]_D^{16}$ +237.8° (c, 1.0)[a]
	121–122° (3)	$[\alpha]_D^{21}$ +234.5° (c, 1.0)[a]
	118.5–119° (4)	$[\alpha]_D^{26}$ +230.5° (c, 1.0)[a]
		$[\alpha]_D^{26}$ +227° (c, 2.8) (4)
Columbianetin tiglate	107–108° (3)	$[\alpha]_D^{16}$ +250.1° (c, 1.0)[a]
		$[\alpha]_D^{21}$ +246.5° (c, 1.0)[a]
		$[\alpha]_D^{26}$ + 243.9° (c, 1.0)[a]
Zosimol	156–158° (1, 2)[b]	$[\alpha]_D^{16}$ +209.4° (c, 0.74)
Columbianetin	164.5–165° (3)	$[\alpha]_D^{16}$ + 165.1° (c, 1.0)[a]
	162.8–163.3° (4)	$[\alpha]_D^{21}$ +164.5° (c, 1.0)[a]

[a] Measurements carried out on a Perkin-Elmer model 141 polarimeter. [b] The discrepancy between this melting point and that of columbianetin is apparently due to ½ mole of methanol of crystallization in contrast to the anhydrous form of columbianetin.

was the tiglate ester of 2′-*tert*-hydroxyisopropyl-2′,3′-dihydrofuro-4′,5′:8,7-coumarin, (*i.e.*, columbianetin tiglate).[1]

Previous studies (3) had encompassed the synthesis of both the angelate (m.p. 117–119°) and tiglate (m.p. 107–108°) esters of columbianetin, and it was apparent that the tiglate ester was not identical with zosimin on the basis of the melting point discrepancy. Since the reported melting point of zosimin (m.p. 119–120°) was so similar to that of columbianetin angelate, (*i.e.*, columbianadin), it seemed reasonable to suspect that they were one and the same. Furthermore, previous experience in this laboratory with a very similar alkaline saponification of columbianadin (3) indicated that tiglic acid was the product instead of the angelic acid that might have been expected. Such a facile conversion of angelic acid to tiglic acid, however, is not unexpected (10).

The difference in specific rotation reported by us for columbianadin $\{[\alpha]_D^{27}$ + 26.5° (c 1.0, dioxane)$\}$ and that obtained for zosimin $\{[\alpha]_D^{16}$ + 272° (c 1.03, $CHCl_3$)$\}$ appears to be one of the principal reasons for deciding on the nonidentity of the two coumarins. However, it is well known that the specific rotation of a given compound can vary widely when using different solvents. When we took the rotations of columbianadin, columbianetin tiglate, and columbianetin in chloroform in order to obtain a direct comparison with zosimin and zosimol (see Table I), the results showed that the apparent wide discrepancy in specific rotations between columbianadin and zosimin as well as between columbianetin and zosimol was substantially eliminated with identical solvents. Nevertheless, the difference in rotation of columbianetin tiglate and angelate was not great enough to make a decision for the identity of either ester with zosimin. The approximately 34° and 44° higher rotation of zosimin and zosimol over columbianetin angelate and columbianetin, respectively, however, suggested an instrumental difference rather than a real difference since these were the only two structural possibilities in each case.

In assessing the evidence for and against the identity of columbianadin with zosimin it was obvious that only a direct comparison of the two compounds would provide an unequivocal answer. Fortunately, Dr. Nikonov kindly supplied several milligrams of zosimin which enabled such a comparison. Infrared spectra in Nujol mull showed the two to be identical in every respect and, furthermore, no depression of melting point was observed in a mixed melting point determination. The optical rotation of Nikonov's sample of zosimin was $[\alpha]_D^{20}$ + 221.2° (c 1.0, $CHCl_3$). This was substantially lower than that reported by him and is in reasonable agreement with that of columbianadin from two independent laboratories (3, 4). It is, therefore, safe to conclude that columbianadin and zosimin are identical.

[1] More recently, Nikonov (9) has suggested that the difference between zosimin and columbianadin may be in an optically isomeric relationship between columbianetin and zosimol since the 4.05 τ position, in the nuclear magnetic resonance spectrum, of the methine proton found by them in zosimin is contradictory to a tiglate formulation (3).

Comparative Utility of the Silyl Ether and Acetate Ester Derivatives of Ethinyl Estradiol for Its Quantitative Gas Chromatographic Determination

Sir:

A recent paper (1) in *J. Pharm. Sci.*, comparing the U.S.P. method with a gas chromatographic determination of ethinyl estradiol, contains several allusions to our paper on the gas chromatographic assay of the estrogen (2), claiming certain advantages for the choice of the trimethyl silyl ether derivative over our use of the acetate derivative. We should like to offer a rebuttal on several of these comparisons.

Boughton, Bryant, Ludwig, and Timma (1) inferred from our work that, "The ethinyl estradiol appears to have been uncontaminated with other steroids . . . ." Since the extraction procedure reported by these authors is essentially identical with ours, one would hardly expect interference in one procedure and not the other. In point of fact, however, the samples on which we reported contained 10 to 20 times the concentration of ethinyl estradiol of an experimental progestational steroid, which resulted in no interference.

The authors (1) further claimed that evaporation of acetic anhydride necessary in our procedure introduces a possible source of error, presumably circumvented by substitution of silylation in their procedure for acetylation in ours. This contention is contradicted by comparison of our reported precision of $\pm 1.7\%$ with the standard deviations of $\pm 1.5\%$ found for the silylation method, which are not statistically different.

The statement that ". . . the authors wished to analyze for at least 50% less ethinyl estradiol than Talmage, Penner, and Geller had analyzed, and for our purposes the acetate derivative did not give sufficient response on the chromatograph" (1) is perhaps the most misleading. We did not find it necessary to use maximum sensitivity in our procedure; using the acetate derivative, sensitivity could easily have been increased by a factor of 10. We have chromatographed unmodified ethinyl estradiol, its silyl ether, and its acetate ester at the same concentration using instrumental conditions previously described (2). The chromatograms shown in Fig. 1 indicate that little sensitivity gain is afforded by use of the silyl ether in preference to the acetate ester derivative; however, it is interesting to note the increase in retention time with increase in molecular weight.

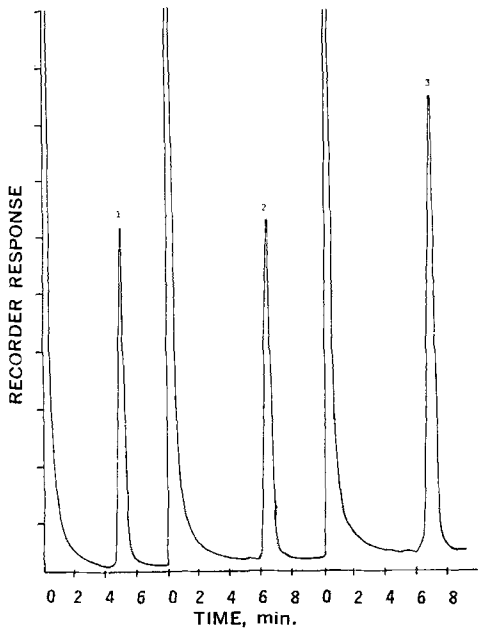

Fig. 1—Comparative chromatogram. Key: 1, ethinyl estradiol; 2, ethinyl estradiol, acetate ester; 3, ethinyl estradiol, silyl ether.

The results shown in Fig. 1 indicate that ethinyl estradiol can be determined by gas chromatography without formation of derivatives. We were aware of this during our work with the acetate ester, but found better precision using the derivative. Subsequent to this work, however, it was determined that the unmodified ethinyl estradiol can be estimated with good precision and accuracy if the column is saturated with the estrogen before quantitative samples are run. We interpret this as saturating the active sites on the column, thus making them unavailable for irreversible adsorption.

Estimation of Rate Constants for Absorption and Elimination from Blood Concentration Data

Sir:

Wagner (1) discussed estimation of the rate constant for elimination from the slope of the descending part of an apparently linear semilogarithmic plot of concentration of drug in blood plasma against time. He pointed out that such a graphical estimate may be lower than the true value of the rate constant. Also, since the estimate of the absorption rate constant depends upon the value of the elimination rate constant, the estimated value of the absorption rate constant may be in error too. It is the purpose of this communication to show that this difficulty may be overcome by methods of digital computation, although Krüger-Thiemer and Eriksen (2) recently reported that it could not. The problem with the data of Krüger-Thiemer and Eriksen (2) was that blood samples were not taken long enough following oral administration.

Several examples were presented by Wagner (3, 4). One example (4) was the fitting of serum concentrations of tetracycline hydrochloride activity observed in a subject following a single oral dose of a capsule of tetracycline HCl[1] 250 mg. The semilogarithmic plot gave an estimate of 0.130 hr.$^{-1}$ for the elimination rate constant. The residuals, plotted semilogarithmically, gave an estimate of 0.810 hr.$^{-1}$ for the absorption rate constant. Use of these preliminary estimates with an iterative digital computer program gave a least squares fit (using equal weights) with a 57.6% reduction in variance; the rate constant for elimination changed to 0.149 hr.$^{-1}$ and the rate constant for absorption changed to 0.716 hr.$^{-1}$. If one assumes the least squares estimates are the "best" values, then the graphical estimate of the absorption rate constant was 13.1% higher, and the graphical estimate of the elimination rate constant was 12.8% lower than the "best" value, respectively. The latter is of the same order of magnitude as in the simulation example of Wagner (1).

Another example is the fitting of average serum concentrations of erythromycin activity observed in a panel of 12 adult male volunteers following oral administration of 500 mg. of erythromycin activity in tablet form. Preliminary graphical estimation, shown in Fig. 1, gave an estimate of 0.899 hr.$^{-1}$ for the absorption rate constant, 0.393 hr.$^{-1}$ for the elimination rate constant, and 0.58 hr. for the lag time. An iterative digital computer program gave a least squares fit (with weighting according to the reciprocal of the average serum concentrations) with a 73.2% reduction in variance; the absorption rate constant changed to 0.708 hr.$^{-1}$, the elimination rate constant changed to 0.444 hr.$^{-1}$, and the lag time changed to 0.602 hr. If one assumes the least squares estimates are the "best" values, then the graphical estimate of the absorption rate constant was 27.0% higher and the graphical estimate of the elimination rate constant was 11.5% lower than the "best" value, respectively. The least squares fit is shown in Fig. 2.

These two examples are representative of a more general phenomenon. Least squares fitting of all observed serum or plasma concentrations of a set almost always results in an increase of 10 to 15% in the magnitude of the elimination rate constant and a decrease in the magnitude of the absorption rate constant compared with estimates obtained graphically using semilogarithmic paper. This implies that, in such cases, the trend line of the terminal data points of the semilogarithmic plot is slightly curved and not linear as one assumes when estimating the elimination rate constant by the graphical method. This is illustrated by Fig. 3, in which the least squares curve is drawn through the data points on semilogarithmic paper.

This underestimation of the elimination rate constant can be anticipated from the equation for plasma or serum concentration, namely:

$$\text{concn.} = (\text{constant})\,(e^{-k_2 t} - e^{k_1 t}) \quad \text{(Eq. 1)}$$

where $k_1 > k_2$. The observations of concentration underestimate $e^{-k_2 t}$ by the amount $e^{-k_1 t}$; this bias is greater for smaller values of t. A line drawn through the terminal points of a semilogarithmic plot of concentration against time will have successively greater bias to the left. This bias causes the line to have a smaller slope than it should have, thus underestimating k_2, the elimination rate constant.

We have assumed in the above discussion that the smallest rate constant estimated is the elimination rate constant and the larger rate constant is the absorption rate constant. This is usually the case but, in rare instances, the assignments could be reversed. We also assume that the estimate of the smallest rate constant by least squares fitting of all the data points is a more valid estimate than the estimate obtained

[1] Marketed as Panmycin Hydrochloride by The Upjohn Co., Kalamazoo, Mich.

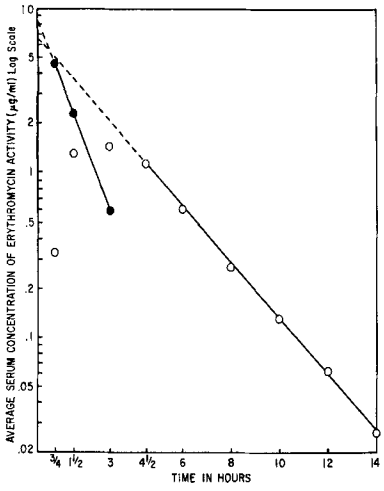

Fig. 1—Illustrates graphical estimation of the rate constants. The terminal linear segment gave an estimate of 0.393 hr.$^{-1}$ for the elimination rate constant. The residuals gave an estimate of 0.899 hr.$^{-1}$ for the absorption rate constant. The intersection of the two lines gave an estimate of 0.58 hr. for the lag time. Key: ○, observed; ●, residuals.

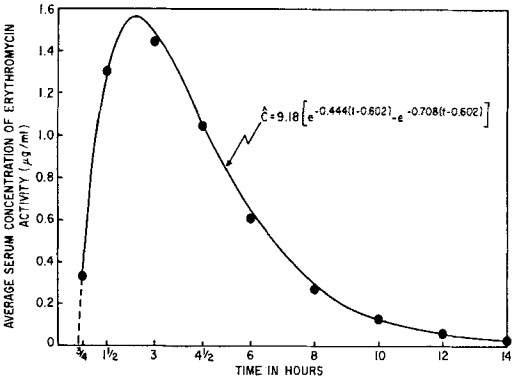

Fig. 2—The black circles are the observed average serum concentrations of erythromycin. The line was drawn by substituting values of time into the equation shown on the figure. The equation was the result of least squares fitting of the observed serum concentrations with a digital computer. Weighting was according to the reciprocals of the average serum concentrations.

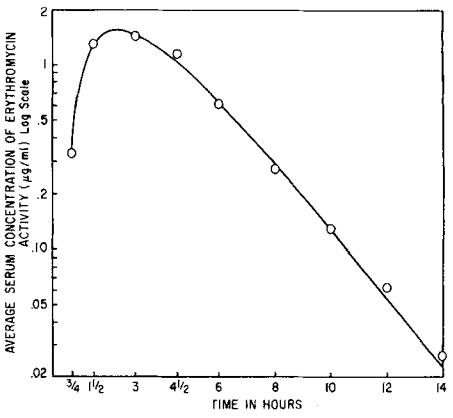

Fig. 3—The circles are the observed average serum concentrations of erythromycin. The line drawn through the points was obtained by substituting values of time into the equation shown on Fig. 2. It should be noted that the line drawn through the terminal six points is slightly curved compared with the straight line in Fig. 1.

graphically from only some of the points. Since most estimates of elimination rate constants reported in the literature were obtained by the latter method, we believe the reported rate constants are lower than the "best" values, and the corresponding half-lives are higher than the "best" values.

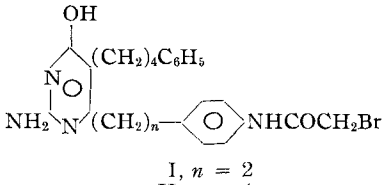
Irreversible Enzyme Inhibitors LXXXVIII. Differential Irreversible Inhibition of Dihydrofolic Reductase from Different Species

Sir:

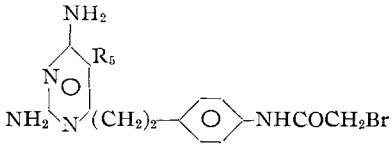
A variety of 2,4-diaminoheterocycles, known to be reversible inhibitors of dihydrofolic reductase, are sufficiently tissue- or species-specific to be useful chemotherapeutic agents (1, 2). Examples are amethopterin for leukemia (3), 5-(*p*-chlorophenyl)-2,4-diamino-6-ethylpyrimidine (4), and 1-(*p*-chlorophenyl)-4,6-diamino-1,2-dihydro-2,2-dimethyl-*s*-triazine (5) as antimalarials; 2,4-diamino-5-(3,4,5-trimethoxybenzyl)pyrimidine as an antibacterial (6); and 1-(*p*-chlorophenyl)-4,6-diamino-1,2-dihydro-2,2-(2′-methyltetramethylene)-*s*-triazine as an anthelmintic (7, 8). The selectivity of amethopterin on certain tissues can be attributed to a difference in the efficiency of the folic acid active-transport system (9). The selectivity of the remaining compounds is most probably due to differences in binding by the aryl groups to the hydrophobic bonding region of dihydrofolic reductase (2, 10–12); these compounds appear to enter cells by passive diffusion (13, 14).

Although numerous 2,4-diaminoheterocycles of the type that enter cells by passive diffusion have been screened in a variety of tumors by the CCNSC, none have shown sufficient selectivity to warrant medical use; thus, to date, differences in the hydrophobic bonding region of dihydrofolic reductases from normal and tumor tissue have not been sufficiently great to be exploitable. Since with active-site-directed irreversible inhibitors an extra dimension of specificity can be obtained which is not present with reversible inhibitors (15–17), such irreversible inhibitors might exhibit more selectivity than reversible inhibitors. That selective irreversible inhibition can be obtained with inhibitors of the dihydrofolic reductases from different sources is the subject of this paper.

Compounds I–IV were evaluated as reversible and irreversible inhibitors of the dihydrofolic reductases from pigeon liver and *E. coli* B; the results are presented in Table I. The 2-amino-4-pyrimidinols (I and II) inactivated both enzymes at rates not differing more than a factor of 2 when compared at equal concentrations of reversible enzyme-inhibitor complex—the rate-determining species (16, 18). In contrast, the 2,4-diaminopyrimidine (III) analog of the 2-amino-4-pyrimidinol (I) showed no inactivation of either enzyme.



I, $n = 2$
II, $n = 4$



III, R = $-(CH_2)_4C_6H_5$
IV, R = $-C_6H_4Cl$-*p*

Although the 2,4-diamino-5-*p*-chlorophenylpyrimidine derivative (IV) was equally effective as a reversible inhibitor of both enzymes, irreversible inhibition showed dramatic selectivity; only the *E. coli* B enzyme was inactivated.

Also noteworthy is the comparative irreversible inhibition of the *E. coli* B dihydrofolic reductase with III and IV; the structural difference resides only in the hydrophobic bonding group at the 5-position, yet IV inactivated the enzyme, but III did not. Apparently the nature of binding of the hydrophobic bonding group (R_5) to the enzyme can change the position of the terminal leaving group, thus effecting the juxtaposition of the leaving group to the enzymic nucleophilic group—as previously predicted (12, 19).

The search for specificity with irreversible inhibitors between dihydrofolic reductases from selected animal tumors and a normal tissue, such as liver, from the same animal is currently being pursued.

Revised Structure of Columbianin

Sir:

Columbianin is a naturally-occurring glycosidic coumarin isolated from *Lomatium columbianum* Math. and Const. (1) and from *L. dissectum* var. *multifidum* (Nutt.) Math. and Const. (2). Willette and Soine (1) suggested structure I for columbianin on the basis that, on acid hydrolysis, it yielded D-glucose and a tertiary alcohol (*i.e.*, columbianetin). The structure of the aglycone (II) was firmly established by spectral studies as well as by chemical degradative evidence and has since then been confirmed (3) and extended (4) by Nielsen and Lemmich to show that the absolute configuration is 8(*S*). Since no quantitative estimation of the D-glucose content was made in the earlier study and because the analytical data (*i.e.*, assuming water of crystallization) corresponded within limits for I and its tetraacetate, the structure assignment was considered adequate.

Recently, in connection with another study, we had occasion to examine the nuclear magnetic resonance (NMR) spectrum of acetylated columbianin and noted that the *O*-acetyl methyls were to be observed as four peaks at τ 7.92, 8.00, 8.04, and 8.07; whereas the *gem*-dimethyls of columbianetin were found as a singlet at τ 8.69. To our surprise, the peak ratio between the *O*-acetyl methyls and the *gem*-dimethyls was found to be 3.52:1 instead of the expected 2:1. This led us to re-examine the structural assignment for columbianin by means of additional analytical data as well as by further degradative studies.

An ebullioscopic determination on the acetate suggested the molecular weight to be about 800 and an acetyl analysis indicated 34.92%, both values being incompatible with the tetraacetate formulation. On the other hand, the results pointed strongly toward a disaccharide moiety in columbianin and a heptaacetate as the acetylated form. Furthermore, additional elemental analyses on the acetate derivative gave much closer correspondence with the values expected for $C_{40}H_{48}O_{21}$ than for the previously suggested $C_{28}H_{32}O_{13} \cdot 2H_2O$. The question of the presence of sugars other than D-glucose had been ruled out in the earlier work (1).

Partial hydrolysis of the glycoside was carried out using an ion exchange resin[1] in the acid cycle (5). Examination of the hydrolysate by paper chromatography was carried out using an ethyl acetate–pyridine–water mobile phase and developing the chromatogram by using the silver nitrate technique (6) for visualization of the

carbohydrate spots. Two spots were observed with one of these being identical to D-glucose in its R_f value. The R_f value of the other spot was consistent with that for disaccharides possessing a 1→6 linkage. Thus, the possibilities, virtually indistinguishable by paper chromatography, were isomaltose (α-linkage) and gentiobiose (β-linkage). The same partial hydrolysis carried out on a preparative scale led to the isolation of several milligrams of the crude disaccharide, $[\alpha]_D^{20}$ −6° (c 2.00, H_2O). Since the specific rotations (7) of the two possibilities are rather far apart—isomaltose, $[\alpha]_D^{24}$ +120° (H_2O); gentiobiose $[\alpha]_D^{20}$ +8.7° (H_2O)—the results strongly suggested gentiobiose as the disaccharide, with the small discrepancy probably being accounted for by extraction of impurities from the paper. Acetylation of the disaccharide provided gentiobiose octaacetate, m.p. 191–192°, $[\alpha]_D^{20}$ −1.86° (c 0.64, $CHCl_3$), identical with the authentic material m.p. 193°, $[\alpha]_D^{19.5}$ −5° (c 1.8, $CHCl_3$) (8) as shown by mixed melting point determination and comparison of infrared spectra.[2] These data indicate conclusively that columbianin is a gentiobioside of columbianetin. The question of whether the gentiobiose moiety is attached by an α- or β-linkage to the aglycone was examined by subjecting the glycoside to the action of β-glucosidase.[3] Enzymatic cleavage takes place stepwise from the nonreducing end of the molecule (9) and, in this case, one would expect to find D-glucose, a new monosaccharidic glucoside, and columbianetin as the products of hydrolysis if the linkage were β. On the other hand, if the glycosidic linkage were α, no columbianetin would be observed although the other two products would be expected. Paper and thin-layer chromatographic examination of the hydrolytic products showed no gentiobiose but did show spots corresponding to glucose and columbianetin (fluorescent) as well as a new fluorescent spot with chromatographic behavior indicating a lesser polarity than that of the original glucoside. This material has been isolated in a crystalline state with an indefinite melting point following softening at about 100° with slow effervescence, a behavior not uncommon to glycosides. Examination of this product by mass spectrometry confirmed the molecular weight of 408 for the $C_{20}H_{24}O_9$ monosaccharidic coumarin by virtue of the molecular ion. Furthermore, two major fragmentation peaks at *m/e* 187 and 229 are, very likely, representative of the coumarin portion of the molecule and represent $[C_{11}H_7O_3]^+$ and $[C_{14}H_{13}O_3]^+$ arising from fragmentation at *a* and *b*, respectively, in I. Complete characterization of this compound is being carried out presently and will be reported at a later date. Columbianetin was also obtained in a crystalline form and identified by mixed melting point and spectral comparison with authentic material. The fact that enzymatic cleavage has been accomplished to yield columbianetin as a final product identifies a β-linkage to the aglycone and, therefore, the structure of columbianin may be assigned as the β-gentiobioside of columbianetin (III).

REVIEWS

The Vitamin Co-factors of Enzyme Systems. By F. A. ROBINSON. Pergamon Press Inc., 44-01 21st St., Long Island City, NY 11101, 1966. ix + 896 pp. 15.5 × 23 cm. Price $25.

"The Vitamin Co-factors of Enzyme Systems" is a timely replacement of the author's earlier book, "The Vitamin B Complex," which was published in 1951. Most of the material from the earlier book has been incorporated in the present volume, in addition to a rather extensive collection of recent knowledge concerning the role of the B complex vitamins as enzyme co-factors.

Earlier books on vitamins were concerned principally with their importance in nutrition and deficiency syndromes, but during the past two decades, a considerable number of studies have been conducted to establish the enzyme co-factor function of the vitamin B complex and its role in metabolic processes. Robinson emphasizes this revolutionary new concept of vitamin B activity.

The volume is composed of an Introduction, a Conclusion, and nine chapters dealing with the B complex vitamins, including thiamine, riboflavin, nicotinic acid, pyridoxine, pantothenic acid, lipoic acid, biotin, folic acid, and vitamin B_{12}. The chapters on folic acid, vitamin B_{12}, and lipoic acid are new additions; *p*-aminobenzoic acid, choline, and inositol are not included in the book because their co-factor function is obscure. Each chapter is divided into subsections for the convenience of the reader. The references which are cited at the end of each section are well selected, but include only those published up to 1963.

The author's discussion of the close inter-relationship between these co-factors and the fundamental basis for the need of these vitamins in proper and sufficient amounts in biological systems is inadequate. His relegation of this area to the 5-page conclusion section may lead the reader to overlook the dynamic aspect of these co-factors acting in biological systems as an interdependent group.

This book is well-organized, the facts are clearly presented, and it serves as an excellent reference source for information about the vitamin B complex.

The Chemistry of Heterocyclic Compounds: Multi-Sulfur and Sulfur and Oxygen Five- and Six-Membered Heterocycles. Part I. By DAVID BRESLOW and HERMAN SKOLNIK. Interscience Publishers, a division of John Wiley & Sons, Inc., 605 Third Avenue, New York, N. Y. 10016, 1966. xxii + 610 pp. 15 × 22.5 cm. Price $33.00.

Part One of the twenty-first volume in the Weissberger series of "The Chemistry of Heterocyclic Compounds" maintains in quite adequate fashion the objective of this series to record the definitive chemistry of heterocyclic compounds. The authors' intent "to review the literature selectively and eclectically," establishing what is valid and denying insubstantial claims, has been followed throughout; an authoritative work has resulted.

This volume deals with the preparation, structure, properties, reactions, and uses of the five-membered heterocycles containing sulfur and oxygen; Part Two will cover the six-membered systems. As an indication of the extent of this subject, over 200 parent heterocycles falling within this classification have already been listed in the *Ring Index*. Among the types of cyclic compounds included in Part One are the following: sulfite and sulfate esters of glycols, anhydrides of sulfite esters of 2-hydroxy acids, anhydrides of 1,2-disulfonic acids, trithioles, esters of γ-hydroxysulfonic acids (sultones), anhydrides of β-sulfocarboxylic acids, sulfonphthaleins, dithioles (cyclic disulfides), α-lipoic acid derivatives, 1,2-dithiolium salts, dithioacetals of sugars and steroids, and esters of trithiocarbonic acid. Known compounds are exhaustively tabulated, but the literature has been selectively rather than thoroughly summarized. The literature has been reviewed through 1962, which unfortunately predates most of the chemistry known for the 1,3-dithiolium salts.

Physiological properties are noted, but the pharmaceutical chemist will find this volume valuable more for the variety of cyclic systems shown that may be obtained from such common intermediates as glycols and hydroxy acids. Some of these heterocycles have already found use as protective groups in organic syntheses, and many show unique reactivities. A great deal of interest is presently being devoted to these compounds, as judged from the high percentage of contemporary references.

The authors are to be congratulated for a fine job, particularly in regard to interpreting some of, the older literature; discussions of crystallographic, spectroscopic, and conformational studies are included. While we must wait for the appearance of Part Two for the index, a ten-page Table of Contents will be found helpful.

The Vitamin Co-factors of Enzyme Systems. By F. A. ROBINSON. Pergamon Press Inc., 44-01 21st St., Long Island City, NY 11101, 1966. ix + 896 pp. 15.5 × 23 cm. Price $25.

"The Vitamin Co-factors of Enzyme Systems" is a timely replacement of the author's earlier book, "The Vitamin B Complex," which was published in 1951. Most of the material from the earlier book has been incorporated in the present volume, in addition to a rather extensive collection of recent knowledge concerning the role of the B complex vitamins as enzyme co-factors.

Earlier books on vitamins were concerned principally with their importance in nutrition and deficiency syndromes, but during the past two decades, a considerable number of studies have been conducted to establish the enzyme co-factor function of the vitamin B complex and its role in metabolic processes. Robinson emphasizes this revolutionary new concept of vitamin B activity.

The volume is composed of an Introduction, a Conclusion, and nine chapters dealing with the B complex vitamins, including thiamine, riboflavin, nicotinic acid, pyridoxine, pantothenic acid, lipoic acid, biotin, folic acid, and vitamin B_{12}. The chapters on folic acid, vitamin B_{12}, and lipoic acid are new additions; *p*-aminobenzoic acid, choline, and inositol are not included in the book because their co-factor function is obscure. Each chapter is divided into subsections for the convenience of the reader. The references which are cited at the end of each section are well selected, but include only those published up to 1963.

The author's discussion of the close inter-relationship between these co-factors and the fundamental basis for the need of these vitamins in proper and sufficient amounts in biological systems is inadequate. His relegation of this area to the 5-page conclusion section may lead the reader to overlook the dynamic aspect of these co-factors acting in biological systems as an interdependent group.

This book is well-organized, the facts are clearly presented, and it serves as an excellent reference source for information about the vitamin B complex.

The Chemistry of Heterocyclic Compounds: Multi-Sulfur and Sulfur and Oxygen Five- and Six-Membered Heterocycles. Part I. By DAVID BRESLOW and HERMAN SKOLNIK. Interscience Publishers, a division of John Wiley & Sons, Inc., 605 Third Avenue, New York, N. Y. 10016, 1966. xxii + 610 pp. 15 × 22.5 cm. Price $33.00.

Part One of the twenty-first volume in the Weissberger series of "The Chemistry of Heterocyclic Compounds" maintains in quite adequate fashion the objective of this series to record the definitive chemistry of heterocyclic compounds. The authors' intent "to review the literature selectively and eclectically," establishing what is valid and denying insubstantial claims, has been followed throughout; an authoritative work has resulted.

This volume deals with the preparation, structure, properties, reactions, and uses of the five-membered heterocycles containing sulfur and oxygen; Part Two will cover the six-membered systems. As an indication of the extent of this subject, over 200 parent heterocycles falling within this classification have already been listed in the *Ring Index*. Among the types of cyclic compounds included in Part One are the following: sulfite and sulfate esters of glycols, anhydrides of sulfite esters of 2-hydroxy acids, anhydrides of 1,2-disulfonic acids, trithioles, esters of γ-hydroxysulfonic acids (sultones), anhydrides of β-sulfocarboxylic acids, sulfonphthaleins, dithioles (cyclic disulfides), α-lipoic acid derivatives, 1,2-dithiolium salts, dithioacetals of sugars and steroids, and esters of trithiocarbonic acid. Known compounds are exhaustively tabulated, but the literature has been selectively rather than thoroughly summarized. The literature has been reviewed through 1962, which unfortunately predates most of the chemistry known for the 1,3-dithiolium salts.

Physiological properties are noted, but the pharmaceutical chemist will find this volume valuable more for the variety of cyclic systems shown that may be obtained from such common intermediates as glycols and hydroxy acids. Some of these heterocycles have already found use as protective groups in organic syntheses, and many show unique reactivities. A great deal of interest is presently being devoted to these compounds, as judged from the high percentage of contemporary references.

The authors are to be congratulated for a fine job, particularly in regard to interpreting some of, the older literature; discussions of crystallographic, spectroscopic, and conformational studies are included. While we must wait for the appearance of Part Two for the index, a ten-page Table of Contents will be found helpful.

Nonionic Surfactants. Vol. I. Edited by MARTIN J. SCHICK. Marcel Dekker, Inc., 95 Madison Avenue, New York, N. Y. 10016, 1966. xxv + 1085 pp. 17 × 24 cm. Price $43.50.

"Nonionic Surfactants" is the first volume in a series designed to review the current knowledge of surfactants. The size of this volume, in excess of 1000 pages, reflects the rate at which the science and technology of this group of surfactants has grown since their introduction in 1930. The manufacture of nonionic surfactants now constitutes a sizeable fraction of the total production of all surfactants and it seems certain that these agents will find applica-

tion in an ever-increasing number of areas. Certainly, their use in pharmaceutical products as dispersing, emulsifying, solubilizing, and wetting agents has contributed to the formulation advances of the last two decades.

The subject matter is contained in 29 chapters and covers the organic chemistry (432 pages), physical chemistry (379 pages), and analytical chemistry (95 pages) of nonionic surfactants, with a final section of 73 pages devoted to the biology of these compounds. It is gratifying to note that several of the chapters have been contributed by authors from Schools of Pharmacy and the pharmaceutical industry.

Following an introductory chapter, the next twelve chapters deal with the organic chemistry of the numerous classes of nonionic surfactants; the preparative procedures, physical properties, and applications are described in each case. Inevitably, the overwhelming portion of this section is concerned with commercial surfactants. This results in a comprehensive coverage of the technical and patent literature pertaining to these compounds. Commercial trademarks abound in the text but are, annoyingly, omitted from the subject index. The average reader, not familiar with the chemical names of every commercial nonionic surfactant, may therefore have to search through no less than 27 tables scattered throughout the text in order to find a particular surfactant. The last chapter in this section discusses the synthesis of homogeneous nonionic surfactants and is a fitting introduction to the next nine chapters describing the physical chemistry of nonionics, since the more meaningful work in this area invariably requires the use of homogeneous compounds.

The chapters devoted to micelle formation, solubilization, detergency, and foaming are standard presentation of the subject matter. Unfortunately, the chapter supposedly dealing with the physical chemistry of emulsification is quite inadequate, especially in view of the comment, made in the introductory chapter, that one of the major applications of nonionic surfactants is in emulsion technology. Only 22 pages in the whole book are devoted to this topic with just over half a page allotted to the applications of nonionic emulsifiers. In contrast, the remaining chapters on surface films, the thermodynamics of micelle formation, the effect of nonionic surfactants on the stability of dispersions, and the configuration and hydrodynamics of the polyoxyethylene chain are excellent and add much to the value of this section of the book.

Four chapters comprise the third section which reviews the analytical chemistry of nonionic surfactants. Following an introductory chapter, the discussion turns to noninstrumental, instrumental, and separational methods of analysis. These chapters are written in a practical vein and succeed in presenting a logical methodology for achieving the separation and identification of this class of compounds.

The biological aspects of nonionic surfactants are dealt with in the final two chapters of the book. The first of these deals with the biological, pharmacological, and toxicological effects of nonionic surfactants on animals and humans. Much of this material, presented in a concise yet highly factual manner in less than 40 pages, is highly relevant to the contemporary practice of pharmacy. The final chapter is a necessarily brief account of the biodegradation of nonionic surfactants.

This then is a text covering a wide range of topics associated with nonionic surfactants. On the whole, the subject matter is well presented and the coverage adequate. The book is not written specifically for any one discipline and so no one in the pharmaceutical sciences is likely to find all the text of direct interest. By the same token, it will undoubtedly be of *some* interest to all those concerned with the science and technology of these compounds. While "Nonionic Surfactants" is not likely to receive a great deal of use as the personal copy of any one individual, it will be a valuable addition to any university or industrial pharmacy library.

Potentiometric Determination of Dissociation Constants

By LESLIE Z. BENET and JERE E. GOYAN*

AT ONE TIME or another almost every pharmaceutical scientist wants to know the dissociation constant[1] for a particular drug. He might want to know whether his drug is in the ionic or nonionic form, if it will be sufficiently soluble in the gastrointestinal fluid, or how the gastric fluid might affect the rate of dissolution of the drug. He might wish to predict the stability or explain the kinetics of degradation for a dissociable drug in various buffer solutions. He might want to hypothesize a mechanism of action, predict the extent of binding, or examine complex formation. In all of these cases and in many others the pharmaceutical scientist needs to know the dissociation constant in order to solve his problem. His first reaction will be to "look it up" and if he is lucky he will find critically evaluated values in either "Dissociation Constants of Organic Acids in Aqueous Solutions" (1) or the companion volume for organic bases (2). However, in most cases he will be working with a drug for which the dissociation constant is not readily available, and unfortunately when dealing with drugs in biological systems at 37° the reliable data available are quite sparse.[2] He will then have to carry out an experimental determination, and will usually turn to the most readily available and easily operated instrument, the laboratory pH meter and its accompanying electrodes.

Potentiometric pH titration is by far the most convenient method for the determination of dissociation constants and, with care, this method can give the experimenter good reproducible results (pKa ± 0.03 units) for acids and bases having pKa values between 2.5 and 11 (errors due to residual junction potentials increase the error outside these limits).

The techniques used in carrying out the titration are standard and are well covered by Albert and Serjeant (4). The meter should be accurately calibrated with at least two standard buffers, the buffers and the solutions to be titrated should all be kept at a constant temperature, all solutions should be carbon dioxide free, the titration should be carried out under nitrogen, and the pH should be read for a large number of

Received from the College of Pharmacy, Washington State University, Pullman, WA 99163, and the *School of Pharmacy, University of California, San Francisco, CA 94122

The authors wish to dedicate this paper to Dean T. C. Daniels, whose leadership at the University of California has done so much to raise the standards of education and research in the pharmaceutical sciences.

[1] Whenever "dissociation constant" is used, it will refer to the *acid* dissociation constant.

[2] There is no universal relationship which will allow one to predict the dissociation constant of a compound at 37° when the more usually available value at 25° is known. The enthalpy of dissociation is a complex function of temperature and consequently the usual Van't Hoff type of plot is not useful. For example, the pKa (thermodynamic) for salicylic acid shows almost no change with values of 2.97 at 25° and 2.95 at 37°, while the values for barbital are 7.98 at 25° and 7.82 at 37°. Hall and Sprinkle (3) have found that the temperature coefficients for the nitrogenous bases between 0° and 40° follow a general pattern in that all become weaker bases as the temperature increases and that the depression in pKa per degree temperature rise becomes progressively larger as the basicity increases.

titrant additions. Up to this point, the procedure is unambiguous; however, the data must be interpreted and the dissociation constant calculated. There are a large number of possible ways in which the data may be treated; all are useful to some extent, but each method has its limitations. These methods, their usefulness, and their limitations are the subject of this review.

The pharmaceutical scientist and most other biological scientists are particularly interested in the aqueous dissociation constant, and this review will concentrate primarily in this area. However, since a great number of drugs are highly insoluble in the unionized form, dissociation constants are often determined in varying percentages of semiaqueous systems and these values are extrapolated to a value for water. These types of calculations will also be discussed. The sections dealing with aqueous and semiaqueous considerations will be applied to monoprotic species or to those polyprotic acids and bases for which the pKa values differ by at least 3 units. A third section of the review will be devoted to a short discussion of polyprotic species with overlapping pKa values.

AQUEOUS SOLUTIONS

Nonlinear Relationships—Nonlinear plots of pH *versus* titrant added are the most familiar and they may be obtained mechanically, utilizing an automatic titrator and a recorder. These plots are often used to determine the dissociation constant by what we shall call the half-neutralization method. This method is based on a corrupted form of the Henderson-Hasselbalch equation,[3]

$$p[H] = pKa^c + \log \frac{[base]}{[acid]} \qquad \text{(Eq. 1)}$$

where p denotes negative logarithm, [ ] concentration, and Ka^c is the stoichiometric dissociation constant. The equation utilizes the principle that when the concentration of the base (conjugate base if we are titrating an acid) equals the concentration of acid, the substance is half-neutralized. At this point the pH of the solution as read on the pH meter equals the pKa of the drug. However, assuming that the pH is equal to the pKa when an amount of strong titrant equal to one-half the concentration of the pure drug has been added can lead to erroneous results other than that due to assuming that the pH read on the meter is the negative logarithm of the hydrogen-ion concentration.[4]

Meites and Goldman (5–9) have examined the dilution and hydrogen-ion effect in relation to the inflection point of acid-base titration curves and have proposed some general equations to demonstrate the errors inherent in assuming that pH = pKa at half-neutralization. Let f be defined as the degree of neutralization of an acid. Where we are considering the titration of V_a^0 ml. of a C_a^0 solution

$$f = \frac{V_b C_b}{V_a^0 C_a^0} \qquad \text{(Eq. 2)}$$

of a weak monobasic acid with a C_b solution of a completely dissociated monoacidic base. Goldman and Meites (7) have derived the following equation to locate the point at which pH actually does equal pKa during potentiometric titrations:

$$f_{pKa} = \frac{1/2 - \{[K_a - (K_w/K_a)]/C_a^0\}}{1 + r\{[K_a - (K_w/K_a)]/C_a^0\}} \qquad \text{(Eq. 3)}$$

where f_{pKa} is the degree of neutralization when p[H] equals pKa, p[H] = negative logarithm of the hydrogen-ion concentration, pKa = negative logarithm of the apparent dissociation constant, K_w = the ion product of water and,

$$r = C_a^0/C_b \qquad \text{(Eq. 4)}$$

From Eq. 3 it can be seen that f_{pKa} will coincide with half-neutralization only when $K_a = (K_w)^{1/2}$. Substantial errors will result from taking pKa to be equal to pH at $f = 1/2$ if K_a is widely different from $(K_w)^{1/2}$ and this will be especially true if the concentrations of the reagents are small.

As an example, consider the titration of a 0.01 M solution of a weak acid ($K_a = 1 \times 10^{-3}$) by a 1.0 M solution of strong base. Putting these values into Eq. 3, $f_{pKa} = 0.40$. If the initial concentration of the weak acid were 0.001, the titration would begin at a pH higher than the pKa (as indicated by the fact that $f_{pKa} < 0$), and the hydrogen-ion concentration at "half-neutralization" would give a value of 2.8×10^{-4}, which would correspond to an error in the pKa of greater than 0.5 unit. It should be noted in Eq. 3 that r, the ratio of the concentration of solution being titrated to the concentration of titrant, also affects the f_{pKa}. For example, if the

[3] In 1908, Henderson (21) showed that the hydrogen-ion concentration of a solution equals the dissociation constant of a weak acid-base substance times the ratio of the concentration of the acid to the concentration of the base. It was not until the next year that Sørensen (22) introduced the term pH. As best as we can determine, Hasselbalch added his name to the Henderson equation by being the first (23) to combine Sørensen's definition with the equation. In any case, it is clear from the early work that all the values were in terms of concentration units.

[4] The pH meter does not give an exact measure of the hydrogen-ion activity. Instead we have an operational definition of the practical pH value and a standard scale fixed by one or more standard buffer solutions whose *assigned* pH values are at least formally consistent with the thermodynamic properties of a solution and the definition of what the activity of a single ion should be. However, for purposes of our discussion, we shall assume that the pH values read on the pH meter are the negative logarithm of the hydrogen-ion activity. For a detailed discussion of this point, consult the work of Bates (36).

TABLE I—LOCATIONS OF f_{pKa} IN WEAK ACID–STRONG BASE TITRATIONS AFTER GOLDMAN AND MEITES (7)

K_a	f_{pKa}[a]	f_i
1×10^{-2}	0.364	0.111
3×10^{-3}	0.456	0.360
1×10^{-3}	0.485	0.463
1×10^{-4}	0.498	0.496
1×10^{-5}	0.4998	0.499
1×10^{-7}	0.5000	0.5000

[a] The values of f_{pKa} were computed from Eq. 3 for $C_a^0 = 0.1$, $r = 1$, and $K_w = 1 \times 10^{-14}$. The values of f_i were computed as described by Meites and Goldman (5) and correspond to the points where the slopes of the titration curves are at a minimum.

0.01 M solution of acid were titrated with 0.01 M strong base, the f_{pKa} would drop to 0.364. This is due to a greater dilution effect, and gives a good illustration of the principle behind the usual instructions calling for a concentrated solution of titrant.

Very often, a variation of the "half-neutralization" method may be used where the pKa is taken to be equal to the pH at the inflection point of the sigmoid titration curve. Once again, this only gives a correct pKa when $K_a = (K_w)^{1/2}$, otherwise f_i (degree of neutralization at the inflection point) precedes f_{pKa} and the divergence increases as acid strength increases. Table I shows a comparison of some of the data of Goldman and Meites (7). The values of f_i are calculated by an iterative procedure applied to a very complex equation[5] similar to Eq. 16 in *Reference 5*.

In an attempt to overcome some of the errors inherent in utilizing the half-neutralization method, especially those due to the fact that the concentration of hydrogen ions is not negligible, as compared to the concentration of acid or base for fairly strong acids (pKa 2–4) and bases (pKa 10–12), Parke and Davis (11) introduced a different nonlinear method for determining dissociation constants. A survey of the pharmaceutical literature shows that until the past few years most dissociation contants were determined by methods which were modifications of that described by Parke and Davis.

These authors used hydrogen-ion binding curves to determine the apparent dissociation constants for a variety of mono- and polyprotic acids and bases. Identical volumes of sample solution and blank were titrated with a strong titrant over the pH range 2–12. The curves of these two titrations were plotted on a graph having pH as the abscissa and the amount of titrant added as the ordinate. A third curve, the difference curve, was then drawn with the units of the ordinate being the differences in milliliters of titrant required for the sample and blank to reach the same pH. Previously prepared transparent masks on which the standard curve has been drawn and the point of inflection marked are then fitted to the difference curve. Since "any titratable group produces an inflection having the same shape regardless of its position on the pH scale, the apparent dissociation constant will be the pH at the point of inflection" (11). In addition to the curve for exactly one equivalent of hydrogen ion bound per mole of sample, other masks for 1.1, 0.90, 0.75, 0.50, and 0.25 equivalent per mole were also included for use with samples of unknown purity or molecular weight.

Garrett (12) has made an analysis of the theoretical basis for the Parke and Davis method. He has shown that for dissociation constants in the range 4–10, the procedure has little advantage over the traditional technique of determining apparent pK's at half-neutralization. He also notes that for dissociation constants in the range 2–4, the technique is invalid, especially for estimates of stoichiometry, due to errors arising in the subtraction of volumes.

Stokes (13) has developed an ingenious graphical method to determine the pH value at the equivalence point, the pH for the pure weak acid, pure conjugate base, pH at $f = 0.5$, and the pH at the inflection points. His treatment is based upon: (*a*) formulating a degree of neutralization in terms of one parameter which is so defined that a weak acid is first neutralized with excess base, then back titrated with strong acid; (*b*) the use of dimensionless quantities throughout the calculations; (*c*) the use of hyperbolic functions; and (*d*) the use of logarithmic diagrams of the type favored by Sillén (14) and other Scandinavian workers, for the solutions of the equations. His procedures are similar to those proposed by Sillén, with the important difference that the preparation of only two permanent graphs is sufficient for all cases of a single monoprotic weak acid–base substance titrated with strong acid or base, in any solvent and at any temperature for which K_w is known. At high enough concentrations of a weak acid–base substance the titration curve will have three inflection points, one each at the acid and basic equivalence point, and one at half-neutralization. All of these points may be determined graphically, if the "high enough" concentrations are attainable physically.

Stokes further points out that in those cases

[5] In trying to solve Eq. 16 (*Reference 5*) the reader should be aware that the definitions for two of the terms are erroneous. Consult *Reference 10* for the corrections.

where the three inflection points do exist, it is possible to obtain both the pKa and the concentration of the weak acid or base without the use of any standardized strong acid or base solutions. Roe (15), commenting on this point in a review article, suggests that this opens up the possibility for the development of a rather unique automatic titrator. The use of Stokes' method for the determination of pKa values is unfortunately limited by manipulative difficulties.

Linear Relations—In 1958, Joseph (16) described the advantage of bringing the sigmoid form of titration curves based on the mass action law into a linear form by logarithmic transformation. This transformation was applied particularly to the Henderson-Hasselbalch equation and Joseph constructed a semilogarithmic plot as well as a slide rule for estimation of the pK values. Druckrey (17) has pointed out that he had previously proposed a similar logarithmic transformation of the mass action law which allowed linear representation on a prepared log-log paper (18). These methods have the advantage of ease in plotting and in visualizing the ratio of unionized to ionized concentration. Joseph (19) has also pointed out that when linear logarithmic plots are prepared for polyprotic species, the diagram clearly indicates the distribution of electrical charge over the molecule as a function of pH. Although linear logarithmic plots are easy to construct and helpful in visualizing the ratio of acid to base concentrations, they offer no improvement in the accuracy of dissociation constant determinations as compared to the methods listed under *Nonlinear Relationships*. The linear methods listed above are based on the corrupted Henderson-Hasselbalch equation and like the half-neutralization method, do not correct for the concentration of hydrogen and hydroxide ions, the dilution effect, or activities. Setnikar (20) has recently used a variant of the Druckrey method (17, 18) to determine the apparent dissociation constants of bases with limited solubility. For this type of determination, the Druckrey method has a real advantage in that initially a plot of pH *versus* degree of neutralization will be linear until the solubility of the conjugate species is exceeded and then the plot will degenerate from linearity. However, even if the solubility of the conjugate species is exceeded before half-neutralization, the initial linear portion of the plot may be extrapolated to the point where the degree of neutralization equals one-half (*i.e.* [acid] = [conjugate base]), and at that point the apparent pKa is equal to the pH.

Nonlogarithmic Linear Relationships—It should not be construed, from the statements above about the possible inaccuracy of methods based on the Henderson-Hasselbalch equation (Eq. 1), that the equation itself is inaccurate. Equation 1 is accurate, and it is only the substitution of approximations for the concentrations of the base and acid that lead to erroneous pKa^c values. The concentration of base at any time during a titration is given by the following equation:

$$[\text{base}] = C_b^0 - [X] + [M] + [H^+] - [OH^-] \quad \text{(Eq. 5)}$$

where C_b^0 = initial concentration of pure weak base,
$[X]$ = concentration of strong acid added,
$[M]$ = concentration of strong base added.

Likewise, the concentration of acid at any time during a titration is given by:

$$[\text{acid}] = C_a^0 + [X] - [M] - [H^+] + [OH^-] \quad \text{(Eq. 6)}$$

where C_a^0 is the initial concentration of pure weak acid. Substituting Eqs. 5 and 6 into the nonlogarithmic Henderson equation (see *Footnote 3*), we obtain:

$$[H^+] = K_a^c \frac{C_a^0 + [X] - [M] - [H^+] + [OH^-]}{C_b^0 - [X] + [M] + [H^+] - [OH^-]} \quad \text{(Eq. 7)}$$

Equation 7 is the general dissociation equation for a monoprotic species. Usually a titration involves the addition of a strong acid titrant to a solution of pure weak base, in which case C_a^0 and $[M]$ are dropped from Eq. 7, or the addition of a strong base titrant to a pure weak acid, in which case C_b^0 and $[X]$ are dropped from the equation. The derivation of Eq. 7 can be found in a number of publications (25, 43, 44).

Hofstee (26) has shown that titration curves can be based on linear nonlogarithmic forms of the equilibrium equation of a dissociation reaction. He stated that "from such curves, in contrast to those based on logarithmic transformations both the end point of the titration and the dissociation constant can be derived." This can be shown by letting Z equal the sum of all the known concentrations at any point in a titration.

$$Z = [X] - [M] - [H^+] + [OH^-] \quad \text{(Eq. 8)}$$

Therefore substituting Eq. 8 into Eq. 7, we get the general Eq. 9:

$$[H^+] = K_a^c \frac{C_a^0 + Z}{C_b^0 - Z} \quad \text{(Eq. 9)}$$

For the titration of a pure weak acid, $C_b^0 = 0$, Eq. 9 can be rearranged to the form:

$$Z = C_a^0 - (1/K_a^c)\, Z[H^+] \qquad \text{(Eq. 10)}$$

Therefore, a plot of Z *versus* $Z[H^+]$ would be a straight line with a slope which equals the negative reciprocal of the dissociation constant and an intercept which equals C_a^0.

For the titration of a pure weak base, $C_a^0 = 0$, Eq. 9 can be rearranged to the form:

$$Z = C_b^0 - K_a^c(Z/[H^+]) \qquad \text{(Eq. 11)}$$

Therefore, a plot of Z *versus* $(Z/[H^+])$ would be a straight line with a slope equal to minus the dissociation constant and an intercept of C_b^0.

Benet and Goyan (24, 25) have expanded on the advantages of this particular method: (*a*) good reproducible results can be determined using titration data from the pH ranges 1.5–4 and 9–11; (*b*) very weak concentrations of acids and bases which might not give clearly defined inflection points on a pH *versus* ml. titrant plot can give accurate results when [H] and [OH] corrections are included in the Z term for a nonlogarithmic plot. The advantages in being able to use low concentrations are (*i*) less problems will be encountered resulting from the precipitation of the unionized species, and (*ii*) the ionic strength and therefore the activity coefficients can be better controlled; (*c*) for a weak acid the titration may start at a pH already larger than the pKa without affecting the accuracy of the determination; (*d*) the line drawn in the nonlogarithmic plot serves as an estimate of the accuracy of the data. Any point which deviates greatly from the line immediately shows that the data at that point are invalid; and (*e*) one of the great advantages of nonlogarithmic titration curves is in the ability to determine the molarity of the solution being titrated without resorting to elegant drying techniques or an elemental analysis. This makes the method a valuable tool when determining the dissociation constant of a new monoprotic species.

Lanza and Mazzei (27, 28) have used a different form of nonlogarithmic linear plots to determine the end points of titrations. They report that in some cases they may detect end points at about tenfold lower concentrations than those required to get a utilizable inflection in a plot of pH *versus* ml. of titrant.

Solomons (29) has also used a straight-line relationship which is nonlogarithmic. Although his terms are different, he has essentially rearranged Eq. 10 into an equation that resembles the Lineweaver-Burk expression for describing enzyme–substrate dissociation (30).

$$1/Z = \frac{[H^+]}{K_a^c C_a^0} + \frac{1}{C_a^0} \qquad \text{(Eq. 10}a\text{)}$$

Equation 10*a* can be graphically represented as a straight line if $(1/Z)$ is plotted against $[H^+]$. The extrapolated line then cuts the $1/Z$ axis at $1/C_a^0$ and the $[H^+]$ axis at $-K_a^c$.

Not all authors recommend plotting the data even though they are using the general equation (Eq. 7). For example, Albert and Serjeant (31) recommend that the titrant should be added in 10 equal portions, each a tenth of an equivalent. Then using a variant of Eq. 7, the pKa is calculated at each of these points, and the average pKa is determined from the average of the 10 different K_a's. It seems that these authors are not using the equation to the greatest advantage, since they must put a predetermined value of either C_a^0 or C_b^0 into each calculation. This is emphasized by a quote from their book (31):

> One of the commonest errors in titrating with alkali is for the values, in the set of pK_a values, to show an upward trend as the titration progresses. This is usually caused by an impurity in the substance undergoing determination, so that not so much of it is present as had been supposed. By far the commonest and most troublesome impurity is water. To avoid this trouble, every substance submitted for determination of pK_a should be of analytical purity and dried under the same conditions that preceded its analysis.

Of course "this trouble" can easily be avoided by plotting the data according to Eq. 10.

Effects of Dilution—The work of Meites and Goldman (5–10), as described previously, deals with the dilution effects on the correspondence of pKa with the inflection points for sigmoid plots of pH *versus* ml. titrant (see Table I). Le Duigou and Lauer (32) have utilized the formulas given by Meites and Goldman (5, 10) to determine the pKa of the boric acid–mannitol complex. Conventional calculations resulted in a concentration-dependent "constant," but the inclusion of the dilution effect gave a true constant.

Leeson and Brown (33) have pointed out that the nonlogarithmic equations of Benet and Goyan (24, 25), Eqs. 10 and 11, are not truly general since the authors worked with concentrated titrant such that volume changes could be ignored. However, Leeson and Brown wished to work with volume changes of about 2–5% and proposed a variation of Eq. 10 using moles. According to their derivations, they would define a term similar to Eq. 8 as:

$$Z' = X - M - H^+ + OH^- \qquad \text{(Eq. 12)}$$

where H^+ = numbers of moles of hydrogen ion present in the solution,
M = numbers of moles of strong base added to the solution,

X = numbers of moles of strong acid added to the solution,
OH^- = numbers of moles of hydroxide ion present in the solution.

In this form, the numbers of moles of M or X can be determined by multiplying the number of ml. of titrant added times its normality divided by 1000. However, the number of moles of hydrogen and hydroxide ions must be obtained from the experimental pH data. First, the activity of hydrogen ions must be converted to a concentration value by methods described below. Then the numbers of moles of hydrogen ion can be found by Eq. 12*a*:

$$H^+ = \frac{V}{1000}[H^+] \qquad \text{(Eq. 12}a\text{)}$$

where V = volume of solution in ml. at any particular point in the titration (*i.e.*, original volume + volume of titrant added).

Deriving a general equation using moles according to the method of Leeson and Brown (33) results in the following:

$$[H^+] = K_a^c \frac{A^0 - Z'}{B^0 + Z'} \qquad \text{(Eq. 13)}$$

where A^0 and B^0 are the values for the numbers of moles of pure weak acid and base present at the beginning of the titration. Both A^0 and B^0 are constants throughout the titration.

For the titration of a pure weak acid, $B^0 = 0$, and Eq. 13 can be rearranged to the form:

$$Z' = A^0 - (1/K_a^c)\,Z'[H^+] \qquad \text{(Eq. 14)}$$

Therefore a plot of Z' *versus* $Z'[H^+]$ would be a straight line with a slope equal to the negative reciprocal of the dissociation constant and an intercept equal to A^0. The nonlogarithmic titration plot using the Leeson and Brown derivation now allows the investigator to use any concentration of titrant that he wishes. The use of this method limits the accuracy of the determination only to the abilities of the pH meter to read correct values and the investigator to convert activities to concentrations.

Activity Effects—"Although venous blood carries considerably more CO_2 than does the arterial blood, the buffers of the blood are so efficient that the pH of venous blood is more acid than that of arterial blood by only 0.01 to 0.03 unit, i.e., pH 7.40 vs. pH 7.43" (34). This is an interesting fact; the body through its complicated buffer systems is able to maintain the *activity* of hydrogen ions within the blood to a variance of about 0.03 pH units. For how many drugs do we know the dissociation constant at 37° within a variance of even ± 0.04 units?[6] In most cases we know an "apparent dissociation constant" at some particular ionic strength that may or may not be given. An "apparent dissociation constant" is one that is determined at half-neutralization, *i.e.*, when the concentration of titrant added equals one-half the original concentration of the weak acid or basic substance, the pH read on the meter equals the apparent dissociation constant. The apparent pKa is usually designated as pKa′ and is a hybrid of the stoichiometric (concentration) pK_a^c and the thermodynamic (activity) pK_a^T or simply pKa.

For the following dissociation we can define the various dissociation constants:

$$HY + H_2O \rightleftharpoons H_3O^+ + Y \qquad \text{(Eq. 15)}$$

$$K_a^T = \frac{(H_3O^+)(Y)}{(HY)} = \frac{[H_3O^+]\ \gamma_{H^+}[Y]\ \gamma_Y}{[HY]\ \gamma_{HY}} = K_a^c\left(\frac{\gamma_{H^+}\ \gamma_Y}{\gamma_{HY}}\right) \qquad \text{(Eq. 16)}$$

$$K_a' = \frac{(H_3O^+)\,[Y]}{[HY]} = K_a^c\,\gamma_{H^+} = K_a^T\left(\frac{\gamma_{HY}}{\gamma_Y}\right) \qquad \text{(Eq. 17)}$$

where ( ) denotes activity, [ ] concentration, and γ molar activity coefficient.

The charges on Y and HY have been omitted in Eqs. 15–17 so that the definitions may be general. It is usually assumed that the activity coefficient (γ) for an uncharged species is 1, so depending on whether we are titrating an acid or a base, Eqs. 16 and 17 may be simplified accordingly.

It may be seen from Eq. 17 that a correctly determined apparent or stoichiometric dissociation constant could readily be converted to a thermodynamic dissociation constant if the activity coefficient of the charged species can be determined. Unfortunately, it is unlikely that the apparent dissociation constant will be correct, as noted previously. However, assuming that the determination is correct (*i.e.*, that the effect of dilution and hydrogen ion has negligible effect on the divergence of f_{pKa} from f inflection) as for substances with pKa's in the 5–9 range, when and how should the activity correction be applied?

Albert and Serjeant (35) have also asked the rhetorical question: "When is it advisable to use activity corrections in calculating the results from a potentiometric titration?" They rec-

[6] For very few at any temperature. The editors of the two compilations of dissociation constants (1, 2) evaluate all determinations with a variance of greater than ± 0.04 pK units as "uncertain," and it is very difficult to find more than a few drugs without the "uncertain" label.

ommend that activity corrections be made: (*a*) if the pH is measured with an instrument calibrated in 0.01 pH units (or greater), and (*i*) the concentration lies between 0.01 and 0.1 *M*, or (*ii*) the hydrogen-ion or hydroxyl-ion concentration is comparable in magnitude to the stoichiometric concentration of the ionized species, or (*iii*) an extraneous salt is added to achieve "constant ionic strength." Also (*b*) if the pH is measured with an instrument calibrated in 0.005 pH units or less.

These are good rules, with a rationale behind each. For instance, (*b*) can be reread as saying that if you have an instrument that is capable of making good, accurate measurements, you should calculate and report a good, accurate dissociation constant. Criteria (*a*) (*i*) sets the limits for use on a less accurate instrument. A 0.1 *M* solution is taken as the upper limit since that is about the greatest concentration where a general equation describing ion interaction may be used to give valid activity coefficients.[7] The lower limit is included to prevent making calculations to a greater accuracy than the meter can feasibly be read. However, we would tend to be a bit more conservative and set the lower concentration limit at 0.005.

Criteria (*a*) (*ii*) is necessary when the hydrogen ion or hydroxide terms in Eqs. 8 or 12 are significant compared to the sum of other terms. Criteria (*a*) (*iii*) is necessary under the very common circumstances where a swamping concentration of a strong electrolyte, such as potassium chloride, has been added to the solution so that the ionic strength of the solution and the activity coefficients will remain constant throughout the titration. If this is not done, the ionic strength of the solution will change appreciably during the titration as titrant is added. For example, consider the titration of a 0.02 *M* solution of a monoprotic weak acid, HA, with a strong base, MOH. Initially this weak acid will be very slightly dissociated, let us say 3% dissociated; at this point in the titration the ionic strength of the solution would only be 0.0006. However, at half-neutralization, the solution would be 0.01 *M* in M^+ ions and 0.01 *M* in A^- ions. At this point the ionic strength would be 0.01. At the end of titration the ionic strength would have risen to 0.02 and thus, throughout the titration a different activity coefficient would have to be calculated after each addition of titrant. It is easy to see from this example that it would be preferable to add a swamping electrolyte and use a constant activity coefficient. However, since 0.1 *M* solutions are the upper limit for calculating reliable activity coefficients (*vide supra*) only 0.08 *M* KCl may be added, and the activity coefficient will still vary throughout the titration from 0.08 to 0.10. Therefore, in using the "conventional" sigmoid titration curves, we are faced with a paradox. We wish to use a low concentration of drug so that a truly swamping concentration of strong electrolyte may be added, but in using a low concentration of drug, we will have a less sharply defined inflection point and will increase the difference between f_{pKa} and f inflection as was pointed out by Goldman and Meites (*vide supra*). Therefore in order to get an accurate pKa from a nonlinear plot, a large concentration of drug should be used, and the activity coefficient should be calculated at the point of inflection.

Using the nonlogarithmic linear titration plots obtained from general Eq. 13, the problem disappears, since low concentration of drug will not impair the accuracy of the method.

Having decided to use activity coefficients, which value should be used? In order to answer this question we must briefly review the relation of activity coefficients to concentration. It is well known that when the activity coefficients of typical electrolytes are plotted against a function of the concentration (the square root of the ionic strength), the activity coefficients begin at 1, pass through a distinct minima, and then may even become greater than 1, and that these minima occur at different concentrations for each electrolyte.

In a simplified manner this may be explained as follows. At infinite dilution the electrolytes are completely dissociated and free to move; however, as the concentration is increased the ions come closer together and there is interionic attraction, which tends to draw ions together and render them less free to move. Therefore, the effective concentration or activity of ions are less than would be expected if complete dissociation took place.

It is well documented that many ions hydrate in water and that certain ions are hydrated to a greater extent than others (37). These hydrated water molecules are said to enter the coordination spheres of the ion and are essentially removed from the available free solvent. This decrease in available solvent seems to increase the effective concentration of the ions.

Actually both of these effects, the interionic attraction and the removal of solvent molecules, occur simultaneously.

[7] This is an unfortunate upper limit when examining drugs in biological systems, since we would, at least, like to know the activity coefficient for an ionizable drug at a sodium chloride concentration of 0.154 *M* (the isotonic concentration.)

At low concentrations the interionic attraction is the dominating factor affecting the activity coefficient; however, as the concentration of electrolyte is increased, more and more solvent water will be sequestered until this effect overcomes the interionic attraction effect and causes the activity coefficient to increase with increasing concentration. Obviously, the solvent sequestering effect will be different for different ions depending on how much water is coordinated to each ion and, therefore, no general relation can be made between activity coefficient and concentration for this effect.

However, Debye and Hückel (38–41) reasoned that in dilute solutions, only the interionic attraction would affect the activity coefficient and that the ions could be regarded as point charges. Starting with these assumptions, they derived what is known as the Debye-Hückel limiting law:

$$\log \gamma_i = -A(z_i)^2 \sqrt{\mu} \qquad \text{(Eq. 18)}$$

where γ_i = ionic activity coefficient,
A = a term made up of universal constants, the temperature, and the dielectric constant of the solvent,
μ = the ionic strength ($\mu = {}^1/_2 \Sigma c_i z_i^2$),
z_i = the charge of the ion.

According to the Debye-Hückel limiting law, all uni-univalent electrolytes at a given concentration should have the same activity coefficient, and experimental determinations show that this is true up to about 0.01 ionic strength (42). However, at an ionic strength of 0.01, the size of the ions begins to have an effect[8] on the interionic attraction and the limiting law must be extended:

$$\log \gamma_i = \frac{-A(z_i)^2 \sqrt{\mu}}{1 + a_i B \sqrt{\mu}} \qquad \text{(Eq. 19)}$$

where a_i = ion size parameter,
B = a constant dependent on the dielectric constant of the solvent and the temperature.

The above equation is considered accurate up to an ionic strength of 0.1 (45), and this sets the upper limit in concentration for determining accurate pKa values as quoted above from Albert and Serjeant.

Hückel (41) in 1925 extended the theory so as to apply to higher concentrations:

$$\log \gamma_i = \frac{-A z_i^2 \sqrt{\mu}}{1 + a_i B \sqrt{\mu}} + C\mu \qquad \text{(Eq. 20)}$$

where C is a constant dependent on the nature of *all* the ions in the solution. This equation has been shown to fit activity data with high precision[9] to about 1.0 M solutions (46).

However, now there are two unknown constants, a_i and C, which must be "guessed" before a calculation of γ_i can be made. Since it is difficult enough making one guess, Eq. 19 limited to ionic strengths no greater than 0.1 has been the equation of choice (25, 35). Benet and Goyan (24, 25) used the single ion size parameters which Kielland (47) determined from theoretical considerations. Kielland presents ion size parameters and individual activity coefficients for 130 inorganic and organic ions. He estimates a 9-Å. parameter for hydrogen ion, 3.5-Å. for hydroxide ions, and 3-Å. for potassium and chloride ions. The 9-Å. value for hydrogen is especially important, since the conversion of hydrogen-ion activity to concentration is the necessary step before any of the generalized equations presented previously may be used.

Leeson and Brown (33), for their calculations, used "the more familiar, experimentally obtained, $\gamma_\pm$ values for HCl as listed in Lewis and Randall" (48). Leeson and Brown make a comparison between the thermodynamic pKa's calculated using Kielland's activity coefficient and the Lewis and Randall mean ionic activity coefficient. They found that the Kielland activity coefficient for acetic acid gave a pKa value of 4.74, while the Lewis and Randall activity coefficient gave a pKa value of 4.76. The literature value for acetic acid may be taken as 4.76 (49, 50).

Leeson and Brown go on to point out that the intercept of the plot of the data for the two different calculations (using Eq. 14 and determining A^0) is not markedly influenced by the choice of the activity coefficient. It is rather the ionization constant (or slope) that reflects the difference. A plot of pK_a^c *versus* $\sqrt{\mu}$ demonstrates that both sets of data are essentially linear. These latter plots were extrapolated to infinite dilution to evaluate the thermodynamic ionization constants reported above. "These results," Leeson and Brown conclude, "indicate that the pK_a obtained with both values [Kielland, and Lewis and Randall] are consistent with the literature. Therefore, since the two sets of the data are the same, the type of activity coefficient

[8] The size of the ion includes its sequestered water of hydration and is defined as the ion size parameter.

[9] The Debye-Hückel equations (Eqs. 18–20) should actually read $\log f_i = \ldots$ since f_i is the activity coefficient when concentrations in moles per liter are used. The activity coefficient γ_i is associated with molality. However, this difference can be ignored for dilute solutions. For example, the two activity coefficients for univalent electrolytes differ by only 0.0004 for 0.1 M NaCl.

TABLE II—SPECIFIC ION-INTERACTION CONSTANTS AFTER GUGGENHEIM AND TURGEON (54)

Electrolyte	B_{MX} at 25° C.
HCl	0.23
NaCl	0.13
NaI	0.18
NaOAc	0.20
NaOH	0.05
KCl	0.09
KI	0.13
KOAc	0.23
KOH	0.11

employed for calculations appears to be a matter of personal choice."

The authors agree with Leeson and Brown that the Lewis and Randall values may be used for hydrogen ion activity coefficients when either KCl or NaCl is used as a swamping electrolyte and the ionic strength is less than one-tenth. There are sound reasons for this, based on the work of Bronsted and Guggenheim.

In 1922 Bronsted (51) proposed that there be a specific ion interaction term in the Debye-Hückel equation dependent on *which* two ions were involved. In 1935, Guggenheim (52) suggested that a standard value of a_i in the vicinity of 3 Å. would improve the empirical success of the Bronsted type of equation without introducing any serious complications. This yields for a simple M-X electrolyte the following equation:

$$\log \gamma_{\pm} = \frac{-A\,|z_+ z_-|\,\sqrt{I}}{1 + \sqrt{I}} + B_{MX} m \quad \text{(Eq. 21)}$$

where m = molality of MX,
B_{MX} = a constant at a particular temperature which characterizes the interaction between cation M and anion X, a specific ion-interaction constant,
I = ionic strength using molal concentrations.

Values for the coefficient B_{MX} for numerous electrolytes in aqueous solution have been determined (52–54) from experimental data and have been tabulated (54). The values derived from freezing point measurements relate to 0°. Those derived from EMF measurements and isopiestic measurements relate to 25° and other temperatures. A few pertinent values are listed in Table II.

As an example, a 0.05 M solution of HCl calculated by Eq. 21 gives a mean ionic activity coefficient $\gamma_{\pm}$ of 0.829 compared to the Lewis and Randall (48) experimentally determined value of 0.830. Using the specific ion-interaction constants, $\gamma_{\pm}$ values may be computed for solutions up to 0.1 M with an estimated accuracy of the order of 0.5% (55), which is certainly sufficient for most purposes.

The Guggenheim type of equation may also be used to calculate the ionic activity coefficient for a specific ion in a solution containing a mixture of electrolytes (56, 57). The equation for a particular cation M′ of charge $z_{M'}$ is:

$$\log \gamma_{M'} = \frac{-A z_{M'}^2 \sqrt{I}}{1 + \sqrt{I}} + \Sigma_X B_{M'X} m_X \quad \text{(Eq. 22)}$$

where each specific ion-interaction constant is multiplied by the molality of the anion involved (m_X) and summed. No terms are present for other cations.

Now consider the titration of a 1×10^{-3} aqueous solution of acidic drug HD at 25° where the ionic strength has been adjusted to 0.05 by the addition of KCl.[10] Calculating the activity coefficient for hydrogen ions using Eq. 22, gives the following:

$$\log \gamma_{H^+} = \frac{-.509\ (1)^2\ \sqrt{.05}}{1 + \sqrt{.05}} + B_{HCl}\,(.0495) + B_{HD}\,(.0005) \quad \text{(Eq. 23)}$$

The value for B_{HCl} can be obtained from Table II. The value for B_{HD} is unknown, but the third term on the righthand side of the equation is insignificant and can be dropped, so the γ_{H^+} will be identical to the one calculated above for a 0.05 M solution of HCl. Equation 22 should hold for the titration of any acid or base and thus the Lewis and Randall mean activity coefficient for HCl would be the correct value to use for the hydrogen-ion activity coefficient.

However, the Lewis and Randall values would be incorrect for use in calculating γ_{HD^+}, γ_{OH^-}, and γ_{D^-}. The activity coefficients for hydroxide ion could be calculated from the Guggenheim equation for X′, a particular anion (56, 57).

$$\log \gamma_{X'} = \frac{-A z_{X'}^2 \sqrt{I}}{1 + \sqrt{I}} + \Sigma_M B_{MX'} m_M \quad \text{(Eq. 24)}$$

where m_M is the molality of the cation involved. Using a swamping electrolyte, this will be the molality of the cation. We cannot calculate the activity coefficients for D^- or HD^+ (negatively and positively charged drug molecules) since there are no specified interionic–attraction coefficients for drugs. In these cases, we must still make a judicious guess as to which ion-size parameter we should put into the Debye-Hückel equation. However, it seems reasonable to expect that we could make a much better guess of the ion-interac-

[10] The convention usually followed is to add that amount of swamping electrolyte which will give the desired ionic strength at half-neutralization of the drug.

tion coefficient for most drugs using the pharmaceutical data for sodium chloride equivalents and cryoscopic properties (58–60) and isopiestic measurements (61) available for almost all acidic and basic drugs in use. One of us is presently examining the reliability of specific ion-interaction coefficients determined from the above-cited data (62).

Summary

For the potentiometric determination of dissociation constants in aqueous solution, the authors recommend the following on the basis of the foregoing review of the literature. Use the most accurate pH meter available and the techniques suggested by Albert and Serjeant (4). Use a concentration of drug between 5×10^{-4} and 1×10^{-3} M, add a swamping electrolyte such as KCl to adjust the ionic strength to 0.05. Take about 15 readings of pH after addition of titrant. Convert pH as read on the meter to hydrogen ion activity using either the Lewis and Randall values for the activity coefficient (48) or those calculated by Eq. 23. Calculate hydroxide-ion concentration, if necessary, from the K_w for the temperature used (63) and the activity coefficient for hydroxide calculated for Eq. 24, or use the values tabulated by Harned and Owen (64) for the ionic activity function of water. Calculate the data according to the method of Leeson and Brown (33). Plot the data after making the appropriate rearrangement of Eq. 13, and determine the slope of the line and K_a^c. Now determine K_a^T by Eq. 16, using the activity coefficient for hydrogen ion calculated from Eq. 23 and the activity coefficient for the drug ion determined by Eqs. 23 or 24 or some judicious choice of an ion size parameter. At present, however, the most accurate yet burdensome method is to calculate pK_a^c at four or more ionic strengths and then plot pK_a^c *versus* $\sqrt{\mu}/1 + \sqrt{\mu}$ and extrapolate to infinite dilution. Following these procedures, it is estimated that an accurate pK_a^T may be determined within ± 0.03 units.

SEMIAQUEOUS SOLUTIONS

For a large number of pharmaceutical compounds, the uncharged species is so insoluble that it is very difficult to determine accurate dissociation constants by even the most sensitive methods previously described. Albert and Serjeant (65) have said:

> When a substance is poorly soluble in water, but highly soluble in a volatile solvent, it is natural to consider determining the ionization constant in a mixture of the two solvents, e.g., in 50% ethanol. This temptation should be resisted, for reasons which will shortly be discussed.

They go on to point out that Hall and Sprinkle (3) plotted pKa against per cent alcohol concentration (range 10%–97%) for 18 different amines and then extrapolated these "hockey-stick" shaped curves back to zero per cent. Albert and Serjeant correctly point out that these values are highly suspect especially when the amine was too insoluble to give values at 10 and 20%.

They also present a table of pKa values of aniline, methylaniline, and dimethylaniline in various percentages of ethanol (66) showing that in solutions of increasing ethanol percentage, aniline, and its *N*-methyl derivatives become weaker bases. They state, "But the effect of the alcohol is least on the unmethylated substance with this paradoxical result: although methylation increases the basic strength in 0% to 35% alcohol, in more highly alcoholic solutions it decreases the basic strength. Dilute dimethylformamide, methyl cellosolve and other glycol derivatives cause this type of trouble also." Actually, these results may not be troublesome at all, and they can be explained by more recent ideas, as will be discussed.

Finally, Albert and Serjeant comment that ". . . the widespread availability of ultraviolet spectrophotometers makes it possible to obtain the pK_a values of many sparingly soluble substances by special methods." However, there are a large number of substances, particularly amines, which are not suitable for spectrophotometric analysis, and thus we must accept the "temptation" and determine the pKa by titration in semiaqueous solvents.

The practice of determining pKa's in varying concentrations of alcohol and plotting these values *versus* per cent alcohol originated with Mizutani (67), who then extrapolated the plot to zero per cent alcohol to find the aqueous pKa. This procedure has been followed by a number of workers dealing with substances of pharmaceutical interest. Marshall (68) determined the dissociation constants of various antihistamines in ethanol–water mixtures. Edmonson and Goyan (69) used the same solvent combination while studying phenobarbital solubility. A methanol–water solvent was used by Chatten and Harris (70) to study phenothiazine and sympathomimetic amines. Garrett (71) measured the variation of apparent dissociation constants for several tetracycline antibiotics in dimethylformamide–water solvent and used the information in the assignment of pK_a' values to functional groups.

Theoretical Considerations—There is no doubt that an investigator can take a known

amount of a substance in a given mixture of nonaqueous solvent–water containing a known amount of ionic substances and reproduce previously reported pH readings using the usual glass electrode–calomel electrode and a pH meter which has been standardized in a specified manner. The problem is to relate this reading and dissociation constant determinations to values obtained in water.

The numerical values of activity coefficients are commonly assigned with reference to a value of one at infinite dilution of the solute in the particular solvent being studied (72). However, there must be some way of relating an activity coefficient in water to that in a solvent containing alcohol, methanol, dioxane, or other organic liquids miscible with water. The medium effect ${}_m\gamma_i$ is a measure of the free energy change on transfer of 1 mole of a substance i from a standard state in water to the standard state in the mixed solvent SH:

$$\gamma_i = ({}_m\gamma_i)({}_s\gamma_i) \qquad \text{(Eq. 25)}$$

where γ_i = activity coefficient of ion i in water,
${}_s\gamma_i$ = activity coefficient of ion i in solvent SH.

The activity coefficients γ_i and ${}_s\gamma_i$, which become unity at infinite dilution in water and in solvent–water mixtures, respectively, characterize the interionic and ion-molecule forces and other effects dependent on the concentration of the medium. The medium effect ${}_m\gamma_i$ reflects the differences in the electrostatic and chemical interactions of the substance i in the two solvents. Of these interactions, solvation is probably the most important when ions are transferred from one medium to another (72).

The equation for the EMF of a cell with a liquid junction yields the following equation:[11]

$$\text{pH} = -\log a_H + \bar{E} \qquad \text{(Eq. 26)}$$

where $\bar{E}_j$ = the liquid-junction potential expressed in pH units.

Now we may define $a_H{}^*$ as the hydrogen-ion activity referred to the standard state in the mixed solvent SH.

$$pa_H{}^* = -\log (m_H)({}_s\gamma_H) \qquad \text{(Eq. 27)}$$

Now combining Eqs. 25, 26, and 27, we obtain:

$$pa_H{}^* = -\log (m_H) - \log (\gamma_H) + \log ({}_m\gamma_H) = \text{pH} - \bar{E}_j + \log {}_m\gamma_H = \text{pH} - \delta \qquad \text{(Eq. 28)}$$

[11] Equation 26 is actually what we are measuring on the pH meter in aqueous solutions. The pH read equals the negative log of the activity of hydrogen ion plus the residual liquid-junction potential. We attempt to cancel out this last term by standardizing the meter with a buffer solution that has the same $\bar{E}_j$ as the solution we are measuring. In practice, these $\bar{E}_j$'s do cancel out quite well for buffers and solutions between pH 3 and 11 in water (73).

where δ is written for $\bar{E}_j - \log {}_m\gamma_H$ and is a constant for a medium of a given composition. Now, $pa_H{}^*$ can be related to the dissociation equilibrium (Eq. 29) in a semiaqueous medium, by Eq. 30:

$$HA + SH \rightleftharpoons A + SH_2{}^+ \qquad \text{(Eq. 29)}$$

$$p({}_sK_a) = pa_H{}^* - \log \frac{m_A}{m_{HA}} - \log \frac{{}_s\gamma_A}{{}_s\gamma_{HA}} \qquad \text{(Eq. 30)}$$

where ${}_sK_a$ is the thermodynamic dissociation constant of acid HA in mixed solvent SH. This equation is just the Henderson-Hasselbalch equation using thermodynamic values for solvent SH.

The values of ${}_s\gamma_i$ can be calculated by the extended Debye-Hückel equation allowing for the effect of changes in dielectric constant:

$$-\log {}_s\gamma_i = \frac{(1.82455 \times 10^6)\, z_i{}^2 \sqrt{\mu}}{(DT)^{3/2}\,[1 + 50.2904\,(DT)^{-1/2} a_i \sqrt{\mu}]} \qquad \text{(Eq. 31)}$$

where D = dielectric constant,
T = temperature in degrees Kelvin,
a_i = the ion size parameter.

Determination of Dissociation Constants (${}_sK_a$) in Semiaqueous Solvents—With the foregoing equations, it is now possible to determine $p({}_sK_a)$ if $pa_H{}^*$ can be determined at a number of points during a titration. The simplest way to determine $pa_H{}^*$ values experimentally would be to apply tabulated corrections to the pH numbers read on a pH meter which had been standardized with aqueous buffer solutions in the usual way (74), *i.e.*, using Eq. 28, $pa_H{}^* = \text{pH} - \delta$. Ong, Robinson, and Bates (75) have carried this correction a step further and applied it to the "seeming" pKa,[12] which is defined as:

$$\text{pKa}'' = \text{pH} - \log \frac{m_A}{m_{HA}} - \log \frac{{}_s\gamma_A}{{}_s\gamma_{HA}} \qquad \text{(Eq. 32)}$$

where pH is the meter reading at any point during the titration, the meter having been standardized with aqueous buffers. Now at any point in the titration we may subtract Eq. 30 from Eq. 32, with the result:

$$\text{pKa}'' - p({}_sK_a) = \text{pH} - pa_H{}^* = \delta \qquad \text{(Eq. 33)}$$

The term δ (Eq. 28) contains two values, the residual junction potential and the medium effect, and is identical with the quantity derived by Bates, Paabo, and Robinson (76) from a comparison of the EMF of cells with and without liquid junctions.

Ong, Robinson, and Bates (75) have calculated the values for acetic acid and anilinium ions in varying weight percentages of methanol (0–70%)

[12] The authors have chosen the term "seeming" pKa so as not to confuse this term with the apparent pKa defined by Eq. 17.

TABLE III—VALUES OF THE CONSTANT $\delta \equiv (\bar{E} - \log {}_m\gamma_H)$ IN METHANOL–WATER[a] AT 25°C. AFTER ONG *et al.* (75)

Wt. % methanol	0	10	20	30	40	50	60	70
δ	0	0.01	0.02	0.04	0.07	0.11	0.15	0.13

[a] A similar set of values could be compiled for ethanol–water mixtures from the data of Bates *et al.* (76), Butbezahl and Grunwald (80), and Gelsema and de Ligny (81) [cited by Bates, Paabo, and Robinson (76) and Bates (36)] although the agreement is not so good as that for methanol–water solutions. (For tabulation of these data, see *Reference 36*, p. 224.)

by determining the pK″ values and subtracting them from the $p({}_sK_a)$ values of Shedlovksy and Kay (77) for acetic acid and the values of Bacarella *et al.* (78) for anilinium. Ong *et al.* then compared their calculated δ values with those obtained from the EMF of cells with and without liquid junctions (76) and to the values obtained by de Ligny and Rehback (79) who also used cells with and without liquid junctions. The agreement for δ values among these workers is good and the recommended values for each weight percentages of methanol are presented in Table III. The table only contains values up to 70% since ionic association may be considered minimal only up to 68 wt.% methanol.

Thus δ may be subtracted from the "seeming" pK″ value to give the true p_sK_a value since δ is independent of the solute composition, provided that the total ionic strength is not high and the pH is neither very high nor very low (the same conditions which were placed on determinations in aqueous solutions). Finally, Ong *et al.* (75) point out that they and Bacarella *et al.* (78) used glass electrodes, while Bates *et al.* (76) and de Ligny and Rehback (79) used hydrogen electrodes.

> The general correlation which all the authors obtained shows . . . that the standard potential of the glass electrode is independent of solvent composition in water–methanol mixtures as, indeed, it should be if the electrode is behaving as a reversible hydrogen electrode. Furthermore, the general agreement shows that there is little dependence of the liquid junction potential on the type of junction used; de Ligny and Rehback (79) formed the junction at the end of a tube with a capillary opening, Bates, Paabo, and Robinson (76) used sintered disks, while porous fibers were used in this work (75).

Previous to the above work, Bates *et al.* (76) felt that the possibility of a shifting asymmetry potential when the glass electrode was transferred from an aqueous medium to an alcoholic medium was sufficient reason to use standard solutions of known pa_H*, having the same solvent composition as the solution to be titrated. Bates (82) has tabulated the values for some methanol–water (76, 83–85) and ethanol–water (76, 81) buffer systems. Recently pa_H* values have been reported for a number of other buffers in methanol–water solvents at varying temperatures: (*a*) tris(hydroxymethyl)aminomethane and its hydrochloride (Tris buffers) (86); (*b*) ammonia–ammonium chloride (87); and (*c*) 4-aminopyridine and its hydrochloride (88). Paabo *et al.* (89) have also resolved the discrepancies in the standardization of the data obtained with silver–silver chloride electrodes in methanol–water solvents, and were able to report mean ionic activity coefficients for hydrochloric acid to three decimal places in varying percentages of water–methanol solvents at 25°.

Relation of Dissociation Constants in Mixed Solvents to Dissociation Constants in Water—As was stated earlier, Mizutani originated the practice of plotting pKa″ *versus* per cent alcohol and extrapolating back to zero per cent to find pKa′ in water. Although this is a logical approach, there are no theoretical relationships to predict how much the plot will curve at various percentages, and if the titrated substance is not soluble in 10 or 20% alcohol, the extrapolation back to 0% may be highly suspect.

Let us now examine what has to be determined in order to develop a theoretical method for converting $p_sK_a^T$ to pKa^T. Consider the dissociation of acid HA in solvent SH and in water:

$$HA + H_2O \rightleftharpoons A + H_3O^+ \qquad \text{(Eq. 34)}$$

$$HA + SH \rightleftharpoons A + SH_2^+ \qquad \text{(Eq. 29)}^{13}$$

$$K_a = \frac{(m_A\gamma_A)(m_{H^+}\gamma_{H^+})}{(m_{HA}\gamma_{HA})} \qquad \text{(Eq. 35)}$$

$${}_sK_a = \frac{(m_{A_s}\gamma_A)(m_{H^+_s}\gamma_{H^+})}{(m_{HA_s}\gamma_{HA})} \qquad \text{(Eq. 36)}$$

Recalling Eq. 25 and dividing Eq. 35 by Eq. 36, we derive Eq. 37:

$$\frac{K_a}{{}_sK_a} = \frac{({}_m\gamma_H)({}_m\gamma_A)}{({}_m\gamma_{HA})} \qquad \text{(Eq. 37)}$$

Taking the log of both sides of Eq. 37, we find that $p({}_sK_a) - pKa$ equals the log of the term on the righthand side of Eq. 37. Therefore, in order to calculate the aqueous dissociation constants from the experimentally determined nonaqueous values, we must be able to determine the medium effect. As stated earlier, the medium effect for an ion reflects the differences in the electrostatic and chemical interactions of the ion with the two solvents (72).

[13] Where we use SH_2^+ to designate the hydronium ion in a mixed solvent.

The standard free energy of transfer of a gram ion of a single ionic species i from water to another solvent SH is given by

$$\Delta G_i^0 = RT \ln {}_m\gamma_i \qquad \text{(Eq. 38}a\text{)}$$

This change in free energy is made up of an electrostatic part, ΔG_{el}, which can be estimated by the Born equation (90) and a nonelectrostatic part which accounts for the specific chemical interactions between the ions and the solvent. At present, there is no known way to characterize all of the nonelectrostatic effects, but since the electrostatic effects will predominate, the predictions of the Born equation are of some interest (91).

The change in free energy arising from charging effects in the process of transferring an ion from water to solvent SH as described by the Born equation is:

$$\Delta G_{el}^0 = \frac{Nz_i^2e^2}{2r}\left(\frac{1}{D_{SH}} - \frac{1}{D_w}\right) \qquad \text{(Eq. 38)}$$

where N = Avogadro's number,
z_i = charge on the ion,
e = the electronic charge,
r = the radius of the ion in the two solvents where the ion is considered a sphere,
D_{SH} = dielectric constant of solvent (SH in water).

Assuming that only electrostatic effects are taking place, substituting Eq. 38a into Eq. 38 and inserting numerical values for the constants at 25° results in Eq. 39:

$$\log {}_m\gamma_i = \frac{121.6z_i^2}{r}\left(\frac{1}{D_{SH}} - 0.0128\right) \qquad \text{(Eq. 39)}$$

Now substituting Eq. 39 into the logarithmic form of Eq. 37, we derive Eq. 40:

$$\mathrm{p}({}_sK_a) - \mathrm{pKa} = 121.6\left(\frac{1}{r_{H+}} + \frac{z_A^2}{r_A} - \frac{z_{HA}^2}{r_{HA}}\right)\left(\frac{1}{D_{SH}} - 0.0128\right) \qquad \text{(Eq. 40)}$$

Now assuming that the radii of all the ions are equal (*i.e.*, $r_{H^+} = r_A = r_{HA}$), it is possible to make the following predictions. For an acid such as acetic acid (where A is negatively charged and HA has no charge), a plot of $\mathrm{p}({}_sK_a)$ *versus* $1/D_{SH}$ (*e.g.*, dissociation constants determined in solutions of varying alcohol percentages) should be a straight line with a positive slope. For an acid such as anilinium chloride (where HA is positively charged and A has no charge) a plot of $\mathrm{p}({}_sK_a)$ *versus* $1/D_{SH}$ should be a straight line with zero slope. It is found [*e.g.*, (66) and (92)] that p_sK_a values for monoprotic acids do indeed increase markedly as the dielectric constant of the solvent decreases. However, the p_sK_a values for cationic acids (HA^+) do not stay constant as predicted above, but usually decrease, pass through a minimum, and then increase at high concentrations of organic solvent.

Unfortunately, the Born treatment often fails. For example, if the data of Shedlovsky and Kay (77) or Bacarella *et al.* (78) for acetic acid in methanol–water is plotted with the above coordinates, the resulting line will be far from straight. Equation 40 also predicts that an acid should have the same dissociation constant in two different solvent mixtures having the same dielectric constant. However, both Speakman (93) and Dondon (94) observed that aqueous dioxane acted as if it had a higher effective dielectric constant than aqueous alcohol of the same actual dielectric constant. In other words, the values of dissociation constants of several acids in aqueous dioxane were reported to be higher than those determined in aqueous alcohol with the same dielectric constant. Yasuda (95) suggests that the usual way of defining K_a assumes that the activity of water is constant, as in the following equilibrium, K_a is defined according to Eq. 41,

$$HA + H_2O \rightleftharpoons H_3O^+ + A \qquad \text{(Eq. 34)}$$

$$K = \frac{(H_3O^+)(A)}{(HA)} \qquad \text{(Eq. 41)}$$

while he proposes a new dissociation constant dependent on the activity of water, which we shall call K_I.

$$K_I = \frac{(H_3O^+)(A)}{(HA)(H_2O)} \qquad \text{(Eq. 42)}$$

Yasuda reasons thus:

> In aqueous solutions K_a may be used, for (H_2O) is nearly constant. But this is not true in mixed solvents containing a limited amount of water. Due consideration should be paid to the fact that the activity of water in mixed solvents changes with the molar fraction of organic solvents. Therefore, the constant K_I defined by Eq. 42 should be used for the estimation of the dissociation of an acid in mixed solvents, in place of K_a defined by Eq. 41.

Yasuda justified ignoring the activity of the nonaqueous portion of the solvent, by the fact that water has an exceptionally high proton affinity and must be included in the equilibrium calculations, whereas the alcohol or dioxane proton affinities are insignificant. Recalculating the work cited above (77, 78, 94, 95), Yasuda plots pK_I *versus* $1/D$ and finds that the anomalies mentioned above disappear and the plot is linear for values of $1/D$ less than 0.02. It appears that at D values greater than 50, the nonelectrostatic terms in the free energy of transfer are no longer negligible.

One month after the publication of Yasuda's paper (95), Shedlovsky (96) presented a similar equation to the Trieste Symposium on Electrolytes; however, his work had a more complete theoretical derivation. Shedlovsky also considered the data of Grunwald *et al.* (78, 92) and Shedlovsky and Kay (77), particularly the dissociation of acetic acid in water–methanol and water–ethanol solvents.

Shedlovsky points out that on dissolving acetic acid in water or in alcohol, the following sequence of events occurs: first, a "force linkage" forms between the acid and solvent molecules; second, a proton shifts from the acid-carboxyl group to a bound solvent molecule forming an ion pair; third, the ion pair dissociates. These steps are shown in the following equations and the over-all dissociation constant for each solvent, K_H and K_R are derived.

$$HA + H_2O \rightleftharpoons HA \cdot H_2O \qquad \text{(Eq. 43)}$$

$$HA \cdot H_2O \rightleftharpoons H_3O^+ \cdot A^- \qquad \text{(Eq. 44)}$$

$$H_3O^+ \cdot A^- \rightleftharpoons H_3O^+ + A^- \qquad \text{(Eq. 45)}$$

$$HA + ROH \rightleftharpoons HA \cdot ROH \qquad \text{(Eq. 46)}$$

$$HA \cdot ROH \rightleftharpoons RH_2O^+ \cdot A^- \qquad \text{(Eq. 47)}$$

$$RH_2O^+ \cdot A^- \rightleftharpoons RH_2O^+ + A^- \qquad \text{(Eq. 48)}$$

$$K_{43}K_{44}K_{45} = \frac{[H_3O^+][A^-]\,\gamma^2}{[HA][H_2O]} = K_H \qquad \text{(Eq. 49)}$$

$$K_{46}K_{47}K_{48} = \frac{[RH_2O^+][A^-]\,\gamma^2}{[HA][ROH]} = K_R \qquad \text{(Eq. 50)}$$

where it is assumed that the activity coefficients of all charged species are identical and that the activity coefficients of uncharged species are one.

The experimentally determined ionization constant ${}_sK_a$, however, depends on both kinds of hydrogen ions.

$${}_sK_a = \frac{[A^-][H_3O^+ + H_2OR^+]\,\gamma^2}{[HA]} = K_H[H_2O] + K_R[ROH] \qquad \text{(Eq. 51)}$$

Now Shedlovsky employs Bjerrum's theory of ionic association (97–99), to show that $H_2OR^+ \ll H_3O^+$, assuming that Eqs. 45 and 48 are controlled by simple coulombic forces. Therefore:

$$K_H = B_H \exp.(-b) \qquad \text{(Eq. 52)}$$

$$K_R = B_R \exp.(-b) \qquad \text{(Eq. 53)}$$

where $b = \left(\frac{e^2}{DkTa}\right)$ in which e is the electronic charge; D the dielectric constant; k is the Boltzman constant; T is the Kelvin temperature; and a is the average ionic diameter for the anion and cation (the distance of closest approach); B is a constant containing e, D, k, T, N (Avogadro's number), r the actual average distance between ions, and the appropriate K values (*e.g.*, B_H contains $K_{43}K_{44}$).

Shedlovsky further assumes that a is a constant over the entire range of solvent composition within a given solvent system. Then

$${}_sK_a[e^b] = B_H[H_2O] + B_R[HOR]$$

Now Shedlovsky points out that Eqs. 43 and 46 are for dipole–dipole interactions and Eqs. 45 and 48 are for ion pair dissociations. He feels that for acetic acid the magnitude of these interactions and dissociations should be approximately the same in both water and alcohol (*i.e.*, $K_{43} = K_{46}$ and $K_{45} = K_{48}$). However, the proton rearrangements, Eqs. 44 and 47, should take place much more readily in water than in alcohol so that K_{44} should be considerably greater than K_{47} and therefore B_H should be much greater than B_R. Therefore, Eq. 51 will reduce to Eq. 54 when Eqs. 52 and 53 are substituted into Eq. 51, along with the simplifying assumption $B_H \gg B_R$.

$${}_sK_a = B_H e^{-b}[H_2O] \qquad \text{(Eq. 54)}$$

This is essentially the same assumption made by Yasuda (95), except that the Shedlovsky equation can now be rearranged to:

$$p_sK_a + \log[H_2O] = \left(\frac{e^2}{(2.303)akT}\right)(1/D) - \log B_H \qquad \text{(Eq. 55)}$$

so that a plot of $p_sK_a + \log[H_2O]$ *versus* $1/D$ should be linear. But Shedlovsky's derivation shows that the slope of the line may be used to measure a, the average ion size of the cation and anion.

In closing this section, let us return to Albert and Serjeant's comment (65) concerning the variation of p_sK_a for aniline, methylaniline, and dimethylaniline in varying percentages of ethanol (66). A plot of $p_sK_a + \log[H_2O]$ *versus* $1/D$ for each of these three compounds are fairly linear below a value of $1/D = 0.02$. However, the three lines cross each other (*i.e.*, they have different slopes) giving rise to what Albert and Serjeant refer to as "paradoxical results." However, as shown, this may only be a result of different ionic sizes, and further work might elucidate these results.[14]

Summary

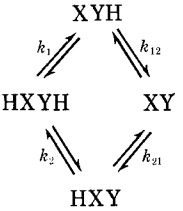
As has been reviewed above, there is presently no completely satisfactory method for converting p_sK_a values to pKa values. Therefore, although good accuracy can be realized in determining p_sK_a

[14] It should be emphasized that a direct correlation with Shedlovsky's equations cannot be derived, since here we are dealing with a protonic acid instead of an uncharged acid. However, an analysis could be made corresponding to the recent work of Paabo, Bates, and Robinson (87), who considered the variation in p_sK_a for ammonia as compared to Tris.

values, this accuracy cannot be carried over to the aqueous dissociation constants. The authors would recommend that semiaqueous titrations be carried out in methanol–water systems if possible, since there is an abundance of data concerning this solvent system. Procedures for determining p_sK_a need not differ from those in aqueous systems, except that Eq. 31 should be used for determining activity coefficients. The values of Ong *et al.* (75) appear to be sufficiently accurate, so that aqueous buffers may be used for standardizing the meter before titrations in a methanol–water system. In extrapolating p_sK_a values back to pKa in water, we recommend plotting $p_sK_a + \log [H_2O]$ *versus* $1/D$, as defined by Shedlovsky (96) and Yasuda (95). As long as p_sK_a values can be determined in solutions with dielectric constants greater than 50, these extrapolations (as per Yasuda and Shedlovsky) seem to give reasonable pKa^T values. Calculations of dissociation constants under these conditions should be accurate to about ± 0.06 pK units.

POLYPROTIC SPECIES

Whenever an acid has more than one ionizable hydrogen, the interpretation of potentiometric titration data becomes more complex. The authors will use the dissociation of a dibasic acid as shown in Scheme I to illustrate the problems,



Scheme I

where the lower case k is used to denote microconstants and the subscripts indicate the order of dissociation (*i.e.*, X is site 1, Y is site 2). Now the titration data will yield the two macroconstants defined as:

$$K_1^T = \frac{[(XYH) + (HXY)]\,(H)}{(HXYH)} = k_1 + k_2 \qquad \text{(Eq. 56)}$$

$$K_2^T = \frac{(XY)\,(H)}{[(XYH) + (HXY)]} = \frac{k_{12}k_{21}}{k_{12} + k_{21}} \qquad \text{(Eq. 57)}$$

If k_1 is much greater than k_2, k_2 and k_{21} will be a negligible pathway and:

$$K_1 = k_1,\ K_2 = k_{12}$$

Thus if K_1 is 1000 times or more larger than K_2, any of the methods outlined earlier may be used. (With polyprotic acids it is often possible to isolate one of the dissociations and determine it independently.)

However, some cases are still bound to occur where K_1 and K_2 overlap and the methods of determining their values differ somewhat from those previously discussed. Probably the oldest method is that due to Noyes (100). The equations are derived by use of the two dissociation equilibria (Eqs. 56 and 57 written in terms of concentration) and the equations for conservation of mass and charge. Where hydroxide-ion concentration may be ignored relative to the other terms in the equation for electroneutrality (*i.e.*, except for extremely weak acids and exp erimental points close to $f = 2$) he obtains:

$$K_1^c = \frac{B_1D_2 - B_2D_1}{A_1B_2 - A_2B_1} \qquad \text{(Eq. 58)}$$

$$K_2^c = \frac{A_1D_2 - A_2D_1}{B_1D_2 - B_2D_1} \qquad \text{(Eq. 59)}$$

Here $A_n = [M_n][H_n] + [H_n]^2 - [H_n][C^0]$

$B_n = 2[C^0] - [M_n] - [H_n]$

$D_n = ([H_n] + [M_n])[H_n]^2$

where [ ] denotes concentration, C^0 is the concentration of the acid being titrated, M is the total concentration of added alkali, and n is used to indicate individual points on the titration curve. Ordinarily, several pairs of data points are taken and the constants averaged to obtain the best estimate of K^c. These values may be converted to K^T values using the activity coefficients due to Kielland (47, 25). For the unusual case where the hydroxide-ion concentration is not negligible, see *Reference 100*. Another method of interest is that of Speakman (101). Using the same basic equations as above, he obtains:

$$\frac{(H)^2Pf_{XY}}{Rf_{HXYH}} = K_1^T\left[\frac{(H)Qf_{XY}}{Rf_{HXY}}\right] + K_1^TK_2^T \qquad \text{(Eq. 60)}$$

or

$$X = K_1^TY + K_1^TK_2^T \qquad \text{(Eq. 61)}$$

where $P = [M] + [H] - [OH]$

$Q = [C^0] - [M] - [H] + [OH]$

$R = 2[C^0] - [M] - [H] + [OH]$

and it is assumed $f_{HXY} = f_{XYH}$.

Thus in this method one uses the experimental data and activity coefficients in obtaining X and Y which are then plotted to obtain K_1^T and K_2^T.

Unfortunately, it is not possible to determine the microconstants from the macroconstants without one additional expression relating the various species (102). This subject is therefore outside the scope of this review, although several interesting papers have been published dealing

with medicinal agents (103–105). In the paper of Riegelman *et al.*, the values obtained for synephrine seem questionable since k_2 is less than k_{21}. Using the same data and equations with the Kielland values for activity coefficient (47), this anomaly disappears (pK_2 9.84 to 9.61, pK_{21} 9.69 to 9.71). This again demonstrates the value of working with reasonable estimates of activity rather than concentrations.

Summary

The determination of macroconstants requires the same degree of experimental care used with monoprotic acids. The data may be manipulated by either of the methods discussed to obtain K^T using the Kielland estimates for activity coefficients.

Effect of Certain Nonsteroid Antirheumatic Drugs on Active Amino Acid Transport Across the Small Intestine

By GERHARD LEVY, NORMAN J. ANGELINO, and TAI MATSUZAWA*

Indomethacin (5 m*M*), phenylbutazone (5 m*M*), and salicylate (15 m*M*) prevent the active transport of the amino acid, L-tryptophan, across the small intestine of the rat. Aspirin (15 m*M*) appears to inhibit somewhat, but does not prevent, this process. Salicylate (15 m*M*) significantly inhibits the active transport of L-tryptophan across the hamster small intestine; aspirin (15 m*M*) has no inhibitory effect. These results are consistent with the relative effectiveness of these drugs as uncouplers of oxidative phosphorylation.

SALICYLATE and certain other nonsteroid anti-inflammatory drugs are potent uncouplers of oxidative phosphorylation (1). They may, therefore, be expected to interfere with the energy supply necessary for active intestinal transport processes (2, 3). Smith (3) has shown that 5 m*M* salicylate inhibits the active transport of glucose and water across the small intestine of the rat, and Quastel (4) has recently reported that 10 m*M* salicylate inhibits the active transport of phenylalanine by the guinea pig intestine. Since the oral administration of salicylate and other anti-inflammatory agents can yield appreciable concentrations of these drugs in intestinal fluids, it is desirable to assess the effect of these substances on active intestinal transport processes. It has been shown that modification of the phenolic group of salicylate causes a loss in uncoupling activity (5), and it became of interest therefore to determine if an inhibitory effect of salicylate may be reduced or circumvented totally by using aspirin. The present communication deals with the effects of salicylate, indomethacin, and phenylbutazone on the active intestinal transport of the neutral amino acid, L-tryptophan, with particular emphasis on the relative effects of salicylate and aspirin.

EXPERIMENTAL

Absorption of L-tryptophan across the rat small intestine was studied by the cannulated everted intestine method developed by Crane and Wilson (6). Male Sprague-Dawley rats, weighing about 250 Gm., were fasted overnight, but had access to drinking water at all times. The small intestine was removed under ether anesthesia and rinsed with Ringer's solution. The intestine was then sleeved onto a glass rod and everted carefully. Two segments of 10-cm. length (when stretched slightly by attaching an 8-Gm. weight and suspending the segment vertically) were obtained, distal ends were tied, and proximal ends were attached to the cannula of the apparatus described by Crane and Wilson (6). An equal number of first (from the proximal end) and second intestinal segments were used in each experiment. These segments will be referred to as proximal and distal segments, respectively. Each everted and cannulated intestine segment was suspended in 45 ml. of Krebs–Ringer–bicarbonate solution (pH 7.4) containing 2 m*M* L-tryptophan maintained at 37° and gassed continuously with a mixture of 95% oxygen and 5% carbon dioxide. The serosal (inner) solution also consisted of 2 ml. of Krebs–Ringer–bicarbonate solution containing 2 m*M* L-tryptophan. Drugs were added to both the mucosal and serosal solutions in equal specified concentrations. After 1 hr. of incubation, aliquots of both solutions were assayed. One of the two segments of intestine obtained from each rat was used for a drug experiment, while the other segment served as a control. Each set of drug and control experiments was carried out with an equal number of proximal and distal segments, except when an odd number of experiments were conducted.

Absorption of L-tryptophan across the hamster small intestine was studied by the everted sac method described by Wilson and DeCarlo (7). Three segments of small intestine, each approximately 6 cm. long, were removed under ether anesthesia from male golden hamsters weighing 100–150 Gm. Everted sacs were prepared and filled with 1 ml. of Krebs–Ringer–bicarbonate solution (pH 7.4) containing 2 m*M* L-tryptophan. The sacs were placed in 15 ml. of the same solution in 50-ml. capacity conical flasks. Both mucosal and serosal solutions contained drugs in equal specified concentrations. The flasks were flushed with a mixture of 95% oxygen and 5% carbon dioxide,

TABLE I—ACTIVE TRANSPORT OF L-TRYPTOPHAN ACROSS THE SMALL INTESTINE OF THE RAT[a]

Mean Concn. Ratio,[b] Serosal/Mucosal			
All Expt.		Successful Expt.[c]	
Proximal Segments	Distal Segments	Proximal Segments	Distal Segments
1.31 (*13*)	1.40 (*13*)	1.43 (*9*)	1.54 (*9*)
All Segments		All Segments	
1.36 (*26*)		1.48 (*18*)	

[a] Cannulated everted segments of rat small intestine were incubated for 1 hr. at 37° in oxygenated Krebs–Ringer–bicarbonate solution (pH 7.4) containing 2 m*M* L-tryptophan. [b] Number of experiments listed in parentheses. [c] Concentration ratio of "controls" ≥1.20.

sealed, placed in a 37° water bath, and agitated moderately by means of a reciprocating shaker. Aliquots of the mucosal and serosal solutions were obtained after 1 hr. of incubation and were assayed.

The composition and method of preparation of Krebs–Ringer–bicarbonate solution are described elsewhere (8). Calcium chloride and magnesium sulfate had to be omitted in the indomethacin experiments due to the formation of precipitates; these salts were also excluded from the solution used in the corresponding control experiments. The drugs used in this study and their respective sources were: 2,4-dinitrophenol (Mann Research Laboratories); indomethacin (Merck Sharp and Dohme); phenylbutazone (Geigy Pharmaceuticals); aspirin (Mallinckrodt); sodium salicylate (Fisher Scientific Co.).

Tryptophan was determined by procedure *A* of the method of Spies and Chambers (9). Dinitrophenol, indomethacin, and phenylbutazone interfered with the tryptophan assay and had to be removed by extraction. For this purpose, an aliquot of the solution to be assayed was diluted with water to 3 ml., 0.5 ml. of 3 *N* hydrochloric acid was added, and the solution was extracted with 20 ml. of ethylene dichloride. The salicylate content of aspirin solutions was determined immediately after completion of the experiments by the method of Brodie *et al.* (10).

RESULTS AND DISCUSSION

The active intestinal transport of L-tryptophan has been studied in detail by Spencer and Samiy (11). This amino acid is transported by the monoamino-monocarboxylic acid transport system, which is responsible for the active transport of at least 14 amino acids (12). In the presently described investigation, L-tryptophan absorption was studied initially by the cannulated everted rat intestine method, using the occurrence of absorption against a concentration gradient (as evidenced by the magnitude of serosal/mucosal concentration ratios) as the criterion of active transport. The results of the experiments with L-tryptophan alone are shown in Table I. Some of the experiments did not yield serosal/mucosal concentration ratios significantly greater than unity; this appeared to be due to technical difficulties. However, there was an excellent correlation between the results obtained with the proximal and the distal intestine segments of any one animal. Using a serosal/mucosal concentration ratio of 1.2 as an arbitrary minimum value to establish active transport, only one out of 13 pairs of intestinal segments yielded dissimilar results in that one segment showed active transport while the other did not. Of the 13 pairs of experiments, nine pairs were designated as "successful" since the segments predesignated as the "control" (*i.e.*, either the proximal or the distal segment of each pair) yielded a serosal/mucosal tryptophan concentration ratio greater than 1.2.

The effects of various drugs on the active transport of L-tryptophan across the rat small intestine are shown in Table II. The results are listed both as the average of all experiments and as the average of the "successful" experiments. A 1 m*M* concentration of the classical uncoupling agent 2,4-dinitrophenol completely abolished active transport of L-tryptophan. Five millimolar indomethacin and 5 m*M* phenylbutazone, respectively, had the same effect. Fifteen millimolar salicylate prevented the active transport of L-tryptophan, while the same concentration of aspirin inhibited, but did not prevent, the active transport process.

To obtain more definitive data concerning the relative inhibitory effect of salicylate and aspirin on the active transport of L-tryptophan, additional experiments were carried out using the small intestine of hamsters. It has been pointed out recently that the hamster is a much more satisfactory experimental animal for active transport studies than is the rat (7). The results obtained were consistent with this statement since all the experiments were "successful" in that each control

TABLE II—EFFECT OF VARIOUS DRUGS ON ACTIVE TRANSPORT OF L-TRYPTOPHAN ACROSS THE SMALL INTESTINE OF THE RAT[a]

Drug	Concn., m*M*	Mean Tryptophan Concn. Ratio,[b] Serosal/Mucosal — All Expt. — With Drug	All Expt. — Without Drug	Successful Expt. — With Drug	Successful Expt. — Without Drug	Statistical Significance[c] of Difference, Drug *vs.* No Drug — All Expt.	Successful Expt.

[a] Cannulated everted segments of rat small intestine were incubated for 1 hr. at 37° in oxygenated Krebs–Ringer–bicarbonate solution (pH 7.4) containing 2 m*M* L-tryptophan. [b] Number of experiments listed in parentheses. [c] Student's *t* test, significant differences $p < 0.05$.

segment yielded serosal/mucosal tryptophan concentration ratios appreciably greater than 1.2. The effects of salicylate and aspirin on L-tryptophan transport across the hamster small intestine are listed in Table III. Fifteen millimolar salicylate significantly inhibited the active transport of L-tryptophan, while the same concentration of aspirin had no inhibitory effect.

The relative inhibitory effectiveness of the drugs tested is consistent with their relative effectiveness as uncouplers of oxidative phosphorylation. Indomethacin and phenylbutazone are approximately equipotent but have greater activity than salicylate in uncoupling oxidative phosphorylation in rat liver mitochondria (1). The cytostatic effect of these agents, as determined by their inhibition of cellular proliferation of Ehrlich ascites in suspension cultures, is of the order: indomethacin > phenylbutazone > sodium salicylate > aspirin, while their inhibitory effect on glucosamine-6-phosphate synthesis in liver homogenates is phenylbutazone > indomethacin > sodium salicylate > aspirin (13). Aspirin has practically no inhibitory effect in the latter system. Similarly, up to 1.24 m*M* aspirin has no significant effect on the oxygen uptake of rat cerebral cortex slices, while salicylate concentrations as low as 0.06 m*M* have a significant effect (14). Brostaff *et al.* have shown that modification of the phenolic hydroxyl group of salicylate (*i.e.*, alteration of its position on the benzene ring, removal, methylation, or substitution) causes a loss of uncoupling activity (5). While the rapid *in vivo* hydrolysis of aspirin to the potent uncoupler salicylic acid has made it difficult to determine the uncoupling activity of aspirin as such, it is reasonable to expect that aspirin either has no or very little uncoupling activity. The results of the present study are consistent with this assumption in that aspirin has less inhibitory effect than salicylate on the active transport of L-tryptophan across the small intestine of the rat. Further, 15 m*M* aspirin does not inhibit L-tryptophan transport across the hamster small intestine, while the same concentration of salicylate has a pronounced inhibitory effect.

There was significant hydrolysis of aspirin to salicylic acid during the absorption experiments but, at least with hamster small intestine, the concentration of salicylate did not become high enough to reach inhibitory levels (Table IV). Aspirin hydrolysis appears to be due mainly to the presence of esterase(s) in the intestinal epithelium, since hydrolysis was appreciably reduced in the absence of intestinal segments or when the intestine had been placed in boiling water to destroy the enzymes. The presence of aspirin hydrolyzing esterase(s) in the intestinal epithelium, as well as in the gastric mucosa (15), is of considerable biopharmaceutic interest because it raises the possibility of appreciable aspirin hydrolysis during gastrointestinal absorption. In this connection it is significant that nonspecific esterase is present in all regions of the human gastrointestinal tract (16). Due to the limited capacity of enzyme systems located in the gastrointestinal mucosa, the extent of aspirin hydrolysis is probably more pronounced when the drug is administered in slowly absorbed form.

One can only speculate as to the clinical implications of the amino acid transport inhibiting effects observed in this study. Patients requiring anti-inflammatory therapy with salicylate, indomethacin, or phenylbutazone may be in nutritional deficiency for many reasons other than impaired absorption. On the other hand, the chronicity of anti-inflammatory drug therapy makes additional and more detailed studies of these effects highly desirable. A next logical step is to determine if the inhibitory effect of these anti-inflammatory agents depends on their presence in intestinal fluids, or if it persists for an appreciable time after exposure of the intestine to these drugs. This is presently being investigated and will be the subject of a future communication.

TABLE III—EFFECT OF ASPIRIN AND SALICYLATE ON ACTIVE TRANSPORT OF L-TRYPTOPHAN ACROSS THE SMALL INTESTINE OF THE HAMSTER[a]

	Mean Tryptophan Concn. Ratio, Serosal/Mucosal			
Drug	First Segment[b] (5 Sacs)	Second Segment (5 Sacs)	Third Segment (5 Sacs)	All Segments (15 Sacs)
None	1.42	1.46	1.42	1.43 ± 0.14[c]
15 m*M* Aspirin	1.36	1.66	1.66	1.56 ± 0.34
15 m*M* Sod. salicylate	1.18	1.16	1.11	1.15 ± 0.08[d]

[a] Everted sacs of small intestine from the golden hamster were incubated for 1 hr. at 37° in oxygenated Krebs–Ringer–bicarbonate solution (pH 7.4) containing 2 m*M* L-tryptophan. [b] Numbered from the pyloric end. [c] Standard deviation. [d] This value differs significantly ($p < 0.01$) from the control and the aspirin values.

TABLE IV—HYDROLYSIS OF ASPIRIN BY SMALL INTESTINE OF THE HAMSTER DURING 1-hr. INCUBATION AT pH 7.4 AND 37°

Conditions	No. of Expt.	Hydrolysis of Aspirin, %
Standard[a]	15	17.4 ± 2.1[c]
No intestine, no tryptophan	15	4.9 ± 0.4
Boiled intestine[b]	3	7.1
No intestine	5	6.3

[a] As described in *Footnote a* of Table III. [b] Intestine was immersed in boiling water for 5 min. [c] Standard deviation.

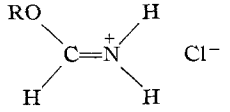
Detection of Some Formiminoesters and the Measurement of Their Rates of Formation Using NMR

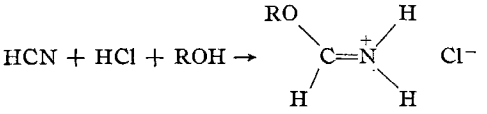
By JAY NEMATOLLAHI* and L. DALLAS TUCK

Formiminoesters have long been postulated as intermediates in the synthesis of formamidines and various heterocyclic compounds. The methyl, ethyl, and isopropyl homologs have been prepared by interaction of hydrogen cyanide with the appropriate alcohol in the presence of dry hydrogen chloride, and the progress of the formation was monitored by NMR at regulated probe temperatures from −25° to 0°. The rate of formation of formiminoesters depends principally on the concentration of hydrogen cyanide. The quartet in the NMR spectrum at a chemical shift near 8 p.p.m. arises from a single proton on a doubly bonded carbon, which is coupled to two nonequivalent protons. This is consistent with the structure:



The lifetime of the nitrogen-proton bond is of the order of 3 sec.

THE FORMIMINOESTER hydrochlorides have long been postulated as intermediates in the syntheses of formamidines and related compounds. These intermediates are presumed to form by interaction of hydrogen cyanide and dry hydrogen chloride with the appropriate alcohol. Pinner (1) established empirical formulas for several of these intermediates and proposed the structure shown in I.



I

Because of the extreme instability of these compounds under ordinary laboratory conditions, their properties have not been explored, and nothing is known about their rates of formation. The authors have confirmed the structure proposed by Pinner using NMR spectrometry and have studied the dependence of the rates of formation on the concentrations of the reactants and on temperature from −25° to 0°.

Received June 13, 1966, from the Department of Pharmaceutical Chemistry, School of Pharmacy, University of California, San Francisco Medical Center, San Francisco, CA 94122

Accepted for publication November 14, 1966.

Presented to the Drug Standards, Analysis and Control Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

This investigation was supported in part by a general research support grant FR 05453 from the Division of Research Facilities and Resources, National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

The authors wish to dedicate this paper to Dean T. C. Daniels, whose leadership at the University of California has done so much to raise the standards of education and research in the pharmaceutical sciences.

DISCUSSION

To explore the possibility of a reaction in the absence of hydrogen chloride, a mixture of liquid hydrogen cyanide and each of the alcohols was allowed to stand for 7 days at temperatures ranging from −10° to 25°. The NMR spectra showed that no reaction occurred during this period.

A series of experiments to test the dependence of the reaction on the concentration of hydrogen chloride proceeded as follows. To mixtures of hydrogen chloride with alcohol, ranging from a catalytic amount to 40% by weight, were added varying amounts of hydrogen cyanide. Unless the hydrogen chloride in the alcohol–HCl mixture exceeded 25% by weight, no reaction occurred based on the NMR spectra. At higher concentrations the reaction proceeded at a rate in which there was a minor dependence on HCl concentration. It was concluded that roughly a stoichiometric amount of hydrogen chloride is necessary in order for the reaction to proceed. From this result it would appear that an intermediate complex is formed which is structurally very close to the protonated imino ester which is the final product. More detailed studies on the effect of the concentration of HCl were not pursued because of the difficulties due to the extreme volatility of HCl under the conditions of these experiments.

Dry trifluoracetic acid was tried as a possible substitute for HCl gas. There was no interaction between HCN and alcohol in this solvent; the NMR spectrum showed only the rapid formation of esters of trifluoracetic acid. Unlike the case with HCl, there is no direct interaction between HCN and trifluoracetic acid (see below).

It is well known that HCN and HCl react to produce a solid from which *s*-triazine can be obtained (2). The product of this reaction does not occur in quantity detectable in the NMR spectrum when alcohol is present. Research on this product is continuing.

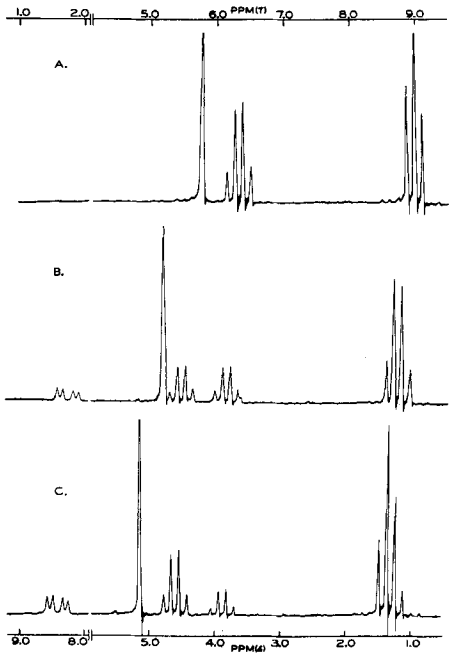

Fig. 1—NMR spectra during the formation of ethyl formimidate at −20°. Key: A, *0 min.;* B, *56 min.;* C, *94 min.*

As long as it remains liquid, the most useful measure of the extent of the formation of the formiminoesters is the integral of the NMR peaks of the imino ester described in a later paragraph. At a late stage of the reaction, a white crystalline solid is precipitated. The solid, which is insoluble in chloroform, reacts instantaneously with water. With dimethylsulfoxide it reacts to produce a brown solution containing incompletely dissolved material. It was desired to know whether the solid was the formiminoester hydrochloride, which would have a limited solubility in the alcoholic medium. The imino ester may react with alcohol in the mixture or with atmospheric water to produce ammonium chloride. Then

$$ROCH{:}NH_2^+Cl^- + 2ROH \rightarrow CH(OR)_3 + NH_4^+Cl^-$$
$$ROCH{:}NH_2^+Cl^- + H_2O \rightarrow HCOOR + NH_4^+Cl^-$$

In both cases soluble compounds with characteristic NMR spectra would be formed—in the former the orthoformate, in the latter, a formate ester. Neither of these compounds was found in the NMR spectrum. The infrared spectrum indicated that the solid was not ammonium chloride. Moreover, the effect of dimethylsulfoxide, together with NMR and I.R. evidence, showed that the solid was different from that observed by direct interaction of HCl and HCN.

NMR Spectrum—The progress of the reaction is illustrated by reference to the ethanol case, the other alcohols differing only in the details of the alkyl portions of the NMR spectrum. In Fig. 1, A, at zero time the triplet at $\delta = 1.0$ ($\tau = 9.0$) and the quartet at $\delta = 3.8$ arise, respectively, from the methyl and methylene portions of ethanol. The sharp singlet at 4.2 is due to HCN, and an additional peak due to mutually exchangeable alcoholic OH and HCl is found offscale to the left. Figure 1,B, shows after a lapse of time a new methylene quartet which grows at the expense of the original quartet. The transformation of the triplet into a quartet of the same over-all intensity is due to the overlap of the ethanol triplet with that of an ethyl group in the product. The fact that the new methylene and methyl multiplets are downfield (left) of ethanol indicates that in the product the ethyl group is associated with a functional group more electronegative than the alcoholic OH. At the same time a new quartet has appeared at $\delta = 8.0$, whose integral is exactly half of the integral of the new CH_2 quartet and is thus due to a single proton. Figure 1,C, shows a continuation of the same process as the product builds up at the expense of the reactants. There is a general downfield shift of the entire spectrum owing to changes in the solvent and acidic properties of the mixture. Table I summarizes the chemical shifts of the various alcohols and the corresponding esters.

TABLE I—CHEMICAL SHIFTS (p.p.m. FROM TETRAMETHYLSILANE) IN THE MIXTURE DURING THE FORMATION OF THE RESPECTIVE FORMIMINOESTER, AS INDICATED

	Methyl Formimidate	Ethyl Formimidate	Isopropyl Formimidate
HCN	3.9–5.4	4.3–5.0	4.1–4.9
Alcohol, αCH	3.0–3.3	3.7–4.1	3.8–4.4
βCH	...	0.9–1.2	1.0–1.2
Ester, αCH	3.9–4.0	4.4–4.8	4.6–5.2
βCH	...	1.1–1.5	1.2–1.35
N=CH—O	7.9–8.3	8.0–8.5	8.0–8.5

The feature of the spectrum which leads to important structural inference is the well-resolved quartet due to a proton on an sp^2 carbon at $\delta = 8$. This indicates the presence of two nonequivalent protons on the nitrogen *cis* and *trans* to the CH. The spin-spin splitting arising from the *cis* coupling is 5 c.p.s. and from the *trans* 14 c.p.s.

The separate lines are sufficiently well resolved that the lifetimes of the states may be calculated directly from their line width, about 2 c.p.s. The net lifetime T_2' is the magnetic lifetime determined by the spin-lattice interaction as modified by the chemical lifetime of the NH protons with respect to exchange (3). A spin-lattice relaxation time T_2 is obtained from the line width of the CH_3 line, and assuming that the same prevails for the NH, the exchange lifetime is found by the reciprocal difference, *viz.*,

$$1/\tau = 1/T_2' - 1/T_2 = 2\pi(\delta\nu_{CH} - \delta\nu_{CH_3}) \approx 3 \text{ sec.}$$

The relative amount of formiminoester formed was determined from the integral of an appropriate section of the NMR spectrum. The methyl singlets of the ester and alcohol were well separated, and their integrals were used as a measure of the extent of the methanol reaction. Because of overlap between the multiplets of the ethyl formimidate and the ethanol, as well as the HCN singlet, it was necessary to use the integral of the downfield peak of the methyl triplet as a measure of the ethanol reaction. In the isopropyl formimidate the integral of the methyl doublet was used. To establish a constant scale

which would cancel out instrumental fluctuations, the relative measure of the formimidate is taken as the ratio of the appropriate integral (see above) to the sum of the integrals of the peaks ascribed to the OH, NH_2, and HCl, which sum should remain constant during the reaction. For each series of measurements on a given mix, the relative concentration of formimidate was plotted against the time of measurement as shown for methyl formimidate in Fig. 2. During the early part of the experiment, the points in these plots describe straight lines, and the initial reaction rates calculated as the slopes are shown in Table II.

The results of the rate measurements of the formation of the methyl formimidate at −10° are the most complete and show a close proportionality with HCN concentration. Little can be said about the relationship of the rate with concentration of HCl or alcohol except the general comments found earlier in this paper. Not enough data were collected from the ethyl and isopropyl experiments to draw similar conclusions, but judging from the qualitative behavior and the time required for precipitation of the solid compound, the same approximate dependence on HCN and HCl prevails. Comparing the three alcohols, it is evident that for a comparable concentration of HCN the rate is higher for the higher homolog.

These temperature dependencies of the rates were used to determine the approximate values for the energy of activation. These are given in Table III, and their respective values seem to indicate a reasonable trend. As one might expect, the simpler structure has a lower energy of activation.

Because of the impossibility of independent adjustment of the concentration of the reactants in a system in which the solvent is itself a reactant, it is difficult to ascertain the dependency of the rate on the concentration of alcohol or HCl. Moreover, in these circumstances, mass action behavior is no longer the primary determinant of rate because of the importance of other variables of the mix, such as viscosity and specific solvation effects. On the other hand, it is the simplicity of the system, particularly the absence of a proton-containing solvent, which makes the study by NMR feasible.

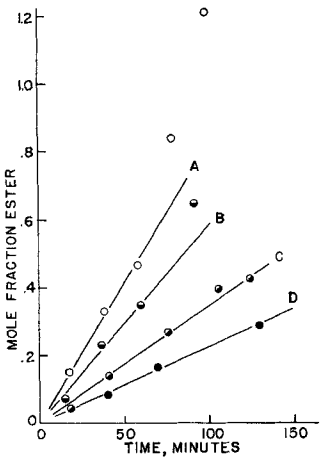

Fig. 2—Mole fraction of product during esterification of methanol at −10° calculated from the NMR integral. The straight lines yield the initial rates. The runs may be readily identified from the summary in Table II.

TABLE II—INITIAL RATES OF FORMATION OF FORMIMINO ESTERS

EXPERIMENTAL

Hydrogen chloride gas, dried by passing through concentrated sulfuric acid, was introduced into a weighed amount of alcohol cooled in a dry ice–acetone mixture. A sintered glass tip was used for the gas dispersion. Three hours were required to produce a solution of 25 to 30% HCl. The amount of hydrogen chloride was determined by the gain in weight. The solution was stored at −20°. The alcohol was dried using magnesium turnings and iodine.

Hydrogen cyanide from a tank was dried by passing through a tower containing $CaCl_2$ and $CaSO_4$ and condensed in an ice–salt mixture at −5°.

To a tared NMR tube was added about 0.5 ml. of HCN, which was then capped, cooled to −20°, and weighed. The tube was placed in a dry ice–acetone bath and to it was added 0.5 ml. of the cooled HCl–alcohol solution. The material was brought to the melting point of HCN just before placing it in the constant-temperature probe of the NMR spectrometer. The first spectrum was run immediately and then at time intervals varying from 5 to 30 min. The tube was not removed from the probe during the experiment.

The solid product remaining in the tube at the end of the experiment was filtered in a dry box under nitrogen atmosphere. The infrared spectrum of this solid was determined in KBr disks.

NMR spectra were run using a Varian A60 spectrometer with a temperature controlled probe. Infrared spectra were determined with a Beckman IR-8 spectrophotometer.

Binding of Cortisol and Its Degradation Products by Human Serum Albumin

By K. J. KRIPALANI and DONALD L. SORBY

The rate of degradation of the 17-dihydroxyacetone function of cortisol has been measured in a phosphate buffer system, pH 7.4 and ionic strength 0.16, at 15.0°, 25.0°, and 35.0°. The results correspond favorably with data in the literature for degradation of prednisolone under similar conditions. The binding of cortisol and its degradation products to human serum albumin was measured at 25.0° by an equilibrium dialysis procedure. The degradation products were found to be bound more strongly than was cortisol, but did not appear to compete with cortisol for binding sites on the protein molecule. In systems having a constant concentration of total corticosteroid, the apparent binding constant of total steroid increases as the fraction of the material present as degradation products increases. The results of this research are important to the design of experiments which attempt to study the binding of steroids containing the 17-dihydroxyacetone function to serum proteins.

INTERACTIONS with various serum proteins may potentially affect the distribution, metabolism, elimination, and therapeutic effects of a drug. Hence, interactions between drugs and proteins have been subjects for study by many investigators. In his extensive review, Goldstein (1) cites several hundred published studies of drug protein interactions. One particularly active area of interest has been the interactions which occur between various steroid hormones and serum proteins. Such interactions appear to be of major importance to the transport and distribution of these compounds. Cortisol, in particular, has received much attention. Sandberg *et al.* (2), Daughaday (3), Slaunwhite *et al.* (4), Brunkhorst and Hess (5), and Westphal (6), among others, have studied the interaction between cortisol and serum albumin. The literature pertaining to steroid–protein interactions has been reviewed by Daughaday (7).

Two plasma components appear to be involved in binding cortisol (8–10). At physiologic levels, cortisol is bound predominantly by an α globulin commonly termed "transcortin" or "corticosteroid binding globulin" (8, 10). Transcortin is present in relatively low concentrations, however, and rapidly becomes saturated in its binding ability if plasma cortisol concentrations rise much above normal physiologic levels. Serum albumin has a lesser affinity for binding cortisol than does transcortin but plays a major role in binding at elevated serum cortisol levels (11). Effects of cortisol concentration on its binding to plasma proteins have been discussed by Daughaday (7) and by Bush (12). For the most part, research on the steroid–plasma protein interaction to date has employed equilibrium dialysis procedures (7). Equilibration times have varied between 18 and 72 hr. One important criterion which must be met in such a study is that the solute molecules must be sufficiently stable so that chemical degradation does not occur to a significant extent during the equilibration period. Oesterling and Guttman (13) and Guttman and Meister (14) have studied prednisolone degradation. Their data show that the extent of degradation of the 17-dihydroxyacetone function might be significant during the average equilibrium dialysis experiment. While similar information pertaining to cortisol was not available, it was considered that it too should be subject to similar rates of degradation. This research was initiated to determine whether cortisol would undergo significant degradation under conditions of the equilibrium dialysis experiment and whether such degradation would significantly alter the results of

protein binding experiments. Such information was needed for development of suitable experimental procedures for protein binding studies currently under way in this laboratory.

EXPERIMENTAL

Reagents and Materials—Phosphate buffer, pH 7.4, ionic strength 0.16, was prepared by dissolving 16.68 Gm. disodium phosphate, $Na_2HPO_4 \cdot 7H_2O$, and 2.209 Gm. monosodium phosphate, $NaH_2PO_4 \cdot H_2O$, in enough freshly boiled distilled water to make 1 L. Hydrocortisone was obtained from a commercial source and was recrystallized from isopropanol. The melting point was 217–219° (uncorrected). Tetramethylammonium hydroxide reagent was prepared by diluting 1 ml. of a 10% solution in water, obtained from Eastman Chemical Co., to 10 ml. with absolute ethanol. Triphenyltetrazolium chloride reagent was prepared by dissolving 1 Gm. of 2,3,5-triphenyltetrazolium chloride, obtained from Nutritional Biochemicals Corp., in enough absolute ethanol to make 100 ml. Crystalline human serum albumin[1] was purchased from Nutritional Biochemicals Corp. Information furnished by the supplier certified that this material was four times recrystallized and was 100% pure albumin by electrophoresis. The crystalline HSA was stored at −7° and was dried under vacuum over calcium chloride, to a constant weight before use. The molecular weight was assumed to be 69,000. All other solvents and chemicals employed at various stages of the experiment were reagent grade or comparable quality.

Thin-Layer Chromatography of Degradation Products—A 5×10^{-4} *M* solution of cortisol in phosphate buffer was prepared. Ethanol was used to facilitate dissolution of the cortisol and was present in the final sample at a concentration of 2%. The solution was stored at 25.0° for 10 days. An aliquot of the solution was then extracted with four 30-ml. portions of freshly distilled chloroform. The combined extracts were designated "extract I." The aqueous residue remaining after extraction was made strongly acidic with concentrated hydrochloric acid and was again extracted with four 30-ml. portions of chloroform. The combined extracts were designated "extract II." Both extracts I and II were concentrated *in vacuo* to 5 ml. Ten-microliter volumes of the concentrated extracts and of a freshly prepared solution of cortisol of identical concentration extracted in a similar fashion were spotted onto thin-layer chromatographic plates coated with Silica Gel G which had been activated at 110° for 1 hr. After drying, the plates were developed with a mixture consisting of 75 parts benzene, 50 parts acetone, and 0.2 part water. After drying, visualization of the spots was accomplished by first spraying with a solution consisting of equal parts of tetramethylammonium hydroxide reagent and triphenyltetrazolium chloride reagent. The plates were heated for 5 min. at 110°. Steroids reacting with the 2,3,5-triphenyltetrazolium chloride appeared as pink spots on the plate. After the pink zones were marked, the plates were sprayed with 70% w/w sulfuric acid and were heated at 110° for 15 min. All spots were then visible as brown-black areas.

Kinetic Experiments—Kinetic experiments were performed at 15.0°, 25.0°, and 35.0°. Flasks containing cortisol solutions of the appropriate concentration[2] in the phosphate buffer were placed in a thermostat maintained within ±0.05° of the desired temperature. These samples also contained 2% ethanol which was used to facilitate dissolution of the cortisol. At various time intervals, aliquots of the solutions were withdrawn and immediately assayed by a spectrophotometric procedure for their content of total steroid and by a colorimetric procedure for the amount of cortisol still possessing the 17-dihydroxyacetone function.

In the spectrophotometric procedure, the absorbance of the solution was measured at 248 mμ with a Beckman DU spectrophotometer. The apparent concentration of cortisol in the sample was calculated from the absorbance reading, using 16,000 as the molar absorption coefficient of cortisol in the buffer medium.

To determine the amount of steroid still possessing the 17-dihydroxyacetone function, the tetrazolium chloride procedure of Mader and Buck (15) was employed. The appropriate aliquot of the test solution was extracted with four 20-ml. portions of freshly distilled chloroform. The combined chloroform extracts were evaporated under vacuum to dryness. The residue was dissolved in 20 ml. absolute ethanol and 1 ml. each of triphenyltetrazolium chloride reagent and tetramethylammonium hydroxide reagent was added. The assay mixture was allowed to stand in the dark for exactly 30 min. One milliliter of glacial acetic acid was then added to quench further color formation. The absorbance of the mixture was determined with a Bausch & Lomb Spectronic 20 colorimeter at 485 mμ. Ten milliliters of buffer solution, treated in a similar fashion, served as a reagent blank for the procedure. The concentration of cortisol still retaining the 17-dihydroxyacetone function was determined by referring to a standard curve of absorbance *versus* concentration for freshly prepared cortisol solutions assayed in an identical fashion.

Spectrophotometric Estimation of Cortisol Binding—A spectrophotometric procedure was employed for preliminary experiments to determine whether degradation of the 17-dihydroxyacetone function of cortisol significantly affected binding to HSA. The method employed was adapted from one proposed by Klotz and Walker (16) and later used by Westphal (17) in his studies of steroid–protein interactions. Solutions of cortisol in the phosphate buffer, $3.86 \times 10^{-5}M$ and $7.88 \times 10^{-5}M$, were prepared. An aliquot of each solution was mixed with an equal volume of a 4×10^{-5} *M* HSA in phosphate buffer. The absorbance of each solution was measured at 248 mμ with the Beckman DU spectrophotometer. HSA, 4×10^{-5} *M*, diluted with an equal volume of phosphate buffer, served as the reference solution in the spectrophotometer.

The apparent molar extinction coefficient of cortisol ($\epsilon_{app.}$) in the presence of HSA was calculated from:

$$\epsilon_{app.} = \frac{1}{Cd} \log \left(\frac{I_0}{I} \right) \qquad \text{(Eq. 1)}$$

where C is the total molar concentration of cortisol,

[1] In this paper, human serum albumin is henceforth designated as HSA.

[2] See Table I for concentrations of cortisol employed in these experiments.

d is the path length of the cell, and log I_0/I is the absorbance of the mixture at 248 mμ.

The stock solutions of cortisol were then placed in a thermostat at 25.0°. During succeeding days, samples were withdrawn and mixed with freshly prepared HSA solutions. The ultraviolet absorbance was measured and the $\epsilon_{app.}$ was calculated as described.

Equilibrium Dialysis Experiments—The effect of cortisol degradation on the binding to HSA was quantitated by an equilibrium dialysis experiment (18). Eight-inch lengths of Visking cellulose dialysis casings (23/32 in. diameter) were immersed in distilled water and heated on a steam cone for 12 hr. The water was changed three times during this period. The inner lumen of each casing was then flushed with a running stream of distilled water. The casings were soaked an additional 0.5 hr. in distilled water and were then transferred to phosphate buffer solution for 6 hr. at room temperature. The casings were used immediately after this length of time.

Solutions of HSA, 4×10^{-5} M, in phosphate buffer were prepared immediately prior to each experiment. Octyl alcohol, 250 mg./L., was added to HSA solutions to prevent microbial attack. Octyl alcohol between 250 mg./L. and 1000 mg./L. did not interfere with the binding of cortisol by HSA.

Excess buffer solution was carefully expressed from the dialysis casings and a knot was tied in one end to make a small bag. A 10-ml. quantity of the HSA solution was pipetted into the bag and, finally, the open end was knotted. The bag was placed inside a 20 × 200-mm. glass-stoppered test tube containing 20 ml. cortisol solution of the appropriate concentration and age. The tubes were stoppered, dipped in paraffin, and placed on a rocker-type shaker completely immersed in a constant-temperature bath at 25.0°. Six different concentrations of cortisol solution between 5×10^{-5} M and 5×10^{-4} M were used in each experiment and duplicate samples were prepared for each concentration. A time period of 24 hr. was sufficient for attainment of diffusional equilibrium between the solutions inside and outside the dialysis bag. Three samples containing 20 ml. buffer solution in place of cortisol were included in each experiment as controls. There was negligible change in the volumes of solution inside and outside the dialysis sac during the course of the experiment. After 24 hr., the tubes were removed from the bath. The solution external to the dialysis bag was assayed as described previously.

Because cortisol was found to bind to the dialysis casing, parallel experiments were run to obtain corrections for "bag binding." Samples were prepared as described above except 10 ml. phosphate buffer was placed inside the bag instead of HSA solution. At the end of the dialysis experiment, the amount of steroid bound to the bag was calculated as the difference between the amount of compound remaining in solution and the amount originally present before equilibration. Ultraviolet spectrophotometric assay procedures were used to measure the steroid concentration in these experiments. A curve was prepared by plotting the amount of steroid bound by the dialysis bag *versus* the concentration of steroid not bound and served to provide correction values for the test samples containing protein.

To evaluate the effect of degradation of the 17-dihydroxyacetone function of cortisol on the binding of HSA, equilibrium dialysis studies were carried out using cortisol solutions which had been aged for periods of time sufficient to obtain a desired degree of degradation. A 5×10^{-4} M stock solution of cortisol in phosphate buffer was prepared by placing the necessary amount of cortisol in a volumetric flask nearly filled with phosphate buffer. The flask was placed on a shaking device in a constant-temperature room at 25° and agitated vigorously until dissolution of the cortisol was complete. This procedure was usually completed within a 6-hr. period. The solution was then made to volume with phosphate buffer and the flask was placed in a thermostat at 25.0° for the desired period of time. The age of the solution was taken as the time elapsed between first contact of the crystalline cortisol with the buffer solution and the end of the dialysis experiment. Dialysis experiments were performed at 25.0° using cortisol solutions aged for 48, 84, and 288 hr. After diffusional equilibrium was attained, two aliquots of the phase external to the dialysis bag were taken for assay. One portion was assayed by measuring the ultraviolet absorbance at 248 mμ. The second portion was assayed by the triphenyltetrazolium chloride method described above.

Calculations—*Total Steroid Bound*[3]—At equilibrium, the concentration of steroid in the volume outside the dialysis bag may be assumed to be equal to the concentration unbound inside the dialysis casing. The concentration of free steroid in the outside volume is given by the ultraviolet absorbance of this solution after equilibrium is established. The difference between the amount of free steroid in the total volume of the system and the amount of steroid initially placed in the test tube gives the amount of steroid bound. This figure also includes the amount of steroid bound to the dialysis bag. The correction for binding to the bag at any free steroid concentration was obtained from the bag binding correction curve described above.

Undegraded Cortisol Bound—The equilibrium concentration of undegraded cortisol in the volume outside the bag is measured by the triphenyltetrazolium assay method. The total concentration of undegraded cortisol can be obtained from assay of the stock solution at the end of the experiment. The difference between the amount of undegraded cortisol remaining free at equilibrium and the total amount theoretically present at this time gives the amount of cortisol which is bound.[4] A correction for bag binding was obtained by referring to the correction curve described above. It was assumed that the affinity for binding to the dialysis casing was the same for cortisol as for its degradation products.

Degraded Cortisol Bound—The data for the binding of degraded cortisol are calculated in the following manner. The equilibrium concentration of degraded cortisol remaining free in a given sample is obtained by calculating the difference between the equilibrium concentrations of total steroid and undegraded cortisol. In similar fashion, the amount of

[3] The term "steroid" is used here to denote all forms still possessing the steroid ring structure and includes cortisol plus its degradation products.

[4] It was assumed that the rate of degradation of cortisol is unchanged in the presence of HSA. In the actual case, the presence of HSA slows the rate of degradation somewhat (19). However, the difference is slight over the 24-hr. period encompassed by the equilibrium dialysis experiment.

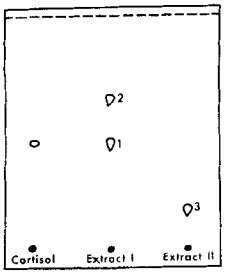

Fig. 1—Thin-layer chromatogram of extracts of a solution of cortisol in phosphate buffer, pH 7.4, μ = 0.16, aged for 240 hr. at 25.0°.

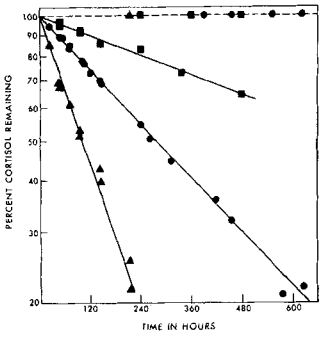

Fig. 2—Disappearance of cortisol from solutions in phosphate buffer, pH 7.4, μ = 0.16, at 15.0° (■), 25.0° (●), and 35.0° (▲), as measured by reaction with triphenyltetrazolium chloride (———) and by ultraviolet absorbance at 248 mμ (– – – –). (See also Table I.)

degradation products bound is calculated from the difference between the concentrations of total steroid bound and the concentration of cortisol bound.

RESULTS AND DISCUSSION

Figure 1 is a diagram of a thin-layer chromatogram of extracts from a cortisol solution aged at 25.0° for 10 days. The freshly prepared cortisol standard produced a spot reacting pink with triphenyltetrazolium chloride. Extract I gave two spots with 70% w/w sulfuric acid marked as 1 and 2 in Fig. 1. Spot 1 reacted with triphenyltetrazolium chloride and has the same R_f as the standard cortisol. It was considered to represent the cortisol remaining undegraded in the test sample. Spot 2 does not react with triphenyltetrazolium chloride and hence must represent a degradation product lacking the 17-dihydroxyacetone function. Extract II gave only one spot, marked 3 in Fig. 1, with sulfuric acid. Spot 3 does not react with triphenyltetrazolium chloride and hence must represent a second degradation product of cortisol also lacking the 17-dihydroxyacetone function. Under aerobic conditions, the degradation of the 17-dihydroxyacetone function of steroids has been reported to involve an oxidative cleavage to yield the corresponding etianic acid (20–22). Chulski and Forist (21) have investigated the effect of solid buffering agents on prednisolone in aqueous solution. Their paper chromatographic examination of the reaction mixture suggested that prednisolone was converted predominantly to a 17β-carboxylic acid and, to a lesser degree, to a 17-keto product. Since the compound represented by spot 3 corresponds to a product possessing acidic characteristics, it is likely that it represents a carboxyl group in place of the 17-dihydroxyacetone function.

It is likely that spot 2 represents a neutral product, probably a 17-keto compound similar to the one reported by Chulski and Forist for prednisolone (21).

TABLE I—RESULTS OF KINETIC STUDIES OF THE DEGRADATION OF THE 17-DIHYDROXYACETONE FUNCTION OF CORTISOL IN PHOSPHATE BUFFER, pH 7.4, IONIC STRENGTH 0.16

Temp., °C.	Apparent First-Order Rate Constant, $(hr.^{-1}) \times 10^3$	Half-Life, hr.	Activation Energy, Kcal./mole
15.0	0.896[a]	773	
	0.912	760	
25.0	2.46	282	
	2.69	258	
35.0	6.80	102	17.0[b]
	6.03	115	

[a] The first value at each temperature represents a solution having an initial concentration of 7.9×10^{-5} *M*, 5.8×10^{-5} *M*, or 7.6×10^{-5} *M*, respectively. The second value at each temperature represents a solution having an initial concentration of 4.1×10^{-4} *M*, 4.1×10^{-4} *M*, or 3.8×10^{-4} *M*, respectively. Rate constants were calculated by the method of least squares from experimental data arranged according to the equation, $\ln c/c_0 = -kt$, where c is the concentration of cortisol at any particular time t, c_0 is the concentration of cortisol when t is zero, and k is the apparent first-order rate constant. [b] Calculated from the Arrhenius equation using the method of least squares applied to the rate constant data.

The ultraviolet absorption by cortisol at 248 mμ is characteristic of the Δ^4-3-keto function of the A ring of the steroid nucleus. Under conditions employed in these experiments, the apparent concentration of cortisol determined by the ultraviolet absorption assay remains constant up to a period of 26 days at 25.0° and up to 9 days at 35.0° (see broken line in Fig. 2). This observation indicates that there is no significant degradation of the A ring of cortisol during the periods of time allowed for experiments in this study. The half-life for the photolytic degradation of the A ring of cortisol under ordinary fluorescent laboratory lighting at room temperature has been reported as 160 days (23). The stability of the A ring allows the ultraviolet absorption assay method to be used to show accurately the concentration of total steroid in aged solutions of cortisol. Inspection of Fig. 2 shows that even when considerable amounts of cortisol have degraded, the ultraviolet absorbance remains unchanged.

The results of kinetic studies of the degradation of cortisol in the phosphate buffer are summarized in Table I and Fig. 2. The degradation of the 17-dihydroxyacetone function follows apparent first-order kinetics at all concentrations and temperatures studied. Figure 3 shows an Arrhenius plot of the rate constant data. The activation energy calculated by the method of least squares from the rate constant data is 17.0 Kcal./mole. Data in Table I may be compared with those obtained by Oesterling and Guttman (13) for prednisolone and by Jensen and Lamb (24) for fluprednisolone. The former investigators reported a rate constant of approximately 0.07 $hr.^{-1}$ for degradation of the 17-dihydroxyacetone function of prednisolone in 0.1 *M* phosphate buffer at 70°.[5] Our data predict a value of 0.109 $hr.^{-1}$. The activation energy reported by Jensen and Lamb was 15.2 Kcal./mole. Their rate constant at 70° was reported as 0.0952 day^{-1} (0.004 hr^{-1}). Oesterling and Guttman have pointed out the strong de-

[5] The value for the rate constant was taken from Fig. 4 of the paper by Oesterling and Guttman (13).

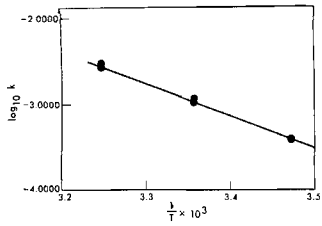

Fig. 3—Arrhenius plot of rate constants for degradation of the 17-dihydroxyacetone function of cortisol in phosphate buffer, pH 7.4, μ = 0.16.

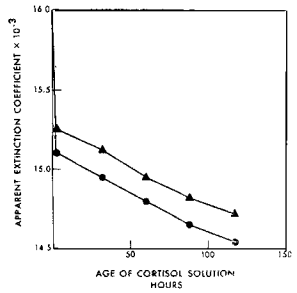

Fig. 4—Effect of aging in phosphate buffer, pH 7.4, μ = 0.16, on the apparent molar extinction coefficient of cortisol at 248 mμ when mixed with freshly prepared solutions of HSA, 2 × 10⁻⁵ M. Initial cortisol concentrations, 1.93 × 10⁻⁵ M (●) and 3.94 × 10⁻⁵ M (▲).

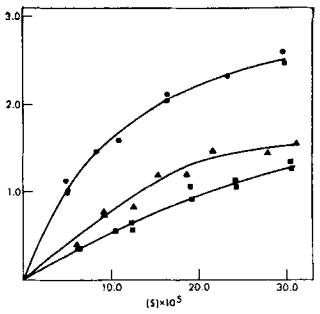

Fig. 5—Binding of total steroid by HSA in systems prepared with solutions of cortisol in phosphate buffer, pH 7.4, μ = 0.16, aged at 25.0° for 48 hr. (■), 84 hr. (▲), and 288 hr. (●).

pendence of the reaction upon the nature of the buffer components, particularly with respect to the content of trace metals in the system. Guttman and Meister (14) have shown the dependence of the reaction upon the hydroxyl-ion concentration. Thus the difference between the rate constants for the different compounds are not unexpected since conditions are not identical in the three different experiments.

Figure 4 shows the results of spectrophotometric studies concerning the effect of sample age on the apparent binding of cortisol by HSA. The large initial decrease in the apparent molar extinction coefficient at 248 mμ can be attributed to the binding interaction between cortisol and HSA (17). As Fig. 4 illustrates, there is a progressive decrease in the apparent molar extinction coefficient of these systems as the cortisol ages. This is indicative of either a greater amount of total steroid being bound or a change in the molar extinction coefficient of the steroid–protein complex. Due to uncertainty about the respective values of the molar extinction coefficients of the various possible steroid–protein complexes, the spectrophotometric method could not be employed to measure the magnitude of the interaction between cortisol or its degradation products and HSA.

Data from equilibrium dialysis studies of protein binding interactions are usually plotted according to:

$$\frac{1}{r} = \frac{1}{nK[S]} + \frac{1}{n} \qquad \text{(Eq. 2)}$$

where r is the average number of molecules of the particular steroid bound per molecule of HSA, n represents the maximum number of binding sites per molecule of HSA, K is the association constant for the interaction, and $[S]$ is the concentration of substrate molecules remaining free in solution when equilibrium between bound and unbound forms is established. This equation is applicable under the conditions that all binding sites have the same intrinsic association constant, K, and that, aside from a statistical factor, the free energy of binding to a particular site is independent of binding at other sites (25). A plot of $1/r$ *versus* $1/[S]$ will yield a straight line with $1/n$ as its intercept on the ordinate axis and $1/nK$ as its slope.

Equation 2 cannot be applied directly to data for aged solutions representing the binding of total steroid by HSA. In these systems, the steroid is present as three different compounds, each of which may bind to the protein with differing affinity. Since data expressing the concentration of each degradation product were not available, an expanded form of Eq. 2 was not employed. Figure 5 shows plots of r *versus* $[S]$ for the binding of total steroid by HSA.

From Fig. 5, it is obvious that the extent of interaction between steroid and HSA increases with the age of the steroid solution. This suggests that the degradation products either bind more strongly than does cortisol or that they are bound to sites not available to cortisol. In the 48-hr. solution, only about 11% of the total steroid is in the degraded form, while approximately 50% is degraded in the 288-hr. material. It is also interesting to note that application of Eq. 2 to the data yields linear plots (Fig. 6). From the slopes of these curves, one obtains values for nK as being 5,700 L./mole, 9,000 L./mole, and 30,000 L./mole at 48 hr., 84 hr., and 288 hr., respectively. Values of n calculated from the intercepts are 5, 5, and 3.6. As stated above, these values are without theoretical meaning; however, they do point out that failure to account for degradation as an experimental variable in these systems may easily go unrecognized. This is particularly true when the assay method employed is not sensitive to the presence of the 17-dihydroxyacetone function.

Figure 7 shows plots of data obtained for the binding of undegraded cortisol in the 48-hr. and 288-hr. samples. It appears that the presence of increased amounts of degradation products in the system at 288 hr. affects the binding of cortisol by HSA. The curves in Fig. 7 represent a visual fit of the data. From these curves, nK values of 4,500 L./mole and 8,900 L./mole are obtained at 48 hr. and 288 hr., respectively. The estimated value of n in each case is 5. Equations for the lines best fitting the experimental data were also calculated by the method of least squares. In this case, nK values were 4,080 L./mole and 10,429 L./mole at 48 hr. and 288 hr., respectively.[6] In this case, however, values for n were 5.3 and 2.1, respectively.

[6] Reciprocals of the 95% confidence intervals of the calculated slopes gave nK values ranging between 5952 and 3106 L./mole at 48 hr. and between 6579 and 26,316 L./mole at 288 hr.

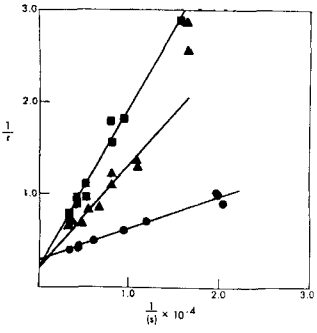

Fig. 6—Plot according to Eq. 2 of the binding of total steroid by HSA in systems prepared with solutions of cortisol in phosphate buffer, pH 7.4, μ = 0.16, aged at 25.0° for 48 hr. (■), 84 hr. (▲), and 288 hr. (●).

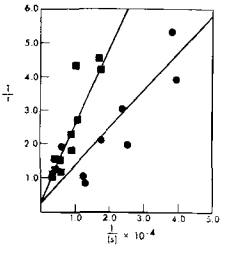

Fig. 7—Plot according to Eq. 2 expressing the binding of undegraded cortisol by HSA in systems prepared with solutions of cortisol in phosphate buffer, pH 7.4, μ = 0.16, aged at 25.0° for 48 hr. (■), and 288 hr. (●).

The values of the intercepts from the least squares calculations indicate that a competition for binding sites may exist between the degradation products and cortisol. This suggests that the affinity between the degradation products and certain sites on the HSA molecule is greater than the affinity of cortisol for the same sites.

This observation is consistent with the observations that the binding of total steroid increases in aged solutions of cortisol. In view of the scatter in the points for the 288-hr. data, there is considerable uncertainty in the value of n obtained from the intercept of the $1/r$ *versus* $1/[S]$ plot. Assigning such significance to the differences in n between 48-hr. and 288-hr. data must be done with caution. Unfortunately, even with repeated experiments, it was impossible to attain the degree of precision in the 288-hr. systems which would allow a more confident assessment of the situation.

Regardless of whether n remains at 5 or indeed is reduced to 2 in systems containing larger amounts of degradation products, it is of interest that the data at 288 hr. suggest that the affinity constant for the interaction between cortisol and HSA must also increase at least by a factor of two or more. This might be explained as being due to an actual difference between the affinity constant of cortisol for some sites as compared to others, especially if one accepts that the decrease in n actually does occur in the 288-hr. system. An alternative explanation would be that binding of the degradation products induces changes in HSA molecules which increase the affinity constant for interaction between cortisol and remaining free sites. Belman (26) has observed changes in the interaction between beryllium and bovine serum albumin when 1% dodecyl sulfate was present. Considerable evidence exists (27–30) that protein molecules are quite flexible and that the secondary and tertiary structure is easily deformed in the presence of certain other molecular species. Karush (27, 30) has suggested that serum albumins possess a number of combining regions, each of which is characterized by a high degree of configurational adaptability. He has also suggested that conformational changes in the protein resulting from binding of a first substrate molecule may induce a capacity for interaction with additional substrate molecules. It appears to be not impossible that an increased binding affinity of cortisol could result from the presence of increasing amounts of its degradation products also being bound by HSA. Brunkhorst and Hess (5) have observed changes in binding capacity caused by increasing concentrations of substrate in their investigations of the cortisol–HSA interaction.

Table II—Values of nK and $\Delta F°$ Reported in the Literature for the Interaction between Cortisol and Human Serum Albumin[a]

Temp., °C.	nK (L./mole) × 10^{-3}	$\Delta F°$ (Kcal./mole)	Ref.
5	5.0	−4.7	(2)
4	6.0	−4.8	(3)
4	2.3	−4.3	(3)
25	5.3[a]	...	(5)
25	4.9[a]	−5.0[b]	(5)
25	4.4[a]	...	(5)
25		−5.5	(31)

[a] The value for nK was dependent upon total concentration of cortisol used in the experiment. [b] Calculated from data given in Table II of *Reference 5*.

It is interesting to compare the results of this experiment with reports of other investigators for the cortisol–HSA interaction (Table II). While nK values in Table II agree favorably with the value obtained in this experiment for the 48-hr. sample, $\Delta F°$ for binding of cortisol in the 48-hr. sample is −4.0 Kcal./mole when n is taken as being 5. The lack of agreement in $\Delta F°$ values between Table II and this experiment is interesting in light of the fact that higher values similar to those in Table II can be obtained if one calculates this parameter from the plots of Fig. 6 for the binding of total steroid from solutions of cortisol aged for varying lengths of time. In such cases, $\Delta F°$ values of −4.1 Kcal./mole, −4.6 Kcal./mole, and −5.4 Kcal./mole are obtained at 48 hr., 84 hr., and 288 hr., respectively. Comparison of these values with those in Table II causes one to question in the experiments cited whether proper control was exerted to insure that cortisol degradation did not take place. Unfortunately, in these reports, no mention was made regarding control of the cortisol samples. Brunkhorst and Hess (5) employed a radiometric assay utilizing cortisol-4-^{14}C. Westphal (17, 31) employed ultraviolet spectrophotometric methods of assay. Neither method would be sensitive to the degradation phenomena reported here.

SUMMARY AND CONCLUSIONS

Data obtained in this research clearly show that the interaction between cortisol and HSA can only be studied by methods which take into account the degradation of the 17-dihydroxyacetone function of cortisol which can occur under usual experimental conditions. These results would also apply qualitatively to other steroids possessing the 17-dihydroxyacetone function.

This research also points out the necessity for considering stability factors in equilibrium dialysis experiments of this type. Competitive binding or other effects imparted by the presence of degradation products can significantly alter experimental results. In addition, since results of dialysis experiments are calculated from concentration differences before and after equilibration, disappearance of solute due to unrecognized chemical instability could be mistaken for binding by the protein and introduce further error into the experiment.

Mechanistic Implication Between Quenching in Liquid Scintillation System and Photosensitivity with Respect to Energy Transfer

By C. T. PENG

A basic mechanism for energy transfer in photosensitive biological systems is postulated.

THE USE OF liquid scintillation system for radiation measurement has been widely accepted. Owing to its high counting efficiency, the internal sample method becomes the preferred mode of assaying radionuclides emitting β particles of low kinetic energy, particularly tritium, ^{14}C, ^{35}S, ^{45}Ca, *etc.* The introduction of a sample in the form of an organic compound into the liquid scintillation system frequently causes fluorescence quenching which manifests itself as a decrease in the counting efficiency of the system. The cause of quenching has been attributed to either a diminished light transmission owing to the color of the sample or a molecular interaction between the scintillator and the sample leading to thermal degradation of the excitation energy or a combination of both (1).

The liquid scintillation system is a sensitized fluorescent donor–acceptor system in which the solvent molecule, by virtue of its presence in an overwhelming number in the medium, absorbs the radiation energy and becomes excited; from the excited states, the solvent molecules may undergo de-excitation by fluorescence emission, nonradiative transition, or excitation transfer. In the presence of solute molecules which can accept the excitation energy from the donor solvent molecule, de-excitation can take place by emission of fluorescence of the solute. Because of the inherently greater fluorescence intensity, the spectrum of the solute characterizes that of the entire system. In the presence of a quencher, transfer of excitation energy is adversely affected. According to theory, energy transfer between unlike molecules is brought about by a resonance mechanism over long distances involving dipole–dipole interaction (2, 3) or dipole–quadrupole interaction (3) or by the exchange mechanism (3, 4) in which an overlap of the wave function of the molecules concerned is necessary.

Mechanistic Implication Between Quenching in Liquid Scintillation System and Photosensitivity with Respect to Energy Transfer

By C. T. PENG

A basic mechanism for energy transfer in photosensitive biological systems is postulated.

THE USE OF liquid scintillation system for radiation measurement has been widely accepted. Owing to its high counting efficiency, the internal sample method becomes the preferred mode of assaying radionuclides emitting β particles of low kinetic energy, particularly tritium, ^{14}C, ^{35}S, ^{45}Ca, *etc.* The introduction of a sample in the form of an organic compound into the liquid scintillation system frequently causes fluorescence quenching which manifests itself as a decrease in the counting efficiency of the system. The cause of quenching has been attributed to either a diminished light transmission owing to the color of the sample or a molecular interaction between the scintillator and the sample leading to thermal degradation of the excitation energy or a combination of both (1).

The liquid scintillation system is a sensitized fluorescent donor–acceptor system in which the solvent molecule, by virtue of its presence in an overwhelming number in the medium, absorbs the radiation energy and becomes excited; from the excited states, the solvent molecules may undergo de-excitation by fluorescence emission, nonradiative transition, or excitation transfer. In the presence of solute molecules which can accept the excitation energy from the donor solvent molecule, de-excitation can take place by emission of fluorescence of the solute. Because of the inherently greater fluorescence intensity, the spectrum of the solute characterizes that of the entire system. In the presence of a quencher, transfer of excitation energy is adversely affected. According to theory, energy transfer between unlike molecules is brought about by a resonance mechanism over long distances involving dipole–dipole interaction (2, 3) or dipole–quadrupole interaction (3) or by the exchange mechanism (3, 4) in which an overlap of the wave function of the molecules concerned is necessary.

Received October 3, 1966, from the Radioactivity Research Center and the Department of Pharmaceutical Chemistry, School of Pharmacy, San Francisco Medical Center, University of California, San Francisco, CA 94122

Accepted for publication November 7, 1966.

The author wishes to dedicate this paper to Dean T. C. Daniels, whose leadership at the University of California has done so much to raise the standards of education and research in the pharmaceutical sciences.

Similar mechanisms may also be evident in biological systems. Aside from photosynthetic processes, the presence of dyes and certain drugs in biological systems causes sensitization to light, presumably as a result of a more efficient localization and utilization of the radiant energy. This report emphasizes the general aspect of energy transfer process in quenching in liquid scintillation system and by analogy extends the principle to energy transfer in photosensitive biological systems with an evaluation of the possibility of the use of the former as a means to elucidate the mechanism involved in the latter.

EXPERIMENTAL

The composition of the liquid scintillator used and the procedure of obtaining the concentration quenching curves have been previously described (5, 6). The quenching constant, q, was obtained from the initial portion of the concentration quenching curve which showed less than 50% reduction of the initial count rate of the sample by quenching.

The excitation sources were toluene-^{14}C and toluene-^{3}H. The ultraviolet excitation was carried out with an Aminco-Bowmann spectrophotofluorometer. The activating wavelength and the fluorescent wavelength were adjusted for each sample to give the maximum meter reading.

RESULTS AND DISCUSSION

Energy Transfer in Quenching in Liquid Scintillation System—The relative abundance of solvent and solute molecules in a liquid scintillator is given in Table I. In such system, toluene is the solvent, 2,5-diphenyloxazole, the primary solute, and 1,4-bis-2(5-phenyloxazolyl)benzene, the secondary solute. The use of a secondary solute is to shift the fluorescence spectrum of the scintillator system to longer wavelength to match the spectral response of the multiplier phototube (7), and its role of energy transfer between solute and solute in the liquid scintillation system need not concern our discussion. Dissipation of radiation energy in the scintillator system under these conditions causes the formation of the excited solvent molecules from which the excitation energy is transferred to the scintillator or the solute molecules which decay by fluorescence emission. In the presence of a quencher, this energy transfer between the excited solvent and the scintillator molecules is interrupted.

Energy transfer by molecular encounter is not so important a process as that by inductive resonance in a liquid scintillation system. The latter mechanism predicts energy transfer over distances as large as 50 to 100 Å. According to Förster (2), resonance transfer requires an overlapping of the absorption spectrum of the acceptor and the fluorescence spectrum of the donor. Since polyatomic molecules have broad spectra in solution, it is likely that coupled transitions can occur between unlike species of organic molecules. This may afford an explanation to the observed fact that addition of an organic compound to a liquid scintillation system frequently causes quenching.

TABLE I—COMPOSITION OF A LIQUID SCINTILLATOR

Compd.	Concn., mole/L.	Abundance Ratio	Av. Radius of Separation Between Adjacent Molecules, Å.
Solvent: Toluene	10.9	345	
Primary solute:			
2,5-Diphenyloxazole	3.16×10^{-2}	1 232	23.2
Secondary solute:			
1,4-bis-2(5-Phenyloxazolyl)benzene	1.36×10^{-4}	1	142

Based on quantum mechanical considerations involving dipole–dipole interaction between molecules, Förster concluded that the rate constant of excitation transfer from donor to acceptor molecules at thermal equilibrium is inversely dependent to the sixth power of the intermolecular distance. By assuming a sharp critical transfer distance with instantaneous excitation transfer for shorter and no transfer for longer distance, a simple exponential formula can be used to approximate the donor fluorescence yield. Thus:

$$\frac{n}{n_0} = \text{exp. } (-\alpha c/c_0) \qquad \text{(Eq. 1)}$$

where n is the fluorescence yield at quencher concentration c; n_0, that in the absence of the quencher; α, a constant; and c_0, the quencher concentration corresponding to the critical transfer distance R_0. Their interrelationship is given by the following equation:

$$c_0 = \frac{3000}{4\pi N R_0^3} \qquad \text{(Eq. 2)}$$

where N is Avogadro's number.

Equation 1 resembles an empirical equation derived by Peng (5, 8) for quenching correction in liquid scintillation counting, based on an observation by Kerr *et al.* (9) that quenching varies exponentially with the concentration of the quencher. Thus:

$$S_a = S_0 \text{ exp. } (-qc) \qquad \text{(Eq. 3)}$$

$$= S_0 \text{ exp. } (-c/c_0) \qquad \text{(Eq. 3}a\text{)}$$

where S_a and S_0 are the apparent specific count rates in the presence and in the absence of the quencher, respectively; c is the quencher concentration, and q, the quenching constant which equals $1/c_0$ or $0.693/c_{1/2}$. c_0 and $c_{1/2}$ are the concentrations of the quencher that reduce the count rate to e^{-1} and $1/2$ of its initial value, respectively. The two equations differ by a constant exponent α which was found to have a value of 1.42 (2), although the theoretical value should be 1.000. It may also be pointed out that c_0, the "relative" critical transfer concentration, can also be obtained from statistical consideration of a random interaction between the excited molecules and the quencher molecules according to poisson distribution with an average of one interaction between them. Such a consideration is

TABLE II—CRITICAL TRANSFER CONCENTRATION (IN ARBITRARY UNITS) AND QUENCHING INDEX OF VARIOUS COMPOUNDS (^{14}C β-EXCITATION)

Compd.	Critical Transfer Concn., c_0, moles/L.	Critical Transfer Distance,[a] R_0, Å.	Quenching Index
CH_3OH	14.18	3.06	1
$HCON(CH_3)_2$	5.2	4.25	1.41
CH_3COOH	1.41	6.70	2.22

C_6H_5NCS	.055	19.35	6.43
Hyamine hydroxide	.0294	23.80	7.90
Benzophenone	.026	24.80	8.23
Benzil	.0055	41.70	13.90

[a] Calculated by Eq. 2. [b] The perdeuterated acetone and chloroform were obtained from New England Nuclear Corp., Boston, Mass.

analogous to that used in deriving the e^{-1} surviving fraction by the target theory in radiobiology (10).

The use of Eq. 3 to obtain c_0 or $c_{1/2}$ in a liquid scintillation system gives only relative values. It has been pointed out that $c_{1/2}$ value depends on the pulse height and consequently varies with the instrument settings of the spectrometer used for the measurement (5). But at given instrument settings, the $c_{1/2}$ values are quite reproducible. It is therefore feasible to use either q or its related values as an index of the quenching property of the compound, provided that the measurement is carried out simultaneously against a selected standard. This index, in order to eliminate variations in instrument settings, should be expressed as a ratio of q or its related value of the compound to that of the standard. Such a ratio would allow a comparison of the quenching properties of various compounds. The absolute value can be calculated once the true critical transfer concentration of the standard is known. Table II shows the arbitrary values of critical transfer concentration c_0 of various compounds and the ratios of their critical transfer distance to that of methanol. It may be noted that perdeuterated acetone and chloroform show insignificant difference in quenching property from their protonated forms indicating an absence of intermolecular isotope effect. The relative magnitude of the quenching index of benzophenone and benzil as given is of interest because they are known to form a donor–acceptor pair (11).

Deviation from Eq. 3 is frequently observed and is attributed to the presence in solution of molecular aggregates of fluorescent molecules which exhibit different quenching properties (6). Figure 1 shows the quenching curves of 2,5-diphenyloxazole in two different concentrations in toluene and in n-hexane with ultraviolet excitation and with varying amounts of carbon tetrachloride as quencher. The composite nature of the quenching curve in toluene can be represented by a summation expression of Eq. 3a. Thus:

$$S = \Sigma S_{0i} \exp.(-c/c_{0i}) \qquad i = 1, 2, 3, \ldots .$$

Since toluene is a very efficient solvent for energy transfer owing to the availability of π electrons, its replacement with n-hexane under similar conditions gives more linear quenching curves. From the linearity of the quenching curve it may be interpreted that in inefficient energy transfer systems there is generally an absence of excimer formation (12) or photoassociation of solute molecules or formation of molecular aggregates of similar nature which frequently occurs in liquid scintillation systems of efficient excitation transfer. Formation of dimers or molecular aggregates in solution has been reported for naphthalene (13) and 2,5-diphenyloxazole (14).

The relationship between the extent of quenching and the concentration of the quencher is frequently governed by the Stern-Volmer equation (15). In liquid scintillation system, Stern-Volmer plots for a number of quenchers studied were found to exhibit a nonlinear relationship over wide concentration ranges. A notable exception is the straight line obtained for hyamine hydroxide as shown in Fig. 2.

The nonlinearity of the Stern-Volmer plot may be interpreted as a result of energy transfer between the triplet state of molecules. Such interpretation is not only in accord with the findings of Terenin and Ermolaev (16) but also with the theoretical evaluation by Inokuti and Hirayama (4) of energy transfer by the exchange mechanism in sensitized luminescence. They demonstrated the constancy of the value of α as 1.00 in Eq. 1 in the approximation of the donor luminescence yield. Approximation with a Stern-Volmer type equation, $n/n_0 = (1 + \beta c/c_0)^{-1}$, would be less meaningful under similar circumstances because the β value which by definition of the equation should remain constant was found to vary with changing values of c/c_0.

Recent studies by pulse radiolysis of various solutions of binary mixtures of anthracene, biacetyl, naphthalene, *cis*- and *trans*-stilbene, *etc.*, indicate that the order of intermolecular energy transfer among these compounds may be related to their triplet energy level (17). Because of the low energy

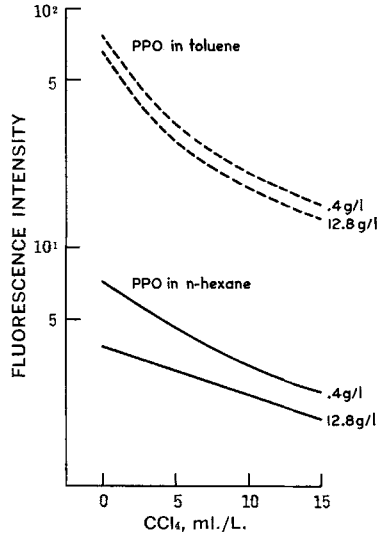

Fig. 1—Carbon tetrachloride quenching curves of 2,5-diphenyloxazole (PPO) solutions by U.V. excitation.

level of the triplet state (E_T: 60.9 Kcal./mole) and an absence of the self-quenching effect, naphthalene has the property to suppress quenching in liquid scintillation systems (18) and to deactivate triplet benzophenone (E_T: 68.5 Kcal./mole) very efficiently (19). These observations constitute further evidence of support for our interpretation. The triplet–triplet energy transfer mechanism can also account for the observed change in the channels ratio which is a measure of the q values as the concentration of the quencher is increased, as shown in Fig. 2 of *Reference 20*. It is likely that at high concentrations, the molecules are in close proximity to each other, and consequently, energy transfer by the exchange mechanism becomes more probable.

Energy Transfer in Photosensitivity—Although the causation of hypersensitivity to light by the administration of drugs and dyes has been reported and exhaustively reviewed in the literature (21–24), the postulated mode of action has not been based on a consideration of energy transfer. As the conditions under which photosensitivity or photodynamic effect[1] occurs coincide in general with the conditions necessary for energy transfer, it is probable that a mechanism based on an intermolecular energy transfer of the radiant energy will be able to account inclusively for the observed facts such as the extremely dilute concentration of dyes that is sufficient to elicit a response, the diversity of the chemical structure of the active agents, the obligatory presence in the photosensitive biological system of compounds which can act as donors or sensitizers in energy transfer, the heavy atom effect, and the dependence of the end effect on light intensity.

A mechanism of energy transfer based on the consideration of similar processes in liquid scintillation system can be postulated to form a common basis for all observations on hypersensitivity to light; this consists of optical excitation of the sensitizer either directly or indirectly with intersystem crossing to the triplet state and formation of the triplet state of the acceptor from both the singlet and the triplet states of the sensitizer by energy transfer. The sequence of events may be represented by reactions *1*, *4*, *7*, *8*, and *10* in Scheme I. The intervening reactions represent a diversion of the excitation energy leading to a reduction of the quantum yield of the triplet acceptor. Once formed, the triplet acceptor will have a greater probability for participation in many biological reactions because of its long lifetime. In photodynamic action, the triplet acceptor can react with oxygen in its ground triplet state to yield the moleoxide according to reactions *12*, *13*, and *15*, similar to those postulated for photooxidation of anthracene (25) and other organic compounds (26).

Alternately, the peroxide can be formed by reaction with excited singlet oxygen molecule. The formation of singlet oxygen ($^1\Delta_g$) from the ground triplet state oxygen ($^3\Sigma_g^-$) is shown in Scheme II as involving the transfer of excitation energy either from singlet or from triplet, donor or acceptor molecules by the exchange mechanism or the triplet–triplet annihilation. In both instances, spin conservation is observed. The singlet oxygen will then react with the acceptor molecule or other oxidizable substances present in biological systems to form peroxides. This mode of reaction *via* singlet oxygen

Formation of the stable peroxide

Scheme II

[1] The term "photodynamic effect" is exclusively used for photosensitivity in the presence of oxygen because both oxygen and light are required for the hypersensitive response.

is in agreement with the evidence from recent photochemical studies (27, 28).

The importance of the triplet state in biological systems has been emphasized (29), especially for its long lifetime in which useful biological work can be done (30). The heavy atom effect which is uniquely linked to the triplet state has been observed in the killing of paramecia by fluorescein dyes as the efficacy decreases from erythrosin to eosin and to fluorescein (31). It is known that the presence of heavy atoms increases the rate of intersystem crossing leading to the population of the triplet state.

All sensitizers for photosensitive biological actions are fluorescent. The fluorescent state is an indication of the lifetime of the excited state of the molecule, as the fluorescence lifetime is usually approximately 10^{-8} sec. which is approximately 10^5 times longer than the lifetime for nonradiative transition. A long-lived state of the sensitizer is necessary to ensure a high probability of energy transfer. For effectiveness in excitation transfer, a maximum overlap of the absorption spectrum of the acceptor and the fluorescence spectrum of sensitizer is required. In riboflavin–cytochrome c system, the overlap integral for long distance resonance energy transfer has been evaluated (32).

The acceptor in photosensitive biological systems will be proteins, nucleic acids, and other normal tissue constituents. These are also fluorescent (33), and some even show phosphorescence. Protein phosphorescence was first observed in 1952 by Debye and Edwards (34). The triplet states of aromatic amino acids and proteins have also been observed and studied with electron spin resonance spectroscopy (35, 36). Together these observations lend credence to the formation of the triplet state by reactions *8* and *10*.

The postulated scheme for photosensitive action may also account for a lack of photosensitivity in many individuals by a quenching mechanism which diverts the excitation energy away from the target acceptor. Some of the strong quenchers such as carbon tetrachloride, pyridine, phenyl isothiocyanate, *etc.*, found in the liquid scintillation system are also toxicants (37). The exceptions are the carbonyl compounds. The presence of carbonyl groups, by their unique alignment in the condensed phase, gives the connective, skeletal, and keratinized tissues their luminescence (38). The strong interaction of the carbonyl group with the sensitizer would ensure a maximum utilization of the absorbed radiant energy. By the same principle, melanin or similar compounds may afford protection to photosensitive action by quenching since compounds with adjacent carbonyl groups such as benzil and biacetyl have been shown to be strong quenchers.

The parallelism in the basic mechanisms of energy transfer between a photosensitive biological system and a liquid scintillation system would allow the latter system to be used as a model for elucidation of the mechanism involved in the former, because the liquid scintillation system is more sensitive in detecting fluorescence quenching than the optical method. As already indicated, measurement in such a system gives only relative values. For absolute values, it needs to be standardized against reference compounds. To resolve color and chemical quenching in the system, a method by Ross (39) for color quenching may be used.

NMR Conformational Analysis of 4-Hydroxycyclohexanone and 1,4-Cyclohexanediols

Coupling Constants Averaging Induced by Conformational Equilibria and by Strong Coupling Effects—Role of Solvent

By WILLIAM F. TRAGER*, BERNARD J. NIST, and ALAIN C. HUITRIC

Significant differences are observed in the NMR spectra of *cis*-1,4-cyclohexanediol and 4-hydroxycyclohexanone measured in different solvents. For the diol the differences are shown to arise from averaging of coupling constants through strong coupling effects. The differences for the ketone result from a combination of the same factors plus differences in conformational equilibria. A discussion of the averaging of coupling constants due to conformational equilibria and due to strong coupling effects is given. The signal band width method for determination of conformational equilibria is shown to be independent of strong coupling effects.

FAILURE to recognize complications resulting from averaging of coupling constants due to strong coupling effects can lead to serious errors in the interpretation of NMR spectra. Early warnings concerning these complications were given by several authors (1–3). In two previous communications concerned with the conformational analysis of *cis*-1,4-cyclohexanediol (4) and 4-hydroxycyclohexanone (5) by NMR, the observation of solvent effects on chemical shifts leading to deceptively simple spectra, as well as solvent effects on conformational equilibria, has been reported. In both cases of solvent effects, the changes produced in the observed spectra are associated with averaging of coupling constants, but of different kinds. The studies were made possible by the use of selectively deuterated compounds. In the present paper the synthesis of the deuterated compounds is reported, and a discussion of averaging of coupling constants due to conformational equilibria and due to strong coupling effects is presented.

DISCUSSION

In a mobile cyclohexane system such as I*a* and I*b* the observed coupling constants J_{XA} and J_{XB} represent the weighted time average values of what they would be in either pure I*a* or pure I*b*. That is, $J_{XA} = NaJ_{aa} + (1 - Na)J_{ee}$ and $J_{XB} = NaJ_{ae} + (1 - Na)J_{ea}$, where Na represents the mole fraction of the compound in conformation I*a*, J_{aa} and J_{ee} are axial–axial and equatorial–equatorial coupling constants, respectively. If the individual values of J_{XA} (J_{aa} in I*a*, and J_{ee} in I*b*) and J_{XB} (J_{ae} in I*a*, and J_{ea} in I*b*) in pure I*a* and I*b* are known, then the conformational position can be calculated from observed coupling constants (6) measured directly from the spectrum, providing that the first-order approximation is valid. This is not always the case because the situation is often complicated by strong coupling effects (1–3).

In an ABX system of the type X—C(A)—C(A)—B, where $J_{XA} \neq J_{XB}$, a first-order spectrum is possible providing the difference between the chemical shifts of A and B ($\nu_B - \nu_A$) is large compared to J_{AB}.

Received September 6, 1966, from the College of Pharmacy, University of Washington, Seattle, WA 98105
Accepted for publication October 21, 1966.
The authors wish to dedicate this paper to Dean T. C. Daniels, whose leadership at the University of California has done so much to raise the standards of education and research in the pharmaceutical sciences.
* U. S. Public Health Service Predoctoral Fellow 5 FI-GM-18,507, 1962–1965.

As ($\nu_B - \nu_A$) approaches J_{AB} proton X is coupled to protons A and B behaving as a set, and individual values of J_{XA} and J_{XB} can no longer be obtained directly from the spectrum. In the limit where $\nu_B = \nu_A$, the signal of X yields a symmetrical triplet with separations equal to $(J_{XA} + J_{XB})/2$ even though J_{XA} and J_{XB} are not actually equal. The same applies to an $(AB)_2X$ system, such as 4-hydroxycyclohexanone-2,2,6,6-d_4 (I), or *cis*-1,4-cyclohexanediol-3,3,4,5,5-d_5 (IV) except that in the limit the signal of the X proton will now give a symmetrical pentuplet with line separations equal to $(J_{XA} + J_{XB})/2$. Thus both conformational equilibria and strong coupling effects tend to average coupling constants, but fortunately in an intrinsically different manner that permits separation of the two effects.

As stated above, the observed coupling constants, J_{XA} and J_{XB}, in a mobile cyclohexane in equilibrium between two chair conformations represent the weighted time average values of what they would be in each of the two alternate chair conformations. Hence, not only the individual magnitudes of J_{XA} and J_{XB} but also the sum of the coupling constants, and, therefore, the width of the signal of the X proton equal to $2(J_{XA} + J_{XB})$ is dependent upon the position of the equilibrium between chair conformations I*a* and I*b* and IV*a* and IV*b* (7–10). Changes in the width of the signal of the X proton reflect a change in the position of the equilibrium. On the other hand strong coupling effects will tend to average the individual values of J_{XA} and J_{XB} and thus cause changes in the pattern of the signal, but in this case the sum of the coupling constants remains constant. The important thing to recognize is that complications from strong coupling effects in systems such as (I*a* $\rightleftarrows$ I*b*) or (IV*a* $\rightleftarrows$ IV*b*) prevent the calculation of individual values of J_{XA} and J_{XB} by first-order approximation, but since the sum $2(J_{XA} + J_{XB})$ is not affected, the width of the signal of the X proton truly reflects the position of the equilibrium.

In the case of *cis*-1,4-cyclohexanediol-3,3,4,5,5-d_5 (IV) equal population of the two chair conformations is expected, and the individual values of observed J_{XA} and J_{XB} should be about 7 c.p.s. and 3.5 c.p.s., respectively (11, 12), providing that ($\nu_B - \nu_A$) is large with respect to J_{AB}. As the ratio $(\nu_B - \nu_A)/J_{AB} \rightarrow 0$, strong coupling effects become operative and J_{XA} and J_{XB} tend to average out. In the limit where $\nu_B = \nu_A$, the signal of the X proton will appear as a symmetrical pentuplet with line separations equal to $(J_{XA} + J_{XB})/2$, about 5 c.p.s., and the combined signals of the A and B protons will give a doublet with the same separation of about 5 c.p.s.

4-Hydroxycyclohexanone—The NMR study was done with 4-hydroxycyclohexanone-2,2,6,6-d_4 (I) in order to simplify the spectra. Spectra of I were obtained in three different solvents: pyridine, D_2O, and $CDCl_3$ (Fig. 1). Pyridine and $CDCl_3$ both yielded deceptively simple spectra while in D_2O the observed spectrum is more closely first order. The results are interpreted as being consistent with a rapid equilibrium between the two chair conformations (I*a* and I*b*) with the differences in the spectra resulting from solvent effects on conformation and/or solvent effects on chemical shifts.

Conformational preference in each solvent was calculated by the signal width method of Garbisch (7) or Feltkemp and Franklin (8–10) using the partially deuterated *trans* and *cis*-4-*tert*-butylcyclohexanol-3(axial),5,5-d_3, II and III, respectively, for conformationally homogeneous models. The advantage[1] of this method over the method employing individual coupling constants (6) is that the observed signal width of the X proton is dependent only upon the conformational equilibrium and not upon strong coupling effects (1–3). Moreover, since vicinal coupling constants in cyclohexane systems are generally much less sensitive than chemical shifts to remote structural changes, the chosen models are suitable for reasonable approximation of the conformational equilibrium by the signal width method but are entirely inadequate for calculation by the chemical shift method (13). That this is so becomes apparent from the fact that the chemical shift of the X proton in 4-hydroxycyclohexanone-2,2,6,6-d_4 (I) both in pyridine and $CDCl_3$ is downfield from the signal of H-1 in III in the corresponding solvent.

The *trans* reference model (II) gave $J_{aa} = 11.0$, $J_{ae} = 4.2$, and $J_{gem} = 12.5$ c.p.s.[2] in $CDCl_3$ and $J_{aa} = 10.7$, $J_{ae} = 4.4$, and $J_{gem} = 12.0$ c.p.s. in pyridine. Accurate values of J_{ea} and J_{ee} could not be obtained from the spectrum of the *cis* isomer (III), but the symmetrical pentuplet of H-1 indicates that $J_{ea} \simeq J_{ee}$ in III, since ($\nu_B - \nu_A$) is outside the boundary of serious strong coupling effects. The value of $2(J_{ea} + J_{ee})$ was 11.0 in $CDCl_3$ and pyridine, indicating that $J_{ea} \simeq J_{ee} \simeq 2.7$ c.p.s. at 37°. The signal width of H-1 in II, equal to $2(J_{aa} + J_{ae})$ was found to be 30.6 c.p.s. in $CDCl_3$ and 30.0 c.p.s. in pyridine.

The mole fraction *Na* of conformer I*a* in the mobile 4-hydroxycyclohexanone system can be calculated from the width of the signal of H-4 in the mobile system, and H-1 in the two conformationally homogeneous models II and III by the equation:

$$Na = \frac{2[J_{XA} + J_{XB}] - 2[J_{ae} + J_{ee}]}{2[J_{aa} + J_{ea}] - 2[J_{ae} + J_{ee}]} = \frac{W - W_a}{W_e - W_a}$$

where J_{XA} and J_{XB} refer to the mobile system; J_{aa}, J_{ae}, J_{ea}, and J_{ee} refer to the models II and III; W is the signal band width of H-4 in the mobile system, W_a and W_e[3] are signal width of H-1 in models III and II, respectively. The accuracy of the results will depend on the reliability of the chosen conformationally homogeneous models. In the present case, the models may not be ideal and the calculated mole fractions of conformer I*a* should be considered good approximations rather than absolute values; but the relative values in the different solvents are very reliable.

By utilizing $W_a = 11.0$ and $W_e = 30.0$ c.p.s. obtained in pyridine[4] and the measured value $W =$

[1] In nonfirst-order spectra it is possible to use the individual coupling constant method if the actual coupling constants can be calculated by complete analysis. Very often this is not possible because of overlapping of signals in the upper field region.

[2] Signs are not assigned, although it is generally understood that geminal coupling constants are of opposite signs to vicinal coupling constants.

[3] The symbols used are those of Feltkamp and Franklin (9). It should be noted that W_a refers to the width of the X proton when the substituent is axial and the X proton equatorial.

[4] The model compounds II and III are not sufficiently soluble for measurement in D_2O. The danger of error due to variations of coupling constants with solvent seems minimal because of the observation that the difference in width of the signal of H-1 in 4-*tert*-butyl-*cis*-4-hydroxycyclohexanol-3,3,5,5-d_4 measured in pyridine and 25% acetic acid in D_2O is only 0.5 c.p.s.

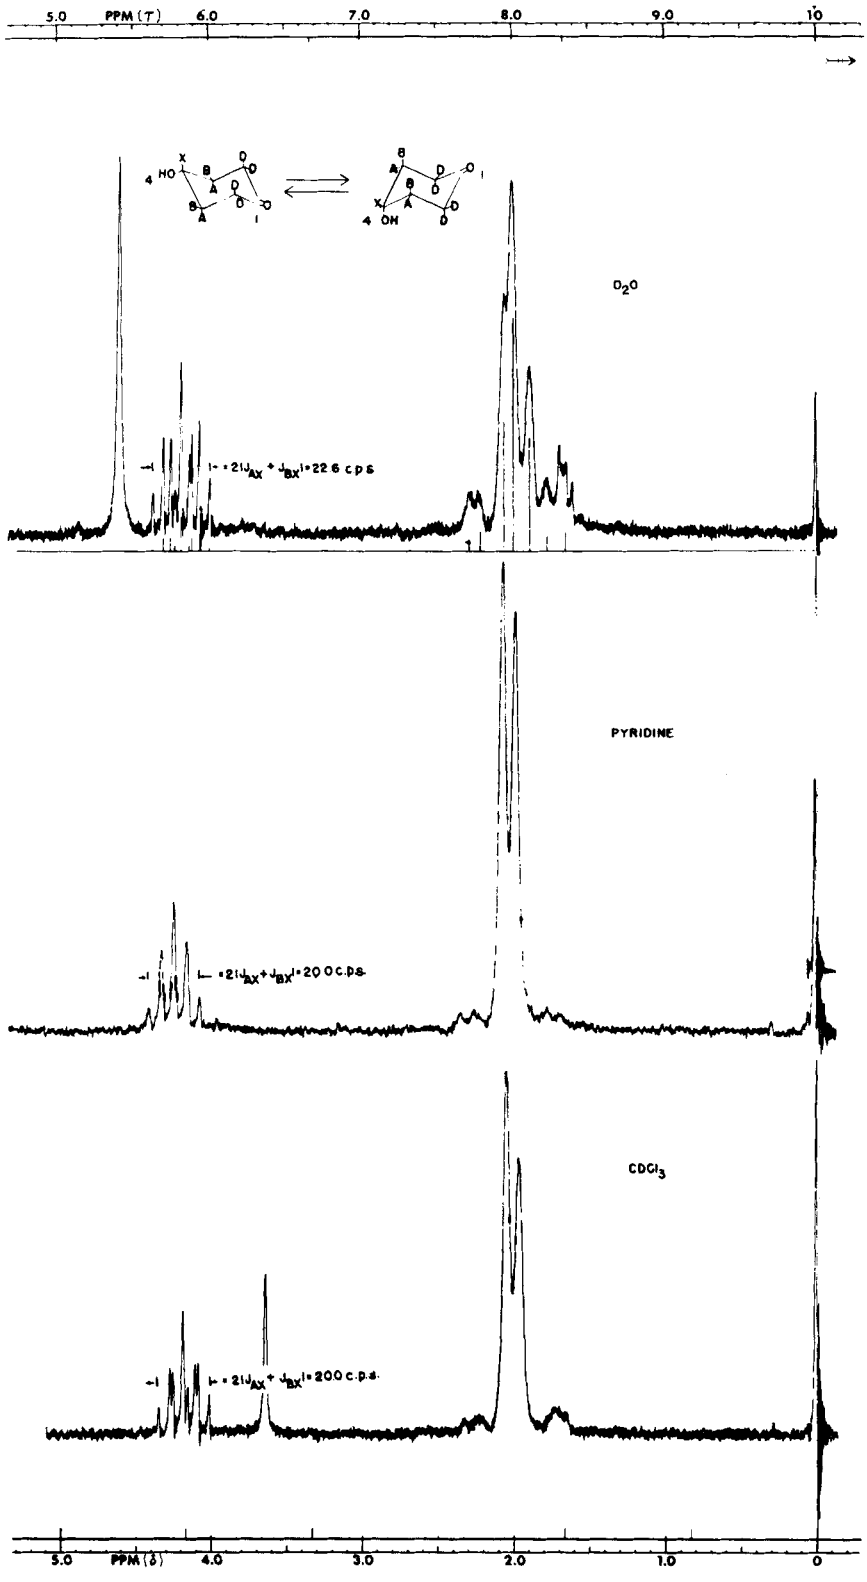

Fig. 1—NMR spectra of 4-hydroxycyclohexanone-2,2,6,6-d_4 in D_2O, pyridine, and deuterated chloroform at 60 Mc. and 37°. TMS and DSS were used as internal references in the organic solvents and D_2O, respectively. The calculated spectrum is shown beneath the observed spectrum in D_2O.

22.6 c.p.s. for the mobile system in D_2O, *Na* is calculated to be 0.61. This corresponds to a 61 ± 4% population of conformer Ia and a conformational free energy difference of 0.27 Kcal./mole for the

hydroxyl group in 4-hydroxycyclohexanone in D_2O The value W was found to be 20.0 c.p.s. in both pyridine and $CDCl_3$. Utilizing the respective W_e and W_a values this gives 47 ± 4% of conformer I*a* in pyridine and 46 ± 4% of conformer I*a* in $CDCl_3$. The apparent 3 to 4% predominance of conformer I*b* is probably not real and probably reflects the fact that models II and III are not exactly ideal. Moreover, a small contribution ($\simeq$ 1%) by nonchair flexible forms which would tend to narrow W is possible based on calculations of Allinger and co-workers (14), who predict that the ground state energy of the most stable flexible form of cyclohexanone and 4-methylcyclohexanone is about 3 Kcal./mole greater than the ground state of the chair conformation. Contribution of a boat form stabilized by intramolecular hydrogen bonding is argued against by the fact that the benzoate ester of 4-hydroxycyclohexanone-2,2,6,6-d_4 gives the typical pentuplet with signal width of 19.2 c.p.s. for the X proton and a doublet with separation of about 4.8 c.p.s. for the combined signals of the A and B protons in pyridine and in chloroform. There is no possibility of hydrogen bonding in the esters. Furthermore, Stolow (16) was unable to detect any evidence of intramolecular hydrogen bonding in 4-hydroxycyclohexanone by infrared studies in carbon tetrachloride.

The larger population of conformer I*a* in D_2O is substantiated by the following treatment. The spectrum in D_2O gives ν_X = 251; ν_B = 124.8; ν_A = 112.2, and J_{AB} = 13.5 c.p.s. The apparent coupling constants of J_{XA} = 7.0 and J_{XB} = 4.3 are erroneous because ($\nu_B - \nu_A$) = 12.6 is within the range of strong coupling complications. By utilizing the coupling constants obtained from II and III in pyridine the expected coupling constants of a rapid equilibrium between I*a* and I*b* with 61% of conformer 1*a* are calculated as:

$$J_{XA} = NaJ_{aa} + (1 - Na)J_{ee} = (0.61)(10.7) + (0.39)(2.7) = 7.6 \text{ c.p.s.}$$

$$J_{XB} = NaJ_{ae} + (1 - Na)J_{ea} = (0.61)(4.4) + (0.39)(2.7) = 3.76 \text{ c.p.s.}$$

When the observed chemical shift of ν_X = 251, ν_B = 124.8, ν_A = 112.2 c.p.s., observed J_{AB} = 13.5 c.p.s.[5] and calculated J_{XA} = 7.6 and J_{XB} = 3.76 c.p.s. were placed in the computer program of Wiberg and Nist (15), the resulting theoretical spectrum [reproduced under the experimental spectrum (Fig. 1)] gave apparent J_{XA} = 7.05 and J_{XB} = 4.3 and reproduced the experimental spectrum exactly.

The results thus indicate that the $-\Delta G_{OH}°$ value of the hydroxyl group in 4-hydroxylcyclohexanone is essentially zero in pyridine and $CDCl_3$, whereas it is 0.27 Kcal./mole in D_2O. The observed solvent effects on conformation are in agreement with the findings of Eliel (17), who postulated that the conformational equilibrium of the hydroxyl group in a cyclohexane system is a function of solvent where the $-\Delta G_{OH}°$ value is greater for proton donating solvents such as water or alcohols. A solvent effect on chemical shifts of the signals of the A and B protons of 4-hydroxycyclohexanone whereby ($\nu_B - \nu_A$) is smaller in pyridine than in $CDCl_3$ is indicated by the difference in the multiplicity but identical width of the signal of the X proton in the two solvents.

cis-1,4-Cyclohexanediol—The NMR spectrum of this compound obtained in pyridine was found to be very different from that obtained in D_2O (4). In order to simplify the spectra the deuterated *cis*-1,4-cyclohexanediol-3,3,4,5,5-d_5 (IV) was prepared and used for this study. In contrast to 4-hydroxycyclohexanone-2,2,6,6-d_4, it is pyridine which gives the approximately first-order spectrum, while D_2O gives the deceptively simple spectrum for IV (Fig. 2). The results are interpreted as being consistent with a rapid equilibrium between the two energetically equivalent chair conformations IV*a* and IV*b*, with differences in spectra arising from solvent effects on chemical shifts. The width of the signal of the X proton of IV in both pyridine and D_2O is 20.2 c.p.s., even though it appears as a seven-peak multiplet in the former solvent and symmetrical pentuplet in the latter. Calculation of the mole fraction of conformer IV*a* in the mobile *cis*-1,4-cyclohexanediol system utilizing the partially deuterated *trans* and *cis*-4-*tert*-butylcyclohexanol-3 (axial), 5,5-d_2, II and III, respectively, for conformationally homogeneous models and the signal width method of Garbisch (7) or Feltkamp and Franklin (8–10), leads to a 48 ± 4% population of conformer IV*a*. This result is in excellent agreement with expected 50% population of conformer IV*a* and attests to the reliability of the method.

The measured values of J_{XA} and J_{XB} for IV in pyridine are 6.7 and 3.4 c.p.s., respectively. Utilizing the model compounds II and III, once again: $J_{XA} = (J_{aa} + J_{ee})/2 = (10.7 + 2.7)/2 = 6.7$ and $J_{XB} = (J_{ea} + J_{ee})/2 = (2.7 + 4.4)/2 = 3.6$ c.p.s., a result in good agreement with the observed couplings and one that should prevail in a system approaching first order. The line separation of the pentuplet in D_2O is 5.0 c.p.s., and this is in excellent agreement with the expected apparent coupling constant $(J_{XA} + J_{BX})/2 = (6.7 + 3.6)/2 = 5.1$ c.p.s. for a system under the influence of strong coupling in the limit where $\nu_A = \nu_B$. Thus, *cis*-1,4-cyclohexanediol-3,3,4,5,5-d_5 provides excellent experimental examples of the phenomenon of averaging of coupling constants due to conformational equilibria and averaging of coupling constants due to strong coupling effects. It also provides an excellent example of complications from strong coupling effects due to solvent effects on chemical shifts.

In an attempt to clarify the solvent effects on chemical shift and provide another method for checking the above results, the following selectively deuterated compounds were prepared: *trans*-1,4-cyclohexanediol-3,3,4,5,5-d_5 (V); 4-*tert*-butyl-*cis*-1,4-cyclohexanediol-3,3,5,5-d_4 (VI); and 4-*tert*-butyl-*trans*-1,4-cyclohexanediol-3,3,5,5-d_4 (VII) (Table I).

It should be possible, from the spectra of structures V, VI, and VII in a given solvent, to approximate the theoretical chemical shifts of the protons A and B in *cis*-1,4-cyclohexanediol-3,3,4,5,5-d_5 (IV) undergoing interconversion between conformations IV*a* and IV*b* in the same solvent. Compounds VI and VII were not sufficiently soluble in deuterium oxide, but it was found that the spectra of IV were identical when obtained from D_2O or from a mixture of 25% acetic acid in D_2O as solvent, a solvent mixture in which VI and VII were sufficiently soluble.

[5] The calculated spectrum is unaltered when J_{AB} is replaced by $-J_{AB}$.

TABLE I—CHEMICAL SHIFTS OF DEUTERATED COMPOUNDS PREPARED[a]

	Pyridine			D_2O or (D_2O–HAc)			Δ(Pyridine vs. D_2O)		
	ν_A	ν_B	ν_X	ν_A	ν_B	ν_X	a	o	x
 V	91.6	125.4	228.4	74.3	110.3	214.5	17.3	15.1	13.9
 VI	127.0	121.0	226.0	92.2	102.1	210.6	34.8	18.9	15.4
 VII	131.6	112.4	257.0	107.0	93.6	239.5	24.6	18.8	17.5

[a] Chemical shifts (from ABX analysis), ν c.p.s. from TMS internal reference at 60 Mc.

It was therefore assumed that the chemical shifts of protons A and B in VI and VII obtained in 25% acetic acid in deuterium oxide could be taken as representative of values that would prevail in pure D_2O. Additional supporting evidence for the validity of this assumption was obtained from the fact that the spectra of *trans*-diol V when obtained in pure D_2O or in 25% acetic acid in D_2O are essentially identical.

In order to approximate the average chemical shift of protons A and B in IV undergoing interconversion between conformations IV*a* and IV*b* in a given solvent it is necessary to have good approximations of the chemical shifts of A and B in each of the conformations IV*a* and IV*b* in that given solvent. Such approximations are possible from the spectra of V, VI, and VII if the assumption is made that the equatorial hydroxyl group on C-4 of V and the equatorial *tert*-butyl group on C-4 of structures VI and VII do not appreciably affect the chemical shifts of protons A and B in structures V, VI, and VII. If this assumption is correct, then the chemical shifts of A and B in conformation IV*a* are the same as those of A and B, respectively, in structure VI. In conformation IV*b*, A and B are best related to A and B, respectively, of structure V except that the hydroxyl group at C-1 of IV is axial in conformer IV*b* but equatorial on C-1 of V. A correction can be made for this from the relative chemical shifts of A in structure VI *versus* VII and likewise for B. From this information the calculated chemical shift for A in IV in D_2O–acetic acid mixture is 92.2/2 + (110.3 − 8.5)/2 = 97 c.p.s. and that of B is 102.1/2 + (74.3 + 14.8)/2 = 95.6 c.p.s. The observed doublet resulting from the combined signals of A and B is centered at 96.5 c.p.s.

The theoretical spectrum was obtained by means of the NMR computer program of Wiberg and Nist (15), using the calculated values of ν_B = 97 c.p.s., ν_A = 95.6 c.p.s., observed value ν_X = 225 c.p.s., and coupling constants of J_{AB} = 12.4,[6] J_{XA} = 6.7, and J_{XB} = 3.4 c.p.s. The theoretical spectrum so obtained is shown in Fig. 2. The agreement with the observed spectrum is excellent.

Similar treatment gave excellent agreement between the calculated and observed spectrum of IV in pyridine. In this case compound V was replaced by compound II as reference model.[7] The chemical shifts of the A and B protons of II in pyridine are 84 and 129 c.p s., respectively. The calculated chemical shifts of the A and B protons in the mobile system IV of ν_A = 124, ν_b = 105 c.p.s. are in excellent agreement with the experimental values of ν_A = 124.2 and ν_b = 104 c.p.s. The larger difference in the chemical shifts of the A and B protons of IV in pyridine compared to D_2O is in agreement with the observation (18) that the 1,3-diaxial deshielding effect of the hydroxyl group is larger in pyridine than in other solvents investigated, including the protic solvents methanol-d_4 and acetic acid.

EXPERIMENTAL

The NMR spectra were determined on a Varian A-60 spectrometer at 37° utilizing TMS as the internal standard for spectra determined in pyridine and $CDCl_3$ and DSS for spectra determined in

[6] The calculated spectrum is unaltered if J_{AB} is replaced by $-J_{AB}$.

[7] Compound V in pyridine exists as a mixture of the two chair conformers with about 15% of the diaxial form (unpublished results). By using Anet's (19) $-\Delta G_{OH}°$ value of 1.25 for the hydroxyl group in cyclohexanol in D_2O compound V is calculated to exist to the extent of 98% in the diequatorial conformation in D_2O.

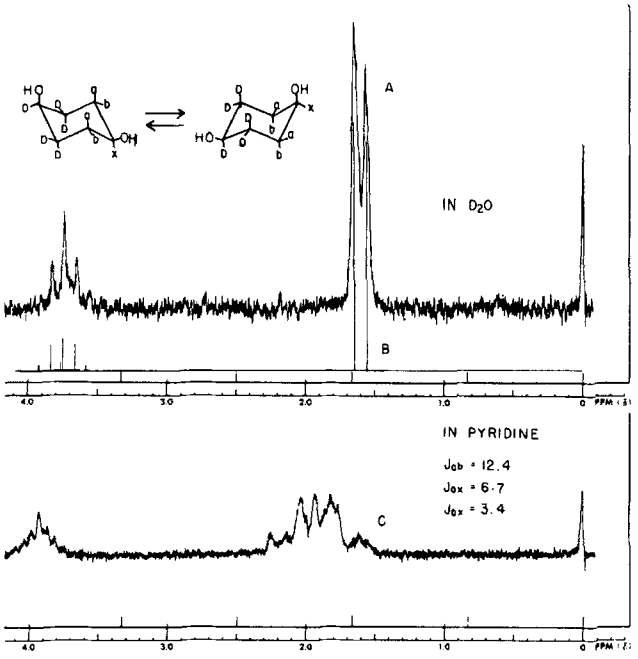

Fig. 2—NMR spectra of cis-*1,4-cyclohexanediol-3,3,4,5,5,-*d_5 *in* D_2O *and pyridine at 60 Mc. and 37°. TMS and DSS were used as internal references in pyridine and* D_2O*, respectively.* B *is the calculated spectrum using calculated chemical shifts as explained in the text.*

D_2O. The concentration of the sample solutions varied between 20 and 25% w/v. Melting points were determined on a Kofler hot-stage.

4-Hydroxycyclohexanone—This compound was prepared in a 27% over-all yield as follows. Commercially available 1,4-cyclohexanediol was converted to 4-hydroxycyclohexyl benzoate (42%) by the method of Jones and Sondheimer (20). The 4-hydroxycyclohexyl benzoate thus obtained was oxidized to 4-ketocyclohexyl benzoate (90%) by the general method of Brown and Garg (21), and finally 4-ketocyclohexyl benzoate was converted to 4-hydroxycyclohexanone (72%) by the method of Jones and Sondheimer (20).

4-Hydroxycyclohexanone-2,2,6,6-d_4 (I)—A solution of 4-hydroxycyclohexanone (25 Gm., 0.22 mole) in 99.8% D_2O (35 Gm., 1.8 moles) containing anhydrous potassium carbonate (0.30 Gm., 0.0022 mole) was allowed to stand at room temperature for 24 hr. The D_2O–water solution was removed from the partially deuterated 4-hydroxycyclohexanone by vacuum distillation. The receiver flask was cooled in a mixture of dry ice–isopropyl alcohol while the distilling flask was warmed in an oil bath (never above 50°). When all of the D_2O–water solution had been removed, the process was repeated twice and the product distilled under reduced pressure, b.p. 70° at 0.2 mm.

cis and trans-1,4-Cyclohexanediol-3,3,4,5,5-d_5 (IV and V)—A mixture of IV and V was obtained by lithium aluminum deuteride reduction of I in ether. The mixture thus obtained was separated by the method described by Brown and Zweifel (22) for a mixture of nondeuterated IV and V.

4-tert-Butyl-cis- and trans-1,4-cyclohexanediol—Anhydrous ether (500 ml.) was added to a 1-L. three-neck flask fitted with a mechanical stirrer, a 500-ml. additional funnel having a nitrogen inlet, a rubber stopper holding a low temperature thermometer, and a nitrogen outlet. A source of dry nitrogen was then fixed to the nitrogen inlet while the nitrogen outlet was fixed to a gas wash bottle containing mineral oil. The system was thoroughly flushed with dry nitrogen, and a slow stream of nitrogen passed through the system for the entire experiment. A solution (100 ml., 1.86 *M*) of *tert*-butyllithium (0.186 mole) in pentane was pipetted into the addition funnel. The pipet had been dried and helium gas blown through it just prior to use. The reaction flask was slowly immersed in a large Dewar flask containing a mixture of dry ice–isopropyl alcohol and the ether cooled to −72°. Vigorous stirring was initiated and the *tert*-butyllithium was added to the ether at such a rate as to maintain the temperature near −70°. The addition took approximately 30 min. A solution of 4-hydroxycyclohexanone (6.0 Gm., 0.0537 mole) in anhydrous ether (300 ml.) was transferred to the addition funnel and then added dropwise to the *tert*-butyllithium–ether–pentane solution, with vigorous stirring, over a period of 2 hr. The temperature was maintained at −72° throughout. Upon completion of the addition the reaction mixture was allowed to stir vigorously at −72° for another 24 hr., and then allowed to slowly warm to room temperature over a period of 4–5 hr. The reaction mixture was treated with 25 ml. of methanol followed by 75 ml. of water. The ethereal layer was separated and the aqueous layer extracted 3 times with ether. The ethereal extracts were combined, dried over anhydrous calcium sulfate, and the ether evaporated, yielding a mixture of 4-*tert*-butyl-*cis*- and *trans*-1,4-cyclohexanediol (5.4 Gm., 60%) and some unreacted 4-hydroxycyclohexanone. Analysis of the crude product by gas chromatography at 200° on a 5 ft. column of 20% basic Carbowax on Chromosorb indicated a 7.3 to 1.3 to 1.4 ratio of 4-*tert*-butyl-*cis*-1,4-cyclohexanediol to 4-*tert*-butyl-*trans*-1,4-cyclohexanediol to unreacted 4-hydroxycyclohexanone. Recrystallization from acetone yielded pure 4-*tert*-butyl-

cis-1,4-cyclohexanediol as large cubical crystals, m.p. 165.5–166°. After recovering most of the *cis* isomer from acetone the pure 4-*tert*-butyl-*trans*-1,4-cyclohexanediol was obtained by crystallization from *n*-heptane–isopropyl alcohol mixture, and finally from pure *n*-heptane as fine needles, m.p. 141.5–142°.

Anal.—Calcd. for $C_{10}H_{20}O_2$: C, 69.70; H, 11.70. Found: (*cis*) C, 70.21; H, 11.76; (*trans*) C, 70.08; H, 11.57.

4-tert-Butyl-cis- and trans-1,4-cyclohexanediol-3,3,5,5-d_4 (VI and VII)—Pure *cis* VI and *trans* VII were obtained by the addition of *tert*-butyllithium to I as described in the preceding section for the corresponding nondeuterated compounds.

1-tert-Butylcyclohexen-4-ol-2,6,6-d_3—A crystal of iodine and a boiling chip were added to a mixture of *cis* VI and *trans* VII (10.0 Gm., 0.0568 mole) contained in a 50-ml. flask fitted with a Dean-Stark water collector. The mixture was heated in an oil bath to 160° and the temperature maintained between 155 and 160° for approximately 15 min. At the end of this period the residual product was transferred into a large sublimator prior to solidification. The material was sublimated and the resulting crystalline product recrystallized from a mixture of methanol and water yielding 7.4 Gm. (80%) of product, m.p. 80–82°. Stolow and co-workers (23) report a m.p. of 86–86.5° for the corresponding nondeuterated compound.

trans and cis-4-tert-Butylcyclohexanol-3(axial),-5,5-d_3 (II and III)—The compounds were obtained by low pressure catalytic hydrogenation of 1-*tert*-butyl cyclohexen-4-ol-2,6,6-d_3 in purified acetic acid (24) with platinum oxide as catalyst according to the procedure described by Sauvage *et al.* (25) for a series of cyclohexenes. The calculated amount of hydrogen was picked up in 1.5 hr., when 8.0 Gm. of alkene was hydrogenated in 15 ml. of acetic acid with 0.8 Gm. of catalyst. After removal of the catalyst, water was added to the acetic acid solution to induce crystallization. Cooling and filtration yielded 7.2 Gm. (80%) of a mixture of II and III in ratio of 3 to 7 as determined by gas chromatography using a basic Carbowax column.

The *cis* and *trans* isomers were separated by column chromatography on neutral alumina using petroleum ether, mixtures of petroleum ether and benzene, and mixtures of benzene and diethyl ether. In a typical experiment 1.5 Gm. of the mixture was chromatographed on 30 Gm. of alumina to yield 1.1 Gm. of pure III, m.p. 80–82°, and 0.3 Gm. of pure II, m.p. 78–79°. This *cis* isomer (III) was eluted with the petroleum ether–benzene mixtures up to 100% benzene, and the *trans* isomer (II) was obtained with benzene and mixtures of benzene and diethyl ether up to 30% of ether. Winstein and Holness (26) have reported a m.p. of 78–79° for nondeuterated II and 81–82° for nondeuterated III.

Modified Cardenolides II

Synthesis, NMR Spectra, and Biological Activity of C-19 Halides and Sulfonates

By MANFRED E. WOLFF and WINSTON HO

The synthesis of 19-halocardenolides by halide displacement of the corresponding 19-*p*-toluenesulfonate esters is described. The NMR spectra of the 19-substituted compounds indicate that the rotation of the 19- group is restricted and that one of the C-19 protons is shielded by the 5,6-double bond.

RECENT STUDIES (1) from this laboratory have allowed the formulation of a picture of steroid receptor interaction involving close spatial interaction of the 19-angular methyl group with a receptor surface. This concept was based on the effect on pharmacological activity of steroids with bulky C-19 substituents. It seemed useful to extend this sort of structure–function analysis to the cardiac aglycones.

It is known that the nature of the C-19 substituent in the aglycones has a profound effect on pharmacological activity (2). Thus, C-19 alcohols are more active than the corresponding aldehydes which are more active than the methyl compounds. These results have been obtained largely from naturally occurring glycosides; comparatively little has been done with respect to synthetic modification of the cardiac aglycones. Lingner *et al.* (3) prepared various derivatives of C-19 aldehydes and alcohols, including oximes, acetals, urethans, ethers, and esters. The nature of the substituent had a major effect on the oral activity of these compounds.

This paper describes the preparation, conformation, and structure–function relationships of C-19 halocardenolides.

DISCUSSION

Chemistry—Work by others (4–8) has resulted in the production of C-19 halo-Δ^5-steroids from the corresponding 19-tosylate or mesylate esters. It has been established that homoallylic carbonium ion intermediates are involved, since S_N2 displacements on saturated 19-tosylates fail. Nucleophilic displacement of 19-tosylates by chloride or bromide gives 19-halides, but other nucleophiles, such as hydroxide, alkoxide, or azide give 5,19-cyclo-6-substituted steroids. It has been concluded that the latter are the kinetically favored products, but the 6-halides are unstable and rearrange further to afford the 19-halides.

The starting material for the present work was monoanhydrostrophanthidin acetate (I), formed from strophanthidin by elimination of the elements of water (9). This material was originally formulated as a 14-ene (10) but Fieser and Goto (11) assigned the corrected Δ^5 structure (I) on the basis of rotations and a reinterpretation of the nature of products of basic isomerization. The reactions of II described in this study, as well as the NMR spectrum of products derived from I, fully support the reassigned structure.

Received September 2, 1966, from the Department of Pharmaceutical Chemistry, School of Pharmacy, University of California, San Francisco, CA 94122

Accepted for publication October 25, 1966.

This research was supported in part by grant HE-09578 from the National Heart Institute, U. S. Public Health Service, Bethesda, Md.

The authors wish to dedicate this paper to Dean T. C. Daniels, whose leadership at the University of California has done so much to raise the standards of education and research in the pharmaceutical sciences.

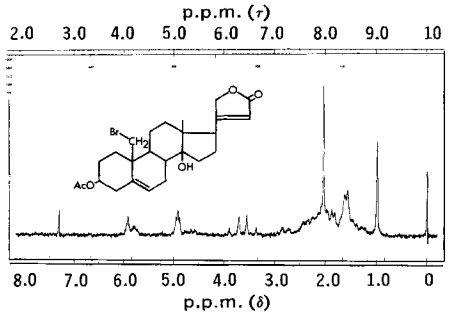

Fig. 1—NMR spectrum of 19-bromo-3β,14β-dihydroxycarda-5,20(22)-dienolide 3-acetate (VI).

Reduction of I with sodium borohydride in methanol solution gave the 19-alcohol (II). The tosylate (III) and the mesylate (IV) were prepared by treatment of II with the appropriate sulfonyl chloride in pyridine solution at 27°. The 19-halocardenolides (V, VI, and VII) were formed readily by the reaction of III and the appropriate lithium halide salt in boiling isopropanol solution.

NMR Spectra—An examination of the NMR spectra (Fig. 1) (Table I) of these C-19 modified steroids has revealed features which shed light on the conformation of the C-19 substituent under the conditions of measurement. Spectral features which did not vary include the 3β-acetate methyl resonance at 121–122 c.p.s., and the C-22 proton, seen centered at 353–354 c.p.s. as a singlet broadened by coupling to protons at C-21. The C-21 protons appear centered at 293–295 c.p.s. in a broadened triplet-like pattern owing to coupling to each other and to allylic coupling to the proton at C-22. The center of the "triplet" is actually the two central peaks of the AB system at C-21 and in a few spectra the satellite peaks can be discerned ($J_{AB} \cong 18$ c.p.s.). The side peaks in the "triplet" are actually due to allylic splitting (12) of the central peaks and $J_{21,22}$ is about 2 c.p.s., in agreement with an angle of about 90° between the plane of the double bond and each of the protons at C-21.

In the 19-halocardenolides (V, VI, and VII) as well as in the 19-hydroxy cardenolide (II), the two protons at C-19 produce an AB quartet having J_{AB} 11–13 c.p.s. which is typical of geminal coupling. Such a quartet could originate from restricted rotation of the 19-angular methyl group and also by selective shielding of one of the C-19 protons by the double bond. That restricted rotation alone does not account for the quartet is seen in the spectrum of the saturated compounds VIII (13) and IX (14), in which the C-19 protons produce broad singlets. The chemical shift of the C-19 protons in the simple saturated system (VIII) (235 c.p.s.), however, lies close to the computed position of one of the protons in II (231 c.p.s.). Moreover, chloride and hydroxyl exert deshielding effects of similar magnitude and it is noteworthy that in V also the low field peak is at 231 c.p.s. Thus, one of the peak positions is in the expected location for a proton of this type. The high field proton is at 215 and 214 c.p.s. in II and V, respectively. Molecular models of compounds II, V, VI, and VII show that the 19-substituent is most readily accommodated between the 2β- and 11β-hydrogens (Fig. 2), and thus the C-19 group is effectively locked into one position. Viewing the C-19 group from the top, this conformation places the lefthand hydrogen in a shielding environment due to the 5,6-double bond. The righthand hydrogen is more distant and appears to be in an area where neither shielding nor deshielding occurs. The spectrum of the doubly unsaturated compound X (15) was wholly in accord with this explanation. Models of X indicate that *both* C-19 hydrogens are located in a similar shielded environment and the spectrum indeed shows a single peak at 219 c.p.s. Thus, the difference in C-19 proton resonance positions between VIII and X is 16 c.p.s., the same value as found for $\delta_A - \delta_B$.

The tosylate (III) exhibits anomalous resonance from protons at C-18, C-6, and C-19. In all cases, the peaks occur at higher field than would be expected. That this shielding effect is due to the phenyl ring rather than the sulfonate group is shown by the spectrum of the mesylate (IV), in which no such anomalies occur.

Since the shielding due to the phenyl ring is seen in three widely separated points (C-6, C-18, and C-19), only the conformation shown in Fig. 3, in which the phenyl ring overlies the steroid, can account for the effect. From this it is also clear that it is the lefthand proton at C-19, rather than the righthand proton, which is shielded by the double bond at C-5, since in III, in which the righthand proton is clearly shielded, $\delta_A - \delta_B$ becomes *smaller*, rather than larger.

Biological Activity—The biological activity of the synthetic cardenolides was determined essentially by the method of Chen (16). Briefly, cats were anesthesized by intraperitoneal administration of 2 ml./Kg. of a freshly prepared aqueous solution containing in each ml. 30 mg. of α-chloralose and 250 mg. of urethan. The femoral vein was injected at 3-min. intervals with 0.5–1.0 ml. of 47.5% alcohol containing 0.2 mg. of drug. These doses

were designed to produce an end point at 30–60 min. Kg.[1] The effect of the drug was monitored by EKG readings.

Because of the lack of material, all compounds were assayed using only one animal. The lethal doses (mg./Kg.) are: III (1.6), V (0.4), and VI (1.5), but obviously no statistical analysis is possible. Arrhythmias typical of cardiotonic steroids were observed in the EKG in all cases. Although no quantitative evaluation can be made, it can nevertheless be concluded that these analogs are not inactive. Since both these compounds, with bulky β-face substituents, and A/B *cis* steroids, in which ring A is bent back, are active, it seems likely that the A ring is not in contact with the cellular receptor surface. This is supported by the activity of many other ring A and ring B modified cardenolide analogs which have been synthesized and tested in this laboratory (17), and is of particular interest in connection with the elegant work of Kupchan *et al.* (18). These workers found that strophanthidin 3-iodoacetate (SIA) irreversibly inhibits transport ATPase and concluded this was due to alkylation of the enzyme at the site where cardiotonic steroids bind. The present study, however, indicates that if transport ATPase is in fact the true receptor, the inhibition is due to exoalkylation (19) at a point removed from the active site. This is in harmony with the concept (20) of the steroid as a *haftgruppe* for the butenolide ring.

EXPERIMENTAL[2]

3β,14β,19-Trihydroxycarda-5,20(22)-dienolide 3-Acetate (II)—To a stirred suspension of 0.6 Gm. of I (9) in 50 ml. of tetrahydrofuran and 30 ml. of methanol, there was added 0.15 Gm. of sodium borohydride in 2 ml. of water. When the reaction was completed (1–2 hr., clear solution), 10 ml. of water was added and the solvent was evaporated under reduced pressure. More water was added, and the precipitated product was filtered, washed with water, and dried. There was obtained 0.55 Gm. of crude product, m.p. 245–252°. Recrystallization from acetonitrile twice gave 0.45 Gm. of crystals, m.p. 260–263°. Further recrystallization from the same solvent gave the analytical sample, m.p. 263–265°; $[\alpha]_D^{19}$ + 1° (c 1, $CHCl_3$).

Anal.—Calcd. for $C_{25}H_{34}O_6$: C, 69.74; H, 7.96. Found: C, 69.34; H, 8.15.

3β,14β-19-Trihydroxycarda-5,20(22)-dienolide 3-Acetate 19-p-Toluenesulfonate (III)—A solution of 0.2 Gm. (0.00046 mole) of II and 0.2 Gm. of *p*-toluenesulfonyl chloride in 10 ml. of pyridine was kept at 27° for 48 hr. It was diluted with ice water and the resulting precipitate was collected and recrystallized from a mixture of methanol and a little acetonitrile to give 0.1 Gm. of colorless crystals, m.p. 155–157°. Further recrystallizations gave the analytical sample, m.p. 156–157°; $[\alpha]_D^{19}$ −41° (c 1, $CHCl_3$).

Anal.—Calcd. for $C_{32}H_{40}O_8S$: C, 65.77; H, 6.84. Found: C, 65.83; H, 6.52.

3β,14β-19-Trihydroxycarda-5,20(22)-dienolide 3-Acetate 19-Methanesulfonate (IV)—A solution of 0.4 Gm. (0.00092 mole) of II and 0.4 Gm. of methanesulfonyl chloride in 35 ml. of pyridine was kept at 27° for 48 hr. and worked up as described for III. Recrystallization from methanol gave the analytical sample, m.p. 145–146°; $[\alpha]_D^{20}$ −27° (c 1, $CHCl_3$).

Anal.—Calcd. for $C_{26}H_{36}O_8S$: C, 61.41; H, 7.14. Found: C, 61.36; H, 7.02.

19-Chloro-3β,14β-dihydroxycarda-5,20(22)-dienolide 3-Acetate (V)—A solution of 0.1 Gm. (0.00017 mole) of III and 0.1 Gm. (0.0023 mole) of lithium chloride in 12 ml. of isopropyl alcohol was heated under reflux for 3 hr. The solvent was evaporated under reduced pressure. The mixture was diluted with water and the resulting precipitate was collected and recrystallized three times from acetonitrile–methanol to give 0.05 Gm. of colorless crystals, m.p. 230–233°. Further recrystallizations gave the analytical sample, m.p. 242–244°; $[\alpha]_D^{19}$ −24° (c 0.6, $CHCl_3$).

Anal.—Calcd. for $C_{25}H_{33}ClO_5$: C, 66.87; H, 7.40. Found: C, 66.97; H, 7.36.

19-Bromo-3β,14β-dihydroxycarda-5,20(22)-dienolide 3-Acetate (VI)—A solution of 0.15 Gm. (0.00025 mole) of III and 0.15 Gm. (0.0017 mole) of lithium bromide in 15 ml. of isopropyl alcohol was heated under reflux for 2.5 hr. After evaporation of the solvent under reduced pressure, water was added to precipitate the product. Recrystallization from acetonitrile–methanol gave 0.06 Gm. of

[1] The authors are greatly indebted to Dr. Bertram Katzung and Mr. Charles Lee for help with the biological studies.

[2] Melting points were determined with a Thomas-Hoover apparatus equipped with a corrected thermometer. Infrared spectra were obtained with a Beckman IR-8 or Perkin Elmer 337 instrument. Microanalyses were performed by the Microanalytical Department, University of California, Berkeley, Calif. Optical rotations were obtained in a 0.5-cm. tube with a Rudolph photoelectric polarimeter. NMR spectra were obtained at a field strength of 60 Mc./sec. on samples in deuteriochloroform solution on a Varian A-60 or A-60A instrument, using tetramethylsilane as internal standard. Peak positions of AB quartets were computed with a punch card program on a Wyle calculator. When only small amounts of sample were available, or when the sample was poorly soluble in deuteriochloroform, a Varian C-1024 computer was used for time averaging.

product, m.p. 190–194°. The analytical sample had m.p. 195–197°; $[\alpha]_D^{19}$ −28° (c 1, $CHCl_3$).

Anal.—Calcd. for $C_{25}H_{33}BrO_5$: C, 60.85; H, 6.74. Found: C, 60.73; H, 6.72.

3β,14β-Dihydroxy-19-iodocarda-5,20(22)-dienolide 3-Acetate (VII)—A solution of 0.1 Gm. (0.00017 mole) of III and 0.1 Gm. (0.0007 mole) of lithium iodide in 20 ml. of isopropyl alcohol was heated under reflux for 2 hr. After evaporation of the solvent under reduced pressure, water was added to precipitate the product. Recrystallization twice from methanol gave 0.03 Gm. of product, m.p. 180–184°. Further recrystallizations from the same solvent gave the analytical sample, m.p. 184–185°; $[\alpha]_D^{19}$ −40° (c 0.6, $CHCl_3$).

Anal.—Calcd. for $C_{25}H_{33}IO_5$: C, 55.56; H, 6.16. Found: C, 55.79; H, 6.24.

Determination of the Conformation of Nicotine and Some Related Compounds by Nuclear Magnetic Resonance and Dipole Moments

By THOMAS R. SIMPSON, JR.*, J. CYMERMAN CRAIG, and W. D. KUMLER

A single NMR signal for protons in the 2- and 5-positions in *N*-methylpyrrolidine indicates rapid inversion of the nitrogen so that the methyl group spends half of its time on each side of the molecule. A single band for protons in the 2- and 5-positions in *N*-methylpyrrolidine *N*-oxide shows that the CH_3 and the O^- provide similar environments. Confirmation of this is obtained from the fact that NMR bands for comparable protons occupy nearly the same positions in *N*-methylpyrrolidine methiodide and *N*-methylpyrrolidine *N*-oxide. Introduction of a pyridine, or a pyridine *N*-oxide, ring in the 2-position causes the methyl protons and one proton on the asymmetric carbon to move upfield and all the other protons to move downfield. The upfield motion of these protons is consistent with the configuration which has the methyl group situated away from the pyridine ring. Dipole moments indicate that oscillation between two conformations is likely in (L)-nicotine and (L)-nicotine *N*-oxide, while (L)-nicotine *N*-oxide and (L)-nicotine *N,N'*-dioxide appear to be fixed in one preferred conformation.

ALTHOUGH the absolute configuration of natural (−)-nicotine is known (1), and nicotine *N*-oxide (compound *6* in Table I) is recognized as the first metabolite of nicotine in animals and plants (see *Reference 2*), no information is available concerning the conformation in which nicotine or its *N*-oxides exist. This problem has now been investigated by the use of techniques of nuclear magnetic resonance and dipole moment measurements.

DISCUSSION

Some previous work on the NMR spectrum of *N*-methylpyrrolidine (compound *1*) has been reported (3). The present results now make possible the unambiguous assignment of the methyl and methylene protons, and the effect of the conversion of the tertiary to a quaternized nitrogen, or to an *N*-oxide, has been observed to produce downfield shifts comparable to those reported in other compounds (3).

The relative downfield shift of the protons in *1* can be accounted for as follows. The *a* protons (Table I), being farthest away from the nitrogen, are shifted downfield the least amount. The others are

Confirmation of this is obtained from the fact that NMR bands for comparable protons occupy nearly the same positions in *N*-methylpyrrolidine methiodide and *N*-methylpyrrolidine *N*-oxide. Introduction of a pyridine, or a pyridine *N*-oxide, ring in the 2-position causes the methyl protons and one proton on the asymmetric carbon to move upfield and all the other protons to move downfield. The upfield motion of these protons is consistent with the configuration which has the methyl group situated away from the pyridine ring. Dipole moments indicate that oscillation between two conformations is likely in (L)-nicotine and (L)-nicotine *N*-oxide, while (L)-nicotine *N*-oxide and (L)-nicotine *N,N'*-dioxide appear to be fixed in one preferred conformation.

ALTHOUGH the absolute configuration of natural (−)-nicotine is known (1), and nicotine *N*-oxide (compound *6* in Table I) is recognized as the first metabolite of nicotine in animals and plants (see *Reference 2*), no information is available concerning the conformation in which nicotine or its *N*-oxides exist. This problem has now been investigated by the use of techniques of nuclear magnetic resonance and dipole moment measurements.

DISCUSSION

Some previous work on the NMR spectrum of *N*-methylpyrrolidine (compound *1*) has been reported (3). The present results now make possible the unambiguous assignment of the methyl and methylene protons, and the effect of the conversion of the tertiary to a quaternized nitrogen, or to an *N*-oxide, has been observed to produce downfield shifts comparable to those reported in other compounds (3).

The relative downfield shift of the protons in *1* can be accounted for as follows. The *a* protons (Table I), being farthest away from the nitrogen, are shifted downfield the least amount. The others are

equidistant, but the *c* and *d* protons are on a carbon to which another carbon is attached and thus appear further downfield than the *b* protons. The presence of only one band for the *c* and *d* protons implies that their environment must be the same, which means that the nitrogen inverts rapidly causing the methyl group to spend half its time on each side of the ring. The methyl group gives a sharp singlet but the peaks for the methylene protons are complex. The *c* and *d* protons give rise to a triplet, while the *a* protons form a more complicated multiplet.

Introduction of oxygen giving *N*-methylpyrrolidine *N*-oxide (compound *2*) causes all protons to move downfield, the *a* proton by 25 c.p.s. and the *b*, *c*, and *d* protons by 60 c.p.s. The *a* protons are one atom farther away from the positively charged nitrogen atom and are deshielded less, as expected (3). However, the fact that there is only one band for the *c* and *d* protons is entirely unexpected, because the protons on the side of the O^- atom would be anticipated to be in a different environment from those on the side of the methyl group. The reason, apparently, is that the O^- and CH_3 group provide, by coincidence, essentially the same environment. This is reasonable because the negative charge on oxygen would oppose its electronegativity and the net effect would be close to that of a methyl group.

If this explanation is correct, then one would expect the chemical shifts for *N*-methylpyrrolidine methiodide (compound *3*), in which a methyl group has replaced the O^-, to come close to those for compound *2*, which they do, differing only by 3, 7, and 2 c.p.s., respectively. The signal for the methyl group in these two compounds is a sharp singlet, while those for the *a*, *c*, and *d* protons are complex multiplets.

Replacement of one of the methyl groups in compound *3* by a deuterium atom, giving compound *4*, results in multiplets for the *c* and *d* protons centered around 220 and 187 c.p.s. This is expected, for the environment around methyl will be different from that around deuterium, which has a lesser tendency to move protons downfield. This change has caused the *a* protons to move upfield by 8 c.p.s., the *b* protons by 14 c.p.s., one of the *c* and one of the *d* protons by 25 c.p.s., and the other *c* and *d* protons downfield by 8 c.p.s. It seems likely that the *c* and *d* protons on the same side as the methyl group give rise to the 187 c.p.s. signal, since they are more analogous to the methyl protons (with respect to the deuterium) than are the other *c* and *d* protons. This reasoning applies irrespective of what combination of inductive, magnetic anisotropy, or solvent effects may be involved.

Introduction of a pyridine ring into compound *1* gives nicotine (compound *5*) which has a sharp singlet at 127 c.p.s. due to the methyl group. There are multiplets centered at 119, 138, and 190 c.p.s. which correspond to 4, 1, and 2 protons, respectively. The signal at 119 c.p.s. can be assigned to the *a* protons, which are farthest from the pyrrolidine nitrogen. The multiplet at 138 c.p.s. was thought to arise from the *d* proton (and was indeed a triplet as expected for this proton), and the multiplet at 190 c.p.s. would then be due to the *c* protons. However, an argument against this assignment is that a calculation of shielding and deshielding effects (4) according to the method discussed by Bible (5), following Johnson and Bovey (6), for any possible conformation of nicotine does not put the *d* proton into a region of shielding and thus could not account for its movement upfield to 138 c.p.s. from its position at 150 c.p.s. in *N*-methylpyrrolidine.

To shed further light on this point, the spectrum of nicotine was examined both at 100 Mc./sec. and at 220 Mc./sec. in benzene.[1] Under these conditions, the multiplet centered at 190 c.p.s. in D_2O was resolved into a triplet and doublets of a triplet. The triplet at 187 c.p.s. can thus be assigned to the *d* proton while the two *c* protons give rise to the triplet at 138 c.p.s. and the multiplet at 192 c.p.s., respectively. This assignment has the advantage that the signal for the *d* proton is now in a region where the calculations place it, as is that for the *b* protons, and the *c* proton opposite the methyl group can be placed in a position consistent with its signal at 138 c.p.s. However, the calculations do not place the other *c* proton far enough downfield by about 40 c.p.s. Nevertheless, this assignment gives rise to better over-all consistency than does the alternative one. The reasons the calculations do not hold in the case of one of the *c* protons may be due to the method (6) having been developed for benzene rather than pyridine, plus the fact that the proton in question has the pyrrolidine nitrogen interposed between it and the pyridine ring for the conformations considered. This would be expected to alter the action of the pyridine ring currents on this proton that take place directly through space.

The Stuart-Briegleb model for L-nicotine shows considerable steric hindrance if the methyl group is placed on the same side of the pyrrolidine ring as the pyridine moiety, and demethylation studies on nicotine (2) indicate the methyl group and pyridine ring to be on opposite sides of the pyrrolidine ring.

The above assignment of the bands for nicotine means that the introduction of the pyridine ring in position 2 of *N*-methylpyrrolidine has shifted the *a* protons downfield by 12 c.p.s., the *c* proton on the same side as the methyl group down by 42 c.p.s., and the *d* proton by 37 c.p.s., while the *b* protons are displaced upfield by 10 c.p.s. and the *c* proton opposite the methyl group by 12 c.p.s.

Placing an oxygen on the pyrrolidine nitrogen gives nicotine *N*-oxide (compound *6*) and the bands are assigned as indicated in Table I. The downfield shift, caused by the change from *5* → *6*, is one of 23 c.p.s. for the *a* protons, 57 c.p.s. for the *b* protons, 36 for the *c* proton on the same side as the methyl group, 90 for the *c* proton opposite methyl, and 94 for the *d* proton. The comparable changes in going from *1* → *2* were 25 c.p.s. for the *a* protons and 60 c.p.s. for the *b*, *c*, and *d* protons. The large effect on the *c* proton opposite the methyl group may be due to the oxygen being interposed between it and the pyridine ring, thus reducing the shielding effect of the ring currents which originally moved this proton upfield in nicotine.

Introduction of an oxygen on the pyridine nitrogen, giving compound *7*, leaves the signals for the protons of the pyrrolidine ring almost unchanged. The largest shift (9 c.p.s.) is that of the *c* proton opposite the methyl group, *i.e.*, the proton closest in space to the pyridine ring with its (now positively charged) nitrogen.

The movement of the protons on the pyridine

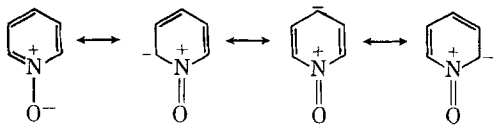
ring in *7* compared with *5* are interpretable in terms of the resonance forms expected in pyridine *N*-oxide (7). These put negative charges (Scheme I) on the *h*, *f*, and *g* carbon atoms which correspond to the 2, 4, and 6 positions, and protons attached to these carbons move upfield by 11, 10, and 13 c.p.s. while the *e* proton, attached to a carbon which has a relative positive charge, is moved downfield by 10



Scheme I

c.p.s. The 3 position on the pyridine ring will likewise be relatively positive, and this is another reason for the downfield shift of the *d* proton attached to the adjacent carbon in *7* compared to *5*.

Conversion of compound *7* to nicotine *N,N'*-dioxide (compound *8*) caused downfield shifts of all aliphatic protons. The *a*, *b*, and *c* protons moved by 30, 56, and 90 c.p.s., respectively, while the *c* proton on the same side as the methyl group moved by 35, and the other *c* proton by 80 c.p.s. All of these values are in good agreement with the comparable change from nicotine to the *N*-oxide, *6*. The positions of the *a*, *b*, *c*, and *d* protons are almost identical in the *N*-oxide (*6*) and the *N,N'*-dioxide (*8*), showing that an oxygen added to the pyridine nitrogen is virtually without effect on the position of the signals for the pyrrolidine protons.

When an additional methyl group is placed on both nitrogens in nicotine, giving compound *9*, all signals move downfield due to the greater effect of a positive charge on nitrogen alone in contrast to a positive charge on nitrogen tempered by a negative charge on the adjacent oxygen. The shifts in the proton signals from compound *8* → *9* are twice as great for the *d* proton (which is closest to the pyridine ring) as for the other protons in the pyrrolidine ring, and the *f* and *h* protons (which have both a relative positive charge due to resonance, and are nearest the pyrrolidine ring) are displaced most in the pyridine ring. The downfield location of the *j* protons compared with the *i* protons results from the greater electronegativity of pyridine compared to pyrrolidine, and to the *j* protons being in or near the plane of the pyridine ring while the *i* protons are above it.

Dipole moments were measured and compared with the theoretical moments for various conformations of (L)-nicotine, *5*; (L)-nicotine *N'*-oxide, *7*; (L)-nicotine *N*-oxide, *6*; and (L)-nicotine *N,N'*-dioxide, *8*. The values used in calculating the theoretical moments are given in Table II, and the observed and theoretical calculated moments for the different configurations and conformations in Table III.

The four extreme conformations of nicotine are shown in Fig. 1. The observed moment for nicotine is close to that for rotation between conformations I and II. It is not quite so close to that for conformation IV. The models indicate that rotation is relatively free between either I and II, or III and IV, but would be prevented between other combinations. If, therefore, the molecule existed in conformation IV, there seems no reason why it should not rotate between III and IV, in which case

[a] In Debye units (D.); measured at 25° C. in dioxane unless otherwise noted. [b] F.R., free rotation between conformations of a configuration. [c] Conformations with the methyl group toward the pyridine ring, which were ruled out by demethylation studies and from space-filling models.

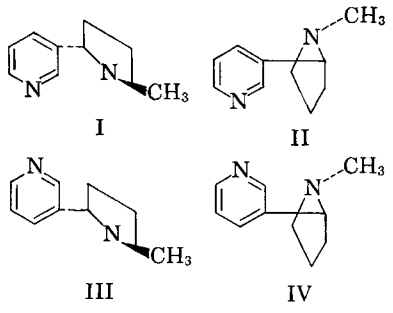

Fig. 1—Four extreme conformations of nicotine. In conformations II and III, the hydrogen on carbon 3 of the pyrrolidine ring is behind H-2 of the pyridine ring, while in conformations I and IV, it is behind H-4 of the pyridine ring. Thus I and IV, and II and III, are not identical since the pyridine ring is inverted. Conversion of conformation I into II, or of III into IV, is achieved by rotating the pyrrolidine ring. Conformation II cannot be converted into III except by breaking the carbon-carbon bond between the rings, rotating one ring, and reassembling.

the calculated moment would be considerably below that observed. Since the conformations with the methyl group next to the pyridine ring are ruled out by demethylation data and space-filling models, they need not be considered further. The most likely structure for nicotine appears to be that of a rotamer between conformations I and II.

The data for (L)-nicotine *N'*-oxide lead to the same conclusion, namely, rotation between conformations I and II for its structure. This is reasonable since the two molecules have the same structural features at the ring junction in the various conformations. The fact that the observed moment is 0.15 D. below that calculated for free rotation suggests that it spends a longer time in conformation II with the lower moment, which would be favored on a dipole interaction basis. With (L)-nicotine *N*-oxide, models indicate steric hindrance alters conformations I and III but not II and IV. In conformation I, an oxygen placed on the pyrrolidine nitrogen interferes with the hydrogen at carbon 2 of pyridine, and does not permit the downward-pointing hydrogen at carbon 3 of the pyrrolidine

[a] Measured in dioxane at 25° C. unless otherwise noted.

ring to rotate into a position behind the hydrogen at carbon 4 of pyridine, as it could in conformation I of nicotine itself. In conformation III of nicotine *N*-oxide, the oxygen interferes with the hydrogen at carbon 4 of pyridine, and thereby prevents the molecule from assuming the conformation III of nicotine itself. The observed moment of nicotine *N*-oxide is considerably less than that calculated for either type of free rotation. Conformation III is closest to the observed moment. The reason the observed moment is 0.25 D. below that calculated for III is probably to be found in the above-mentioned proximity of the $\overset{+}{N}—\overset{-}{O}$ group to carbon 4 of the pyridine ring, which has a partial positive charge due to resonance, thus tending to reduce the moment between $\overset{+}{N}$ and $\overset{-}{O}$.

The same situation exists in (L)-nicotine *N,N'*-dioxide where the observed moment again comes closest to that calculated for conformation III. Here, however, the observed moment is 0.25 D. above the calculated one, and this is understandable because the resonance in the pyridine-*N*-oxide ring places a partial negative charge on carbon 4 which would now enhance the $\overset{+}{N}—\overset{-}{O}$ dipole. In both compounds, the evidence indicates the compounds exist in the conformation with the smallest dipole moment which is favored both from dipole interaction and from steric considerations.

EXPERIMENTAL

The dielectric constants were measured with a WTW Dipolmeter model DM-01 with a DF L-2 4-ml. cell with a thermostated jacket maintained at a temperature of 25.00° ± 0.03°. The P_{E_2} values are molar refractions calculated from refractive indices of the solutions measured with the D sodium line at 25.00° ± 0.03°. Densities were measured with a pycnometer of approximately 2-ml. capacity. Solvents were refluxed over sodium twice and distilled twice from a 1-M. column. Dipole moments were calculated using the Halverstadt-Kumler (8) method, for which programs were developed for use on both the IBM 1620 and 1401 computers. The results are given in Table IV.

Acetylsalicylic Acid Hydrolysis in Human Blood and Plasma I

Methodology and *In Vitro* Studies

By PHILLIP A. HARRIS and SIDNEY RIEGELMAN

The *in vitro* hydrolysis of acetylsalicylic acid in 90 vol. per cent human blood and plasma was studied at therapeutically significant levels (below 15 mcg./ml.) by a spectrophotofluorometric method. Several new analytical aspects are presented. The discrepancies with earlier investigations are discussed.

IT IS WELL KNOWN that acetylsalicylic acid (ASA) rapidly hydrolyzes in aqueous solution, and its hydrolysis is accelerated by esterases found in the blood or plasma (1). Morgan and Truitt (2) recently reviewed the literature relating to the hydrolysis of ASA in blood and plasma. The hydrolysis would be expected to be a second-order process dependent upon both the enzyme and the substrate concentrations. At low aspirin and fixed enzyme concentrations, the reaction should reduce to a pseudo first-order reaction. Some of the previous investigations on this subject have been run in highly diluted plasma and at high aspirin levels (2). The excessive concentration of ASA might swamp the enzyme and cause

This investigation was supported in part by research funds from the American Arthritis Foundation, Northern California Chapter, and training grant GM 0728 from the National Institutes of Health, U.S. Public Health Service, Bethesda, Md.
The authors wish to dedicate this paper to Dean T. C. Daniels, whose leadership at the University of California has done so much to raise the standards of education and research in the pharmaceutical sciences.

ring to rotate into a position behind the hydrogen at carbon 4 of pyridine, as it could in conformation I of nicotine itself. In conformation III of nicotine *N*-oxide, the oxygen interferes with the hydrogen at carbon 4 of pyridine, and thereby prevents the molecule from assuming the conformation III of nicotine itself. The observed moment of nicotine *N*-oxide is considerably less than that calculated for either type of free rotation. Conformation III is closest to the observed moment. The reason the observed moment is 0.25 D. below that calculated for III is probably to be found in the above-mentioned proximity of the $\overset{+}{N}—\overset{-}{O}$ group to carbon 4 of the pyridine ring, which has a partial positive charge due to resonance, thus tending to reduce the moment between $\overset{+}{N}$ and $\overset{-}{O}$.

The same situation exists in (L)-nicotine *N,N'*-dioxide where the observed moment again comes closest to that calculated for conformation III. Here, however, the observed moment is 0.25 D. above the calculated one, and this is understandable because the resonance in the pyridine-*N*-oxide ring places a partial negative charge on carbon 4 which would now enhance the $\overset{+}{N}—\overset{-}{O}$ dipole. In both compounds, the evidence indicates the compounds exist in the conformation with the smallest dipole moment which is favored both from dipole interaction and from steric considerations.

EXPERIMENTAL

The dielectric constants were measured with a WTW Dipolmeter model DM-01 with a DF L-2 4-ml. cell with a thermostated jacket maintained at a temperature of 25.00° ± 0.03°. The P_{E_2} values are molar refractions calculated from refractive indices of the solutions measured with the D sodium line at 25.00° ± 0.03°. Densities were measured with a pycnometer of approximately 2-ml. capacity. Solvents were refluxed over sodium twice and distilled twice from a 1-M. column. Dipole moments were calculated using the Halverstadt-Kumler (8) method, for which programs were developed for use on both the IBM 1620 and 1401 computers. The results are given in Table IV.

Acetylsalicylic Acid Hydrolysis in Human Blood and Plasma I

Methodology and *In Vitro* Studies

By PHILLIP A. HARRIS and SIDNEY RIEGELMAN

The *in vitro* hydrolysis of acetylsalicylic acid in 90 vol. per cent human blood and plasma was studied at therapeutically significant levels (below 15 mcg./ml.) by a spectrophotofluorometric method. Several new analytical aspects are presented. The discrepancies with earlier investigations are discussed.

IT IS WELL KNOWN that acetylsalicylic acid (ASA) rapidly hydrolyzes in aqueous solution, and its hydrolysis is accelerated by esterases found in the blood or plasma (1). Morgan and Truitt (2) recently reviewed the literature relating to the hydrolysis of ASA in blood and plasma. The hydrolysis would be expected to be a second-order process dependent upon both the enzyme and the substrate concentrations. At low aspirin and fixed enzyme concentrations, the reaction should reduce to a pseudo first-order reaction. Some of the previous investigations on this subject have been run in highly diluted plasma and at high aspirin levels (2). The excessive concentration of ASA might swamp the enzyme and cause

The authors wish to dedicate this paper to Dean T. C. Daniels, whose leadership at the University of California has done so much to raise the standards of education and research in the pharmaceutical sciences.

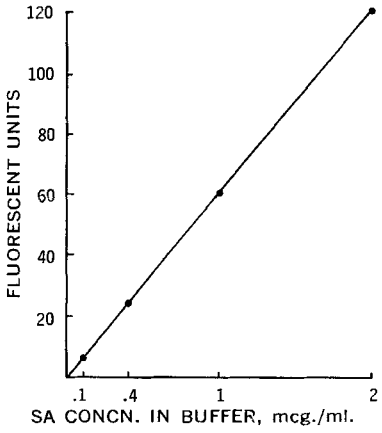

Fig. 1—Standard curve for salicylic acid in phosphate buffer (0.1 M, pH 7) using the Aminco Bowman spectrophotofluorometer. The activating wavelength was 315 mμ (uncorrected) and the emission wavelength was 420 mμ (uncorrected). (See Footnote 1.)

the reaction to follow zero-order kinetics. High dilution of the blood and plasma may have been required for the analytical approach utilized, but extrapolation back to undiluted blood cannot be made with certainty. These circumstances make it difficult to apply the results to an *in vivo* system.

The object of this paper is to report a method of studying ASA hydrolysis in virtually undiluted blood and plasma (90 vol. %) and at therapeutically significant concentrations (below 15 mcg./ml.).

EXPERIMENTAL

Rate Study—The subjects were four healthy males and one healthy female, ranging in age from 26 to 42 years. Blood was drawn from the antecubital vein into a heparanized syringe. The experiment was started soon after drawing the blood and lasted in most instances for 1 hr. All rate studies were carried out with U.S.P. acetylsalicylic acid which we found to contain less than 0.1% free salicylic acid (SA).

The blood sample was divided into two parts. One part was used for the study of the hydrolysis of ASA in whole blood. The other was centrifuged at 2200 RCF for 20 min., and the separated plasma was then used for the study of the hydrolysis of ASA in plasma. From each 10 ml. of blood or plasma, 1 ml. was removed for a blank analysis. Then 1 ml. of ASA in isotonic NaCl solution was added to the remainder, resulting in a 10% dilution of the blood. Two initial concentrations of ASA (13 mcg./ml. and 6.5 mcg./ml.) in the blood or plasma were used. The rate studies were carried out at 37°, and in most cases data points were obtained at 5, 10, 20, 30, 45, and 60 min.

Spectrophotofluorometric Assay—One-milliliter samples of blood or plasma were withdrawn from the test medium, mixed immediately with 1 ml. isotonic NaCl solution, and extracted with 5 ml. ether containing oxalic acid (8 mg./ml.). The extraction with acidified ether serves several functions: (*a*) the oxalic acid partitions into the aqueous phase rendering it acidic to a pH of approximately 2; (*b*) the esterases in the blood and plasma are immediately inactivated; (*c*) whole blood mixes well with the ether before clumping occurs; and (*d*) under these pH conditions this volume of ether virtually completely extracts the ASA and SA. These phenomena were verified by preliminary experiments using spectrophotometric and spectrophotofluorometric measurements.

The sample of ether and blood or plasma was centrifuged and 3 ml. of ether was withdrawn and extracted with 3 ml. phosphate buffer (0.1 *M*, pH 7). Nitrogen gas was bubbled through the buffer for 2 or 3 min. to remove residual ether, since the presence of ether affects the SA fluorescence in the buffer.

The fluorescence of salicylic acid in pH 7 phosphate buffer was determined using the Aminco-Bowman spectrophotofluorometer by activating at a wavelength of 315 mμ (uncorrected) and reading the emission at 420 mμ (uncorrected).[1] (ASA is not fluorescent under these conditions.) The slits were placed in the following order: 1/2, 1/16, 1/8, 1/8, 1/16, 1/8, and 3/16, respectively.

Buffer solutions containing both ASA and SA from blood or plasma samples were analyzed fluorometrically for free SA within 2 to 3 hr. after extraction. At pH 7 and room temperature, ASA hydrolysis proceeds relatively slowly with a half-life of approximately 3 days (3). However, when heated to 100° hydrolysis is very rapid with a half-life of approximately 10 min. The buffer solutions were heated at 100° in stoppered tubes for 1.5 hr., which completely hydrolyzes the intact ASA, and analyzed for total SA (*i.e.*, that liberated by hydrolysis of ASA and the free SA).

The fluorescence of each sample was determined at three dilutions. First, 1.0 ml. of undiluted sample was read; then 1.0 ml. of buffer was added and the sample read again; finally, another 1.0 ml. of buffer was added and the sample read again. This was done so that quenching corrections could be applied. The recovery of ASA and SA was greater than 98%, with somewhat better recovery of ASA than of SA due to its more favorable partition characteristics.

RESULTS AND DISCUSSION

Spectrophotofluorometric Assay—Figure 1 is a plot of fluorescence against various concentrations of SA in pH 7 phosphate buffer. The fluorescence reading of SA is linear with concentration over the range of concentrations studied. The concentrations used in this standard curve were the same magnitude as those encountered in the actual experiments after the dilution involved in the extractions.

The lower limit of detection of SA using the Aminco-Bowman spectrophotofluorometer is approximately 1.0 ng./ml. However, the blank readings obtained from blood and plasma are equivalent to a 25 ng./ml. of SA and remain constant before and after heating. The lowest amount of

[1] The Aminco-Bowman spectrophotofluorometer used in this study was not standardized to precise wavelength, and the values of excitation reported are probably 5 to 10 mμ too high.

free SA determined was at least 125 ng./ml. However, this is a false evaluation of the accuracy of the method, since the relative reproducibility of the readings is important and the total method is a difference method requiring an assessment of the relative error of the reading of the free salicylate and the total salicylate. It was the authors' experience that there was an over-all error of approximately 1 to 2% in the procedure. Therefore, the authors would not be able to discriminate accurately less than 2 parts of ASA in the presence of 100 parts of SA regardless of the concentrations.

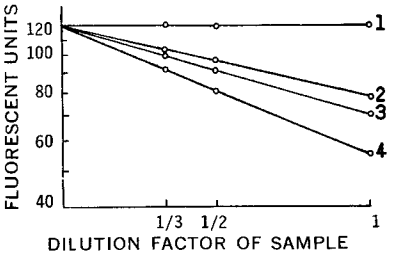

Fig. 2—Semilogarithmic plots illustrating the method of quenching correction. Key: 1, a standard buffer solution of SA; 2, 3, and 4, standard buffer solutions of SA shaken with ether containing quenching components from blood.

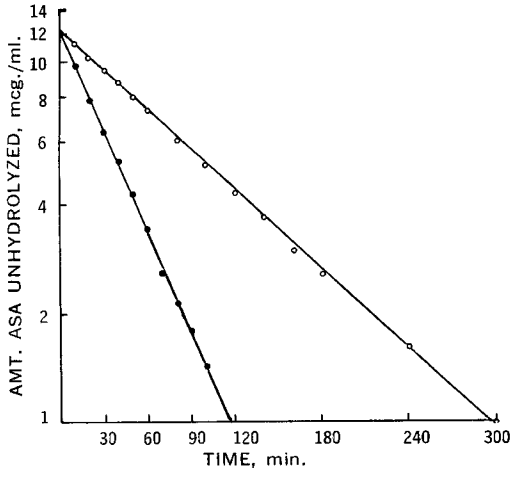

Fig. 3—Semilogarithmic plots of the hydrolysis of ASA carried out for 100 min. with blood and 300 min. with plasma. Initial ASA concn. was 13 mcg./ml. Key: ●, blood; ○, plasma.

It was found that the SA fluorescence in whole blood extracts was highly quenched. This was true of plasma extracts also but to a much lesser extent. A quenching correction procedure was developed in this laboratory analogous to that developed by Peng (4) for quenching corrections in scintillation counting of radioactive samples. It was observed that quenching obeys the Beer-Lambert law. A 1.0-ml. sample of the quenched solution was diluted in three increments and the fluorescence readings corrected for dilution (*i.e.*, if diluted $^1/_2$ the reading is multiplied by 2, if diluted $^1/_3$, by 3, *etc.*). The readings were plotted on semilogarithmic paper with the abscissa as the dilution factor and the ordinate as the corrected fluorescence reading. A line was drawn through these points and the intercept on the ordinate was taken as the true fluorescence in the absence of quenching components from the blood. If a standard buffer solution of SA in the absence of quenching components from the blood is diluted and read by this procedure, there is no change in the fluorescence reading. This is shown in Fig. 2 as the horizontal line along with three samples representing blood extractions with acidified ether subsequently shaken with the standard buffer solution of SA. Each sample varied in the degree of quenching as shown by the different slopes obtained. This is apparently a function of the amount and manner of shaking in the ether extraction of blood which can release varying amounts of quenching components. In assessing the true value by extrapolation, it was found that the method was reproducible with a range of ±1% of the standard.

Rate Data—It is apparent from Fig. 3 that the hydrolysis of ASA in blood and plasma appears to obey pseudo first-order kinetics for more than three half-lives. A summary of all the half-lives obtained, including repeated determinations at different times with the same subject, is shown in Table I. Figure 4 shows typical plots of hydrolysis data at initial ASA concentrations of 13 and 6.5 mcg./ml. in blood and plasma from three subjects

It is to be noted that while the half-lives in these systems are not exactly reproducible, they are reasonably close indicating that the hydrolysis in this concentration range obeys first-order kinetics. However, this system is first order only at constant enzyme concentration. Since the blood and plasma were diluted reproducibly in each experiment, the differences in hydrolysis rates in repeated experiments in the same subject might be explained in terms of day-to-day variations of enzyme concentration in the blood.

Table I shows an average value of approximately 30 min. for the half-life of hydrolysis in whole blood and slightly over 1 hr. in plasma. It is important to note that the studies carried out in this investigation are at the levels of ASA that might be expected in the body from normal doses (5).

However, the results do not agree with the recent report of Morgan and Truitt (2), wherein they studied the hydrolysis of ASA in thirtyfold dilutions of serum and blood and at a concentration of 2.4×10^{-3} *M* ASA (433 mcg./ml.), a level 33 times the concentrations used in this study. Their reported average rate constants for ASA hydrolysis at 25° are 4.74×10^{-2} hr. ($t_{1/2}$ = 14.7 hr.) and 11.7×10^{-2} hr.$^{-1}$ ($t_{1/2}$ = 5.9 hr.) for serum and blood, respectively. They also showed that at 37° the rate is about twice that at 25°. These half-lives can only be compared to our own by linearly correcting for enzyme dilution by dividing by 30 and by 2 to correct for temperature. If we adopt such a correction procedure, even though Morgan and Truitt used a 3.3% serum concentration, we obtain half-lives of approximately 15 min. and 6 min for serum and blood, respectively. These are approximately 1/4 to 1/5 the estimates of the half-lives for hydrolysis obtained in the present study. Edwards (6) studied the hydrolysis of ASA in guinea pig plasma from 1 to 50 vol. %. Below approximately 15%, there was considerable departure from linearity.

The observation that the hydrolytic rate in whole blood is about twice as rapid as in plasma suggests the presence of higher concentrations of the hydrolyzing enzyme(s) or additional enzyme(s) in the red blood cells or in the leucocytes. Red blood cells are known to possess a high content of acetylcholinesterase. A recent review (7) includes a discussion of esterases found in leucocytes.

SUMMARY

An assay for acetylsalicylic acid is reported based on a spectrophotofluorometric assay of the free and total salicylate content. Using this assay the hydrolytic rate of acetylsalicylic acid in 90 vol. % human whole blood and plasma at levels of 13 and 6.5 mcg./ml. was studied. The hydrolysis was found to obey pseudo first-order kinetics. The mean half-lives of hydrolysis were 32 ± 0.91 min. (mean ± S.E.) for blood and 65.92 ± 1.98 min. for plasma at the 13 mcg./ml. level. At the 6.5 mcg./ml. level the values were 29.6 ± 0.77 min. for blood and 69.2 ± 2.96 min. for plasma.

Determination of Acetylsalicylic Acid and Salicylic Acid in Plasma

By MALCOLM ROWLAND and SIDNEY RIEGELMAN

A specific and sensitive method has been developed for the determination of acetylsalicylic acid and salicylic acid in plasma. Both of these compounds are extracted from acidified plasma with ether. A portion of the ether extract is concentrated, reacted with a silanizing reagent in carbon disulfide, and the silyl derivative of acetylsalicylic acid is analyzed by gas–liquid chromatography using dibutyl maleate as the internal standard. Another portion of the ether extract is extracted with phosphate buffer and the salicylate read spectrophotofluorometrically. Only 0.5 ml. or less of plasma is required for analysis and one can readily determine 0.4 mcg. acetylsalicylic acid/ml. in the presence of 100 mcg. salicylic acid/ml.

IN THE PAST, whole blood and plasma acetylsalicylic acid (ASA) levels have been calculated as the difference in the salicylic acid (SA) concentrations before and after hydrolysis of an aqueous extract of the sample (1–3). Such methods have large errors when SA is present in vast excess of ASA, a situation which often occurs in practice. Recently, ASA has been separated from SA by a paper chromatographic method (4) or by selective extraction (5), and assayed spectrophotofluorometrically after subsequent hydrolysis of ASA to SA.

Direct determinations of ASA have been made using gas–liquid chromatography (GLC) (6, 7) but these have been confined to tablet formulations. Crippen *et al.* (8) have chromatographed ASA as its methyl ester, while Horii *et al.* (9) have separated a large number of aromatic acids, including SA, as their trimethylsilyl derivatives. However, in none of the above methods has ASA been determined specifically in blood or plasma. A specific and sensitive method for the determination of ASA and SA in plasma, requiring only 0.5 ml. sample, is now presented. The ASA is determined directly by GLC as its trimethylsilyl derivative and the SA is determined spectrophotofluorometrically.

EXPERIMENTAL

Materials—The majority of materials used were analytical grade from Baker Chemical Co. The ASA sample from Merck contained less than 0.1% SA as shown by spectrophotofluorometric assay. Hexamethyldisilazane (HMDS), trimethylchlorosilane (TMCS), and most gas chromatographic materials were obtained from Applied Science Laboratories.

Received December 27, 1966, from the School of Pharmacy, University of California, San Francisco Medical Center, San Francisco, CA 94122

Accepted for publication April 4, 1967.

This investigation supported in part by a grant-in-aid from the Glenbrook Laboratories, New York, N.Y.

The authors acknowledge the technical assistance of Mr. George King. Malcolm Rowland thanks the Welcome Foundation for a travel grant.

The authors wish to dedicate this paper to Dean T. C. Daniels, whose leadership at the University of California has done so much to raise the standards of education and research in the pharmaceutical sciences.

Apparatus—An F & M model 700 gas chromatograph, with a flame ionization detector, model 810 electrometer, 220 power proportioning temperature controller, and a Hewlett-Packard 7127 A recorder, was used for ASA determinations. An Aminco-Bowman spectrophotofluorometer, model 8210, was used for SA assays.

Analytical Procedure

Reagents—(*a*) Fifty per cent w/v potassium fluoride in distilled water. (*b*) Heparin solution 1000 units /ml. (free of preservatives). (*c*) Distilled ether, prepared daily. (*d*) Distilled carbon disulfide, prepared daily. (*e*) Five per cent w/v potassium hydrogen sulfate in distilled water. (*f*) Hexamethyldisilazane (HMDS). (*g*) Trimethylchlorosilane (TMCS). (*h*) Dibutyl maleate standard solution, 1 mcg./ml. ether. (*i*) Carbon disulfide solution; each ml. CS_2 containing 2 μl. silanizing reagent (20 parts HMDS/1 part TMCS). (*j*) Phosphate buffer (0.1 *M*), pH = 7.0.

Collection and Storage of Samples—A 5-ml. sample of whole blood was placed immediately into a centrifuge tube containing 50 μl. heparin solution and 50 μl. potassium fluoride solution, the tube being kept in an ice bath. The blood was gently mixed and kept in the ice bath for 2 min. (final blood temperature = +2°). The blood was then centrifuged, and the plasma pipetted off and stored in dry ice until required for analysis.

Analysis—Plasma (0.05–0.5 ml.) was pipeted into a centrifuge tube containing 0.5 ml. potassium bisulfate solution (which acted as an acidifying medium and adjusted the pH to 2.0), extracted with 7 ml. of ether, and then centrifuged.

ASA Assay—A 5-ml. aliquot of the above ethereal extract was pipetted into a centrifuge tube containing 1 ml. dibutyl maleate standard (1 mcg./ml. ether). The combined ethereal solutions were concentrated on a water bath at 42° to about 50 μl. Carbon disulfide reagent (1 ml.) was then added to the solution which was then once again concentrated on a water bath at 60° to about 50 μl. Approximately 1 μl. of the concentrate was injected for analysis into the chromatograph. The peak height ratio of ASA derivative to dibutyl maleate was measured and the concentration of ASA determined by reference to a calibration curve. Freshly prepared ASA aqueous standards (1–10 mcg./ml.) were assayed in the same manner and run with each batch of plasma samples.

The column was 100–120 mesh Gas Chrome Q onto which was coated 3% DC QF-1, and packed into a 7-ft., 1/8-in. o.d. stainless steel tube. The op-

erating conditions were as follows: column temperature, 125°; injection block and detector temperatures, 200° and 180°, respectively; nitrogen pressure, 40 lb./sq. in.; hydrogen pressure, 16 lb./sq. in.; air pressure, 20 lb./sq. in.

SA Assay—A 1-ml. aliquot of the above ethereal extract of the acidified plasma was re-extracted with 5 ml. phosphate buffer (pH 7.0) in a centrifuge tube. The sample was centrifuged, excess ether sucked off, and nitrogen blown through the phosphate buffer for 30 sec. to remove the dissolved ether (which modified the spectrophotofluorometric readings). The solutions were then read on the spectrophotofluorometer, activation wavelength, 315 mμ. (uncorrected); emission wavelength, 420 mμ (uncorrected).[1] Fluorescent measurements of standard solutions of SA in phosphate buffer (0.1–1.0 mcg./ml.) were made at the same time. In a number of samples the phosphate solutions were heated for 1 hr. at 100° to hydrolyze the ASA to SA, and the total SA was then measured.

Calibration Curves—The following concentrations of ASA and SA were added to plasma obtained from a subject who had not taken any drugs during the previous week (mcg. ASA/ml.–mcg. SA/ml.: 0/0, 0.4/100, 1.0/80, 2.0/40, 4.0/20, 10/10, and 20/4.0). The samples of plasma were then assayed for ASA and SA by the above methods. With ASA, the peak height ratio of ASA to dibutyl maleate was plotted against the concentration of ASA; and with SA, the fluorescence was plotted against the concentration of SA.

RESULTS AND DISCUSSION

Inhibition of the Hydrolysis of ASA in Whole Blood—The hydrolysis of ASA in whole blood at 37° is very rapid, $t_{1/2}$ = 30 min. (10). Therefore, it is very important to inhibit the enzymatic hydrolysis after withdrawal of blood samples; otherwise, appreciable error in the estimation of ASA occurs. Normally the hydrolysis has been stopped by addition of whole blood into acid. However, this also hemolyzes the red blood cells and this was to be avoided since the interest was in assaying ASA plasma levels.

Initially, the concentration of free[2] and total[2] SA was determined, by the method of Harris and Riegelman (10), in blood samples taken at 2, 5, 10, and 15 min. after the addition of 1 ml. of solution containing 200 mcg. ASA/ml. of normal saline to 9 ml. of freshly drawn heparinized blood. The blood was left out at room temperature. The above experiment was repeated with the addition of 5 mg. potassium fluoride/ml. blood (100 μl. of 50% KF per 10 ml. blood) prior to mixing with the ASA solution. No hemolysis of the blood occurred when using this amount of potassium fluoride. The hydrolysis of ASA was also determined when blood was maintained in an ice bath (+1°) both with and without the addition of 5 mg. KF/ml. blood. The appearance of free SA, rather than the disappearance of unchanged drug, was used to calculate the degree of hydrolysis. The results, given in Table I, indicate that while fluoride and cold each decrease hydrolysis, the combination of both is best.

Table I—The Effect of Temperature and Potassium Fluoride on the Hydrolysis of Acetylsalicylic Acid in Whole Blood

Conditions	% ASA Hydrolyzed					
Time, min.:	2	5	10	15	20	60
Room temp.	3.5	9.6	13.6	21	...	...
Room temp. + KF (5 mg./ml.)	1.5	1.8	7.0	11	...	...
Ice bath (+1°)	...	3.7	...	8.6	...	...
Ice bath (+1°) + KF (5 mg./ml.)	...	0.8	0.8	...	0.85	1.1

In a separate experiment, the effect of centrifugation on the hydrolysis of ASA was investigated. Fresh heparinized blood containing 20 mcg. ASA/ml. and 5 mg. KF/ml. was cooled in an ice bath and divided into four parts. Each sample of whole blood was immediately assayed for free and total SA and the remainder of each sample was centrifuged for 3 min., the buckets of the centrifuge being previously cooled in a refrigerator. Each centrifuged sample was then shaken and assayed for free and total SA. It was found that there was no increase in the degree of hydrolysis of ASA when centrifuged under these conditions. Therefore, since the total time taken between withdrawal of the blood sample and the separation of the plasma is approximately 15 min., the hydrolysis of ASA was never greater than 2%.

Preparation of Sample for Analysis—Potassium hydrogen sulfate is a useful acidifying agent; a 5% solution has a pH of 1.6. The mixing of an equal volume of this solution with plasma gives a final pH of 1.9–2.2. Under these conditions extraction of ASA and SA with ether is quantitative, as shown by spectrophotofluorescent measurements.

Gas Chromatography—Marked difficulty was experienced in chromatographing free ASA or SA on isophthalic acid/Carbowax terephthalic acid and terephthalic acid/FFAP columns. In all cases a complex peak was obtained with both SA and ASA, while a symmetrical peak was obtained with benzoic acid. This phenomenon may be due to the decarboxylation of SA and ASA at the operating temperatures of 180° or more required for these columns.

A symmetrical peak of the ASA-trimethylsilyl derivative was obtained on SE-30, QF-1, and XE-60 columns. Although three derivatives of salicylic acid are possible with HMDS, only two derivative peaks were obtained, a major and a minor one. These were not investigated further, other than it was noted that they were obtained in the same ratio after repeated recrystallization of SA. The QF-1 column gave the best separation of the ASA and SA derivative peaks and thus was chosen for the analysis of ASA.

Carbon disulfide was chosen as the final reaction solvent since the flame ionization detector does not respond to this compound. The formation of the TMS derivative appeared to be almost spontaneous and quantitative in this solvent, since there was no increase in the peak height ratio of ASA–TMS derivative to internal standard before or after heating the reaction mixture for 1 hr. at 40°.

[1] Although ASA is extracted into the phosphate buffer, this compound does not fluoresce. Neither does ASA quench the fluorescence of SA since varying amounts of ASA did not affect the linearity of the SA calibration curve. However, it is important to read the SA fluorescence promptly since ASA does hydrolyze in phosphate buffer ($t_{1/2}$ at 25° approximately 2.5 days) liberating SA.

[2] The term free SA is used here to mean both protein bound and unbound SA, and total SA is the sum of the free SA and that produced by the hydrolysis of ASA to SA.

Key: 1, *salicylic acid–trimethylsilyl derivative* (T_r = *1.5 min.*); 2, *dibutyl maleate (marker;* T_r = *4.6 min.*); 3, *acetylsalicylic acid trimethylsilyl derivative* (T_r = *5.4 min.*).

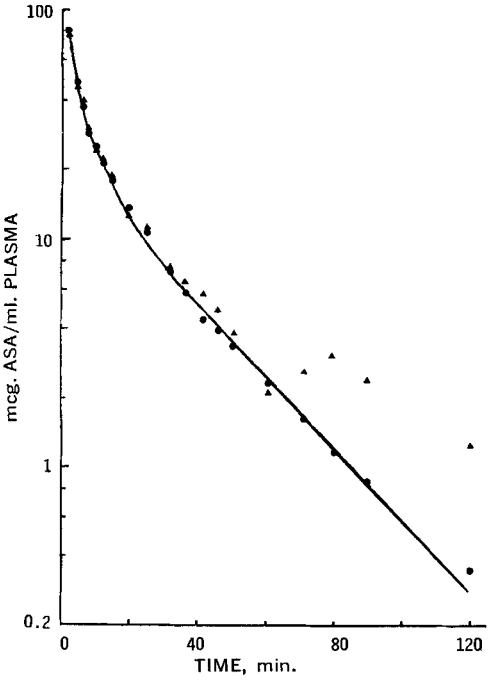

Fig. 2—Comparison of the gas–liquid chromatographic method (●) with the differential salicylic acid method (▲) for the determination of the acetylsalicylic acid plasma levels after the intravenous administration of acetylsalicylic acid.

A large number of compounds were screened as an internal marker. The most promising were methyl myristate, methyl tridecanoate, dimethyl phthalate, and dibutyl maleate; the last proved the best. Dibutyl maleate is soluble and stable in ether and carbon disulfide, does not react with HMDS, and gives a symmetrical peak close to the ASA–TMS derivative (Fig. 1).

Determination of SA in Plasma—Although SA gives a TMS derivative with HMDS, the drug was assayed spectrophotofluorometrically. The reasons for this were: (*a*) the retention time for the major SA–TMS peak was 1.5 min., which is on the solvent peak, rendering measurements of this peak height extremely difficult and inaccurate with concentrations of less than 10 mcg./ml. (*b*) Since generally SA concentrations are much larger than the ASA concentrations, constant changing of the attenuation switch would be necessary if both the SA and the ASA peaks are to be seen on the same scale. This demands constant attention of the analyst. On the other hand, the fluorescence method is sensitive and all samples can be analyzed in one batch.

Specificity, Sensitivity, and Reproducibility—Plasma from many subjects who had not ingested either ASA or SA were analyzed for these drugs. The GLC method for ASA was found to be specific, as no peak was ever observed, in these blank plasma samples, at the same retention time as the ASA–TMS derivative or that of the internal marker, dibutyl maleate. Also, neither salicylamide, which occasionally is formulated with ASA, nor the metabolite of SA, salicyluric acid, gave interfering peaks under the present assay conditions. The GLC method is quite sensitive as 0.2 mcg. ASA/ml. plasma could be readily demonstrated. The fluorescent method for SA determination is also very sensitive, and it is reasonably specific as no blank plasma sample gave a fluorescent reading greater than that equivalent to 0.5 mcg. SA/ml. plasma.

For reproducible results in the ASA determinations it was found necessary to saturate the column. This is readily achieved by rapidly injecting 4–5 samples and waiting about 15 min. for the column to clear. When this was carried out, the peak height ratio of standards were within 2% at the beginning and end of the run, and the calibration curve was linear from 0.4–20 mcg. ASA/ml. plasma. Also, samples of plasma with ASA added in concentrations of 1.0, 10, and 20 mcg./ml. were analyzed for ASA. (Seven samples were analyzed at each concentration.) The relative standard deviations (in per cent) of peak height ratio at 1, 10, and 20 mcg. ASA/ml. plasma were 1.8, 2, and 1.5%, respectively.

The SA calibration curve was linear from 2–100 mcg. SA/ml. plasma and the relative standard deviations (per cent) of the fluorescent readings at 5, 20, and 50 mcg. SA/ml. plasma were 1.7, 2.1, and 0.8%, respectively. (Seven samples were analyzed at each concentration.)

In addition, it was shown that both the ASA and SA calibration curves were unaffected by the presence of a large amount of the other drug, *e.g.*, with 0.4 mcg. ASA/ml. plasma the same peak height ratio was obtained in the presence or absence of 100 mcg. SA/ml. plasma. This further demonstrates the specificity of each of these assays.

Stability of ASA and SA in Plasma—Plasma samples, obtained from subjects who had taken ASA, were analyzed for ASA and SA. Analyses were made immediately, and 1, 2, 3, and 7 days after collection of the samples, and then once again after 30 days. All plasma samples were stored at dry ice temperature.

No loss of ASA or SA occurred in any samples stored up to 1 week. Further, several samples have been studied after 1 month or more of storage, and the variations of results were within the standard error of the method.

CONCLUSIONS

The present method for the simultaneous determinations of ASA and SA in plasma is simple and relatively rapid, since at least 20 samples can be analyzed in 5 hr. The stability of ASA under the sample and storage conditions enable determinations to be made at the analyst's convenience. The advantage of this method over the differential SA method for the determination of low concentrations of ASA in the presence of large amounts of SA is clearly shown in Fig. 2. Forty minutes after the administration of 650 mg. of ASA, the SA levels usually reach 40–50 mcg./ml., and shortly thereafter one must be able to determine as little as 0.4 mcg. ASA/ml. in the presence of the above vast excess of SA. It is only with a GLC method that the biological half-life of ASA can be accurately determined. Also, the recently proposed alternative method of Cotty *et al.* (5) may not be any more useful than the differential methods due to relative errors indicated in the published results. The methods presented in this paper are now being used to study the pharmacokinetics of ASA and SA in man and to investigate the influence of dosage forms on the absorption of ASA.

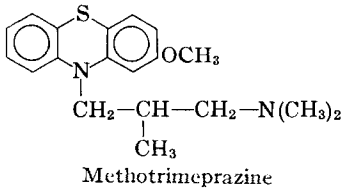
Estimation of Methotrimeprazine in Brain and Correlation of Brain Levels with Pharmacologic Activity

By ABDEL-HALIM M. AFIFI* and E. LEONG WAY

A method for estimating methotrimeprazine in brain by ultraviolet spectrophotometry was developed which is based on extracting the compound from alkalinized tissue with 1 per cent butanol in cyclohexane and determining its absorbance in acid at 250 mμ. A high degree of specificity for methotrimeprazine was conveyed to the procedure by subjecting the organic solvent extract of tissue to several buffer washes. Following intravenous injection of the compound in mice, methotrimeprazine was found to be metabolized rapidly during the first hour, after which its rate of disappearance slowed considerably. Brain levels were maximal at 1 hr. and were still appreciable at 4 hr. The onset and duration of pharmacologic effects as measured by a loss in coordinated motor ability varied directly with the concentration of drug in the brain, suggesting that the parent compound is principally responsible for mediating the response.

THE PHENOTHIAZINE DERIVATIVE, methotrimeprazine maleate (levomepromazine, and R.P. 7044),[1] until recently an investigational drug in the United States,[2] has been used for some time in Europe by psychiatrists as an alternative for chlorpromazine. The structures of the two agents are shown for comparison.



Methotrimeprazine

depressant effects of other CNS agents. The analgetic effect of methotrimeprazine was noted by Sigwald *et al.* in the clinic (2).

More recently Lasagna *et al.* (3) reported that when injected methotrimeprazine appeared to be as effective as morphine, milligram for milligram, in the alleviation of postpartum pain, and that 15 mg. of methotrimeprazine gave as much relief as 75 mg. of meperidine in the management of pain during childbirth (4). The therapeutic potential of such a potent nonaddicting analgetic with minimal respiratory depressant properties prompted the study of the metabolism of the compound. The present report, using the mouse, is the first in a series concerning the biologic disposition of methotrimeprazine. A study in humans has been previously reported by Allgén *et al.* (5).

EXPERIMENTAL

Estimation of Methotrimeprazine in Mouse Carcass and Brain—The procedure used by Salzman and Brodie (6) for chlorpromazine was adapted and modified for methotrimeprazine. The method is based on determining the compound by ultraviolet spectrophotometry after its extraction from alkalinized tissue homogenate with a suitable organic solvent. The homogenate is obtained by mincing 1 part of tissue with 4 parts of 0.1 *N* H_2SO_4 in an electric blender.

Assay Procedure—Pipet 5 ml. of tissue homogenate into a 40-ml. glass-stoppered extraction tube; add 1 ml. of 10% NaOH and 25 ml. of cyclohexane containing 1% *n*-butanol. Shake for 5 min. and separate the two layers by centrifugation at 2500 r.p.m. Transfer 23 ml. of the organic phase to another 40-ml. extraction tube containing 10 ml. of 0.2 *M* phosphate buffer, pH 6.4. Shake for 5 min. and separate by centrifugation. Remove the buffer layer and add another 10 ml. of fresh buffer and repeat the washing process twice more. Transfer 20 ml. of the organic phase to a tube containing 4 ml. of 0.1 *N* H_2SO_4. Shake for 5 min., centrifuge, and remove the organic phase completely by aspiration. Transfer about 3 ml. of the aqueous acid phase to a quartz cell and determine its absorbance at 250 mμ in a Beckman DU spectrophotometer. The amount of methotrimeprazine recovered from a sample containing the drug is read from the corresponding standard curve derived from known amounts of methotrimeprazine added to each tissue homogenate.

Appraisal of Specificity of the Method—Countercurrent distribution (7) and partition behavior at varying pH values (8) were employed to characterize the ultraviolet absorbing material extracted from the carcasses of mice given methotrimeprazine.

Countercurrent Distribution—Two mice were injected intravenously with 15 mg./Kg. methotrimeprazine and sacrificed after 1 hr. The total carcass was diluted 1:5 with 0.1 *N* sulfuric acid and homogenized thoroughly in an electric blender. The homogenate was made alkaline with sodium hydroxide and extracted three times with 5 times its volume of cyclohexane containing 1% *n*-butanol. The extracts were pooled and divided into two parts. One part was used directly for countercurrent distribution and the other portion was washed three times with 0.2 *M* phosphate buffer, pH 6.4, before being subjected to countercurrent transfer. In each experiment an eight plate transfer separation was carried out in a system consisting of equal parts of 1% *n*-butanol in cyclohexane and 0.2 *M* phosphate buffer, pH 4, moving the lower aqueous phase. At the end of the distribution, 1 ml. of 10% sodium hydroxide was added to each tube. After shaking and centrifuging, an aliquot of the organic solvent was transferred to another tube containing 4 ml. of 0.1 *N* sulfuric acid, and the acid layer was analyzed for methotrimeprazine in the usual manner. A distribution curve was obtained by plotting the fraction of the total amount of methotrimeprazine present in each tube against the number of the tube, and the experimental distribution curve was fitted according to the method of Way and Bennett (9).

Partition Behavior—The alternative technique for appraising specificity of the procedure consisted of determining the distribution ratios of authentic methotrimeprazine in an organic solvent–water system at various pH values of the aqueous phase, and comparing them with those obtained for the extracted substance recovered from mice sacrificed after receiving methotrimeprazine. The carcass was homogenized as before in 4 parts of 0.1 *N* H_2SO_4, and after the addition of sufficient alkali, the homogenate was extracted with five times its volume of 1% *n*-butanol in cyclohexane. Duplicate 10-ml. aliquots of the organic solvent extract were washed three times with 0.2 *M* phosphate buffer of pH 6.4 and then equilibrated with 4 ml. of 0.1 *N* sulfuric acid. Other 10-ml. samples of the organic solvent extract were similarly washed and then equilibrated with equal volumes of 0.2 *M* phosphate buffer solutions of pH 7, 6, 5, or 4, respectively. After removal of the buffer phase, the organic solvent layer was shaken with 4 ml. of 0.1 *N* H_2SO_4. The organic solvent layer was discarded and the amount of methotrimeprazine in the acid aqueous phase was determined. The results were compared with those obtained from a similar treatment of authentic methotrimeprazine in aqueous solution.

Rate of Metabolism—The rate of disappearance of methotrimeprazine was studied in 23 intact mice. Methotrimeprazine, 15 mg./Kg., was injected into the tail vein of Swiss-Webster mice weighing 30 ± 5 Gm. The drug was dissolved in isotonic solution to give a concentration of 2 mg./ml. At fixed time intervals of 15, 30, 60, 120, 240 min., and 24 hr., at least two and generally four mice were individually homogenized and assayed for methotrimeprazine as described previously; the results are expressed as per cent of drug recovered.

Brain Concentrations of Methotrimeprazine—Mice were injected subcutaneously with methotrimeprazine and then sacrificed by decapitation at 15, 30, 60, 90, 120, 180, and 240 min.; two mice were used at each time interval. The brains were extirpated, weighed, diluted 10 times with 0.1 *N* sulfuric acid, and analyzed for methotrimeprazine in the usual manner.

Onset and Duration of Pharmacologic Effects—The time-response relationship of methotrimeprazine was assessed in mice in conjunction with brain concentration determinations. Two tests for central

nervous system activity were used: "analgesia," by the tail flick method of D'Amour and Smith (10); and coordinated motor ability, by the method of Dunham and Miya (11).

For analgetic activity, the reaction time for mice to remove their tails from a thermal stimulus, provided by a beam of light focused 1.5 cm. from the blackened tip of the mouse tail, was determined prior to drug injection and every 20 min. after subcutaneous administration of methotrimeprazine at doses of 2, 4, and 8 mg./Kg. A cut-off time of 5 sec. was used to prevent damage to the tail.

To test coordinated motor activity, the time an animal remained on a rotating rod was determined. One end of a wooden rod, 48 in. long and 1.2 in. in diameter, was connected to the motor shaft of an electric kymograph. The two ends of the rod were inserted into ball bearings supported by suitable clamps at a height of 28 in. above the table top to discourage animals from jumping off the roller. The speed selector was set so that the rod made 15 r.p.m. In order that multiple tests could be performed simultaneously, cardboard disks were placed along the rod at suitable distances to divide it into five compartments. Untreated animals after conditioning can maintain their balance on the rotating rod for at least 20 min. Performance trials were conducted on 10 mice at 15, 30, and then every 30 min. after subcutaneous injection of 4 mg./Kg. of the drug. The time each animal remained on the rotating rod was recorded up to a limit of 1 min. An animal remaining on the rod at the end of this observation period was assigned a relative activity of 1.0 and any perfomance value of less than 60 sec. was expressed as a fraction. The average relative activities and the mean deviations were calculated and plotted against time.

RESULTS

Precision and Specificity of the Procedure—The application of single extraction techniques in conjunction with ultraviolet spectrophotometry appeared to be quite satisfactory for estimating methotrimeprazine in the mouse carcass or brain. Based on the standard curve obtained for methotrimeprazine extracted from water, the recovery of methotrimeprazine added to the tissue homogenates at concentrations ranging from 5 to 20 mcg. of drug per Gm. of wet tissues exceeded 90%. The blank correction was negligible, amounting to less than 0.1 mcg. of drug equivalent for brain and to less than 0.5 mcg. for the carcass.

The procedure was found to possess a high degree of specificity for methotrimeprazine. The countercurrent distribution experiments indicate that specificity is conveyed to the procedure by washing the solvent extract of tissue with a suitable buffer. As seen in Fig. 1, the distribution curve of the unwashed extract did not yield a curve with the distribution characteristics of a single substance. On the other hand, with the washed solvent extract of mouse homogenate, the experimental distribution curve with a maximum at tube 4 exhibited the characteristics of a single substance. With the latter curve, the calculated values of each tube for a partition ratio, K, of 0.93 yielded a theoretical curve which fitted almost perfectly with the experimental curve. When the K of methotrimeprazine added to a mouse homogenate was determined for the same system used in the countercurrent distribution, it was found to be 0.90. Thus, there is a strong evidence indicating that the substance characterized by countercurrent distribution is actually methotrimeprazine and that the introduction of a three-buffer washing removes interfering substances and renders the method highly specific for methotrimeprazine. The major fraction in the unwashed extract of total mouse homogenate appears to be biotransformation products and only about 30% of the ultraviolet absorbing material represents unchanged methotrimeprazine.

The partition behavior of biologically recovered methotrimeprazine at varying pH was also virtually identical to that of authentic methotrimeprazine. As can be noted in Table I, the distribution ratios of the recovered material in a solvent buffer pair system of varying pH were highly similar to those for authentic methotrimeprazine, and the probability for two different compounds to have the same distribution ratios under such rigidly defined conditions appears rather remote.

Rate of Metabolism in Intact Mice—Figure 2 represents a plot of the average per cent of the dose of methotrimeprazine recovered against the time interval after injection of the drug. The heavy line indicates the calculated mean recovery for each interval and the broken lines the range. Considerable varia-
